This work is provided "as is," and the publisher disclaims any and all warranties, express or implied, including any warranties as to accuracy, comprehensiveness, or currency of the content of this work.

This work is no substitute for individual patient assessment based upon healthcare professionals' examination of each patient and consideration of, among other things, age, weight, gender, current or prior medical conditions, medication history, laboratory data and other factors unique to the patient. The publisher does not provide medical advice or guidance and this work is merely a reference tool. Healthcare professionals, and not the publisher, are solely responsible for the use of this work including all medical judgments and for any resulting diagnosis and treatments.

Given continuous, rapid advances in medical science and health information, independent professional verification of medical diagnoses, indications, appropriate pharmaceutical selections and dosages, and treatment options should be made and healthcare professionals should consult a variety of sources. When prescribing medication, healthcare professionals are advised to consult the product information sheet (the manufacturer's package insert) accompanying each drug to verify, among other things, conditions of use, warnings and side effects and identify any changes in

dosage schedule or contraindications, particularly if the medication to be administered is new, infrequently used or has a narrow therapeutic range. To the maximum extent permitted under applicable law, no responsibility is assumed by the publisher for any injury and/or damage to persons or property, as a matter of products liability, negligence law or otherwise, or from any reference to or use by any person of this work.

FOREWORD

Emil Novak of Johns Hopkins University School of Medicine and Hospital edited the ***Textbook of Gynecology***, which was first published in 1941, and remained the standard in the field for many years thereafter. The 14th edition of that landmark text, published in 2007, was given a new title, ***Berek and Novak's Gynecology***, honoring both Dr. Jonathan S. Berek and the late Dr. Novak, whose significant contributions sustained and, where necessary, recalibrated the work through several previous editions, thereby preserving its vitality and relevance for new generations of physicians. The book retains its prominence as one of the major comprehensive textbooks in the discipline, a status it is certain to maintain in the 16th edition.

For this 16th edition, Dr. Berek again assembled an impressive array of contributors—clinicians and researchers, leaders in their respective fields—who bring insightful knowledge and valuable perspectives to their respective areas of expertise. The result is a comprehensive treatment of current practice—but with an eye toward future developments—in the science and practice of gynecology and its related subspecialties. Innovative developments in research and clinical practice are treated in detail. For example, in keeping with the expansion of one gynecologic subspecialty the section on Urogynecology with its chapters on the urinary tract, prolapse, and anorectal are necessary reading for comprehension of this discipline. The substantially expanded field of minimally invasive gynecologic surgery is covered thoroughly in the chapters dealing with endoscopy, hysterectomy, and robotics. Not surprising, given Dr. Berek's reputation as a leader and innovator in gynecology and gynecologic oncology, this textbook indisputably remains the definitive encyclopedia on that subject. The basic science section is intertwined beautifully with the principles of practice, promoting an understanding of the many changes in clinical medicine in recent years. Compassion and sensitivity are evident throughout the work, especially in the sections dealing with sexuality and related sexual issues. In keeping with sensitivity, the chapter on violence toward women is critical for the care of women and it has now become an even greater responsibility of ours.

The traditional areas of gynecology are presented in an exciting format with all the information the practicing gynecologist requires in order to provide excellent patient care. Another attractive feature is that it is published with substantial full-color

illustrations and graphics that greatly enhance the readability and accessibility of the material.

Practitioners of the medical specialty of gynecology, both clinicians and researchers, are wholly dedicated to the care and well-being of women. As both a teaching tool and reference, this new edition of ***Berek and Novak's Gynecology*** will prove to be, as previous editions were, an invaluable asset to them as they ply their important work.

Massachusetts General Hospital Boston, Massachusetts

PREFACE

The first edition of ***Novak's Textbook of Gynecology***, written by the distinguished Dr. Emil Novak of Johns Hopkins, became an essential international reference for the practice of gynecology. This 16th edition is the carefully nurtured descendant of that book and retains the useful format of my four previous editions of the text, enhanced by full-color illustrations and photographic reproductions.

As with the prior editions, the goal is to provide a comprehensive summary of the specialty of gynecology. All chapters were thoroughly revised to provide timely information and references. The illustrations and photographs were updated and made more accessible and informative.

This textbook, originated by the faculty of the Johns Hopkins University School of Medicine, continues to reflect the contributions of that great institution. After the 5th edition and the subsequent death of Dr. Novak in 1957, many physicians from Johns Hopkins, and some members of the Vanderbilt faculty, helped carry the torch—Dr. Edmund R. Novak through the ninth edition in 1979; Drs. Howard W. Jones, Jr. and Georgeanna Seegar Jones through the 10th edition in 1981; and Drs. Howard W. Jones, III, Lonnie S. Burnett, and Anne Colston Wentz through the 11th edition in 1988. These editors, assisted by contributors from the faculty at Johns Hopkins, especially Drs. J. Donald Woodruff and Conrad G. Julian, helped define the specialty of gynecology during the latter half of the 20th century and shaped the practice of gynecology as we know it today—its surgical and medical therapies, reproductive endocrinology, assisted reproductive technologies, gynecologic oncology, urogynecology, and infectious diseases. As a graduate of Johns Hopkins University School of Medicine, I am honored to contribute to that rich tradition.

Berek & Novak's Gynecology, 16th edition, is presented in eight sections. The first section, General Principles, includes the initial assessment of the gynecologic patient, her medical history and physical examination, and techniques to improve physician communication skills. This section addresses ethical principles of patient care, quality assessment and improvement, clinical research, and the epidemiology of gynecologic conditions, with chapters that summarize the scientific basis for the specialty—anatomy and embryology, molecular biology and genetics, and reproductive physiology. The

second section, Gynecology Topics, covers puberty, pediatric and adolescent gynecology, adult gynecology, chapters on benign diseases of the female reproductive tract—the evaluation of pelvic infections, uterine fibroids, pain, intraepithelial diseases, the function of the female reproductive tract from puberty through menopause, and the evaluation of benign breast disease. A new chapter on a sensitive and consequential topic appears in this section—violence against women and sexual assault. The third section, Primary Medical Care, emphasizes the importance of primary health care for women: preventive care and screening, and psychiatric care and complementary medicine. The fourth section, Operative Gynecology, covers perioperative care and the operative management of benign gynecologic conditions using endoscopy, hysterectomy, and robotics. The fifth section, Urogynecology, contains chapters on the urinary tract, prolapse, and anorectal problems. The sixth section, Early Pregnancy Issues, includes the management of early pregnancy loss and ectopic pregnancy. The seventh section, Reproductive Endocrinology and Infertility, summarizes the management of amenorrhea, major endocrine disorders, and infertility. The eighth section, Gynecologic Oncology, covers malignant diseases of the female reproductive tract and breast cancer.

I am especially grateful to my talented content editor, Deborah Berek, who diligently evaluated and assisted the entire project from the initial manuscripts through page proofs. I appreciate the many people at Lippincott Williams & Wilkins who helped me, especially Charley Mitchell, whom I consider the best editor in medical book publishing and with whom I worked for more than a quarter of a century. I gratefully acknowledge the many individuals who contributed to this book and extend my gratitude to Ashley Fischer and Kayla Smull for their dedication and commitment to enthusiastically and skillfully shepherd the manuscript during the editorial process. I acknowledge the outstanding work of Chris Miller at Aptara who diligently and expertly worked with me to accomplish the final page layout and formatting of this book. I offer my admiration and thanks to Tim Hengst, an outstanding medical illustrator, for the excellent illustrations, anatomic drawings, and thematic designs for all the editions under my guidance. I acknowledge the invaluable support of my mentors—Dean Sherman Mellinkoff, Drs. J. Donald Woodruff, Kenneth J. Ryan, J. George Moore, and William J. Dignam—and I extend my gratitude to my colleagues Drs. Isaac Schiff, Beverly Mitchell, and Dean Emeritus Philip Pizzo. Each of these physicians and scholars graciously provided essential guidance and encouragement. My special thanks to Laurie Lacob, Nicole Kidman and Keith Urban, Trisha Yearwood and Garth Brooks for their support of the Stanford Women's Cancer Center—and for the help, encouragement, and friendship that stimulated this project.

After 12 years as Chair of the Department of Obstetrics and Gynecology at the Stanford

University School of Medicine, I stepped away from the position in 2017 to pursue other academic activities at Stanford University and the Stanford University School of Medicine. The powerful generosity of spirit and commitment to causes that support women and their health guides the work of my colleagues at Stanford and has been a source of pleasure and inspiration for me. The community surrounding the university shares this commitment to improving the health and welfare of women, and I am gratified by their efforts on behalf of women and their families.

I look forward to the specialty's continued positive impact on the health of women throughout the world. It is my fervent hope that our work will benefit all women, reducing the numbers of those who are afflicted with diseases of the female reproductive tract and breast, preserving their ability to participate in their families and communities. To that end, this book is offered as a resource to assist and encourage all who study the specialty of gynecology.

Jonathan S. Berek

Summary

KEY POINTS

1 We are all products of our environment, our background, and our culture. The importance of ascertaining the patient's general, social, and familial situation cannot be overemphasized. The physician should avoid being judgmental, particularly with respect to questions about sexual practices, gender identity, and sexual orientation.

2 Good communication is essential to patient assessment and treatment. The foundation of communication is based on key skills: empathy, attentive listening, expert knowledge, and rapport. These skills can be learned and refined.

3 The concepts of medical professionalism initially codified in the Hippocratic Oath demand that physicians be circumspect with all patient-related information. For physician–patient communication to be effective, the patient must feel that she is able to discuss her problems in depth and in confidence.

4 Different styles of communication may affect the physician's ability to perceive the patient's status and achieve the goal of optimal assessment and successful treatment. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest response.

5 Some patients lack accurate information about their illnesses. Incomplete or inadequate understanding of an illness can produce increased anxiety, dissatisfaction with medical care, distress, coping difficulties, unsuccessful treatment, and poor treatment response.

6 After a dialogue is established, the patient assessment proceeds with obtaining a complete history and typically, performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details.

7 At the completion of the physical examination, the patient should be informed of the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately; this discussion should take place after the examination, with the patient clothed.

The practice of gynecology requires many skills. In addition to medical knowledge, the gynecologist should develop interpersonal and communication skills that promote patient– physician interaction and trust. The assessment must be of the "whole patient," rather than confined to her general medical status. It should include any apparent medical conditions and the psychological, social, and family aspects of her situation. **To view the patient in the appropriate context, environmental and cultural issues that affect the patient must be taken into account.** This approach is valuable in routine assessments, and in the evaluation of specific medical conditions, providing opportunities for preventive care and counseling on an ongoing basis.

VARIABLES THAT AFFECT PATIENT STATUS

Many external variables exert an influence on the patient and on the care she receives. Some of these factors include the patient's "significant others"—her family, friends, and personal and intimate relationships (Table 1-1). **These external variables include psychological, genetic, biologic, social, and economic issues.** Factors that affect a patient's perception of disease and pain and the means by which she has been taught to cope with illness include her education, attitudes, understanding of human reproduction and sexuality, and family history of disease (1–3). Cultural factors, socioeconomic status, religion, ethnicity, language, age, gender identity, and sexual orientation are important considerations in understanding the patient's response to her care.

Table 1-1 Variables That Influence the Status of the Patient

Patient
Age
History of illness
Attitudes and perceptions
Sexual orientation
Habits (e.g., use of alcohol, tobacco, and other drugs)
Family
Patient's status (e.g., married, separated, living with a partner, divorced)
Caregiving (e.g., young children, children with disabilities, aging parents)
Siblings (e.g., number, ages, closeness of relationship)
History (e.g., disease)
Environment
Social environment (e.g., community, social connectedness)
Economic status (e.g., poverty, insuredness)
Religion (e.g., religiosity, spirituality)
Culture and ethnic background (e.g., first language, community)
Career (e.g., work environment, satisfaction, responsibilities, stress)

We are all products of our environment, our background, and our culture. The importance of ascertaining the patient's general, social, and familial situation cannot be overemphasized (4,5). Cultural sensitivity may be particularly important in providing reproductive health care (6).

[1] The context of the patient's support system and family can and should be ascertained directly. The family history should include a careful analysis of those who had significant illnesses, such as cancer or an illness that the patient perceives to be a potential explanation for her own symptoms. The patient's perspective of her illness can provide important information that guides the physician's judgment; specific questioning to elicit this perspective can improve satisfaction with the interaction (4,7). The patient's understanding of key events in the family medical history and how they relate to her is important. The patient's sexual history, sexual orientation, relationships, and practices should be understood, and her functional level of satisfaction in these areas should be determined. **The physician should avoid being judgmental, particularly**

with respect to questions about sexual practices, gender identity, and sexual orientation (see Chapter 17).

COMMUNICATION

[2] Good communication is essential to patient assessment and treatment. The patient–physician relationship is based on communication conducted in an open, honest, and careful manner that allows the patient's situation and problems to be accurately understood and effective solutions developed collaboratively. Good communication requires patience, dedication, and practice and involves careful listening and attention to verbal and nonverbal communication.

The foundation of communication is based on four key skills: empathy, attentive listening, expert knowledge, and the ability to establish rapport. These skills can be learned and refined (4,5,8). When the initial relationship with the patient is established, the physician must vigilantly pursue interviewing techniques that continue to create opportunities to foster an understanding of the patient's concerns. Trust is the fundamental element that encourages open communication of the patient's feelings, concerns, and thoughts, rather than withholding information (9).

One very basic element of communication—sharing a common language and culture—may be missing when a clinician interacts with a patient of limited or no English proficiency. Language concordance between the physician and patient is assumed in many discussions of communication. More than 21% of Americans speak a language other than English at home, and of these 41% reported to the Census Bureau that they speak English less than very well (10). Language barriers are associated with limited health literacy, compromised interpersonal care, and lower patient satisfaction in health care encounters (11,12). While language-concordant health care professionals are optimal, in-person medical interpreters can mitigate these effects; video and telephonic interpretation provide technologic solutions that help mitigate communication challenges with individuals of limited English proficiency (13). The State of California recognized the importance of communication in patient–physician interactions through a provision in the Health and Safety Code that states "where language or communication barriers exist between patients and the staff of any general acute care hospital, arrangements shall be made for interpreters or bilingual professional staff to ensure adequate and speedy communication between patients and staff" (14). Training future physicians to work with interpreters is receiving increasing attention in US medical schools and will contribute to improved clinical practice and reduce health care disparities (15).

[3] Although there are many styles of interacting with patients, each physician must determine and develop the best way that she or he can relate to patients. Physicians must convey that they are able and willing to listen and that they receive the information with

utmost confidentiality (1,4). **The concepts of medical professionalism initially codified in the Hippocratic Oath demand that physicians be circumspect with all patient-related information.** The Health Insurance Portability and Accountability Act (HIPAA), which took effect in 2003, established national standards intended to protect the privacy of personal health information. Initial fears expressed about the impact of HIPAA regulations and the potential for legal liability led to discussions of appropriate communication and physicians' judgments based on the ethical principles of confidentiality in providing good medical care (16,17) (see Chapter 2).

Communication Skills

It is essential for the physician to communicate with a patient in a manner that allows her to continue to seek appropriate medical attention. The words used, the patterns of speech, the manner in which words are delivered, even body language and eye contact, are all important aspects of the patient–physician interaction. The traditional role of the physician was paternalistic, with the physician expected to deliver direct commands or "orders" and specific guidance on all matters (5). Now patients appropriately demand and expect more balanced communication with their physicians. Although they may not have equivalent medical expertise, they do expect to be treated with appropriate deference, respect, and a manner that acknowledges their personhood as equal to that of the physician. Doctor–patient communication is receiving more attention in medical education and is being recognized as a major task of lifelong professional learning and a key element of successful health care delivery (18).

Patients with rare or unusual conditions sometimes have more specific medical knowledge of a given medical problem than the physician does. When this is the case, the physician must avoid reacting defensively. A 2013 poll indicated that one-third of Americans had researched symptoms or diagnoses online; 46% of those individuals reported that their online research led them to seek medical care, while 38% decided to manage their suspected health conditions without consulting a clinician (19). The patient often lacks broader knowledge of the context of the problem, awareness of the variable reliability of electronic sources of information, the ability to assess a given study or journal report within a historical context or in comparison with other studies on the topic, knowledge of drug interactions, an ability to maintain objective intellectual distance from the topic, or essential experience in the art and science of medicine. The physician possesses these skills and extensive knowledge, whereas the patient has an intensely focused personal interest in her specific medical condition. Surveys of physicians' perceptions of the impact of Internet-based health information on the doctor–patient relationship found positive and negative perceptions; physicians express concerns about a hindrance to efficient time management during an office visit, but a positive perception of the potential effects on the quality of care and patient outcomes

(20). **A collaborative relationship that allows patients greater interactive involvement in the doctor–patient relationship can potentially lead to better health outcomes** (21–23).

Physician–Patient Interaction

The pattern of the physician's speech can influence interactions with the patient. Some important components of effective communication between patients and physicians are presented in Table 1-2. There is evidence that scientifically derived and empirically validated interview skills can be taught and learned, and conscientious use of these skills can result in improved outcomes (24). A list of such skills is found in Table 1-3.

[3] For physician–patient communication to be effective, the patient must feel that she is able to discuss her problems in depth and in confidence. Time constraints imposed by the pressures of office scheduling to meet economic realities make this difficult; both the physician and the patient frequently need to reevaluate their priorities. If the patient perceives that she participates in decision making and that she is given as much information as possible, she will respond to the mutually derived treatment plan with lower levels of anxiety and depression, embracing it as a collaborative plan of action. She should be able to propose alternatives or modifications to the physician's recommendations that reflect her own beliefs and attitudes. There is ample evidence that patient communication, understanding, and treatment outcomes are improved when discussions with physicians are more dialogue than lecture. When patients feel they have some room for negotiation, they tend to retain more information regarding health care recommendations. The concept of collaborative planning between patients and physicians is embraced as a more effective alliance than the previous model in which physicians issued orders. The patient thus becomes more vested in the process of determining health care choices. For example, decisions about the risks and benefits of menopausal hormone therapy must be discussed in the context of an individual's health and family history, including her personal beliefs and goals. The woman decides whether the potential benefits outweigh the potential risks, and she is the one to determine whether or not to use such therapy. Whereas most women prefer shared decision making in the face of uncertainty, with an evidence-based discussion of her risks and benefits, others may want a more directive approach (25). **The physician's challenge is to be able to personalize the interaction and communication.**

Table 1-2 Important Components of Communication Between the Patient and Physician: The Physician's Role

The Physician Is:
A good listener

Empathetic
Compassionate
Honest
Genuine
Respectful
Fair
Facilitative
The Physician Uses:
Understandable language
Appropriate body language
A collaborative approach
Open dialogue
Appropriate emotional content
Humor and warmth
The Physician Is Not:
Confrontational
Combative
Argumentative
Condescending
Overbearing
Dogmatic
Judgmental
Paternalistic

Table 1-3 Behaviors Associated With the 14 Structural Elements of the Interview[a]

Preparing the Environment
Create privacy
Eliminate noise and distractions
Provide comfortable seating at equal eye level

Provide access
Preparing Oneself
Eliminate distractions and interruptions
Focus
Self-hypnosis
Meditation
Constructive imaging
Let intrusive thoughts pass through
Observation
Create a personal list of categories of observation
Practice in a variety of settings
Notice physical signs
Presentation
Affect
What is said and not said
Greeting
Create a personal stereotypical beginning
Introduce oneself
Check the patient's name and how it is said
Create a positive social setting
Introduction
Explain one's role and purpose
Check the patient's expectation
Negotiate about differences in perspective
Be sure expectations are congruent with the patient's
Detecting and Overcoming Barriers to Communication
Develop personal list of barriers to look for
Include appropriate language
Physical impediments such as deafness, delirium

Include cultural barriers
Recognize the patient's psychological barriers, such as shame, fear, and paranoia
Surveying Problems
Develop personal methods of initiation of problem listing
Ask "What else?" until problems are elicited
Negotiating a Priority Problem
Ask the patient for priorities
State own priorities
Establish mutual interests
Reach agreement on order of addressing issues
Developing a Narrative Thread
Develop personal ways of asking the patient to tell her story
Ask when last felt healthy
Ask about entire course of illness
Ask about recent episode or typical episode
Establishing the Life Context of the Patient
Use first opportunity to inquire about personal and social details
Flesh out developmental history
Learn about the patient's support system
Learn about home, work, neighborhood, safety
Establishing a Safety Net
Memorize complete review of systems
Review issues as appropriate to specific problem
Presenting Findings and Options
Be succinct
Ascertain the patient's level of understanding, cognitive style
Ask the patient to review and state understanding
Summarize and check
Tape record and give the tape to the patient

Ask the patient's perspectives
Negotiating Plans
Activate the patient
Agree on what is feasible
Respect the patient's choices whenever possible
Closing
Ask the patient to review plans and arrangements
Clarify what to do in the interim
Schedule next encounter
Say goodbye

[a]**Lipkin M Jr**. Physician–patient interaction in reproductive counseling. *Obstet Gynecol* 1996;88:31S–40S. Derived from **Lipkin M, Frankel RM, Beckman HB, et al.** Performing the interview. In: **Lipkin M, Putnam SM, Lazare A,** eds. *The Medical Interview: Clinical Care, Education, and Research*. New York: Springer-Verlag; 1995:65–82.

There is evidence that when patients are heard and understood, they become more vocal and inquisitive and their health improves. Participation facilitates investment and empowerment. **Good communication is essential to the maintenance of a relationship between the patient and physician that will foster ongoing care.** Health maintenance, therefore, can be linked directly to the influence of positive interactions between the physician and patient. Women who are comfortable with their physician may be more likely to raise issues or concerns and convey information about potential health risks and be more receptive to the physician's recommendations. This degree of rapport may promote the effectiveness of health interventions, including behavior modification. It helps ensure that patients return for regular care because they feel the physician is genuinely interested in their welfare and they have confidence in the quality of treatment and guidance they receive.

When patients are ill, they feel vulnerable, physically and psychologically exposed, and powerless. The physician, by virtue of his or her knowledge and status, has power that can be intimidating. It is essential that the physician be aware of this disparity and ensure that the "balance of power" does not shift too far away from the patient. Shifting it back from the physician to the patient may help improve outcomes (1,22). Physicians' behaviors can suggest that they are not respectful of the patient. Such actions as failing to maintain scheduled appointment times, routinely holding substantive discussions when the patient is undressed, or speaking to her from a standing position while she is lying down or in the lithotomy position can emphasize the imbalance of

power in the relationship.

In assessing the effects of the patient–physician interaction on the outcome of chronic illness, three characteristics associated with better health care outcomes were identified (26):

1. **An empathetic physician and a high level of patient involvement in the interview.**
2. **Expression of emotion by the patient and physician.**
3. **Provision of information by the physician in response to the patient's inquiries.**

Among patients with diabetes, these characteristics resulted in improved diastolic blood pressure and reduction of HgA1c. The best responses were achieved when an empathetic physician provided as much information and clarification as possible, responded to the patients' questions openly and honestly, and expressed a full range of emotions, including humor. Responses improved when the relationship was not dominated by the physician (26).

Studies of gender and language have shown that men tend to dominate conversations, interrupt more frequently, and control the topics of the conversation (27). As a result, male physicians may tend to take control, and this imbalance of power may be magnified in the field of obstetrics and gynecology, in which all the patients are women. Male physicians may be more assertive than female physicians. Men's speech tends to be characterized by interruptions, command, and lectures, and women's speech is characterized by silence, questions, and proposals (27,28). Some patients may feel more reticent in the presence of a male physician, whereas others may be more forthcoming with a male than a female physician (29). Women's preference for a male or female physician may be based on gender as well as experience, age, competency, communication styles, and other skills (30–32). Although these generalizations clearly do not apply to all physicians, they can raise awareness about the various styles of communication and how they shape the physician–patient relationship (28). These patterns indicate that **[4] all physicians, regardless of their gender, need to be attentive to their style of speech because it may affect their ability to elicit open and candid responses from their patients** (33,34). Women tend to express their feelings in order to validate, share, and establish an understanding of their concerns or establish a shared understanding of their concerns (27,35).

Different styles of communication may affect the physician's ability to perceive the patient's status and to achieve the goal of optimal assessment and successful treatment. The intimate and highly personal nature of many gynecologic conditions requires particular sensitivity to evoke an honest patient response.

Style

The art of communication and persuasion is based on mutual respect and fosters the development of the patient's understanding of the circumstances of her health. Insight is best achieved when the patient is encouraged to question her physician and not pressured to make decisions. Patients who feel "backed into a corner" have the lowest compliance with recommended treatments (36).

Following are techniques to help achieve rapport with patients:

1. **Use positive language (e.g., agreement, approval, and humor)**.
2. **Build a partnership (e.g., acknowledgment of understanding, asking for opinions, paraphrasing, and interpreting the patient's words).**
3. **Ask rephrased questions.**
4. **Give complete responses to the patient's questions.**

The manner in which a physician guides a discussion with a patient will determine the patient's level of understanding and her ability to successfully complete therapy. The term *compliance* has long been used in medicine; it suggests that the patient will follow the physician's recommendations or "orders." The term is criticized as being overly paternalistic; an alternative term, *adherence* to therapy, is preferable (37,38). This term still implies that the physician will dictate the therapy. A more collaborative approach is suggested by the phrase *successful use* of therapy, which can be credited mutually to the physician and the patient. With this phrase, the ultimate success of the therapy appropriately accrues to the patient (39). If a directive is given to take a prescribed medication without a discussion of the rationale for its use, patients may not comply, particularly if the instructions are confusing or difficult to follow. Barriers to adherence may result from practical considerations: Nearly everyone finds a four times daily (qid) regimen more difficult than daily use. A major factor in successful use is the simplicity of the regimen (40,41). Practical factors that affect successful use include financial considerations, insurance coverage, and literacy (42). A discussion and comprehension of the rationale for therapy, along with the potential benefits and risks, are necessary components of successful use; but they may not be sufficient in the face of practical barriers. The specifics of when and how to take medication, including what to do when medication is missed, have an impact on successful use. Positive physician–patient communication is correlated with patient adherence to medical advice (43).

[7] The presentation style of the information is key to its effectiveness. As noted, the physician should establish a balance of power in the relationship, including conducting serious discussions about diagnosis and management strategies when the patient is fully clothed and face-to-face with the physician in a private room. Body language is important during interactions with patients. The physician should avoid an

overly casual manner, which can communicate a lack of respect or compassion. The patient should be viewed directly and spoken to with eye contact so that the physician is not perceived as "looking off into the distance."

Laughter and Humor

Humor is an essential component that promotes open communication. It can be either appropriate or inappropriate. Appropriate humor allows the patient to diffuse anxiety and understand that (even in difficult situations) laughter can be healthy (44,45). Inappropriate humor would horrify, disgust, offend, or generally make a patient feel uncomfortable or insulted. Laughter can be used as an appropriate means of relaxing the patient and making her feel better.

Laughter is a "*metaphor for the full range of the positive emotions.*" It is the response of human beings to incongruities and one of the highest manifestations of the cerebral process. It helps to facilitate the full range of positive emotions—love, hope, faith, the will to live, festivity, purpose, and determination (44). Laughter is a physiologic response, a release that helps us feel better and allows us to accommodate the collision of logic and absurdity. Illness, or the prospect of illness, heightens our awareness of the incongruity between our existence and our ability to control the events that shape our lives and our outcomes. We use laughter to combat stress, and stress reduction is an essential mechanism used to cope with illness.

Table 1-4 Importance Attached to the Patient–Physician Relationship[a]

Rank	Physicians' Support Services	Always or Often (%)	Rarely or Never (%)
1	Answering the patient's questions about the disease and its treatment, side effects, and possible outcomes	99	1
2	Making sure that the patient clearly understands the explanation of the medical treatment procedures	99	1
3	Encouraging the patient to develop an attitude of hope and optimism concerning treatment outcome	95	5
4	Adjusting treatment plans to enhance compliance when the patient exhibits noncompliance	88	12
5	Directly counseling family members	87	13
6	Continuing to serve as primary physician when the patient receives supplementary treatment at another facility	85	15
7	Providing referral to social support groups	83	17
8	Providing the patient with educational materials	81	19
9	Helping the patient develop methods to improve the quality of his or her life	74	26
10	Assisting the patient in determining which of his or her coping mechanisms are most productive and helping to activate them	62	38
11	Providing referral to psychological counseling services	57	43

[a]Results of a physician survey of 649 oncologists in regard to patient–physician communication.

Modified from **Cousins N.** *Head First: The Biology of Hope and the Healing Power of the Human Spirit.* New York: Penguin Books; 1989:220, with permission.

Strategies for Improving Communication

All physicians should appreciate the importance of the art of communication during the medical interview. It is essential that interactions with patients are professional, honorable, and honest. Issues that were reported to be important to physicians regarding patient–physician interactions are presented in Table 1-4. Similarly, patients suggested the importance of many of these same issues in facilitating participatory decision making (46).

Following are some general guidelines that can help improve communication:

1. **Listen more and talk less.**
2. **Encourage the pursuit of topics introduced by and important to patients.**
3. **Minimize controlling speech habits such as interrupting, issuing commands, and lecturing.**
4. **Seek out questions and provide full and understandable answers.**
5. **Become aware of any discomfort that arises in an interview, recognize when it originates in an attempt by the physician to take control, and redirect that attempt.**
6. **Assure patients that they have the opportunity to discuss their problem fully.**
7. **Recognize when patients may be seeking empathy and validation of their feelings rather than a solution. Sometimes all that is necessary is to be there as a compassionate human being.**

In conducting interviews, it is important for the physician to understand the patient's concerns. Given the realities of today's busy office schedules, an additional visit may be required to discuss some issues in sufficient depth. In studies of interviewing techniques it was shown that although clinicians employ many divergent styles, the successful ones tend to look for "windows of opportunity" (i.e., careful, attentive listening with replies or questions at opportune times). This communication skill is particularly effective for exploring psychological and social issues during brief interviews. The chief skill essential to allow the physician to perceive problems is the ability to listen attentively.

An interview that permits maximum transmission of information to the physician is best achieved by the following approach (9):

1. **Begin the interview with an open-ended question.**
2. **As the patient begins to speak, pay attention to her answers, her emotions, and her general body language.**
3. **Extend a second question or comment, encouraging the patient to talk.**
4. **Allow the patient to respond without interrupting, perhaps by employing silence, nods, or small facilitative comments, encouraging the patient to talk while the**

physician is listening.

5. **The physician should periodically summarize his or her understanding of the history to confirm accuracy.**
6. **Expressions of empathy and understanding at the completion of the interview along with a summary of the planned assessments and recommendations will facilitate the closure of the interview.**

Attentiveness, rapport, and collaboration characterize good medical interviewing techniques. Open-ended questions (*"How are you doing?" "How are things at home?" "How does that make you feel?"*) are generally desirable, particularly when they are coupled with good listening skills (47).

Premature closure of an interview and an inability to get complete information from the patient may occur for several reasons. They may result from failure to recognize the patient's particular concern, from not providing appropriate opportunity for discussion, from the physician's discomfort with sharing the patient's emotion, or perhaps from the physician's lack of confidence that he or she can deal with the patient's concern. One of the principal factors undermining the success of the interview is lack of time. This is a realistic concern perceived by physicians, but skilled physicians can facilitate considerable interaction even in a short time by encouraging open communication.

[5] Some patients lack accurate information about their illnesses. Incomplete or inadequate understanding of an illness can produce dissatisfaction with medical care and increased anxiety, distress, and coping difficulties, resulting in unsuccessful treatment and poor treatment response. As patients increasingly request more information about their illnesses and more involvement in decisions about their treatment, and as physicians attempt to provide more open interactive discussions, there is an even greater need to provide clear and effective communication. Although patients vary in their intellectual abilities, medical sophistication, anxiety, denial, and the ability to communicate, the unfortunate occurrence of impaired patient comprehension can be the product of poor physician communication techniques, lack of consultation time, and in some cases, the withholding of information considered detrimental to patient welfare.

If clinical findings or confirmatory testing strongly suggests a serious condition (e.g., malignancy), the gravity and urgency of this situation must be conveyed in a manner that does not unduly alarm or frighten the individual. Honest answers should be provided to any specific questions the patient may want to discuss (48).

Allowing time for questions is important, and scheduling a follow-up visit to discuss treatment options after the patient has an opportunity to consider the options and recommendations is often valuable. The patient should be encouraged to bring a partner or family member with her to provide moral support, serve as another

listener to absorb and digest the discussion, and assist with questions. The patient should be encouraged to write down any questions or concerns she may have and bring them with her to a subsequent visit; important issues may not come to mind easily during an office visit. If the patient desires a second opinion, it should always be facilitated. Physicians should not feel threatened by patient attempts to gain information and knowledge.

Valuable information can be provided by interviews with ancillary support staff and by providing pamphlets and other materials produced for patient education. Some studies demonstrated that the use of pamphlets is highly effective in promoting an understanding of the condition and treatment options. Others showed that the use of audiotapes, videotapes, or information on an Internet site has a positive impact on knowledge and can decrease anxiety.

There are numerous medical Web sites that can be accessed, although the accuracy of the information is variable and must be carefully reviewed by physicians before recommending sites to patients. Physicians should be familiar with Internet sources offering accurate information and be prepared to provide the addresses of these sites if the patient expresses interest (49).

The relationship between the patient and her physician, as with all aspects of social interaction, is subject to constant change. The state of our health is dynamic and it affects our ability to communicate with others, including conversations between patients and physicians. **Open communication between patient and physician can help achieve maximum effectiveness in the diagnosis, treatment, and compliance for all patients.**

Talk to the heart, speak to the soul.

Look to the being and embrace the figure's form.
Reach deeply, with hands outstretched.
Talk intently, to the seat of wisdom,
as life resembles grace.

Achieve peace within a fragile countenance.
Seek the comfort of the placid hour
Through joyous and free reflection
know the other side of the flesh's frame.
JSB

HISTORY AND PHYSICAL EXAMINATION

[6] After a dialogue is established, the patient assessment proceeds with obtaining a complete history and, if indicated, performing a physical examination. Both of these aspects of the assessment rely on good patient–physician interchange and attention to details. During the history and physical examination, risk factors that

may require special attention should be identified. These factors should be reviewed with the patient when developing a plan for her future care (see Chapter 21).

Depending on the setting—ambulatory office, inpatient hospitalization, or outpatient surgical center—record keeping is typically facilitated by forms or templates (increasingly, electronic templates as a component of the electronic medical record [EMR]), which provide prompts for important elements of the medical, family, and social history. One challenge is that paper forms and electronic records do not always "mesh," and these paper and electronic records may be periodically unavailable. Efforts to develop patient-held medical records are not yet widely adopted, although the increasing use of smart phones with health applications ("apps") facilitates patient record keeping of data such as blood pressure readings, medication lists, and activity records. Menstrual-cycle tracking is now part of the movement that has been termed the "quantified self" (50,51).

History

After the chief complaint and characteristics of the present illness are ascertained, the medical history of the patient should be updated. Increasingly, this information is available electronically in the EMR, but should be confirmed with the patient. The record should include her complete medical and surgical history, her reproductive history (including menstrual and obstetric history), her current use of medications (including over-the-counter and complementary and alternative medications), and a thorough family and social history.

A technique for obtaining information about the present illness is presented in Table 1-5. **The physician should consider which other members of the health care team might be helpful in completing the evaluation and providing care. Individuals who interact with the patient in the office—from the receptionists to medical assistants, nurses, advance practice nurses (nurse practitioners or nurse midwives)—can contribute to the patient's care and may provide additional information or insight or be appropriate clinicians for providing follow-up. In some teaching hospitals, residents or medical students may provide care and participate in an office setting. The role that each of these individuals plays in a given office or health care setting may not be apparent to the patient; care should be taken that each individual introduces her- or himself at the opening of the interaction and explains his or her role on the team. It may be necessary to discuss the roles and functions of each individual member of the team.** In some cases, referral to a nutritionist, physical or occupational therapist, social worker, psychologist, psychiatrist, or sex counselor would be helpful. Referral to or consultations with these clinicians and with physicians in other specialty areas should be addressed as needed. The nature of the relationship between the obstetrician-gynecologist and the patient should be clarified. Some women

have a primary clinician whom they rely on for primary care. Other women, particularly healthy women of reproductive age, consider their obstetrician-gynecologist their primary clinician. The individual physician's comfort with this role should be discussed and clarified at the initial visit and revisited periodically as required in the course of care. These issues are covered in Section III, Preventative Health Care and Primary Care (see Chapters 21 and 22). Laboratory testing for routine care and high-risk factors is presented in Chapter 21.

Physical Examination

A thorough gynecologic physical examination is typically performed at the time of the initial visit, periodically, and as needed throughout the course of treatment (Table 1-6). The extent of the physical examination during the gynecologic visit is often dictated by the patient's primary concerns and symptoms. For example, for healthy teens without symptoms who are requesting oral contraceptives before the initiation of intercourse, a gynecologic examination is not necessarily required.

Gynecologists have traditionally recommended an annual pelvic examination to screen for asymptomatic conditions, although the evidence for the utility of the screening examination has been called into question (52,53). The American College of Obstetricians and Gynecologists continues to strongly recommend an annual visit as an opportunity for a woman and her ob-gyn to discuss whether an examination is appropriate for her (54). While strongly supporting shared decision making around annual pelvic examinations for asymptomatic women, those with symptoms suggestive of gynecologic disease, including menstrual problems, vaginal discharge, incontinence, infertility, or pelvic pain, should have a pelvic examination (54). Some aspects of the examination—such as assessment of vital signs and measurement of height, weight, blood pressure, and calculation of a body mass index—should be performed routinely during most office visits. Typically, examination of the breasts and abdomen and a complete examination of the pelvis are considered to be essential parts of the gynecologic examination.

Prior to performing the female pelvic examination, and while the patient is still fully clothed, she should be questioned about previous experiences with the examination. Is this her first gynecologic examination? Have previous examinations been difficult or painful? Has she experienced past physical or sexual abuse? While attention should always be given to performing a gentle and atraumatic examination, for individuals with a past history of trauma, the gynecologic examination can trigger flashbacks or can retraumatize. Women should be informed that if the examination is too difficult for them, they can request that it be discontinued. For women who are undergoing their first gynecologic examination, it may be useful to ask what they have heard about the gynecologic examination or to state: *"Most women are nervous before their first exam,*

but afterward, most describe it as 'uncomfortable.'"

Abdominal Examination

With the patient in the supine position, an attempt should be made to encourage her to relax as much as possible. Her head should be leaned back and supported gently by a pillow so that she does not tense her abdominal muscles. Flexion of the knees may facilitate relaxation.

The abdomen should be inspected for signs of an intra-abdominal mass, organomegaly, or distention that would, for example, suggest ascites or intestinal obstruction. Auscultation of bowel sounds, if deemed necessary to ascertain the nature of the bowel sounds, should precede palpation. The frequency of intestinal sounds and their quality should be noted. In a patient with intestinal obstruction, "rushes," and the occasional high-pitched sound, can be heard. Bowel sounds associated with an ileus may occur less frequently but at the same pitch as normal bowel sounds.

Table 1-5 Technique of Taking the History of the Present Illness

1. **The technique used in taking the history of the present illness varies with the patient, the patient's problem, and the physician. Allow the patient to talk about her chief symptom.** Although this symptom may or may not represent the real problem (depending on subsequent evaluation), it is usually uppermost in the patient's mind and most often constitutes the basis for the visit to the physician.

   During the phase of the interview, establish the temporal relation of the chief symptom to the total duration of the illness. Questions such as, *"Then up to the time of this symptom, you felt perfectly well?"* may elicit other symptoms that may antedate the chief one by days, months, or years. In this manner, the patient may recall the date of the first appearance of illness.

   Encourage the patient to talk freely and spontaneously about her illness from the established date of onset. Do not interrupt the patient's account, except for minor promptings such as, *"When did it begin?"* and *"How did it begin?,"* which will help in developing the chronologic order in the patient's story.

   After the patient has furnished her spontaneous account (and before the next phase of the interview), it is useful to employ questions such as, *"What other problems have you noticed since you became ill?"* The response to this question may reveal other symptoms not yet brought forth in the interview.

   Thus, in the first phase of the interview, the physician obtains an account of the symptoms as the patient experiences them, without any bias being introduced by the examiner's direct questions. Information about the importance of the symptoms to the patient and the patient's emotional reaction to her symptoms are also revealed.

2. **Because all available data regarding the symptoms are usually not elicited by the aforementioned techniques, the initial phase of the interview should be followed by a series of direct and detailed questions concerning the symptoms described by the patient.** Place each symptom in its proper chronologic order and then evaluate each in accordance with the directions for analyzing a symptom.

   In asking direct questions about the details of a symptom, take care not to suggest the nature of

the answer. This particularly refers to questions that may be answered “yes” or “no.” If a leading question should be submitted to the patient, the answer must be assessed with great care. Subject the patient to repeated cross-examination until you are completely satisfied that the answer is not given just to oblige you.

Finally, before dismissing the symptom under study, inquire about other symptoms that might reasonably be expected under the clinical circumstances of the case. Symptoms specifically sought but denied are known as negative symptoms. These negative symptoms may confirm or rule out diagnostic possibilities suggested by the positive symptoms.

3. **The data secured by the techniques described in the first two phases of the interview should now suggest several diagnostic possibilities.** Test these possibilities further by inquiring about other symptoms or events that may form part of the natural history of the suspected disease or group of diseases.

4. **These techniques may still fail to reveal all symptoms of importance to the present illness, especially if they are remote in time and seemingly unrelated to the present problem.** The review of systems may then be of considerable help in bringing forth these data. A positive response from the patient on any item in any of the systems should lead immediately to further detailed questioning.

5. **Throughout that part of the interview concerning the present illness, consider the following factors:**

a. **The probable cause of each symptom or illness, such as emotional stress, infection, neoplasm.** Do not disregard the patient’s statements of causative factors. Consider each statement carefully, and use it as a basis for further investigation. When the symptoms point to a specific infection, direct inquiry to water, milk, and foods eaten; exposure to communicable diseases, animals, or pets; sources of sexually transmitted disease; or residence or travel in the tropics or other regions where infections are known to exist. In each of the above instances, ascertain, if possible, the date of exposure, incubation period, and symptoms of invasion (prodromal symptoms).

b. **The severity of the patient’s illness, as judged either by the presence of systemic symptoms, such as weakness, fatigue, loss of weight, or by a change in personal habits.** The latter includes changes in sleep, eating, fluid intake, bowel movements, social activities, exercise, or work. Note the dates the patient discontinued her work or took to bed. Is she continuously confined to bed?

c. **Determine the patient’s psychological reaction to her illness (anxiety, depression, irritability, fear) by observing how she relates her story as well as her nonverbal behavior.** The response to a question such as, *“Have you any particular theories about or fear of what may be the matter with you?”* may yield important clues relative to the patient’s understanding and feeling about her illness. The reply may help in the management of the patient’s problem and allow the physician to give advice according to the patient’s understanding of her ailment.

Modified with permission from **Hochstein E, Rubin AL**. *Physical Diagnosis*. New York: McGraw-Hill; 1964:9–11.

The abdomen is palpated to evaluate the size and configuration of the liver,

spleen, and other abdominal contents. Percussion prior to palpation may suggest organomegaly. Evidence of fullness or mass effect should be noted. This is particularly important in evaluating patients who may have a pelvic mass and in determining the extent of omental involvement, for example, with metastatic ovarian cancer. A fullness in the upper abdomen could be consistent with an "omental cake." All four quadrants should be carefully palpated for any evidence of mass, firmness, irregularity, or distention. A systematic approach should be used (e.g., clockwise, starting in the right upper quadrant). If there is an area of particular tenderness, the examination typically focuses on this area last. The patient should be asked to inhale and exhale during palpation of the edge of the liver. With a history of acute pain, rebound tenderness (suggesting peritoneal irritation) should be ascertained.

Table 1-6 Method of the Female Pelvic Examination

The patient is instructed to empty her bladder. She is placed in the lithotomy position (Fig. 1-1) and draped properly. The examiner's right or left hand, depending on his or her preference, is gloved. The pelvic area is illuminated well, and the examiner faces the patient. The following order of procedure is suggested for the pelvic examination:
A. **External Genitalia**
1. Inspect the mons pubis, labia majora, labia minora, perineal body, and anal region for characteristics of the skin, distribution of the hair, contour, and swelling. Palpate any abnormality.
2. Separate the labia majora with the index and middle fingers of the gloved hand and inspect the epidermal and mucosal characteristics and anatomic configuration of the following structures in the order indicated below:
a. Labia minora
b. Clitoris
c. Urethral orifice
d. Vaginal outlet (introitus)
e. Hymen
f. Perineal body
g. Anus
3. If disease of the Skene glands is suspected, palpate the gland for abnormal excretions by milking the undersurface of the urethra through the anterior vaginal wall. Examine the expressed excretions by microscopy and cultures. If there is a history of labial swelling, palpate for a diseased Bartholin gland with the thumb on the posterior part of the labia majora and the index finger in the vaginal orifice. In addition, sebaceous cysts, if present, can be felt in the labia minora.
B. **Introitus**

With the labia still separated by the middle and index fingers, instruct the patient to bear down. Note the presence of the anterior wall of the vagina when a cystocele is present or bulging of the posterior wall when a rectocele or enterocele is present. Bulging of both may accompany a complete prolapse of the uterus.

The supporting structure of the pelvic outlet is evaluated further when the bimanual pelvic examination is done.

C. **Vagina and Cervix**

Inspection of the vagina and cervix using a speculum should always precede palpation.

The instrument should be warmed with tap water—not lubricated—if vaginal or cervical smears are to be obtained for the test or if cultures are to be performed.

Select the proper size of speculum **(Fig. 1-2)**, warmed and lubricated (unless contraindicated). Introduce the instrument into the vaginal orifice with the blades oblique, closed, and pressed against the perineum. Carry the speculum along the posterior vaginal wall, and after it is fully inserted, rotate the blades into a horizontal position and open them. Maneuver the speculum until the cervix is exposed between the blades. Gently rotate the speculum around its long axis until all surfaces of the vagina and cervix are visualized.

1. Inspect the vagina for the following:
    a. The presence of blood
    b. Discharge. This should be studied to detect trichomoniasis, monilia, and clue cells and to obtain cultures, primarily for gonococci and chlamydia.
    c. Mucosal characteristics (i.e., color, lesions, superficial vascularity, and edema). The lesion may be:
        i. Inflammatory—redness, swelling, exudates, ulcers, vesicles
        ii. Neoplastic
        iii. Vascular
        iv. Pigmented—bluish discoloration of pregnancy (Chadwick sign)
        v. Miscellaneous (e.g., endometriosis, traumatic lesions, and cysts)
    d. Structural abnormalities (congenital and acquired)
2. Inspect the cervix for the same factors listed above for the vagina. Note the following comments relative to the inspection of the cervix:
    a. Unusual bleeding from the cervical canal, except during menstruation, merits an evaluation for cervical or uterine neoplasia.
    b. Inflammatory lesions are characterized by a mucopurulent discharge from the os and redness, swelling, and superficial ulcerations of the surface.
    c. Polyps may arise either from the surface of the cervix projecting into the vagina or from the cervical canal. Polyps may be inflammatory or neoplastic.
    d. Carcinoma of the cervix may not dramatically change the appearance of the cervix or may appear as lesions similar in appearance to an inflammation. Therefore, a biopsy should be

performed if there is suspicion of neoplasia.

D. **Bimanual Palpation**

The pelvic organs can be outlined by bimanual palpation; the examiner places one hand on the lower abdominal wall and the finger(s) (one or two) (see **Fig. 1-3**) of the other hand in the vagina (or vagina and rectum in the rectovaginal examination) (see **Fig. 1-4**). Either the right or left hand may be used for vaginal palpation. The number of fingers inserted into the vagina should be based on what can comfortably be accommodated, the size and pliability of the vagina, and the weight of the patient. For example, adolescent, slender, and older patients might be best examined with a single-finger technique.

1. Introduce the well-lubricated index finger and, in some patients, both the index and the middle finger into the vagina at its posterior aspect near the perineum. Test the strength of the perineum by pressing downward on the perineum and asking the patient to bear down. This procedure may disclose a previously concealed cystocele or rectocele and descensus of the uterus.
   Advance the fingers along the posterior wall until the cervix is encountered. Note any abnormalities of structure or tenderness in the vagina or cervix.
2. Press the abdominal hand, which is resting on the infraumbilical area, very gently downward, sweeping the pelvic structures toward the palpating vaginal fingers.
   Coordinate the activity of the two hands to evaluate the body of the uterus for:
   a. Position
   b. Architecture, size, shape, symmetry, tumor
   c. Consistency
   d. Tenderness
   e. Mobility

   Tumors, if found, are evaluated for location, architecture, consistency, tenderness, mobility, and number.
3. Continue the bimanual palpation, and evaluate the cervix for position, architecture, consistency, and tenderness, especially on mobility of the cervix. Rebound tenderness should be noted at this time. The intravaginal fingers should then explore the anterior, posterior, and lateral fornices.
4. Place the “vaginal” finger(s) in the right lateral fornix and the “abdominal” hand on the right lower quadrant. Manipulate the abdominal hand gently downward toward the vaginal fingers to outline the adnexa.
   A normal tube is not palpable. A normal ovary (about 4 × 2 × 3 cm in size, sensitive, firm, and freely movable) is often not palpable. If an adnexal mass is found, evaluate its location relative to the uterus and cervix, architecture, consistency, tenderness, and mobility.
5. Palpate the left adnexal region, repeating the technique described previously, but place the vaginal fingers in the left fornix and the abdominal hand on the left lower quadrant.
6. Follow the bimanual examination with a rectovaginal–abdominal examination.
   Insert the index finger into the vagina and the middle finger into the rectum very gently. Place the other hand on the infraumbilical region. The use of this technique makes possible higher exploration of the pelvis because the cul-de-sac does not limit the depth of the examining finger.
7. In patients who have an intact hymen, examine the pelvic organs by the rectal–abdominal

technique.

E. **Rectal Examination**

1. Inspect the perianal and anal area, the pilonidal (sacrococcygeal) region, and the perineum for the following aspects:
    a. Color of the region (Note that the perianal skin is more pigmented than the surrounding skin of the buttocks and is frequently thrown into radiating folds.)
    b. Lesions
        i. The perianal and perineal regions are common sites for itching. Pruritus ani is usually indicated by thickening, excoriations, and eczema of the perianal region and adjacent areas.
        ii. The anal opening often is the site of fissures, fistulae, and external hemorrhoids.
        iii. The pilonidal area may present a dimple, a sinus, or an inflamed pilonidal cyst.
2. Instruct the patient to “strain down” and note whether this technique brings into view previously concealed internal hemorrhoids, polyps, or a prolapsed rectal mucosa.
3. Palpate the pilonidal area, the ischiorectal fossa, the perineum, and the perianal region before inserting the gloved finger into the anal canal.
   Note the presence of any concealed induration or tenderness in any of these areas.
4. Palpate the anal canal and rectum with a well-lubricated, gloved index finger. Lay the pulp of the index finger against the anal orifice and instruct the subject to strain downward. Concomitant with the patient’s downward straining (which tends to relax the external sphincter muscle), exert upward pressure until the sphincter is felt to yield. Then, with a slight rotary movement, insinuate the finger past the anal canal into the rectum. Examine the anal canal systematically before exploring the rectum.
5. Evaluate the anal canal for:
    a. Tonus of the external sphincter muscle and the anorectal ring at the anorectal junction.
    b. Tenderness (usually caused by a tight sphincter, anal fissure, or painful hemorrhoids).
    c. Tumor or irregularities, especially at the pectinate line.
    d. Superior aspect: Reach as far as you can. Mild straining by the patient may cause some lesions, which are out of reach of the finger, to descend sufficiently low to be detected by palpation.
    e. Test for occult blood: Examine the finger after it is withdrawn for evidence of gross blood, pus, or other alterations in color or consistency. Smear the stool to test for occult blood (guaiac).
6. Evaluate the rectum:
    a. Anterior wall
        i. Cervix: size, shape, symmetry, consistency, and tenderness, especially on manipulation
        ii. Uterine or adnexal masses

iii. Rectouterine fossa for tenderness or implants
In patients with an intact hymen, the examination of the anterior wall of the rectum is the usual method of examining the pelvic organs.

b. Right lateral wall, left lateral wall, posterior wall, superior aspect; test for occult blood

Pelvic Examination

The pelvic examination is usually performed with the patient in the dorsal lithotomy position (Fig. 1-1). The patient's feet should rest comfortably in stirrups with the edge of the buttocks at the lower end of the table so that the vulva can be readily inspected and the speculum can be inserted in the vagina without obstruction from the table. Raising the head of the examination table, if possible, may facilitate relaxation. Drapes should be placed to provide a measure of cover for the patient's legs but should be depressed over the abdomen to allow observation of the patient's expression and to facilitate communication.

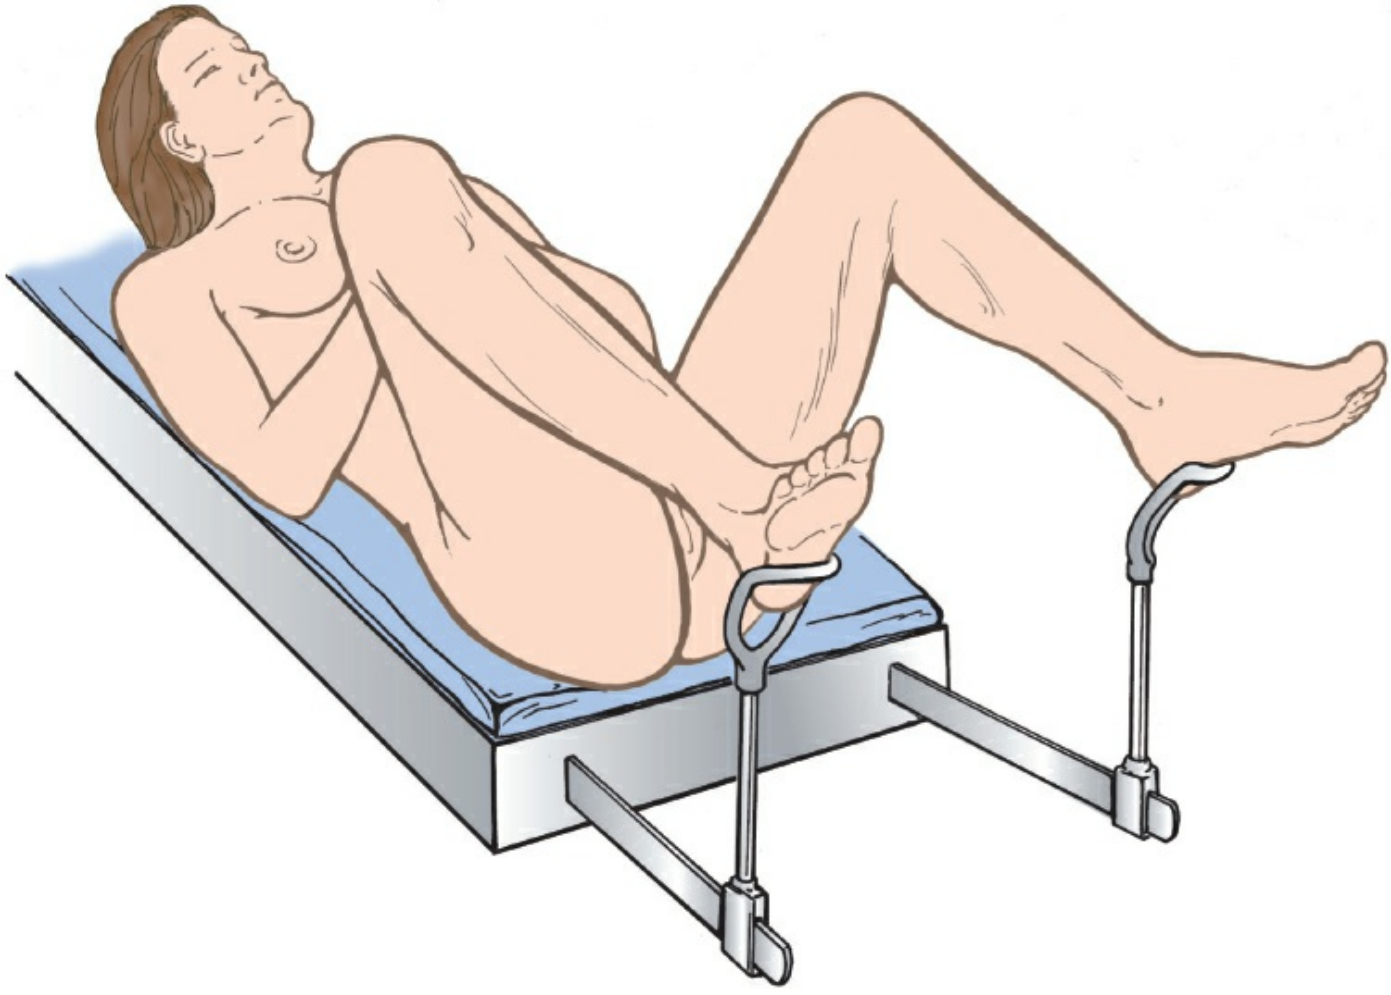

FIGURE 1-1 The lithotomy position for the pelvic examination.

Before each step of the examination, the patient should be informed of what she will feel next: "*First you'll feel me touch your inner thighs; next I'll touch the area around the outside of your vagina*." The vulva and perineal area should be carefully inspected. Evidence of any lesions, erythema, pigmentation, masses, or irregularity should be noted. The skin quality should be noted and any signs of trauma, such as excoriations or ecchymosis. Areas of erythema or tenderness are noted, particularly in women with vulvar burning or pain, as might be seen with vulvar vestibulitis or localized provoked vulvodynia. The presence of any visible lesions should be quantitated and carefully described with regard to their full appearance and characteristics on palpation (i.e., mobility, tenderness, consistency). A drawing of the location of skin lesions is helpful. Ulcerative or purulent lesions of the vulva should be evaluated and tested for infection as outlined in subsequent chapters, and biopsy should be planned for any lesions if the diagnosis is not apparent on inspection. It may be helpful to ask the patient if she is aware of any vulvar lesions and to offer a mirror to demonstrate any lesions.

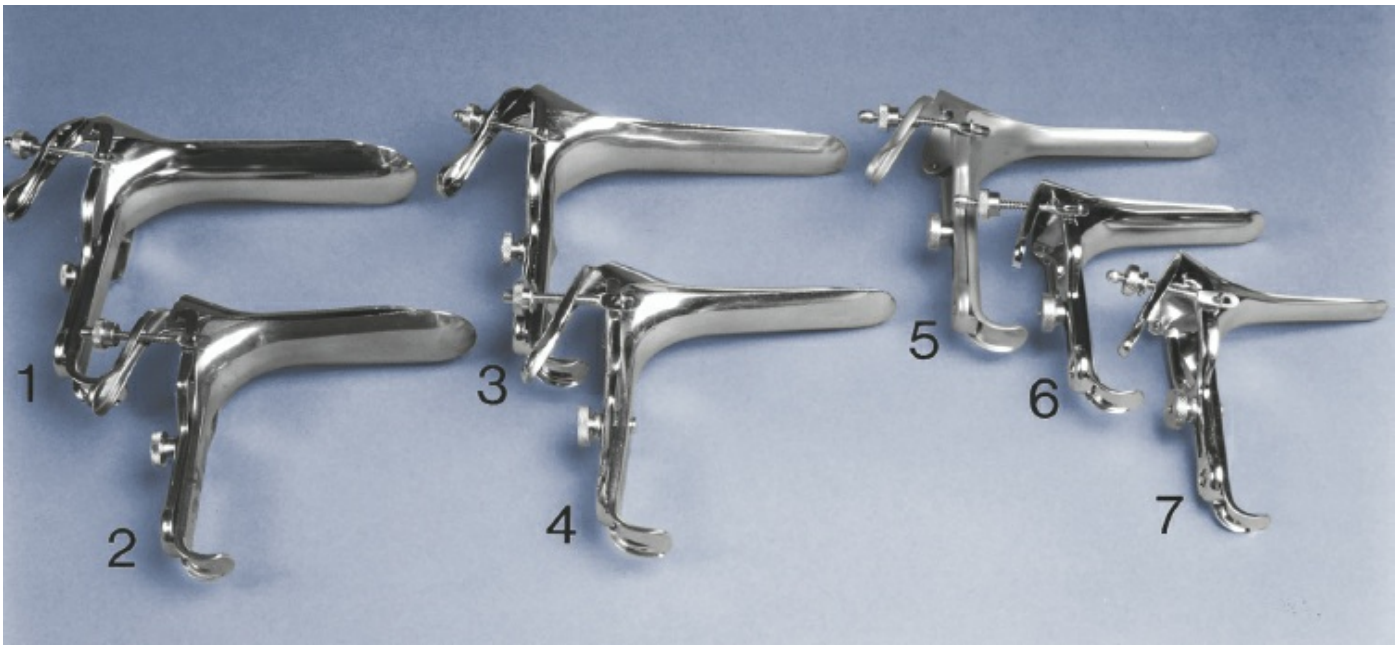

FIGURE 1-2 Vaginal specula: (*1*) Graves extra long; (*2*) Graves regular; (*3*) Pederson extra long; (*4*) Pederson regular; (*5*) Huffman "virginal"; (*6*) pediatric regular; and (*7*) pediatric narrow.

After thorough visualization and palpation of the external genitalia, including the mons pubis and the perianal area, a speculum is inserted into the vagina. In a healthy adult who is sexually active, a Pederson speculum is usually appropriate. The types of specula that are used in gynecology are presented in Figure 1-2.

The smallest-width speculum necessary to produce adequate visualization should be used. The larger Graves speculum may be required in women who have lax vaginal walls, are pregnant, or will be undergoing cervical or endometrial biopsies or

procedures. In some women, a longer speculum (either Pederson or Graves) may facilitate visualization of the cervix in a manner that is less uncomfortable to the patient. If any speculum other than the typically sized specula is used, the patient should be informed and documented in the medical record. It can be helpful to encourage the patient to remind the clinician before her next examination. The speculum should be warmed before it is inserted into the vagina; a heating pad or speculum warmer should be placed under the supply of specula. **If lubrication is required, warm water generally is sufficient or a small amount of lubricant can be used without interfering with cervical cytology testing.** The patient should be asked to relax the muscles of her distal vagina before the insertion of the speculum to facilitate the placement and to avoid startling her by this portion of the examination. After insertion, the cervix and all aspects of the vagina should be carefully inspected. Particular attention should be paid to the vaginal fornices, because lesions (e.g., warts) may be present in those areas and may not be readily visualized.

The appropriate technique and frequency for cervical cytology testing are presented in Chapter 16. **Biopsy should be performed on any obvious lesions on the cervix or in the vagina.** An endometrial biopsy usually is performed with a flexible cannula (see Chapter 10). Any purulence in the vagina or cervix should be cultured (see Chapter 15). **Testing for sexually transmitted diseases should be performed routinely in adolescents and young adults as recommended by the Centers for Disease Control and Prevention.**

After the speculum is removed, lubrication is applied to the examination glove, and **one or two (the index or index and middle) fingers are inserted gently into the vagina to palpate the uterus and adnexal areas.** In general, in right-handed physicians, the fingers from the right hand are inserted into the vagina and the left hand is placed on the abdomen to provide counter pressure as the pelvic viscera are moved **(Fig. 1-3)**. In patients with pelvic pain, a stepwise "functional pelvic examination" involves the sequential palpation of anatomic structures, including the vaginal introitus, pelvic floor muscles, bladder, rectum, cervix, and cul-de-sac. These areas are assessed for tenderness and a specific source of pain. Pelvic floor muscle spasm is a common concomitant of pelvic pain. The vagina, its fornices, and the cervix are palpated carefully for any masses or irregularities. One or two fingers are placed gently into the posterior fornix so the uterus can be moved. With the abdominal hand in place, the uterus usually can be palpated just above the surface pubis. In this manner, the size, shape, mobility, contour, consistency, and position of the uterus are determined. The patient is asked to provide feedback about any areas of tenderness, and her facial expressions are observed during the examination.

The adnexa are palpated gently on both sides, paying particular attention to any enlargements. The size, shape, mobility, and consistency of any adnexal structures

should be carefully noted.

When indicated, a rectovaginal examination should be performed to evaluate the rectovaginal septum, the posterior uterine surface, the adnexal structures, the uterosacral ligaments, and the posterior cul-de-sac. Uterosacral nodularity or posterior uterine tenderness associated with pelvic endometriosis or cul-de-sac implants of ovarian cancer can be assessed in this manner. Hemorrhoids, anal fissures, sphincter tone, rectal polyps, or rectal lesions including carcinoma may be detected. A single stool sample for fecal occult blood testing obtained in this manner is not adequate for the detection of colorectal cancer and is not recommended **(Fig. 1-4)** (55).

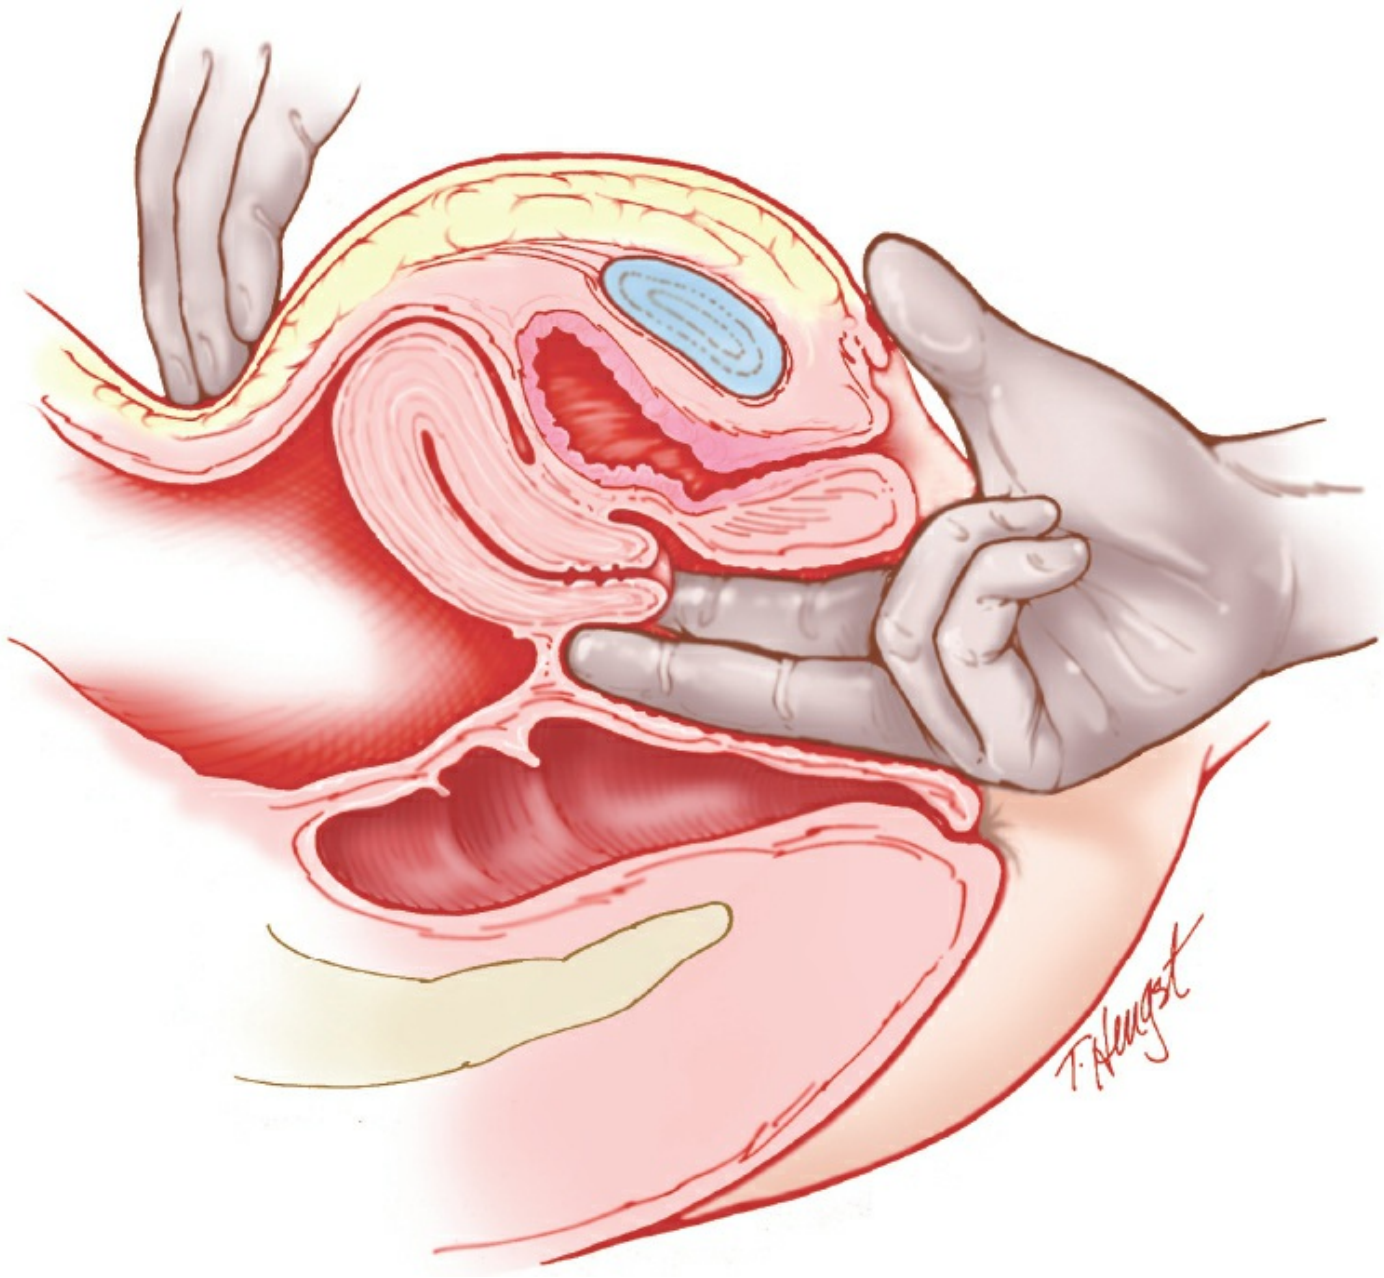

FIGURE 1-3 The bimanual examination.

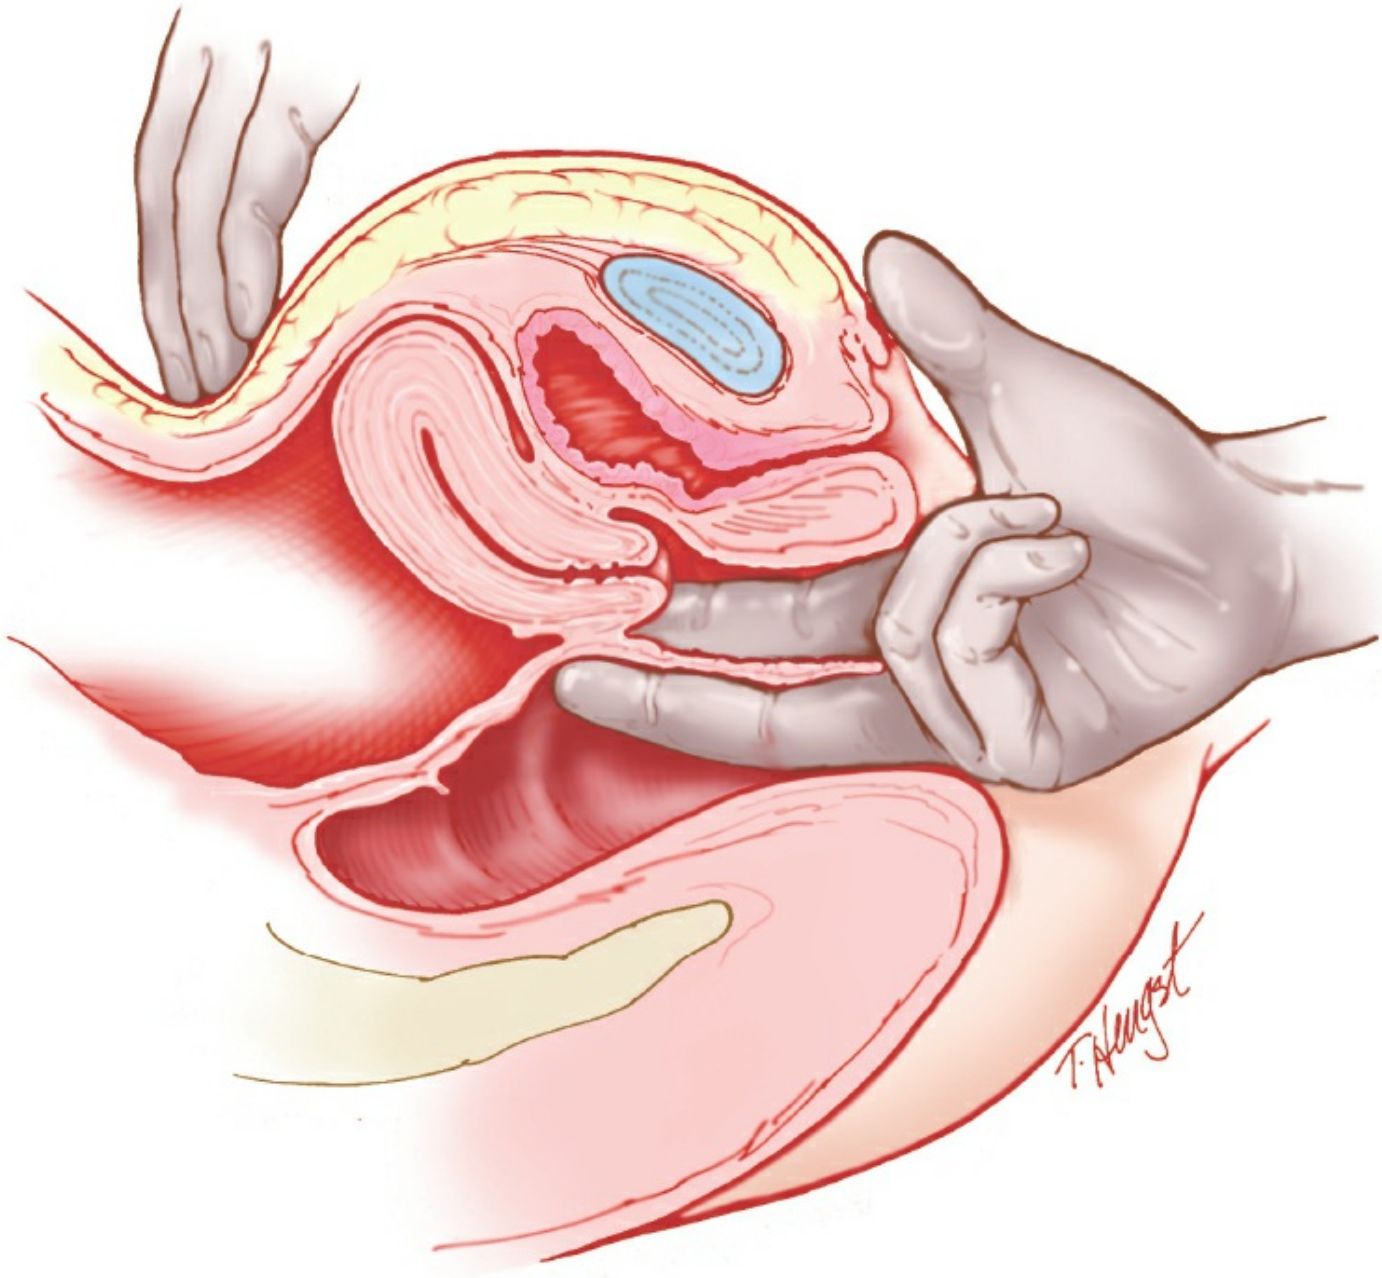

FIGURE 1-4 The rectovaginal examination.

At the completion of the physical examination, the patient should be informed of the findings. When the results of the examination are normal, the patient can be reassured accordingly. When there is a possible abnormality, the patient should be informed immediately; this discussion should take place after the examination with the patient clothed. A plan to evaluate the findings should be outlined briefly and in clear, understandable language. The implications and timing of any proposed procedure (e.g., biopsy) should be discussed, and the patient should be informed when the results of any tests will be available.

Pediatric Patients

A careful examination is indicated when a child presents with genital symptoms such as itching, discharge, burning with urination, or bleeding. The examiner should be familiar with the normal appearance of the prepubertal genitalia. The normal unestrogenized hymenal ring and vestibule can appear mildly erythematous. The technique of examination is different from that used for examining an adult and may need to be tailored to the individual child based on her age, size, and comfort with the examiner.

A speculum examination should not be performed in a prepubertal child in the office. A young child usually can be examined best in a "frog leg" or "butterfly leg" position on the examining table. Some very young girls (toddlers or infants) do best when held in their mother's arms. Sometimes, the mother can be positioned, clothed, on the examination table (feet in stirrups, head of table elevated) with the child on her lap, the child's legs straddling her mother's legs. The knee–chest position may be helpful for the examination (56). The child who is relaxed and warned about touching will usually tolerate the examination satisfactorily. An otoscope can be used to examine the distal vagina if indicated. Two percent *lidocaine* jelly may be used as a topical anesthetic to facilitate the examination if needed.

Some children who were abused, who had particularly traumatic previous examinations, or who are unable to allow an examination may need to be examined under anesthesia, although a gentle office examination should almost always be attempted first. If the child had bleeding and no obvious cause of bleeding is visible externally or within the distal vagina, an examination under anesthesia is indicated to visualize the vagina and cervix completely. A hysteroscope, cystoscope, or other endoscopic instruments can be used to provide magnification and as a light source for vaginoscopy, which should be performed under anesthesia.

Adolescent Patients

A pelvic examination may be less revealing in an adolescent than in an older woman, particularly if it is the patient's first examination or if it takes place on an emergency basis. **An adolescent who presents with excessive bleeding should have a pelvic examination if she had intercourse, if the results of a pregnancy test are positive, if she has abdominal pain, if she is markedly anemic, or if she is bleeding heavily enough to compromise hemodynamic stability.** The pelvic examination occasionally may be deferred in young teenagers who have a classic history of irregular cycles soon after menarche, who have normal hematocrit levels, who deny sexual activity, and who will reliably return for follow-up. A pelvic examination may be deferred in adolescents who present to the office requesting oral contraceptives before the initiation of intercourse or at the patient's request, even if she has had intercourse. Newer testing methods using DNA amplification techniques allow noninvasive urine testing for gonorrhea and chlamydia (57). Guidelines recommend that cervical cytology testing in

most adolescents be initiated at age 21 for virtually all young women, with the exception of those who are HIV-infected or otherwise immunocompromised (58).

Other diagnostic techniques (such as a transabdominal pelvic ultrasound) can substitute for or supplement an inadequate examination. An examination usually is required when there is a question of pelvic pain, genital anomaly, pregnancy-related condition, or possibility of pelvic infection. **The key to a successful examination in an adolescent lies in earning the patient's trust, explaining the components of her examination, performing only the essential components, and using a very careful and gentle technique.** It is helpful to ascertain whether the patient has had a previous pelvic examination, how she perceived the experience, and what she heard about a pelvic examination from her mother or friends.

Before a first pelvic examination is performed, a brief explanation of the planned examination (which may or may not need to include a speculum), instruction in relaxation techniques, and the use of *lidocaine* jelly at the vaginal introitus/ hymenal ring can be helpful. An explanation should be provided to the patient (and her mother, if the patient chooses), about the anatomy of the hymen, noting that after menarche, the hymen is elastic and typically easily distensible, and that a gynecologic examination does nothing to impact virginity (59). The patient should be encouraged to participate in the examination by voluntary relaxation of the introital muscles or by using a mirror if she wishes. If significant trauma is suspected or the patient finds the examination too painful and is truly unable to cooperate, an examination under anesthesia may be necessary. The risks of general anesthesia must be weighed against the value of information that would be obtained by the examination.

Confidentiality is an important issue in adolescent health care. A number of medical organizations, including the American Medical Association, the American Academy of Pediatrics, and the American College of Obstetrics and Gynecologists, endorsed adolescents' rights to confidential medical care. Particularly with regard to issues as sensitive as sexual activity, it is critical that the adolescent be interviewed alone, without a parent in the room. After assurances of confidentiality (with the caveats dictated by state law relating to mandatory reporting of suspected physical or sexual abuse), the patient should be asked whether she engaged in sexual intercourse, whether she used any method of contraception, used condoms to minimize the risks of sexually transmitted diseases, or she feels there is any possibility of pregnancy.

Follow-Up

Arrangements should be made for the ongoing care of patients, regardless of their health status. Patients with no evidence of disease should be counseled regarding health behaviors and the need for routine care. For those with signs and symptoms of a medical disorder, further assessments and a treatment plan should be discussed. The

physician must determine whether she or he is equipped to treat a particular problem or whether the patient should be directed to another health professional, either in obstetrics and gynecology or another specialty, and how that care should be coordinated. If the physician believes it is necessary to refer the patient elsewhere for care, the patient should be reassured that this measure is being undertaken in her best interests and that continuity of care will be ensured. Patients deserve a summary of the findings of the visit, recommendations for preventive care and screening, an opportunity to ask any additional questions, and a recommendation for the frequency of any follow-up or ongoing care visits. Ideally, the recommendations for care should be transmitted to the patient in written form, as an "after visit summary" noting diagnoses, medications prescribed, and recommendations for testing such as blood tests or imaging and follow-up visits.

SUMMARY

The management of patients' gynecologic symptoms, and abnormal findings and signs detected during examination, requires the full use of a physician's skills and knowledge. Physicians are challenged to practice the art of medicine in a manner that leads to effective alliances with their patients. The value of skilled medical history taking cannot be overemphasized. **Physicians should listen carefully to what patients are saying about the nature and severity of their symptoms.** They should listen to what patients may not be expressing: their fears, anxieties, and personal experiences that lead them to react in a certain manner when faced with what is often, to them, a crisis (such as the diagnosis of an abnormality on examination, laboratory testing, or pelvic imaging).

Physicians should supplement their formal education and clinical experience by constantly seeking valid new information and honing their communication skills. To meet the challenges posed by the complexities of patient care, physicians must learn to practice evidence-based medicine, derived from the very latest data of highest quality. Computers make the world of information management accessible to both physicians and patients. Physicians need to search the medical literature to acquire knowledge that can be applied, using the art of medicine, to patient care that maintains health, prevents disease, alleviates suffering, and manages and cures illness.

CHAPTER 2

Principles of Patient Care

Susan L. Zweizig, Joanna M. Cain

Patient and Physician: Professionalism
- Disclosing Medical Errors and Unanticipated Outcomes
- Confidentiality
  - *Record Keeping*
  - *Legal Considerations*
- Informed Consent
  - *Autonomy*
  - *Surrogate Decision Makers*
- Beneficence and Nonmaleficence
  - *Medical Futility*
  - *Quality of Life*

Professional Relations
- Conflict of Interest
  - *Health Care Payors*
  - *Legal Problems*
- Harassment
- Stress Management, Burnout and Prevention

Society and Medicine
- Justice
- Health Care Reform

KEY POINTS

1 Professionalism is the foundation of patient care and is as much an ongoing educational endeavor as is learning new procedures or techniques.

2 The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege.

3 Informed consent is a process whereby the physician educates the patient about the medical condition, associated risks and benefits of treatment, explains reasonable medical alternatives, and explores her values in this context.

4 The concept of autonomy does not allow a patient's wishes to take precedence over good medical judgment.

5 For children, parents are the surrogate decision makers, except in circumstances in which their decision is life threatening and might not be the choice a child would make later, when individual adult beliefs and values are formed.

6 Creating a highly professional environment of safe culture, lack of harassment, high professional behavior standards, and disclosure of unexpected outcomes benefit patients and health professionals.

7 Prevention of burnout and maintenance of physician wellness are ethical responsibilities of the health care system and are vital to the fiduciary relationship between a physician and their patients.

The practice of gynecology, as with all branches of medicine, is based on ethical principles that guide patient care. These principles and concepts create a framework for ethical decision making that applies to all aspects of practice:

- **Autonomy: a person's right to self-rule, to establish personal norms of conduct, and to choose a course of action based on a set of personal values and principles derived from these concepts**
- **Confidentiality: a person's right to autonomy in deciding how and to whom personal medical information will be communicated**
- **Beneficence: the obligation to promote the well-being of others or, in medicine, to act in the best interest of the patient, defined by meeting a goal of medicine through the care offered**
- **Covenant: an agreement or commitment between two or more parties for the performance of some action**
- **Fiduciary relationship: a relationship founded on faith and trust and the obligation to act in a trustworthy manner**
- **Informed consent: the patient's acceptance of a medical intervention after adequate discussion and consideration of the nature of the procedure, its risks, benefits, and alternatives**
- **Justice: medical resources should be distributed fairly and individuals or groups have the right to claim what is due to them based on certain personal properties or characteristics**
- **Nonmaleficence: obliges health professionals to avoid doing harm, assuring that benefits of interventions outweigh the potential harms of intervention**

PATIENT AND PHYSICIAN: PROFESSIONALISM

Health care providers fulfill a basic need—to preserve and advance the health of human beings. Despite the challenges imposed by the commercial aspects of the medical environment, for most physicians, the practice of medicine remains very much a "calling," a giving of oneself to the greater good. The behavior of health professionals is evaluated in accordance with these ethical principles and concepts by other professionals and the public who share the belief in the "calling" of medicine. There are examples of unprofessional behaviors that mar this professional image. They are demonstrably easier to see in others than ourselves, including unprofessional behavior in shouting at or mistreating others, lack of recognition of conflicts of interest that could affect patient care, or inappropriate interactions with students, patients, or colleagues. These behaviors, such as boundary violations or learner abuse, erode the professional standing of the physician. Lapses do not always represent inherent flaws in professionals, "*most lapses represent deficiencies in judgment and skill. They occur when the physician in question fails to recognize the presence of a challenge to professionalism or lacks the skill to handle a challenge at the time it occurs*" (1). As Lucey and Souba note, **[1]** the solution to unprofessional behavior is not recrimination but development of a set of skills that allow professionals to recognize and address these professional challenges—and those skills need to be developed and reinforced by individuals and by the whole community of practicing physicians throughout their professional careers (1). Professionalism is as much an ongoing educational endeavor as is learning new procedures or techniques, and "*we should assume that our peers want to be professional and that they will welcome interventions from a trusted colleague when circumstances suggest that a lapse is imminent*" (1). **[6]** Creating an environment where we can help one another in this way improves the quality and safety of the care for our patients by preventing unprofessional behavior. **An environment without fear of recrimination, harassment, or unprofessional behavior fosters ease in speaking up for patients' interests and promotes safer environments for everyone. This is a fundamental principle of excellence in patient care (2).**

Professionalism has to balance the differences between fiduciary and contractual relationships between physician and patient: "*The kind of minimalism that a contractualist understanding of the professional relationship encourages produces a professional too grudging, too calculating, too lacking in spontaneity, too quickly exhausted to go the second mile with his patients along the road of their distress*" (3). There is a relationship between physician and patient that extends beyond a contract and assumes the elements of a fiduciary relationship—a covenant between parties. **The physician, having knowledge about the elements of health care, assumes a trust relationship with the patient where her interests are held paramount. Both the**

patient and the physician have rights and responsibilities in this relationship, and both are rewarded when those rights and responsibilities are upheld. Honesty, disclosure, confidentiality, and informed consent are expressions of that trust or covenantal relationship. This cannot be accomplished without some self-awareness on the physicians' part. Health care systems and the governing bodies of medicine have a similar obligation to patients in maintaining physician health through the identification and prevention of provider burnout or dysfunction.

Disclosing Medical Errors and Unanticipated Outcomes

[6] In creating a trustworthy and safe environment, the timely and appropriate disclosure of unanticipated outcomes improves the trust patients have in their health care team and, with complete documentation and reporting, ensures that all medical errors or near misses are used to improve the environment of care. If we are obligated as professionals by our trust relationship with our patients, then patients should expect truthfulness, including being made aware of individual or systemic errors, which, as Kohn et al. noted in *To Err Is Human*, are inevitable in the delivery of health care (4). **[6] A climate that supports a no-fault discussion of errors creates an environment conducive to restructuring the systems or procedures that make it possible for errors to occur and is critical in the development of a safety culture.**

Medical errors can create a keen sense of shame, humiliation, and failed responsibility in health professionals, and efforts have begun to identify and develop the skills and methods for disclosing and learning from them. Support for individuals facing these feelings and preparing to disclose is critical in this development. **[6] Skills that seem common to disclosure are explaining medical facts with honesty and truthfulness (responsibility and answering questions), empathy (and apology), stating how future errors will be prevented, and using good communication skills (5). These are skills that require training and development and should not be taken for granted.** Many institutions have risk management groups or other support groups that can be helpful in development of skills and can accompany or lead such a discussion in the absence of those skills. Disclosure and apology cause apprehension for physicians—particularly in the discipline of obstetrics and gynecology where litigation has adversely affected practice patterns (defensive medicine) and heightened a reluctance to disclose medical errors for fear of litigation (6,7). Apology raises particular anxiety about implying culpability and inciting litigation, so help with framing an apology is always appropriate. **The obligation of trust (fiduciary relationship) that we have with our patients is an important part of healing—and we owe it to our patients and ourselves to develop the robust curricula and support at all levels of medical care to make disclosure the step toward solution and healing that it can be**

for physician and patient.

Confidentiality

The patient seeking assistance from a health professional has the right to assurance that the information exchanged during that interaction is kept private. [2] **Privacy is essential to the trust relationship between doctor and patient. Discussions are privileged information. The right to privacy prohibits a physician from revealing information regarding the patient unless the patient waives that privilege.** Privileged information belongs to the patient except when it impinges on the legal and ethical rights of institutions and society at large, regardless of the setting. In a court situation, for example, physicians cannot reveal information about their patients unless the patient waives that privilege. If privilege is waived, the physician may not withhold such testimony.

[2] **A physician applying the principle of autonomy will respect a patient's privacy and maintain a process that protects confidentiality. The right of privacy must be maintained even when it does not seem intrinsically obvious. A patient's family, friend, or spiritual guide, for example, has no right to medical information regarding the patient unless the patient specifically approves it, except when the patient is unable to provide that guidance because of their medical circumstance.** In that circumstance, health providers must exercise their judgment based on their assessment of the involvement of that particular person with the patient's health. This may seem obvious, but often can be overlooked, such as when a health care giver receives a call from a concerned relative inquiring about the status of a patient. The response may be a natural attempt to reassure and inform a caring individual about the patient's status. However, for her own reasons, the patient may not want certain individuals informed of her medical condition. Thus, confidentiality can unintentionally be breached. It is wise to ask patients about who may be involved in decision making and who may be informed about their status. [2] **If a health care giver is unclear of the patient's wishes regarding the person requesting information, the reply should indicate that the patient's permission is necessary before discussing her status. When trying to contact patients for follow-up of medical findings, it is never appropriate to reveal the reason for contact to an individual other than the patient.**

Record Keeping

Health care professionals are a part of record-keeping organizations. Those records are used for multiple purposes in medicine and are a valuable tool in patient care. There is an increasing tendency for ancillary organizations to collect, maintain, and disclose information about individuals with whom they have no direct connection. Health care professionals must be aware of this practice and its ramifications. Patients sign a

document, often without understanding its meaning, upon registering with a health care institution or insurance plan. That document waives the patient's privilege to suppress access and gives insurers, and often other health care providers who request it, access to the medical record. The consequences of such disclosure for patients can be significant in terms of insurance coverage and potential job discrimination. Even with health care reform and improved attention to pre-existing conditions as part of that reform (8), this continues to be a concern because individuals may have shifts in the pools of insurance available to them and their costs may vary. This concern must be weighed against the need for all health care providers involved with an individual to be informed about past or present diseases or activities that may interfere with or complicate management. The use of illegal drugs, a positive HIV test result, genetic testing results, and even a history of cancer or psychiatric illness are all exceptionally important to health care providers in evaluating individual patients. When revealed to outside institutions, these factors may affect the patient's ability to obtain medical care, insurance, or even credit. **Everything that is written in a patient's record should be important to the medical care of that patient, and extrinsic information should be avoided.** It is appropriate for physicians to discuss with patients the nature of medical records and their release to other parties so that patients can make an informed choice about such release.

The Health Insurance Portability and Accountability Act (HIPAA) was enacted in 1996 and effective compliance of the "privacy rule" was instituted in April 2003. This rule imposed additional requirements for access to patient records for clinical research and guidelines for protecting electronic medical records. Although the intent of the act was laudable, the extent to which privacy is improved is still unknown. The potential harm to the public from misunderstanding of HIPAA requirements or the cost of those requirements that may inhibit critical research is also unknown. Exceptions from the requirement to obtain patient authorization to share health information include areas such as patient treatment, payment, operations (quality improvement, quality assurance, and education), disclosure to public health officials and health oversight agencies, and legal requirements (9). It is important that researchers understand the influence of these rules in all settings; preplanning for clinical database research to include consent for research database efforts when the patient first enters the office or institution will make this critical research possible. **The security of medical records is a concern for individual patients and physicians and for health systems and researchers.**

Legal Considerations

The patient's privilege to keep their records or medical information private can be superseded by the needs of society, but only in rare circumstances. The classic legal decision quoted for the needs of others superseding individual patient rights is that of *Tarasoff v. Regents of the University of California* (10). That decision establishes that

the special relationship between a patient and doctor may support affirmative duties for the benefit of third persons. It requires disclosure if "*necessary to avert danger to others*" but still in a fashion "*that would preserve the privacy of the patient to the fullest extent compatible with the prevention of the threatened danger.*" This principle is compatible with the various codes of ethics that allow physicians to reveal information to protect the welfare of the individual or the community. In other words, "the protective privilege ends where the public peril begins" (11).

Legislation can override individual privilege. The most frequent example is the recording of births and deaths, which is the responsibility of physicians. Various diseases are required to be reported depending on state law (e.g., HIV status may or may not be reportable in individual states, whereas AIDS is reportable in all states). Reporting any injuries caused by lethal weapons, rapes, and battering (e.g., elder and child abuse) is mandatory in some states and not others. The regulations for the reporting of these conditions are codified by law and can be obtained from the state health department. **[4]** These laws are designed to protect the individual's privacy as much as possible while still serving the public's interest. **Particularly in the realm of abuse, physicians have a complex ethical role regardless of the law. Victims of abuse must feel supported and assured that the violent act they survived will not have an adverse effect on how they are treated as people.** Their sense of vulnerability and their actual vulnerability may be so great that reporting an incident may increase their risk for medical harm.

Informed Consent

[3] Informed consent is a process that involves an exchange of information directed toward reaching mutual understanding and informed decision making. Ideally, informed consent should be the practical manifestation of respect for individual patient preferences and autonomy (12). An act of informed consent is often misunderstood to be getting a signature on a document. The intent of the individual involved in the consent process is often the protection of the physician from liability. Nothing could be further from either the legal or ethical meaning of this concept.

[3] Informed consent begins with a conversation between physician and patient that teaches the patient about the medical condition, explores her values, and informs her about the reasonable medical alternatives. Informed consent is an interactive discussion in which one participant has greater knowledge about medical information and the other participant has greater knowledge about that individual's value system and circumstances affected by the information. This process does not require an arduous lecture on the medical condition or extensive examination of the patient's psyche. It does require adjustment of the information to the educational level of the patient and respectful elicitation of concerns and questions. Fear that the information

may frighten patients, fear of hearing the information by the patient, a lack of ability to comprehend technical information, the accuracy of the information given, and an inability to express that lack are among the many barriers facing physicians and patients engaging in this conversation (13). [1] **Communication skills are part of the art of medicine,** and observation of good role models, practices, and positive motivation can help to instill this ability in physicians.

Autonomy

[4] **Informed consent arises from the principle of autonomy.** Pellegrino defines an autonomous person as "*one who, in his thoughts, work, and actions, is able to follow those norms he chooses as his own without external constraints or coercion by others*" (14). This definition contains the essence of what health care providers must consider as informed consent. The choice to receive or refuse medical care must be in concert with the patient's values and be freely chosen, and the options must be considered in light of the patient's values.

[4] **Autonomy is not respect for a patient's wishes against good medical judgment.** Consider the example of a patient with inoperable, advanced-stage cervical cancer who demands surgery and refuses radiation therapy. [4] **The physician's ethical obligation is to seek the best for the patient's survival (beneficence) and avoid the harm (nonmaleficence) of surgery, even if that is what the patient wishes.** Physicians are not obligated to offer treatment that is of no benefit, and the patient has the right to refuse treatment that does not fit into her values. Thus, this patient could refuse treatment for her cervical cancer, but she does not have the right to be given any treatment she wishes, which in this case is a treatment that would cause harm and no benefit.

Surrogate Decision Makers

[5] **If the ability to make choices is diminished by extreme youth, mental processing difficulties, extreme medical illness, or loss of awareness, surrogate decision making may be required. In all circumstances, the surrogate must make every attempt to act as the patient would have acted (15).** The hierarchy of surrogate decision makers is specified by statutory law in each state and differs slightly from state to state. For adults, the first surrogate decision maker in the hierarchy is usually a court-appointed guardian if one exists and second is a durable power of attorney for health care if it exists, followed by relatives by degree of presumed familiarity (e.g., spouse, adult children, parents). For lesbian couples, this presents issues in some states even with changes in federal law that make marriage for same-sex couples legal. In this situation, the creation of a durable power of attorney can address this issue proactively. **Physicians should make sure their patients are aware of the need to have clear instructions about who they would want to speak for them if they are not able—in some cases it is not the person specified by the state guidelines.** For example,

elderly women may not want their elderly (and slightly senile) spouse making decisions and prefer a friend or children—and should have a durable power of attorney for health care that ensures that will be the case.

[5] For children, parents are the surrogate decision makers, except in circumstances in which the decision is life threatening and might not be the choice a child would make later, when individual adult beliefs and values are formed. The classic example of this is the Jehovah's Witness parents who refuse life-saving transfusions for their child (16). Although this case is the extreme, it illustrates that the basic principle outlined for surrogate decision making should apply to parents. Bias that influences decision making (in protection of parental social status, income, or systems of beliefs) needs to be considered by physicians because the potential conflict may lead parents to decisions that are not in the best interest of the child. If there is a conflicting bias that does not allow decisions to be made in the best interest of the child or that involves a medical threat to a child, legal action to establish guardianship (normally through a child protective agency by the courts) may be necessary. This action can destroy the patient (child)–physician relationship and the parent–physician relationship. It may affect the long-term health and well-being of the child, who must return to the care of the parents. Such decisions should be made only after all attempts to educate, clarify, and find alternatives are exhausted.

[5] The legal age at which adolescents may make their own decisions regarding their health care varies by state and national laws. There is a growing trend to increase the participation of adolescents who are capable of decision making for their own health care. Because minors often have developed a value system and the capacity to make informed choices, their ability to be involved in decisions should be assessed individually rather than relying solely on the age criteria of the law and their parents' views (17).

A unique area for consideration of informed consent is providing care or conducting clinical research in foreign settings or caring for individuals from other countries who have differing viewpoints regarding individual autonomy. For example, if the prevailing standard for decision making by a woman is that her closest male relative makes it for her, how is that standard accommodated within our present autonomy-based system? In international research, these issues presented major concerns when women were assigned to placebo or treatment groups and consent was accepted from male relatives (18). The potential of coercion when no other access to health care is available creates real questions about the validity and freedom of choice for participants in entering clinical research studies in order to access health care in under-resourced areas (19). When caring for patients from different cultures and countries in daily practice, it is important to recognize that these issues exist in a microcosm. **Ensuring that the patient can make the choice herself or that she freely chooses to have a relative make it for her remains an important element of**

informed consent.

Beneficence and Nonmaleficence

[1] The principles of beneficence and nonmaleficence are the basis of medical care—the "to do good and no harm" of Hippocrates. These issues can be clouded by other decision makers, consultants, family members, and sometimes financial constraints or conflicts of interest. Of all the principles of good medical care, benefit is the one that continually must be reassessed. Simple questions can help clarify choices. What is the medical indication? How does the proposed therapy address this issue? How much will this treatment benefit the patient? How much will it extend the patient's life? Does it meet a goal of medicine, such as curing a disease, ameliorating symptoms, reducing suffering, or educating about a disease? When confronted with multiple medical problems and consultants, physicians should ask how much treatment will be of benefit given all the patient's problems (e.g., failing kidneys, progressive cardiomyopathy, HIV-positive status, and respiratory failure) rather than considering treatment of one problem without acknowledging that the overall benefit is limited by the presence of all the other problems.

An additional area of balancing beneficence and nonmaleficence is ensuring that the medicine we practice is the safest and of the highest quality relative to medical evidence. The safety and quality agenda in medicine is growing and necessitates consideration of the role of experience (number of procedures, simulation for ongoing maintenance of skills and development of skills, team training) in ensuring that our patients have access to the highest quality of care. When evidence shows improved outcomes for specific interventions—for example, with timing difference in preoperative antibiotics—health care professionals must participate in and embrace efforts to achieve those metrics on behalf of their patients as part of their fiduciary duty and their obligation to seek the benefit of their patients. Steps specific to this in obstetrics and gynecology are listed by the American College of Obstetricians and Gynecologists as **developing the commitment to encourage a culture of patient safety, implementing safe medication practices, reducing the likelihood of surgical errors, improving communication with health care providers and patients, and working with patients to improve safety** (20).

The benefit or futility of the treatment, along with quality-of-life considerations, should be evaluated for all aspects of patient care. It is best to weigh all of the relevant issues in a systematic fashion. Some systematic approaches depend on a sequential gathering of all the pertinent information in four domains: medical indications (benefit and harm), patient preferences (autonomy), quality of life, and contextual issues (justice) (11). Other approaches identify decision makers, followed by facts, and then ethical principles. **It is important for physicians to select an ethical model of**

analysis under which to practice, one that will provide sufficient experience with an ethics-based analytic system in order to help clarify the issues when confronting troubling and complex decisions.

Medical Futility

The essence of good medical care in sometimes challenging situations is to attempt to be as clear as possible about the outcomes of the proposed interventions. If the proposed intervention (e.g., continued respiratory support or initiating support) has a slight or highly unlikely chance of success, intervention might be considered futile. **Physicians have no obligation to continue or initiate therapies that are not of benefit** (21). The decision to withdraw or withhold care is one that must be accompanied by an effort to ensure that the patient or her surrogate decision maker is educated about the decision and agrees with it. Other issues, such as family concerns, can and should modify decisions if the overall well-being of the patient and of the family is best served. For example, waiting (within reason) to withdraw life support may be appropriate to allow a family to reach consensus or a distant family member to see the patient for the last time.

Quality of Life

Quality of life is a much used, often unclear, term. In the care of patients, quality of life is the effect of therapy on the patient's experience of living based on her perspective. It is perilous to assume that health care givers know what quality of life represents for a particular patient (11). It is instructive to attempt to understand what is important to an individual patient's quality of life and seek the patient's perspective. The results may be surprising. For example, when offered a new drug for ovarian cancer, a patient might prefer to decline the treatment because the side effects may not be acceptable, even when there may be a reasonable chance that her life may be slightly prolonged. Conversely, the physician may believe that further treatment offers little benefit but the patient finds joy and fulfillment in entering a phase I clinical trial because it adds meaning to her life to give information to others about the possibilities of a new treatment. Informing patients of the experiences of others who have faced these choices may help in decision making, but it is never a substitute for the choice of the individual patient.

PROFESSIONAL RELATIONS

Conflict of Interest

All professionals have multiple interests that affect their decisions. Contractual and covenantal relationships between physician and patient are intertwined and complicated by health care payers and colleagues, which create considerable

pressure. The conflict with financial considerations directly influences patients' lives, often without their consent. Rennie described that pressure eloquently: "*Instead of receiving more respect (for more responsibility), physicians feel they are being increasingly questioned, challenged, and sued. Looking after a patient seems less and less a compact between two people and more a match in which increasing numbers of spectators claim the right to interfere and referee*" (22). One response to this environment is for the physician to attempt to protect his or her efforts by assuming that the physician–patient relationship is only contractual in nature. For example, a pre-existing contract, insurance, a relationship with a particular hospital system, or a managed care plan may discourage referral to a specialist, removing the physician's responsibility. All health care professionals will experience this tension between a covenantal or contractual relationship. However, the ethical requirement to put the patient's best interests forward and to provide trustworthy information about options remains.

Health Care Payers

An insurance coverage plan may demand that physicians assume the role of gatekeeper and administrator. Patients can be penalized for a lack of knowledge about their future desires or needs and the lack of alternatives to address the changes in those needs. Patients are equally penalized when they develop costly medical conditions that would not be covered if they moved from plan to plan. These situations often place the physician in the position of being the arbiter of patients' coverage rather than acting as an advocate and adviser. It is an untenable position for physicians because often they cannot change the conditions or structure of the plan but are forced to be the administrators of it.

In an effort to improve physician interest in and compliance with decreasing costs, intense financial conflicts of interest can be brought to bear on physicians by health care plans or health care systems. If a physician's profile on costs or referral is too high, he or she might be excluded from the plan, thus decreasing his or her ability to earn a living or to provide care to certain patients with whom a relationship has developed. Conversely, a physician may receive a greater salary or bonus if their management of patients causes the plan or the health system to be more profitable.

These conflicts are substantially different from those of fee-for-service plans, although the ultimate effect on the patient can be the same. In fee-for-service plans, financial gain conflicts of interest have the potential to result in failure to refer a patient or to restrict referral to those cases in which the financial gain is derived by return referral of other patients (23). Patients who have poor insurance coverage may be referred differently from those who have better coverage. Patients may be unaware of these underlying conflicts of interest, a situation that elevates conflict of interest to an ethical problem. A patient has a right to know what her plan covers, to whom she is

being referred and why, and the credentials of those to whom she is referred. The reality is that health care providers make many decisions under the pressure of multiple conflicts of interest. Physicians can be caught between self-interest and professional integrity. Failure to recognize and address conflicts of interest that impact decision making harm the relationship of individuals and society to health care providers. **[6] Focusing clearly on the priority of the patient's best interest and responsibly rejecting choices that compromise the patient's needs are ethical requirements.**

Legal Problems

[6] Abuses of the system (e.g., referral for financial gain) led to proposals and legislation, often referred to as Stark I and II, affecting physicians' ability to send patients to local laboratories and facilities in which they have a potential for financial gain. There were clearly documented abuses, but the same legislation would negatively affect rural clinics and laboratories whose sole source of financial support is rural physicians. States vary on the statutory legislation regarding this issue. Regardless of the laws, it is ethically required that financial conflicts of interest are revealed to patients (24–26).

Another abuse of the physician–patient relationship caused by financial conflicts of interest is fraudulent Medicare and Medicaid billings. This activity resulted in the Fraud and Abuse Act of 1987 (42 U.S.C. at 1320a–7b), which prohibits any individual or entity making false claims or soliciting or receiving any remuneration in cash or any kind, directly or indirectly, overtly or covertly, to induce a referral. Indictments under these laws are felonies, with potential fines, jail sentences, and loss of the license to practice medicine. Physicians should be aware of the legal ramifications of their referral and billing practices.

Harassment

The goal of medicine is excellence in the care of patients and, often, research and education that will advance the practice of medicine. Everyone involved in the process should be able to pursue the common goal on equal footing and without harassment that interferes with employees', learners', or colleagues' ability to work or be promoted equally in that environment. Every office and institution should have an assessment strategy to ensure that the work environment is conducive to focusing on work and learning and not hostile to individuals.

Every office and institution must have written policies on discrimination and sexual harassment that detail inappropriate behavior and state-specific steps to be taken to correct an inappropriate situation and make sure they are widely accessible and available. The goal is to ensure appropriate reporting and procedures for taking appropriate action and protecting victims, educating or rehabilitating an

offender, and preventing the reoccurrence of the behavior.

In the United States, the legal support for this right is encoded in both statutory law through the Civil Rights Act of 1964 (42 U.S.C.A. at 2000e–2000e–17 [West 1981 and Supp. 1988]) and reinforced with judicial action (case or precedent law) by state and U.S. Supreme Court decisions. Charges of sexual harassment can be raised as a result of unwelcome sexual conduct or a hostile workplace. Employees are not the only ones to experience sexual or other harassment; learners such as medical students or nursing students can experience it and have a high reported prevalence of it. Sexual or other harassment for students can interfere with the educational process and trigger federal discrimination liability, including loss of federal funds encoded in Title IX protections (27).

Stress Management, Burnout and Prevention

[7] **In addition to the acknowledged stress of the time pressures and responsibility of a career in medicine, the health care environment is associated with an increasing incidence of physician burnout, a serious threat to physician wellness and the safety and quality of care that their workforce provides.** Addressing this problem is a shared responsibility of the physicians themselves and the health care systems where they work. Individual physician responsibility should include awareness and education about this issue, addressing professional priorities, and having a plan for work–life balance that includes self-care and wellness.

Burnout is a work-related syndrome characterized by emotional exhaustion, depersonalization, and feelings of low personal accomplishment. Practitioners who are burned out have been found to have higher rates of depression, alcohol abuse, and suicidal ideation and are more likely to have experienced medical errors in their practice (28–30). Physician burnout is associated with absenteeism, lapses in professionalism, and early retirement. There is a widening gap in satisfaction with work–life balance and increase in burnout among US physicians, with burnout in obstetrician–gynecologists measured over 50%, second only to emergency medicine physicians (31). This level of distress puts the field of obstetrics and gynecology at risk for depletion of qualified providers, with physicians and others retiring early or leaving medicine entirely.

Addressing burnout in our specialty requires support for physicians through focus on the workplace drivers of this problem, of which there are many. Time spent directly with patients is an important source of reward for physicians and this time is limited by organizational and regulatory demands that are compounded by market forces. Loss of physician autonomy and resultant excessive administrative tasks consume already limited time, distancing physicians from the meaning and value of their work, thereby diminishing the rewards associated with work. In a study of obstetrics and gynecology

providers done in collaboration with the AMA, the strongest single predictor of emotional resilience and sense of accomplishment for individual physicians was control over schedule and hours worked (32).

[6] Alignment of values between the worker and the **[7]** workplace, enhancing communication, establishing a culture of respect, mutual support, and expressing appreciation, have all been shown to improve efficiency, reduce errors, and improve workflow in physician practices and are most effective when supported by leadership. High-quality leaders prioritize improvement of workplace culture and creation of community along with nurturing support for flexibility and physician work–life balance. Strength in leadership, measured by composite leadership scores, is strongly correlated with decrease in burnout (33,34). The personal experience of burnout frequently involves loss of meaning and joy in one's work, isolation, and lack of community. For busy clinicians, isolation has become an occupational hazard and mindfulness or reflective practice in groups can be a very effective outlet. Some data reflect that getting physicians together for a meeting or a meal improves camaraderie and decreases burnout (34,35).

[7] All physicians should develop personal awareness and a commitment to a plan for self-care. Various strategies have been advocated and studied to prevent burnout, and there is no uniform approach that will be successful for every physician. Definition of values or what is most important in life can clarify priorities and facilitate setting limits, establishing time away from work, and planning time for relationships or other revitalizing activities. Many preventative measures and interventions involve wellness practices, stress reduction, and reconnection with the meaning of work and the reasons why physicians entered medical careers. Contemplative practices including mindfulness meditation, cultivation of awareness, and narrative medicine are interventions that have been studied in prevention or amelioration of physician burnout (36). Writing a mission statement reflecting why the physician chose medicine has been recommended as a simple strategy to refocus on the meaning of work.

Though formal mindfulness practice is not for everyone, focusing on the moment, the self, or the breath can allow for regrouping and improve one's sense of being grounded and more in control. Small actionable steps such as improving sleep and exercise and setting boundaries on work time can help. Specific wellness practices and their relationship to burnout have been studied in US surgeons. Incorporating a strategy that prioritized work–life balance, focusing on what is most important in life, and finding meaning in one's work were all found to be helpful in reducing burnout (37). General health habits such as exercise and attending primary care visits have also been found to be important.

Women's health care providers have a significant risk for burnout and face poorer personal, mental, and physical health; increased medical errors; disengagement; and resultant early retirement. Professional well-being is important for our patients and for

the career, personal, and family life of the individual physician.

SOCIETY AND MEDICINE

Justice

[1] Some of the ethical and legal problems in the practice of gynecology relate to the fair and equitable distribution of burdens and benefits. How benefits are distributed is a matter of great debate. There are various methods of proposed distribution:

- **Equal shares** (everyone has the same number of health care dollars per year)
- **Need** (only those people who need health care get the dollars)
- **Queuing** (the first in line for a transplant gets it)
- **Merit** (those with more serious illnesses receive special benefits)
- **Contribution** (those who have paid more into their health care fund get more health care)

Each of these principles could be appropriate as a measure of just allocation of health care dollars, but each will affect individual patients in different ways. Just distribution has become a major issue in health care. The principles of justice apply only when the resource is desired or beneficial and to some extent scarce (38).

The traditional approach to medicine was for practitioners to accept the intense focus on the individual patient. Changes in medicine will alter the focus from the patient to a population: "*in the emerging medicine, the presenting patient, more than ever before, will be a representative of a class, and the science that makes possible the care of the patient will refer prominently to the population from which that patient comes*" (39). Physicians increasingly have accumulating outcomes data (population statistics) to modify the treatment of an individual in view of the larger population statistics. If, for example, the outcome of radical ovarian cancer debulking is only 20% successful in a patient with a certain set of medical problems, that debulking may be offered instead to someone who has an 85% chance of success. Theoretically, the former individual might have a successful debulking and the procedure might fail in the latter, but population statistics were used to allocate this scarce resource. The benefit was measured by statistics that predict success, not by other forms of justice allocation by need, queuing, merit, or contribution. This approach represents a major change in the traditional dedication of health care solely to the benefits, however small, of individual patients. With scarce resources, the overall benefits for all patients are considered in conjunction with the individual benefits for one patient.

There was always inequity in the distribution of health care access and resources. This inequity is not seen by those health care providers who do not care for the patients who are unable to gain access, such as those who lack transportation, live in

rural areas, or where limits are imposed by lack of health care providers, time, and financial resources. Social discrimination leads to inequity in the distribution of health care. Racial and ethnic minorities are less likely to see private physicians or specialists, with clear impacts on outcomes of care, regardless of their income or source of health care funding (40). Thus, health care is rationed by default.

To reform the health care system requires judicial, legislative, business mandates, and attention to the other social components that can pose obstacles to the efforts to expand health care beyond a focus on individual patients.

Health Care Reform

The tension between understanding health as an inherently individual matter (in which the receipt of health care is critical to individual well-being) and as a communal resource (in which distribution of well-being throughout society is the goal) underpins much of the political and social debate surrounding health care reform (41). The questions of health care reform are twofold: (1) What is the proper balance between individual and collective good? and (2) Who will pay for basic health care? Because much of health care reform requires balancing competing goals, legislation to achieve reform should specifically address how this balance can be achieved. The role of government can be:

- Regulating access of individuals to health care
- Regulating potential harms to the public health (e.g., smoking, pollution, drug use)
- Promoting health practices of benefit to large populations (e.g., immunization, fluoridation of water)

Even with the changes in health care structure in the United States, health care payers, not individual providers, often make decisions regarding the distribution of and access to coverage and resources. The health insurance industry determines what are "reasonable and customary" charges and what will be covered. The government decides (often with intense special-interest pressure) what Medicare and Medicaid will cover. These decisions directly affect patient care. For that reason, health care providers cannot ethically remain silent when the health and well-being of their individual patients and their communities are adversely affected by health care reform decisions.

Research on the outcomes of care provided by gynecologists or affected adversely by systems for financing health care (financial aspects, safety, quality-of-life measures, survival, morbidity, and mortality) will allow the discipline to have a voice in determining choices for women's health care. This is an ethically important responsibility for all women's health care providers.

CHAPTER 3

Quality, Safety, and Performance Improvement

John P. Keats, Joseph C. Gambone

What Is Quality Care?
- Patient-Centered Care
- Clinical Variation in Patient Care
- Role of Organizational Leadership
- Communication
- Operating Room Safety
- Application of Safety Technology
- Disruptive Provider Behavior
- Disclosure and Apology for Adverse Events
- Safety in the Office Setting
- High Reliability
- A Process for Performance Improvement
- The Business Case for Quality and Safety

KEY POINTS

1 Quality is the degree to which health services increase the likelihood of desired health outcomes.

2 Every physician assumes responsibility for safety and excellence of care in their own practice environment.

3 Communication problems are the most frequently identified root cause of serious adverse events in hospitals.

4 Drills and rehearsals for emergency situations improve outcomes and enhance safety.

5 Disruptive behavior in the hospital setting can have adverse effects on patient safety and overall quality of care.

6 There is mounting evidence that improving quality and safety in health care can reduce cost and increase value.

WHAT IS QUALITY CARE?

Nearly two decades ago, the Institute of Medicine (IOM) published two seminal works in the fields of patient safety and medical care quality: *To Err Is Human* and *Crossing the Quality Chasm* (1,2). Despite the heightened awareness and increased public focus on the crucial issues of quality and safety raised by these publications, there is limited published evidence of significant progress toward improving the safety and quality of this country's health care (3). This slow progress caused some leaders in the patient safety movement to call for a redesign of education for health care professionals in order to equip these individuals with the essential knowledge, skill, and attitude required to function safely and effectively in the health care delivery environment of the 21st century. Although this imperative affects all health professions, it is particularly compelling for medical education because physicians' actions and decisions dictate the parameters of care to be provided by most other health care professionals (4). Recent changes in reimbursement methods for health care services that put a greater emphasis on value (better clinical outcomes and avoidance of complications) rather than volume (fee-for-service) are creating more interest in clinical performance improvement (5).

[1] The IOM defined quality as "the degree to which health services for the individual and populations increase the likelihood of desired health outcomes . . . consistent with current professional knowledge" (6). This assertion acknowledges that health care quality is important and applicable to entire groups of people and each individual patient. Implicit is the obligation to be sensitive to the flexible meaning of "desired health outcomes" because desired outcomes may differ from the perspective of hospitals, physicians, patients, and their families. Adherence to the definition includes rigorous application of accepted standards of knowledge and therapy to any clinical problem, a process now referred to as evidence-based medical practice (7). The IOM summarizes its definition of quality care in "Six Aims for Improvement" **(Table 3-1)**.

Patient-Centered Care

Many industries have recognized that one of the best definitions of quality is meeting customer expectations. The "centering" of patient care requires a focus on meeting appropriate expectations. The involvement of patients in health care decision making is traditionally restricted to the legal requirement for informed consent where the discussion tends to be limited to the benefits and risks of a plan or procedure. A more complete discussion of individual expectations, appropriate patient preferences, and the

inclusion of all reasonable alternatives for care encourages a more collaborative process.

The PREPARED checklist (Table 3-2) is one method that may be used for guiding informed collaborative choice and patient-centered care (Table 3-2) (8).

Table 3-1 Six Aims for Quality Health Care

Care should be:	
Safe (first among equals)	Timely
Effective	Efficient
Patient-centered	Equitable

Clinical Variation in Patient Care

Individual patients receiving identical diagnoses might not be given identical treatments. This is known as clinical variation and can be broadly categorized as falling into two types. One is *necessary* clinical variation, an alteration in medical practice that is required by the differing needs of individual patients. This modification may be in response to differences in the patients themselves because of age, overall health status, or other clinical characteristics; or it may be caused by differing desired outcomes as part of a patient-centered approach to care (9). This kind of variation is expected in any system of care. The other type is *unexplained* clinical variation, which comprises differences in medical care and patient management that are not accounted for by differences in patient symptoms, objective findings, or patients' goals for care. **These treatment discrepancies could account for wide variations in the cost of care without any demonstrable difference in outcomes as measured by achievement of therapeutic goals, morbidity, or mortality** (10–12). Often this unexplained variation is the result of management choices made by physicians in cases that fall into areas of discretion in clinical judgment, where no single course is clearly correct. Sometimes this variation is unexplained and unintended. It is this unexplained or unintended variation that is considered one of the greatest barriers to the delivery of consistent, high-quality care (13). The specialty of gynecology is subject to this treatment inconsistency. Significant geographic variations in hysterectomy rates, largely unexplained by the clinical characteristics of those local populations, have been reported (14,15). Further study and reduction of unnecessary variation in these rates could contribute to making medical care more efficient and equitable.

Table 3-2 PREPARED Checklist Process for Informed Communication and Patient-Centered Care

Plan:	Course of action being considered

Reason:	Indication or rationale
Expectation:	Chances of benefit and failure
Preferences:	Patient-centered priorities
Alternatives:	Other reasonable options/plans
Risks:	Potential harms from considered plans
Expenses:	Direct and indirect costs
Decision:	Fully informed collaborative choice

Role of Organizational Leadership

[2] Creating a safe environment for the delivery of medical care requires the active participation of organizational leadership. Each physician assumes a significant responsibility for safety and excellent care in his or her own practice environment. Inadequate leadership around safety issues erodes physician and staff morale and can contribute to the occurrence of patient harm and adverse clinical outcomes (16). In the hospital, oversight for issues of safety and quality is shared by the hospital board, executive leadership, and medical staff leadership, including physicians who serve as chief medical officer, vice president of medical affairs, or department chairs. A new position being adopted by many hospitals is the patient safety officer (17). This individual takes direct responsibility for overseeing all aspects of the hospital patient safety program and reports to the hospital chief executive officer or board of directors. It is an emerging role for physicians who want to make patient safety the focus of their professional lives.

An important method for improving the safety environment in a hospital is the adoption of the tenets of a safety construct referred to as "Just Culture" (18). **Just Culture recognizes that human error cannot be completely eliminated from any complex system such as health care.** People sometimes make mistakes. They can be held accountable for following procedural rules to reduce harm to patients resulting from human error. **Adverse outcomes and near misses encourage the organization to examine its processes of care with an eye to continuous improvement. With such a system in place, the reporting of safety problems and concerns will often increase dramatically.** This permits the hospital or other health care organizations to initiate programs that address these issues and make "first, do no harm" a priority.

Communication

[3] An assessment of the factors leading up to serious adverse events in hospitals

revealed that communication problems were the most frequently identified root cause, occurring in almost three-fourths of cases (19). Assuring clear and timely communication between all caregivers is perhaps the single most important measure to improve the safety and quality of medical care. Structured communication techniques in the health care setting are referred to under the title "team resource management." The basic principle of team resource management is to foster an atmosphere conducive to enabling individuals with different roles to achieve a successful outcome to a complex operation (20). Despite differing roles, training, and ranking within a perceived hierarchy and the inclusion of some individuals who may not have worked together as a team before, it is understood that each participant shares an overarching responsibility. That responsibility is to communicate with all team members whenever they see anything that is potentially unsafe or when other team members are not acting appropriately in a given situation. This concept is particularly applicable in the operating room, which is by nature a highly complex environment. **Everyone present—physicians, nurses, house staff, and technicians—must keep patient safety foremost in their minds. No one should hesitate to raise questions and concerns when an unsafe situation is observed.**

Certain situations in health care are particularly prone to miscommunication. One example is during the stress of emergency situations, when a physician may be rapidly ordering medications, blood transfusions, or initiating procedures. A technique referred to as "call-outs" helps ensure that critical orders are correctly received. The person to whom the verbal order is directed repeats the order verbatim to acknowledge that it is accurately received and accepts responsibility for carrying it out. Hearing this call-out assures the ordering physician that the order was received, who will be performing it, and creates an opportunity to correct the order if it was misheard. Telephone orders are well known to be sources of misinterpretation of physicians' treatment intentions (21). Check-back is a technique to minimize errors in this medium. In a typical situation, a doctor calls a nurse to order a medication for a patient. Check-back has three components. First, the physician gives the medication order to the nurse. Second, the nurse repeats the order back to the physician, specifying medication name, dose, route, and timing of administration. Lastly, the physician confirms to the nurse that the order was correctly received. When a handoff of a patient from one physician to another occurs, that presents a third opportunity for miscommunication. A relay team approach to care is occurring more frequently in medical education as a result of residency work-hour restrictions (22). To minimize errors in this setting, it is wise to use a structured script for communicating critical clinical information. One such script is from a program published by the Agency for Healthcare Research and Quality (AHRQ) called Team Strategies and Tools to Enhance Performance and Patient Safety (TeamSTEPPS). It is the mnemonic I PASS the BATON, which is essentially a checklist of clinical items to be related to the person assuming the care of the patient **(Fig. 3-1)**

(23). The key point is that management handoffs should be a formal process that does not rely on memory to convey crucial information.

I	Introduction	Introduce yourself and your role/job (include patient)
P	Patient	Name, identifiers, age, sex, location
A	Assessment	Present chief complaint, vital signs, symptoms, and diagnosis
S	Situation	Current status/circumstances, including code status, level of (un)certainty, recent changes, and response to treatment
S	SAFETY Concerns	Critical lab values/reports, socioeconomic factors, allergies, and alerts (falls, isolation, etc.)
THE		
B	Background	Comorbidities, previous episodes, current medications, and family history
A	Actions	What actions were taken or are required? Provide brief rationale
T	Timing	Level of urgency and explicit timing and prioritization of actions
O	Ownership	Who is responsible (person/team) including patient/family?
N	Next	What will happen next? Anticipated changes? What is the plan? Are there contingency plans?

FIGURE 3-1 I PASS the BATON. (From Team STEPPS Program of the U.S. Agency for Healthcare Research and Quality [AHRQ]).

An important feature of team resource management is the ability of any team member to "stop the line"—that is, to halt the process or procedure when they perceive a risk to patient safety. One recommended technique is the "CUS" method.

This acronym represents three possible sets of "code words" that any team member may use to stop the procedure until the safety concern is addressed. The letters in the acronym stand for "I'm *C*oncerned"; "I'm *U*ncomfortable"; and "I have a *S*afety concern." Another method is the "Two-Challenge Rule." This indicates that when a team member has a safety concern, he or she should bring it to the attention of the physician in charge of the procedure. If the concern is not acknowledged or adequately addressed, the team member should address it a second time. If the concern is still unanswered or uncorrected, the team member is obligated to go up the chain of command to a supervisor or higher-ranking physician to have his or her concerns satisfied.

All of these techniques can contribute to a safer environment for patient care in the operating room, emergency department, and in hospital rooms. However, none of them can be very effective without practice. **[4]** The use of drills and simulations in training programs to rehearse these techniques in mock emergency situations in anesthesia (24) and other surgical disciplines (25,26) is well established. The use of simulators to teach basic surgical techniques including laparoscopy and robotic surgery are becoming more common (27,28). **Drills and rehearsals for emergency situations improve outcomes and enhance safety** (29,30).

Operating Room Safety

The operating room is by its nature a highly complex health care environment. It is a potential site for adverse events, which can be catastrophic. These include wrong patient surgeries, wrong site surgeries, and retained foreign objects. All of these occur in hospitals, despite recognition that these events should never take place (31,32). The Joint Commission, a national accrediting body for hospitals, has developed the Universal Protocol™ that all surgeons and operating rooms should follow (33). There are three major components of the Universal Protocol. **First is to conduct a preprocedure verification process** that confirms the identity of the patient and his or her understanding of what procedure is to be performed. **Second is marking of the operative site** by the surgeon, which is especially critical in cases involving bilateral structures. This is to be done in the preoperative area with the patient awake as a confirmation of accuracy. **Third is the performance of a surgical "time-out"** in the operating room prior to the start of the surgery to confirm the correct patient identity and correct planned procedure. **Failure to perform any of these steps increases the risk of performing the wrong operation on the wrong patient.**

The traditional use of checklists resulted in dramatic increases in the safety of aviation (34). Their use in medicine is demonstrated to significantly decrease complications when used consistently to verify that procedural steps are not overlooked. A simple five-step checklist for central-line placement in the intensive care unit was shown to reduce the incidence of catheter-related sepsis to almost zero

(35,36). Similarly, checklists are advocated for use in the surgical suite to ensure that critical steps for error prevention and patient safety are not overlooked. The World Health Organization (WHO) released a surgical checklist in 2009 under their "Safe Surgery Saves Lives" program (37). It involves items to be reviewed and documented before the induction of anesthesia, before the skin incision, and before the patient leaves the operating room. Use of the WHO checklist was shown to reduce major complications of surgery from 11% to 7% and the major surgery inpatient death rate from 1.5% to 0.8% (38). The use of checklists such as this to improve patient safety in the operating room should become more widespread.

The inadvertent retention of foreign bodies such as sponges, instruments, or other objects at the conclusion of surgery is a continuing source of patient harm. Risk factors associated with retained foreign bodies are emergency surgery, unexpected change in surgical procedure, high patient body mass index (BMI), and failure to perform sponge and instrument counts (39). Systems must be established to prevent these occurrences, and surgeons need to be aware of the contributing risk factors listed above (40). **The most commonly retained item is a surgical sponge. Strict adherence to guidelines for tracking surgical sponges is necessary to reduce the incidence of this serious complication.** One comprehensive program to assist in adherence is called "Sponge Accounting" (41,42). It involves standardized counting and recording of sponges at the start of the case and as additional sponges are added to the surgical field. At the conclusion of the surgery, all sponges are placed in special transparent holders to allow visual confirmation that all sponges were taken out of the patient. Other systems employ radiofrequency tagging of all sponges so that retained sponges can be detected easily before the surgical wound is closed (43).

Application of Safety Technology

Computerized physician (prescriber) order entry system (CPOE) is a prescription ordering system where the prescriber enters ordering information directly into a computer, typically as part of a hospital or office electronic medical record. Most modern systems can check for errors and make suggestions based on preprogrammed guidelines and protocols. CPOE is known to reduce serious medical errors and prevent otherwise undetected adverse drug events (ADEs) (44). When CPOE systems are properly designed and implemented, they can improve workflow efficiency by supplying real-time dosing information and other decision-support protocols and guidelines. Poorly designed or improperly implemented CPOE systems, however, have the potential to decrease efficiency and increase medication error.

Medication safety is a high priority for quality improvement initiatives. Avoiding abbreviations that may lead to medication error increases patient safety (45). **Avoiding abbreviations that can be misread is an important and effective**

improvement, especially when orders are handwritten. One easily remembered and important rule about the written medication order is "always lead and never follow" a decimal point when using zeros. An order that is written as .1 mg should be written as 0.1 mg—an example of leading with a zero. It can be very dangerous for the written period to be missed, resulting in 1 mg being given to a patient rather than 0.1 mg. The leading zero should alert to the correct dosage. An order that is written as 1.0 mg should be written as 1 mg—never following with a zero, so that a patient is not mistakenly given 10 mg of a drug if the period is missing or not seen. Exclusive use of properly designed and implemented CPOE systems can eliminate misread written orders.

Disruptive Provider Behavior

In 2009, as part of its accreditation standards, the Joint Commission proposed that all health care organizations with professional staffs develop and implement a Code of Conduct Policy along with an education program that addresses disruptive behavior. **[5]** Disruptive physician (provider) behaviors include inappropriate conduct in the hospital setting, resulting in conflict or confrontation. These behaviors can range from verbal or physical abuse to sexual harassment. In recent years disruptive behavior in the hospital setting has become more evident, if not more common. One study showed that the vast majority of surveyed physicians, nurses, and administrators had witnessed disruptive behavior by physicians (46). Nurses and other hospital employees also commit disruptive behavior, but it is far less common than disruptive physician behavior. **Disruptive behavior in the hospital setting can have adverse effects on patient safety and overall quality of care.**

Team building that encourages collegial interaction and a sense that all members of the health care team are important to the process and present valuable contributions can promote a culture that reduces the likelihood of disruptive behavior.

Disclosure and Apology for Adverse Events

Organized medicine is increasing its focus on the prevention of medical error. A controversial issue involving medical error is the prompt disclosure and apology for any medical errors that occur. In the past many, if not most, health care organizations focused on managing the legal risk of medical error. The conventional wisdom was that any disclosure and apology for error would promote litigation and bigger payouts. **The Joint Commission and other professional organizations require or endorse active disclosure to the patient when adverse events occur, including those caused by error** (47).

Lucian Leape, one of the fathers of the modern patient safety movement, pointed out

that a patient has an ethical right to full disclosure of medical error (48). Although an apology is not an ethical right, it is a therapeutic necessity, according to Leape. Three programs are worth noting in any discussion of disclosure and apology for medical error. First is the University of Michigan's patient safety program, which addresses the need to disclose medical error in several publications (49). Important points are made about a patient's rights concerning disclosure of medical error and that an apology for errors can be a productive benevolent gesture rather than an admission of fault. The authors point out several fallacies about disclosure, including that disclosing medical error always leads to litigation and that error always means negligence.

Secondly, several programs are under way to test the assertion that disclosure and apology can decrease the likelihood of litigation. COPIC, a Colorado medical insurance company, found that full disclosure results in small early settlements and dramatically reduced law suits and payouts (50).

Table 3-3 Medical Director Responsibilities in an Office Setting

• Motivation of staff to create a "safety culture"
• Credentialing and privileging for office procedures
• Developing/updating/enforcing office policies
• Conducting regular mock safety drills
• Tracking and reporting adverse events
• Establishing a nonpunitive quality improvement process

Lastly, The Sorry Works! Coalition, a coalition of doctors, insurers, and patient advocates, urges the use of full disclosure and apology for medical errors (51). They point out that the current tort system has failed, resulting in higher and higher malpractice premiums without decreasing the rate of medical error. Demands for caps on malpractice awards and greater disciplinary measures for providers are largely ineffective. The Sorry Works! Coalition advocates early disclosure with apology and financial settlements without litigation as the way to deal with medical error.

Safety in the Office Setting

Thus far, most efforts to improve safety involved activities that occur in the inpatient setting. This is a logical initial approach because most risky procedures and tests are performed in the hospital setting. There is a trend to adapt some invasive procedures and tests to be offered in the office setting. Gynecologic procedures such as hysteroscopy and loop excision of the cervix are examples of this. It is anticipated that there will be increasing numbers of "risky" invasive procedures performed in the office setting. The American College of Obstetricians and Gynecologists (ACOG) established

a Task Force on Patient Safety in the Office Setting in 2009.

The charge to the task force was to "assist, inform, and enable Fellows of the College to design and implement processes that will facilitate a safe and effective environment for the more invasive technologies currently being introduced into the office setting." The task force produced a monograph and an article containing an executive summary of their work and recommendations (52,53). The task force addressed issues of leadership in the office setting; competency and assessment; teamwork and communication; anesthesia safety; measurement (of processes and outcomes); and tools such as checklists, time-outs, and drills.

In the hospital setting, leadership for safety is provided at multiple levels, starting with the department chair, with assistance from designated personnel in risk management and quality assurance. In the office setting, this responsibility must be assumed by one individual in a solo practice and one or several in a group practice. One individual should be designated as medical director and his or her responsibilities are outlined in Table 3-3.

The process of competency assessment should be similar to the credentialing and privileging systems that hospitals use. The determination that a provider is qualified (credentialed) and competent to perform specific procedures (privileged) is equally important in the office setting. Procedures initially performed solely in an inpatient setting should be converted to the office setting only after the provider has demonstrated competency in an accredited operating room setting.

Effective communication with office personnel and with patients was identified by the task force as an essential element for creating a culture of safety in the office setting. Regular meetings should be held with all office staff to establish and implement patient safety and quality improvement protocols.

Anesthesia safety is critical for avoiding adverse outcomes in the office setting. As office-based procedures become more invasive, many practices have incorporated certified anesthesia personnel into the office team. The level of anesthesia achieved, not the agents used, should be the primary issue regarding anesthesia safety. When nonanesthesia-certified providers are managing the patient, appropriate credentialing and privileging should be documented.

The task force strongly recommends the use of checklists, drills, and time-outs to verify the appropriate progress of office-based procedures. Checklists improve safety and effectiveness in other industries besides health care (34,36). Verifying that the correct procedure is being performed on the correct patient during a time-out for confirmation is useful in the office setting, and drills and simulations are essential activities in high reliability organizations. Advances in technology are expected to move many more invasive procedures into the office setting, and patients and providers will expect that these are performed with high reliability and safety.

Through the Presidential Task Force Report, ACOG provided a blueprint for

improving patient safety in the office setting (52,53).

High Reliability

Patient care delivery is often as consequential and error prone as running a nuclear power plant or operating an aircraft carrier. The science of high reliability which is applied in those two activities is being introduced into health care, particularly in the hospital setting. The ability to operate highly complex and hazardous technologic systems essentially without error over long periods of time is the hallmark of a "High Reliability Organization" (54,55). Using techniques such as simulations, checklists, and situational awareness, delivery of care is increasingly managed by medical teams who work together to reduce medical error to very low levels (56). The concept of "Six Sigma" is meant to define an ideal of restricting errors to one error in about one million events (57). Although this may be an unreachable goal in something as complex as patient care, the concept is meant to establish a very high standard.

A Process for Performance Improvement

Professional organizations like ACOG and others have been partnering with their fellows and fellows' institutions to address clinical performance issues such as high cesarean delivery and other surgical rates by organizing courses in basic and advanced patient safety. One protocol that has been successfully implemented in ACOG's advanced course is illustrated in Table 3-4. The protocol outlines and emphasizes the need for proper planning of any performance improvement effort and the need for ongoing monitoring in order to sustain the positive changes. Participating leadership teams have used these worksheets to create a roadmap for institutional change to achieve a variety of goals in patient safety and quality improvement.

The Business Case for Quality and Safety

[6] How can the application of the quality and safety principles outlined above result in cost savings in the delivery of health care? The business case for quality and safety is built on the concept of the elimination of waste in medical care. Brent James, executive director for the Institute for Healthcare Delivery Research at Intermountain Healthcare in Salt Lake City, identifies two main types of waste in health care (58). The first is *quality waste*, which can be thought of as rework or scrap. This is the failure to achieve the desired outcome of medical care the first time around. This would include such diverse events as medication errors that result in patient harm, hospital-acquired infections, wrong site surgeries, and retained foreign objects at surgery. The second type is *inefficiency waste*. This refers to excessive resource consumption to achieve an outcome when a different alternative is available to more

efficiently achieve a similar outcome. An example would be performing an inpatient hysterectomy for menorrhagia that could be treated equally well with outpatient medication or endometrial ablation. James estimated that together these two sources account for as much as 50% of the expenditures on health care in this country (58). While many experts considered this a wild exaggeration, this view was given some credence in 2012 in a comprehensive review of the American health care delivery system by the IOM (59). This publication estimated that in 2009, waste in the medical delivery system resulted in the loss of $750 billion from productive use, enough to provide health insurance coverage to 150 million people. The conclusions from this group are shared by proponents of value-based delivery of patient care (60), where emphasis is put on obtaining the best clinical outcomes while using the most efficient amount of resources (the value equation). The Centers for Medicare and Medicaid (CMS) have adopted payment methods that are based upon this value equation (61). Combating all sources of wasted health care dollars will require a widespread adoption of the principles discussed: the use of evidence-based medical treatments and safety technology; the elimination of unexplained clinical variation in our processes of care; the direct involvement of patients in monitoring their own care; improved teamwork and communication between providers in different disciplines; and all of these under the guidance of committed health care leadership able to rally support for these efforts. The twin aims of improving the safety and quality of medical care are goals that all physicians should actively pursue.

Table 3-4 ACOG Process of Performance Improvement*

STEP I) Identify a Performance Improvement or Patient Safety Problem:				
Identify areas of concern/interest for performance improvement or patient safety within your department/organization				
Search and review	Departmental/organizational data for areas of concern with respect to performance or patient safety. This may be based on a recent incident that has occurred or one that is suggested in the literature	**Have any surveys been done to identify areas of concern? Has data been collected over time to measure the number of adverse events that have occurred due to this problem/issue?**	**What is the current level of error/satisfaction in your organization? Numerator and Denominator?**	**What is the goal for improving the level of performance/safety?** **Has any benchmarking been done to establish realistic goals?**
Checklist for identifying the safety problem:				
1. Identify a performance improvement/patient safety problem that is of concern in your department/organization. a. Determine that this is a performance/safety problem that has widespread interest in the department/organization. b. Why is it important to accomplish this change now? c. What is the basis of comparison (benchmark)?				
2. List the adverse event(s) associated with this problem. a. How was this decided on? b. What measures will be used to assess the change project?				
3. How will the department/organization support the change? a. What resources will be required? b. How will the sponsor demonstrate their support?				
STEP II) Plan for Measurement of Results:				
SMART goals				
Specific	Define as narrowly and unambiguously as possible what it is that you are targeting in your improvement project. Your specific target or goal must be expressed in quantitative terms.			
Measurable	Your target has to be something quantifiable. See below for more details to be assessed for this item.			
Attainable	Your target must be realistic in terms of your organization's ability to achieve it. In general, goals of 100% or "never" are not realistic.			
Relevant	The parameter you are trying to improve must be something perceived as important and desirable to key stakeholders, such as physicians, nurses, administration, and patients. Make the case as to why this is relevant to each group.			
Time-bound	Determine a specific end point for the improvement project by which time you will achieve the amount of improvement decided on in "Specific" above.			
Checklist for Measurement of Results:				
1. What is currently being measured in this area at your institution? a. Is this the best metric to follow? What others may be important?				
2. How will you define what you want to improve? a. Definition should be unambiguous (e.g., "improving neonatal outcome" is ambiguous; "reducing the percentage of newborns with 5-minute Apgar less than 7" is not)				
3. In what format will you measure what you want to improve? a. Will you use simple counts? Percentages? Rates? i. If percentages or rates, what will you use as numerator and denominator? b. Do you need to design a new measurement tool or can you use one already in place? c. How are measurements currently being presented? Are run charts or control charts routinely used?				
4. Do you need to develop a data collection plan? a. How will the data be stratified? b. Will the data collection require sampling?				
STEP III) Identify All Stakeholders for Safety Problem or Improvement Opportunity:				
Identify all those who have a stake (may cause or be affected by the consequences) in the project				
Stakeholders	Identify all those who have a stake in the project, either who create or are affected by the consequences of the care process.	**List all those who could cause or who could be affected by the consequences of the care process?**	**Do they understand the responsibilities of their role in the care process?**	**How can these stakeholders be incented to improve outcomes?**

Clinical stakeholders	Identify all providers and nursing staff who will participate in the clinical care involved with the project. This should also include the patient.			
Nonclinical stakeholders	Identify others, such as administrators, who could have a stake in the outcomes of the care process.			
Checklist for identifying all stakeholders:				
1. Identify all individuals who are involved in the clinical and overall care. a. Anyone who could create consequences or be affected by the consequences of the care is a stakeholder in the process. b. Are all stakeholders identified?				
2. Include both clinical and nonclinical individuals who may be stakeholders. a. Are all clinical stakeholders identified? b. Are all nonclinical stakeholders identified?				
3. Is the patient included as a stakeholder? a. Can the patient become an active stakeholder (e.g., patient signs correct operative site for surgery) in the care process? b. How will this be accomplished?				
STEP IV) Identify Required Roles:				
Identify individuals who will assume key roles in your change process				
Sponsor(s)	Sanction change from a leadership level. Must agree to be a highly visible supporter of change effort. Preferably has authority to commit resources to the project. Consider developing sponsorship at multiple levels.	**Who could play this role?**	**Do they understand the responsibilities of this role?**	**If not, who will coach them?**
Agents(s)	Support the sponsors and facilitate change. Needs knowledge of the change process and be trusted by physicians. Will be responsible for gathering and reviewing data and provide support to those coping with the change.			
Champion(s)	Respected opinion leaders who agree to be "early adopters" of the change. Best if they are seen as frontline practitioners and not part of management.			
Checklist for aligning the change team:				
1. Create the "burning platform" and/or the vision. a. What is the problem to be corrected or the opportunity for improvement that exist? b. Why is it important to accomplish this change now?				
2. What is the proposed change? a. How was this decided on? b. What measures will be used to assess the change project?				
3. How will the sponsors support the change? a. What resources will be required? b. How will the sponsor demonstrate their support?				

(*continued*)

4. How will the agents support the change? a. How will they communicate and support the change process? b. How will they deal with resistance?				
5. How will the champions support the change? a. What does it mean for them to cross the bridge first? b. How will they communicate their experience to others?				
STEP V) Plan for Dealing With Resistance (In Advance):				
Identify areas where resistance to the planned change(s) is likely				
Search and review	Departmental/organizational data for experiences in the past when change was proposed	Minutes of departmental meetings may be helpful to identify individuals who do not like change or who generally oppose making changes	Information from interviewing present and past opinion leaders; careful that "personality issues" are not involved	The literature for information from other locations where the same or similar change(s) were made
Checklist for identifying individuals/departments who may resist the planned change(s):				
1. Review past improvement efforts for clues as to who may oppose any change a. Start with individuals/departments who are most likely to be affected by the change(s) b. Brainstorm about individuals who are generally opposed to any/all changes c. Send out information about the proposed change(s) and the reason(s) for them				
2. Ask for feedback in writing by a certain date				
3. Follow up with phone calls/e-mails getting "buy in" or reasons for opposition from those who have not responded				
4. Consider modifying the change(s) based on the feedback from those who may oppose or who are only "lukewarm" about the proposed change(s) a. What are the possible compromises? b. Will the proposed change(s) still be effective if suggested modifications are made?				
STEP VI) Plan for Monitoring, Follow-up, and Sustainability of Change:				
Measuring change	a. How will you measure change once the process is in place? b. How often and to whom will you report the data? c. What will your criteria be for determining the success of the project and deciding how to adjust it if goals are not being met?			
Follow-up	a. How will you expand the process beyond your pilot setting?			
Sustainability	a. How will you celebrate short-term wins? b. How will you incorporate measures of this process into the standard quality reporting functions of department or hospital leadership? c. Who will be responsible for monitoring that any improvement is sustained?			
Checklist for monitoring, follow-up, and sustainability of change:				
1. Who will pilot your change? a. Select a single unit or small group of physicians to initially institute the change process b. Decide how long the pilot will run and intervals at which you will gather and report data

Summary

KEY POINTS

1 *Clinical research* includes all research involving human participants and represents a range of research disciplines and approaches, including patient-oriented research, clinical trials, epidemiology, and outcomes research.

2 *Clinical trials* are a subset of clinical research where human participants are prospectively assigned to an intervention.

3 *Randomized clinical trials are a subset of clinical trials* that use a controlled experimental design to assess the effectiveness of an intervention on an outcome.

4 *Outcomes research* and *health services research* include studies that seek to identify the most effective and efficient intervention, treatments, and services for patient care.

5 Study designs include *experimental studies* (clinical trials), *observational studies* (cohort studies, case-control studies, and cross-sectional studies), and *descriptive studies* (case reports and case series).

6 *Scientific validity* of a research study is evaluated by understanding the study question, how the study was designed, and whether chance, bias, or confounding could have accounted for the findings.

7 All study designs have inherent strengths and weaknesses and the quality of the methods of the individual study and its scientific validity must be evaluated to determine the study's overall quality of evidence.

STUDY DESIGNS

Medical practice is evolving to include complex options for patient treatment and preventive care, in part because clinical research methods and techniques to guide patient care have advanced. To evaluate whether new treatments and diagnostic approaches should be integrated into clinical practice or decide whether study results reported in the literature are valid, clinicians should understand the fundamental strengths and limitations of clinical research methods and the level of evidence different types of studies provide.

[1] Clinical research, which encompasses all research involving human participants, includes patient-oriented research involving understanding mechanisms of human disease, studies of therapies or interventions for disease, clinical trials, and epidemiology (1). It does not include secondary studies using publicly available datasets or studies using **[2]** existing biologic specimens. Clinical trials, a subset of clinical research, are studies that evaluate the effects of an intervention on participants by prospectively assigning participants to intervention groups (1).

Epidemiologic methods and behavioral research are used in clinical research to examine the distribution of disease and the factors that affect health and how people make [4] health-related decisions. Outcomes research and health services research include studies that seek to identify the most effective and efficient intervention, treatments, and services for patient care.

The purpose of a research study is to test a hypothesis and to measure an

association between *exposure (or treatment)* and an outcome (e.g., disease occurrence, prevention, symptom score, quality of life). The type of study design influences the way the study results should be interpreted. Selection of study design should be based on the specific research question being addressed.

[5] *Analytic studies are often subdivided into experimental studies (clinical trials) and observational studies (cohort studies, case-control studies, and cross-sectional studies).*

Descriptive studies **(case reports and case series) can provide useful information for informing future analytic studies.**

The common types of clinical research study methods, strengths and weaknesses of the specific study method, and interpretation of the results are presented. **Well-designed and executed clinical trials have been presumed to represent the highest level of evidence for evaluating health interventions; however, work in evidence-based medicine has urged that study design is only one of several factors that drives the [7]quality of evidence within a study.** It should be noted that all study designs have inherent strengths and weaknesses and the quality of the methods of the individual study and its scientific validity must be evaluated to determine the study's overall quality of evidence (2,3). **[6] *Scientific validity* of a research study is evaluated by understanding the study question, how the study was designed, and whether chance, bias, or confounding could have accounted for the findings.**

ANALYTIC STUDIES

Clinical Trials

[2] Clinical trials include any study where participants are prospectively assigned to receive an intervention or treatment (which may include being assigned to a control group) and the outcomes to be measured are clearly defined at the time the trial is designed. **[4] Features of *randomized clinical trials* include randomization (in which participants are randomly assigned to exposures), unbiased assessment of outcome, and analysis of all participants based on the assigned exposure (an "intention to treat" analysis).**

There are many different types of clinical trials, including studies designed to evaluate treatments, prevention techniques, community interventions, quality-of-life improvements, and diagnostic or screening approaches (4). Investigators conducting randomized clinical trials are expected to register the trial to comply with mandatory registration and results reporting requirements (5,6).

Clinical Trial Phases

New investigational drugs or treatments are usually evaluated by clinical trials in

phases which begin with small trials designed to determine treatment safety (phase 1) and progress to large-scale studies designed to determine efficacy and side effects (phase 3) (Table 4-1) (7).

Randomized Controlled Double-Blinded Clinical Trial

The *randomized controlled double-blinded clinical trial* design minimizes bias when evaluating the effect of an intervention on an outcome because randomizing treatment assignment minimizes the influence of confounders and *blinding* both the participant and the investigator minimizes the possibility that ascertainment of the outcome is influenced by treatment group assignment. When studies are not randomized or blinded, bias may result from preferential assignment of treatment based on patient characteristics or an unintentional imbalance in baseline characteristics between treatment groups, leading to *confounding* (8).

Although not all studies can be designed with blinding, the efforts used in the trial to minimize bias from nonblinding should be explained. Investigators are expected to provide evidence that the factors that might influence outcome, such as age, stage of disease, medical history, and symptoms, are similar in patients assigned to the study protocol compared with patients assigned to placebo or traditional treatment. Published reports from the clinical trial are expected to include a table showing a comparison of the treatment groups with respect to potential confounders and to demonstrate that the groups did not differ in any important ways before the study began.

CONSORT Checklist

Clearly defining the outcome or criteria for successful treatment helps ensure unbiased assessment of the outcome. A well-designed clinical trial has a sufficient number of subjects enrolled to ensure that a "negative" study (one that does not show an effect of the treatment) has enough statistical power to evaluate the predetermined (a priori), expected treatment effect. **The Consolidated Standards of Reporting Trials (CONSORT) Statement is an evidence-based, minimum set of recommendations for reporting on randomized controlled trials developed by the CONSORT Group to alleviate the problems arising from inadequate reporting of randomized controlled trials.** The 25-item CONSORT checklist (Table 4-2) and flow diagram (Fig. 4-1) offer a standard way for authors to prepare reports of trial findings, facilitating their complete and transparent reporting, and aiding their critical appraisal and interpretation (9).

Table 4-1 Phases of Clinical Trials

Stage of Testing	Trial Aim	Numbers of Participants

Phase 1	Evaluate treatment safety, determine safe dosage range. Data are collected on the treatment (dose, when, and how it is taken) and how participants respond (in terms of effects and side effects).	Involve 20–100 healthy volunteers or people with the disease or condition
Phase 2	Evaluate treatment efficacy, further evaluate safety and tolerability.	Involve up to several hundred people with the disease or condition
Phase 3	Definitively determine the efficacy of treatment for the intended population, compare with other available treatments, assess adverse events and side effects.	Involve 30–3,000 participants, often within randomized clinical trials
Phase 4	Evaluate for uncommon serious side effects and adverse effects, optimal use including identifying subgroups that may benefit more or less from the treatment under study. These trials are particularly important for identifying rare adverse events when medications and devices are utilized in larger populations. These studies are conducted after the intervention has been approved by the FDA.	Large trials or observations studies, registries, with thousands of participants

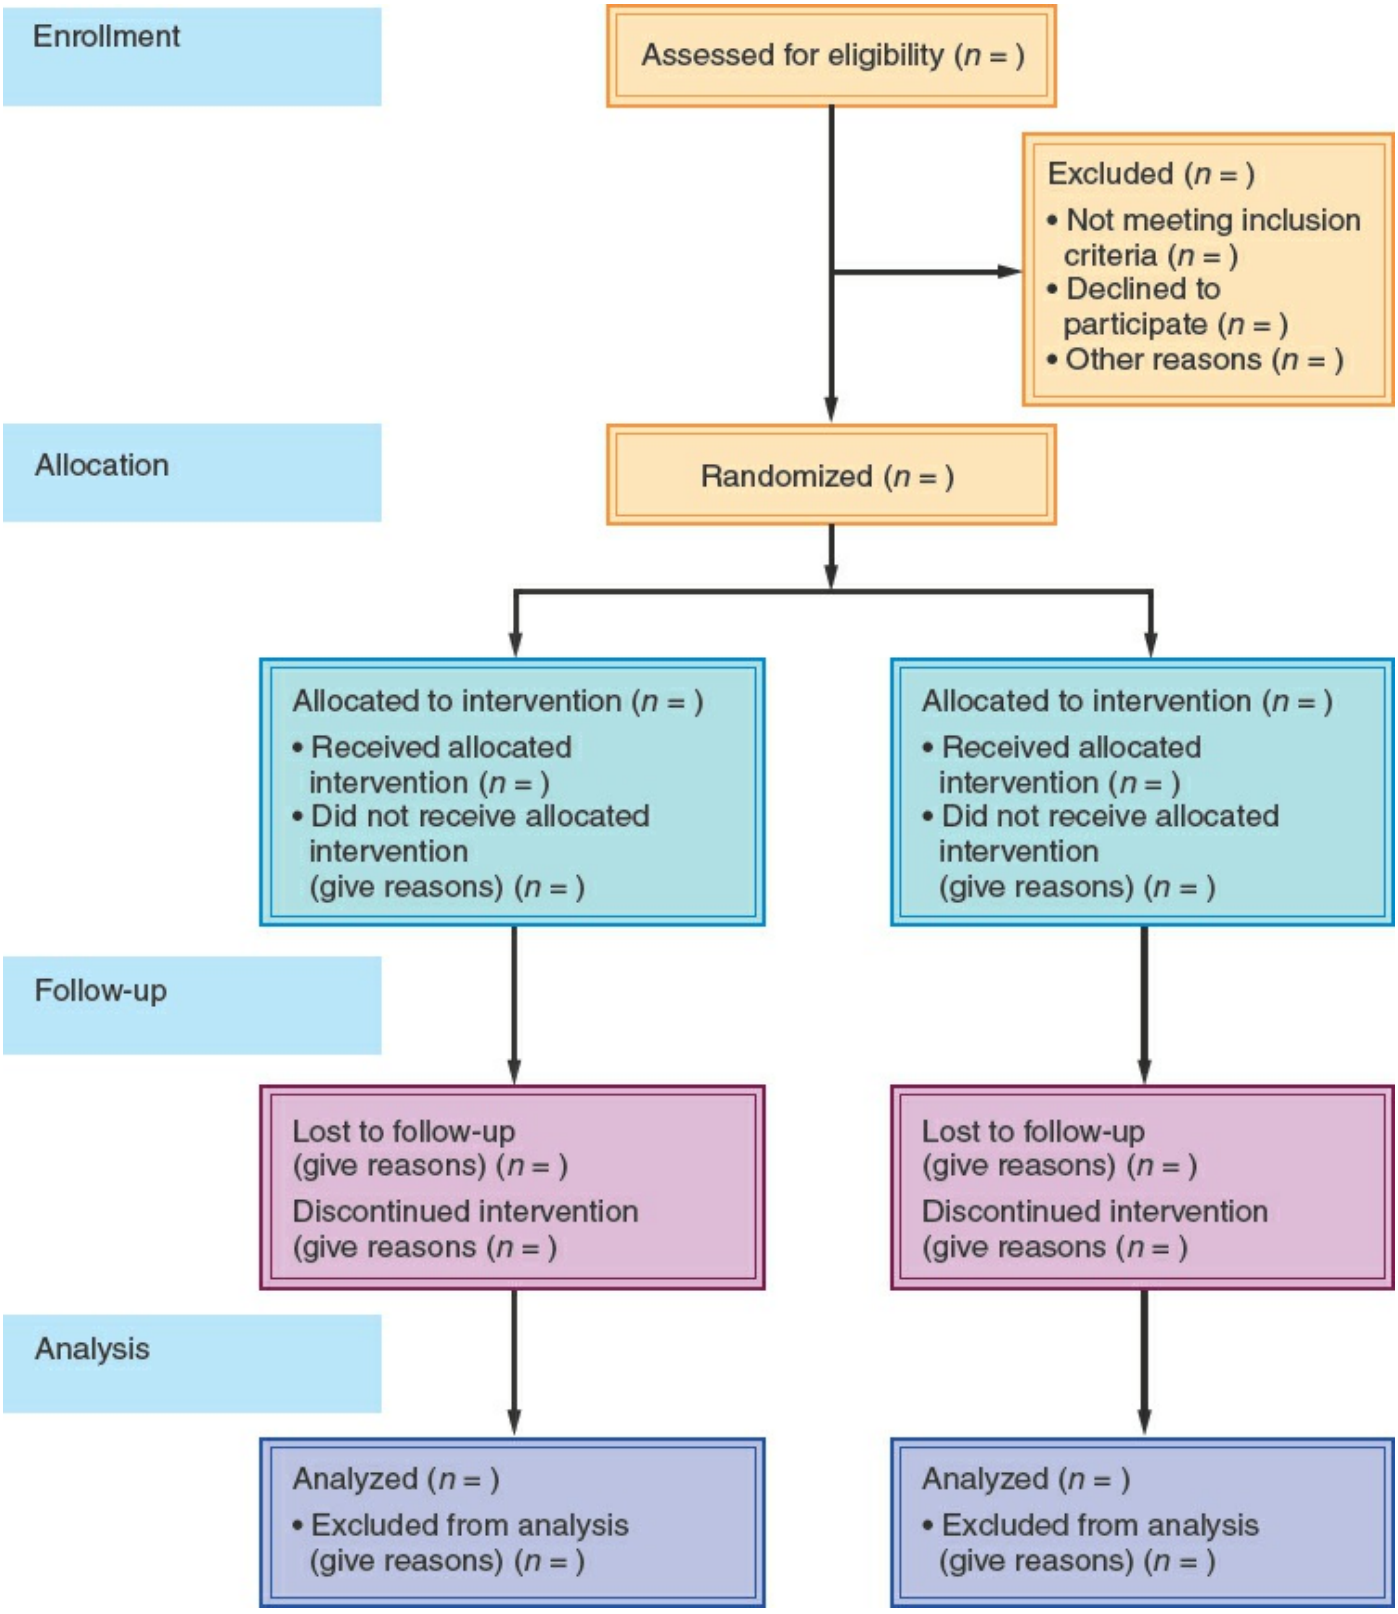

FIGURE 4-1 CONSORT flow diagram.

Clinical Trial Design Considerations

[3] Well-designed and correctly performed clinical trials can clearly determine the efficacy of an intervention and identify causal relationships, because they provide

information about the relative and absolute risks and minimize concerns about bias and confounding (see section Presenting and Understanding the Results of Analytic Studies). Potential weaknesses of clinical trials include cost restraints, length of time required to complete the study, feasibility of recruitment and implementation, and issues with applicability to populations outside of the strictly controlled study environment. Some clinical research questions are not amenable to clinical trials because of ethical issues with assigning patients to treatment groups, nature of the exposure being studied (such as socioeconomic status, weight, environmental exposures, and other patient characteristics), and urgent and emerging medical issues (e.g., the impact of Zika virus on pregnancy outcomes) (2).

When evaluating the results from a clinical trial, consider how restrictive inclusion and exclusion criteria may narrow the participant population to an extent that there may be concerns about external validity or generalizing the results. Other concerns include blinding, loss to follow-up, and clearly defining the outcome of interest. When the results of a randomized controlled trial do not show a significant effect of the treatment or intervention, the methods should be evaluated to understand what assumptions (expected power and effect size) were made to determine the necessary sample size for the study.

Intention-to-Treat Analysis

Randomized controlled trials should be evaluated with an intention-to-treat analysis, which means that all of the people randomized at the initiation of the trial should be accounted for in the analysis with the group to which they were assigned. Unless part of the overall study design, even if a participant stopped participating in the assigned treatment or "crossed over" to another treatment during the study, they should be analyzed with the group to which they were initially assigned. All of these considerations help to minimize bias in the design, implementation, and interpretation of a clinical trial (8).

Table 4-2 CONSORT Checklist

Section/Topic	Item No.	Checklist Item	Reported on Page No.
Title and Abstract			
	1a	Identification as a randomized trial in the title	_____
	1b	Structured summary of trial design, methods, results, and conclusions (for specific guidance see CONSORT for abstracts)[a]	_____
Introduction			
Background and objectives	2a	Scientific background and explanation of rationale	_____
	2b	Specific objectives or hypotheses	_____
Methods			
Trial design	3a	Description of trial design (such as parallel, factorial) including allocation ratio	_____
	3b	Important changes to methods after trial commencement (such as eligibility criteria), with reasons	_____
Participants	4a	Eligibility criteria for participants	_____
	4b	Settings and locations where the data were collected	_____
Interventions	5	The interventions for each group with sufficient details to allow replication, including how and when they were actually administered	_____
Outcomes	6a	Completely defined prespecified primary and secondary outcome measures, including how and when they were assessed	_____
	6b	Any changes to trial outcomes after the trial commenced, with reasons	_____
Sample size	7a	How sample size was determined	_____
	7b	When applicable, explanation of any interim analyses and stopping guidelines	_____
Randomization: sequence generation	8a	Method used to generate the random allocation sequence	_____
	8b	Type of randomization; details of any restriction (such as blocking and block size)	_____
Allocation concealment mechanism	9	Mechanism used to implement the random allocation sequence (such as sequentially numbered containers), describing any steps taken to conceal the sequence until interventions were assigned	_____
Implementation	10	Who generated the random allocation sequence, who enrolled participants, and who assigned participants to interventions	_____
Blinding	11a	If done, who was blinded after assignment to interventions (e.g., participants, care providers, those assessing outcomes) and how	_____
	11b	If relevant, description of the similarity of interventions	_____
Statistical methods	12a	Statistical methods used to compare groups for primary and secondary outcomes	_____
	12b	Methods for additional analyses, such as subgroup analyses and adjusted analyses	_____
Results			
Participant flow (a diagram is strongly recommended)	13a	For each group, the numbers of participants who were randomly assigned, received intended treatment, and were analyzed for the primary outcome	_____
	13b	For each group, losses and exclusions after randomization, together with reasons	_____
Recruitment	14a	Dates defining the periods of recruitment and follow-up	_____
	14b	Why the trial ended or was stopped	_____
Baseline data	15	A table showing baseline demographic and clinical characteristics for each group	_____
Numbers analyzed	16	For each group, number of participants (denominator) included in each analysis and whether the analysis was by original assigned groups	_____
Outcomes and estimation	17a	For each primary and secondary outcome, results for each group, and the estimated effect size and its precision (such as 95% confidence interval)	_____
	17b	For binary outcomes, presentation of both absolute and relative effect sizes is recommended	_____

(*continued*)

Section/Topic	Item No.	Checklist Item	Reported on Page No.
Ancillary analyses	18	Results of any other analyses performed, including subgroup analyses and adjusted analyses, distinguishing prespecified from exploratory	_____
Harms	19	All important harms or unintended effects in each group (for specific guidance, see CONSORT for harms)[a]	_____
Discussions			
Limitations	20	Trial limitations, addressing sources of potential bias, imprecision, and if relevant, multiplicity of analyses	_____
Generalizability	21	Generalizability (external validity, applicability) of the trial findings	_____
Interpretation	22	Interpretation consistent with results, balancing benefits and harms, and considering other relevant evidence	_____
Other Information			
Registration	23	Registration number and name of trial registry	_____
Protocol	24	Where the full trial protocol can be accessed, if available	_____
Funding	25	Sources of funding and other support (such as supply of drugs), role of funders	_____

[a]We strongly recommend reading this statement in conjunction with the CONSORT 2010 Explanation and Elaboration for important clarifications on all the items. If relevant, we also recommend reading CONSORT extensions for cluster randomized trials, noninferiority and equivalence trials, nonpharmacologic treatments, herbal interventions, and pragmatic trials. Additional extensions are forthcoming: for those and for up-to-date references relevant to this checklist, see www.consort-statement.org.

Observational Studies

Observational studies can evaluate exposures and outcomes that are not amenable to an experimental design (e.g., exposure is known or suspected to have harmful effects). Not all research questions can be addressed with clinical trials because of ethical issues (unethical to willingly subject participants to known harmful exposures), the nature of the exposures being studied (inherent participant characteristics), and feasibility issues (rare outcomes such as unusual adverse events and diseases).

Observational studies, including cohort, case-control, and cross-sectional studies, are analytic studies that take advantage of "natural experiments" in which exposure is not assigned by the investigator; rather, the individuals are assessed by the investigator for a potential exposure of interest (present or absent) and outcomes (present or absent). The timing of the evaluation of the exposure and outcome defines the study type.

Cohort Studies

Cohort studies often are referred to as longitudinal studies. Cohort studies involve identifying a group of exposed and unexposed individuals and following both groups over time to compare the rate of disease (or outcome) in the groups. Cohort studies may be prospective, meaning that the exposure is identified before outcome, or retrospective, in which the exposure and outcome have already occurred when the study is initiated. **Even in a retrospective cohort study, the study is defined by the fact that the cohorts were identified based on the exposure (not the outcome), and individuals should be free of disease (outcome) at the beginning time point for the**

cohort study (Fig. 4-2).

In a study that includes a survival analysis, the two cohort groups (exposed and unexposed) begin with a population that is 100% well (or alive) at the beginning of the study. The groups are followed over time to calculate the percentage of the cohort that is still well (or alive) at different time points during the study and at the end of the study. Although a survival analysis typically describes mortality after disease (i.e., cancer patients who died within 5 years), it can be adapted to other events and outcomes (e.g., the percentage of women who become pregnant while using long-acting contraceptives).

Cohort Study Design

Strengths of cohort studies include the ability to obtain attributable and relative risks (RRs) because the occurrence of the outcome is being compared in two groups (see section Presenting and Understanding the Results of Analytic Studies). In these studies, only associations can be established, not causality. Because randomization is not part of the study design, the investigator must consider that a factor associated with the exposure may lead to the outcome rather than the exposure itself. Misclassifying the exposure or the outcome and confounding variables are potential sources of bias in cohort studies.

Given that truly prospective cohort studies can be expensive and take a long time for completion, there should be compelling evidence for the public health importance of the exposure(s) and association(s) being addressed. Issues related to sample size and participant retention in the study protocol are as important in cohort studies as they are in randomized controlled trials.

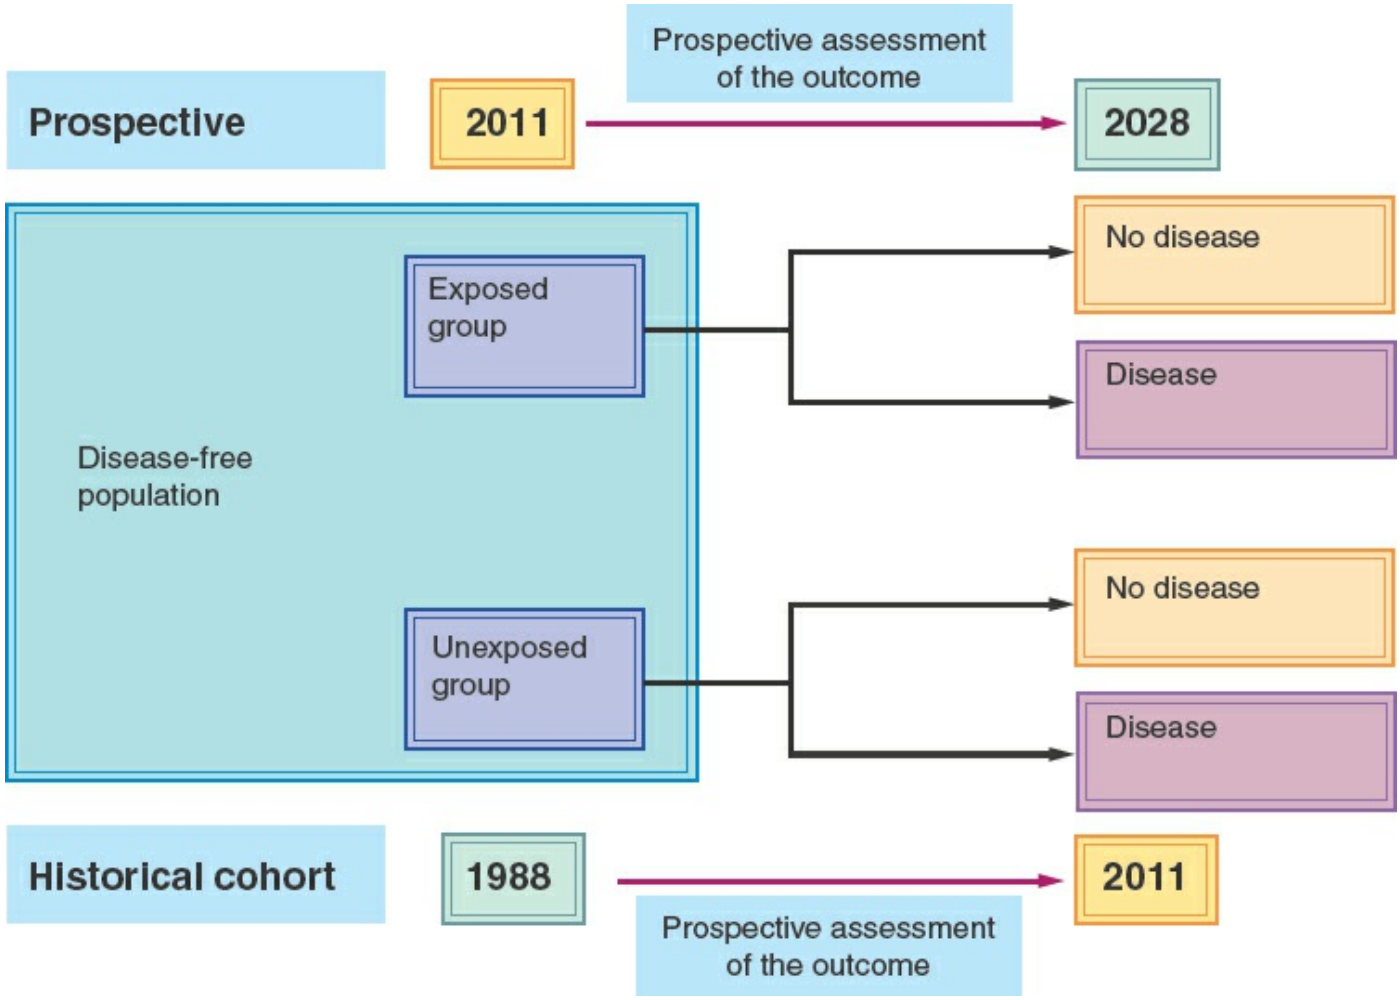

FIGURE 4-2 Schematic of prospective and retrospective cohort study designs.

Case-Control Studies

A case-control study starts with the identification of individuals with a disease or outcome of interest and a suitable control population without the disease or outcome of interest. The controls should represent a sample of the population from which the cases arose and who were at risk for the disease or outcome but did not develop it. The relationship between a particular attribute or exposure to the disease is retrospectively studied by comparing how the cases and controls differed in that exposure **(Fig. 4-3)**.

Odds Ratio

The measure of association for a case-control study is the odds ratio (OR), which is the ratio of exposed cases to unexposed cases, divided by the ratio of exposed to unexposed controls (see section Presenting and Understanding the Results of Analytic Studies). **If an entire population could be characterized by its exposure and disease status, the exposure OR would be identical to the RR obtainable from a cohort study of the same population.** Although the RR cannot be calculated directly from a

case-control study, it can be used as an estimate of the RR when the sample of cases and controls are representative of all people with or without the disease and when the disease being studied is uncommon. Attributable risk is not directly obtainable in a case-control study.

Case-Control Study Considerations

The advantages of case-control studies are that they are lower in cost and easier to conduct than other analytic studies. Case-control studies are most feasible for examining the association between a relatively common exposure and a relatively rare disease. Disadvantages include greater potential for selection bias, recall bias, and misclassification bias.

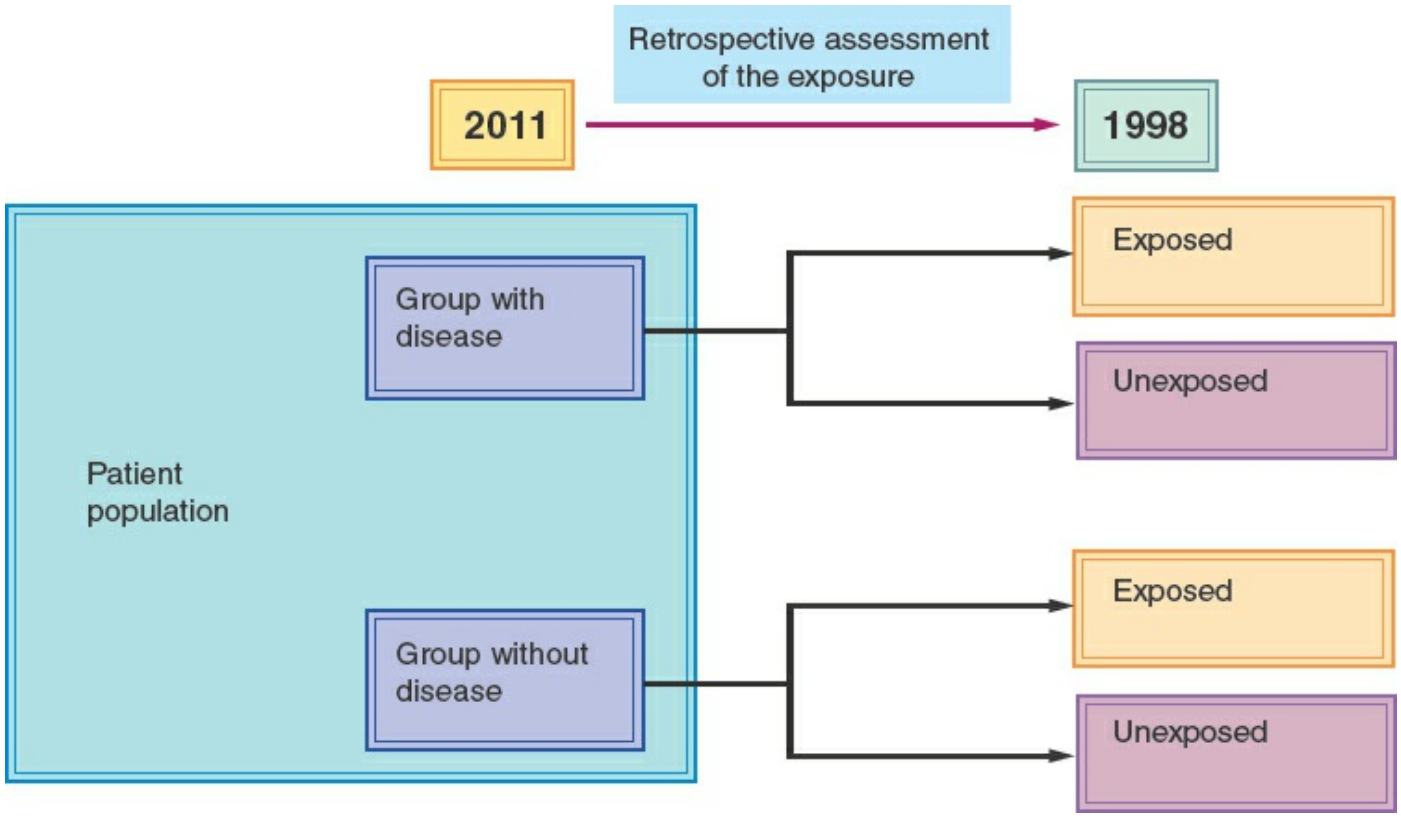

FIGURE 4-3 Schematic of case-control study design.

Case-control studies may be especially prone to selection bias and recall bias. Investigators need to understand sampling issues around which cases and controls were selected for their study and how these may have affected exposure rates. Subtle issues, such as interviewer technique, may affect the likelihood that cases may recall or report exposures more readily than controls.

Cross-Sectional Studies

Cross-sectional studies assess both the exposure and the outcome at the same point in time. Individuals are surveyed to provide a "snapshot" of health events in the

population at a particular time. Cross-sectional studies are often called prevalence studies because the disease exists at the time of the study, and the longitudinal follow-up and disease duration are not known. **Prevalence (PR) is the existing number of cases at a specific point in time.**

Cross-sectional studies are often done to evaluate a diagnostic test. The value of the test (predictor) is compared with the outcome (disease). The results of these evaluations are often presented as *sensitivity* and *specificity*. The sensitivity and specificity represent the characteristics of a given diagnostic test and do not vary by population characteristics. In contrast, the negative predictive value (NPV) and positive predictive value (PPV) of a test do vary with the baseline characteristics of a population such as PR of a disease **(Fig. 4-4)**.

Cross-Sectional Study Considerations

Although cross-sectional studies are primarily descriptive, they may contribute information about suggested risk factors for a disease by showing how that disease varies by age, sex, race, or geography. In *ecologic studies*, disease rates in various populations are correlated with other characteristics measured at the population level (such as diet, ultraviolet radiation exposure, work or home environment).

Caution must be used in interpreting findings from a cross-sectional study because there is no temporal relationship between the exposure and the outcome; therefore, causality cannot be established. Cross-sectional data can be valuable in informing analytic study designs or used as supporting data for documenting the consistency of an association.

DESCRIPTIVE STUDIES

Descriptive studies, case reports and case series, do not include comparison groups.

Case Reports and Case Series

In a case report or case series, the characteristics of individuals who have a particular exposure or outcome are described. Examples include series of patients with a particular disease, patients who had a particular surgical procedure, or an adverse outcome (such as ureteral injury at the time of hysterectomy). A case report usually describes an unusual clinical scenario or procedure in a single patient, whereas a case series usually includes a larger group of patients with similar exposures or outcomes. Although **members of a case series share a particular characteristic, it cannot be assumed that there is a cause-and-effect relationship.**

Hypotheses about exposures and disease may be developed from descriptive studies that should be explored in analytic studies. Because a case series has no

comparison group, statistical tests of association between the exposure and outcome cannot be performed. A case series usually does not yield any measure of association other than estimates of the frequency of a particular characteristic among members included in the case series.

PRESENTING AND UNDERSTANDING THE RESULTS OF ANALYTIC STUDIES

To present the results of clinical trials or observational studies, a variety of rates and measures may be derived, as summarized below. **To judge the scientific validity of the results of clinical studies, an investigator needs to consider whether the finding could have occurred simply by chance, by performing appropriate statistical testing, or if there are other possible explanations for the reported association, including bias or confounding.** Besides statistical significance and freedom from bias or confounding, there are several additional criteria that can be applied to judge whether the treatment truly did affect disease outcome or whether an exposure truly caused the outcome, as outlined below.

Rates and Measures

The terminology associated with rates and measures include the following (Fig. 4-5):

- ***Incidence (IR)*—frequency of newly identified disease or event (outcome).**
- ***Prevalence (PR)*—frequency of an existing disease or outcome during a specified period or point in time.**
- ***Odds Ratios (OR)*—ratio of the probability of an exposure in one group (cases) compared with probability of the exposure in another group (controls).**
- ***Relative Risk (RR)*—ratio of risk in the exposed group compared with the risk in the unexposed group.** If the RR = 1 (or not significantly different from 1) then the risk in the exposed group is equal to the risk in the unexposed group. RR >1 may suggest a positive association with the exposed group having greater risk than the unexposed group, whereas RR <1 implies a negative association with the exposed group having less risk than the unexposed group.
- ***Absolute Risk Reduction (ARR)*—the difference in risk between the unexposed (control) group and the exposed (treatment) group.**
- ***Relative Risk Reduction (RRR)*—the percentage of reduction in the risk comparing the unexposed (control) group to the exposed (treatment) group.**

- ***Number Needed to Treat (NNT)*—represents the number of people who would need treatment (or the intervention) to prevent one additional outcome (to calculate the NNT, take the inverse of the ARR, i.e., 1 ï ARR).**
- ***Sensitivity*—among the people who have the outcome, this is the proportion who have a positive test.**
- ***Specificity*—among the people who do not have the outcome, this is the proportion who have a negative test.**
- ***Negative Predictive Value (NPV)*—among the people who have a negative test, this is the proportion who do not have the outcome.**
- ***Positive Predictive Value (PPV)*—among the people who have a positive test, this is the proportion who have the outcome.**

	Disease +	Disease −	
Test +	95 (a)	5 (b)	100
Test −	5 (c)	95 (d)	100
	100	100	200

Prevalence of disease is 50%

Sensitivity (a/a + c): 95/100 = 95%
Specificity (d/b + d): 95/100 = 95%
PPV (a/a + b): 95/100 = 95%
NPV (d/c + d): 95/100 = 95%

	Disease +	Disease −	
Test +	95	50	145
Test −	5	950	955
	100	1,000	1,100

Prevalence of disease is 9%

Sensitivity: 95/100 = 95%
Specificity: 950/1,000 = 95%
PPV: 95/145 = 65.5%
NPV: 950/955 = 99.5%

FIGURE 4-4 Comparison of sensitivity, specificity, and predictive values when the prevalence of the disease varies.

	Outcome +	Outcome –
Exposure +	a	b
Exposure –	c	d
	100	100

- **Overall incidence rate (IR):** (a + c) ÷ (a + b + c + d)
- **Odds ratio (OR):** (a/b) ÷ (c/d)
- **Relative risk (RR):** (a/(a + b) ÷ (c/c + d))
- **Relative risk reductions (RRR):** 1-RR x 100%
- **Absolute risk reduction (ARR):** (a/(a + b)) – (d/(c + d))
- **Number needed to treat (NNT):** 1 ÷ ARR

FIGURE 4-5 Calculating rates and measures.

Statistical Testing

Statistical testing is used in clinical research for hypothesis testing in which the investigator is evaluating the study results against the null hypothesis (that there is

no difference between the groups). Results from statistical testing allow the investigator to evaluate how likely it is that the study result is caused by chance rather than an intervention or exposure (*p* value). In the case where a study failed to find a significant difference, it is equally important to describe the likelihood that the study conclusion was wrong and that a difference truly exists. Finally, it is important to provide as precise a measure of the treatment effect or association as possible and convey to the reader the plausible range in which the "true" effect resides (or confidence interval [CI]).

p Value and Statistical Significance

The *p* value is a reflection of the probability of a *type I error (alpha).* This reflects the probability that a difference between study groups could have arisen by chance alone. In other words, it is the probability that there is a difference between therapies, interventions, or observed groups when a true difference does not exist.

Historically in the medical literature, a *p* value of less than or equal to 0.05 was used to determine statistical significance. This reflects a probability of 1 in 20 that the null hypothesis was incorrectly rejected based on the results from the study sample. This *p* value may be adjusted downward if multiple associations are being tested and the chances of false discovery are high. In genome-wide association studies, in which hundreds of thousands of genetic variants are tested between groups, *p* values are frequently set at 10^{-7} (0.0000001).

Beta Error and Power

***Type II (or beta) error* reflects the probability of failing to reject the null hypothesis when in reality it is incorrect (i.e., there truly was a treatment effect or a difference between the observed groups).** In clinical trials it is important for the investigator to address the beta error, even in the design stage of the study. Study planners should determine the *power* (or 1 - the *beta error*) that they would like their study to have to detect an association and, given assumptions made about the differences expected between treatments, design the study size accordingly. Be aware that small clinical trials cited as evidence for "no effect of therapy," may not have an adequate sample size to address the study question; in essence, the study is not powered to detect the difference.

Confidence Intervals

CI provide the investigator an estimated range in which the true statistical measure (e.g., mean, proportion, and RR) is expected to occur. A 95% CI implies that if the study were to be repeated within the same sample population numerous times, the CI estimates would contain the true population parameter 95% of the time. In other words, the probability of observing the true value outside of this

range is less than 0.05. When evaluating measures of association, such as OR or RR with 95% CI, values that include 1 (no difference) are not considered statistically significant.

Meta-analysis

Meta-analysis is a quantitative study design that involves the systematic collection of data from previous studies, evaluation of the data, and combination of the data (where appropriate). Meta-analyses can improve precision of the effect measure and narrow the CI by aggregating treatment effects data from several clinical trials to provide a summary measure. Commonly performed by the Cochrane Collaboration within their systematic evidence reviews, well-designed meta-analyses can provide high-quality evidence that can be used for clinical decision making (10). There are important considerations in interpreting the meta-analysis, including whether studies were similar enough in their design, study population, and outcome measurement to be aggregated and whether or not there were sufficient good-quality studies available for analyses (2). Guides for systematic reviews and meta-analysis that involve randomized controlled trials (i.e., the Preferred Reporting Items for Systematic Reviews and Meta-Analyses [PRISMA] statement) and observational studies (i.e., the Meta-analysis Of Observational Studies in Epidemiology [MOOSE] guidelines) are excellent resources for the investigator and the reviewer (11,12).

Bias

***Bias* is a systematic error in the design, conduct, or analysis of a study that can result in invalid conclusions.** It is important for an investigator to anticipate the types of bias that might occur in a study and correct them during the design of the study, because it may be difficult or impossible to correct for them in the analysis.

- ***Information bias* occurs when participants are classified incorrectly with respect to exposure or disease.** This may occur if records are incomplete or if the criteria for exposure or outcome were poorly defined, leading to misclassification.
- ***Recall bias* is a specific type of information bias that may occur if cases are more likely than controls to remember or to reveal past exposures.** In addition to establishing well-defined study criteria and accessing complete records, information bias may be reduced by blinding interviewers to a participant's study group.
- ***Selection bias* may occur when choosing cases or controls in a case-control study and when choosing exposed or unexposed subjects in a cohort study. A systematic error in selecting participants may influence the outcome by distorting the measure of association between the exposure and the**

outcome. Including an adequately large study sample and obtaining information about nonparticipants may reduce bias or provide information to evaluate potential selection bias.

Confounding

A *confounder* is a factor that is associated with the outcome (e.g., disease) and the exposure. The confounder may account for the apparent effect of the exposure on the disease or mask a true association. Confounders have unequal distributions between the study groups.

- Age, race, and socioeconomic status are potential confounders in many studies. Results may be adjusted for these variables by using statistical techniques such as stratification or multivariable analysis. Adjusting for confounding variables aids in understanding the association between the outcome and exposure if the confounding variables were constant.
- Multivariable analysis is a statistical technique commonly used in epidemiologic studies that simultaneously controls a number of confounding variables. The results from an adjusted analysis include the adjusted OR or RR that reflects an association between the exposure and the outcome and accounts for the specific known confounders that were included in the analysis.

Causality and Generalizability

The criteria needed to establish a causal relationship between two factors, especially exposure and disease, are defined (13). Although there are nine separate criteria for judging whether an association is likely to be causal, several of these criteria are most relevant for clinical studies.

- ***Biologic gradient*** *or* ***dose response*** refers to a relationship between exposure and outcome such that a change in the duration, amount, or intensity of the exposure is associated with a corresponding increase or decrease in disease risk.
- ***Plausibility*** refers to knowledge of the pathologic process of the disease or biologic effects of the exposure that would reasonably support an association. Plausibility overlaps with another concept, *coherence*, which also refers to compatibility with the known biology of the disease.
- ***Experiment*** refers to the evidence that the disease or outcome can be prevented or improved by an experiment that eliminates, reduces, or otherwise counters the exposure.
- ***Consistency*** refers to whether the association was repeatedly observed by different investigators, in different locations and circumstances.

- ***Temporality*** refers to the concept that cause must precede effect. For example, is it possible in a case-control study that symptoms of preclinical disease could lead to the exposure? Investigators must demonstrate that the exposure was present before the disease developed.
- ***Strength*** refers to the strength of association. The further the deviation of the RR or OR from 1, the stronger the association and the easier it is to accept that the study results are real. For example, studies have shown that the possession of a BRCA1 mutation may increase the lifetime risk for breast cancer by 14- to greater than 30-fold (varies by age) (14).

SUMMARY

Reviewing the medical literature is part of the ongoing education for those who provide clinical care. Incorporating research findings into clinical care is enhanced by understanding different study designs, their strengths and weaknesses, and the measures of association they are able to provide. Evaluating whether there is enough evidence available to support changing a specific medication, procedure, or protocol used to care for patients is the cornerstone to improving clinical practice. In a field that is rapidly progressing, understanding clinical research helps physicians provide optimal care for the women they treat every day.

Summary

KEY POINTS

1 Approximately 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system that provide special

implications in pelvic surgery.

2 An understanding of the development of pelvic floor disorders and their safe and effective management requires a comprehensive knowledge of the interrelationships between the bony pelvis and its ligaments, pelvic muscles and fasciae, nerves and blood vessels, and pelvic viscera.

3 A comprehensive knowledge of pelvic anatomy is crucial for the pelvic surgeon. This understanding of specific anatomic relationships is required for safe and successful surgery, as well as the development of new clinical and surgical techniques.

4 There is significant variation in the branching pattern of pelvic blood vessels between individuals, and patterns of blood flow may be asymmetric from side to side in the same individual. The pelvic surgeon should be prepared for deviations from "textbook" vascular patterns.

5 About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures, most commonly laparoscopic hysterectomy; risk is increased with distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids.

6 An understanding of the embryologic development and anatomy of the female pelvis is fundamental to the knowledge base of a practicing gynecologist.

The anatomy of the fundamental supporting structures of the pelvis, including the genital, urinary, and gastrointestinal viscera, are presented in this chapter. Because significant variation has developed in the names of many common anatomic structures, the terms used here reflect current nomenclature according to the *Nomina Anatomica*; other commonly accepted terms are included in parentheses (1).

EMBRYONIC DEVELOPMENT

The female urinary and genital tracts are closely related, anatomically and embryologically. Both are derived largely from primitive mesoderm and endoderm, and there is evidence that the embryologic urinary system has an important inductive [1] influence on the developing genital system. **About 10% of infants are born with some abnormality of the genitourinary system, and anomalies in one system are often mirrored by anomalies in another system (2).**

Developmental defects may play a significant role in the differential diagnosis of certain clinical conditions and have special implications in pelvic surgery (2–7). **Thus, it is important for gynecologists to have a basic understanding of embryology.**

Following is a presentation of the urinary system, internal reproductive organs, and external genitalia in order of their initial appearance, although much of the development of each of these three regions proceeds synchronously at an early embryologic age (Table 5-1).

Urinary System

Kidneys, Renal Collecting System, Ureters

The kidneys, renal collecting system, and ureters derive from the longitudinal mass

of mesoderm (known as the nephrogenic cord) found on each side of the primitive aorta. This process gives rise to three successive sets of increasingly advanced urinary structures, each developing more caudal to its predecessor.

The *pronephros*, or "first kidney," is rudimentary and nonfunctional; it is succeeded by the "middle kidney," or *mesonephros*, which is believed to function briefly before regressing. Although the *mesonephros* is transitory as an excretory organ, its duct, the *mesonephric (wolffian) duct*, is of singular importance for the following reasons:

1. It grows caudally in the developing embryo to open, for the first time, an excretory channel into the primitive cloaca and the "outside world."
2. It serves as the starting point for development of the metanephros, which becomes the definitive kidney.
3. It ultimately differentiates into the sexual duct system in the male.
4. Although regressing in female fetuses, there is evidence that the mesonephric duct may have an inductive role in development of the paramesonephric or müllerian duct (3).

The ureteric buds, which sprout from the distal mesonephric ducts, initiate the development of the *metanephros*; these buds extend cranially and penetrate the portion of the nephrogenic cord known as the *metanephric blastema.* The ureteric buds begin to branch sequentially, with each growing tip covered by metanephric blastema. Ultimately, the metanephric blastema forms the renal functional units (the nephrons), whereas the ureteric buds become the collecting duct system of the kidneys (collecting tubules, minor and major calyces, renal pelvis) and the ureters. Although these primitive tissues differentiate along separate paths, they are interdependent on inductive influences—neither can develop alone.

The kidneys initially lie in the pelvis but subsequently ascend to their permanent location, rotating almost 90 degrees in the process as the more caudal part of the embryo in effect grows away from them. Their blood supply, which first arises as branches of the middle sacral and common iliac arteries, comes from progressively higher branches of the aorta until the definitive renal arteries form and previous vessels regress. **The definitive kidneys become functional in the late 7th to early 8th weeks of gestation.**

Table 5-1 Development of Genital and Urinary Tracts by Embryologic Age

Weeks of Gestation	Genital Development	Urinary Development
4–6	Urorectal septum	Pronephros
	Formation of cloacal folds,	Mesonephros/mesonephric duct

	genital tubercle	
	Ureteric buds, metanephros	
	Genital ridges	Exstrophy of mesonephric ducts and ureters into bladder wall
6–7	End of indifferent phase of genital development	Major, minor calyces form
	Development of primitive sex cords	Kidneys begin to ascend
	Formation of paramesonephric ducts	
	Labioscrotal swellings	
8–11	Distal paramesonephric ducts begin to fuse	Kidney becomes functional
	Formation of sinuvaginal bulbs	
12	Development of clitoris and vaginal vestibule	
20	Canalization of vaginal plate	
32	Renal collecting duct system complete	

Bladder and Urethra

The cloaca forms as the result of dilation of the opening to the fetal exterior. During the 7th week of gestation, the cloaca is partitioned by the mesenchymal urorectal septum into an anterior urogenital sinus and a posterior rectum. The bladder and urethra form from the most superior portion of the urogenital sinus, with surrounding mesenchyme contributing to their muscular and serosal layers. The remaining inferior urogenital sinus is known as the *phallic* or *definitive urogenital sinus*. Concurrently, the distal mesonephric ducts and attached ureteric buds are incorporated into the posterior bladder wall in the area that will become the bladder trigone. As a result of the absorption process, the mesonephric duct ultimately opens independently into the urogenital sinus below the bladder neck.

The *allantois*, which is a vestigial diverticulum of the hindgut that extends into the umbilicus and is continuous with the bladder, loses its lumen and becomes the fibrous band known as the *urachus* or *median umbilical ligament*. **In rare instances, the urachal lumen remains partially patent, with formation of urachal cysts, or completely patent, with the formation of a urinary fistula to the umbilicus** (4).

Genital System

Although genetic gender is determined at fertilization, the early genital system is indistinguishable between the two genders in the embryonic stage. This is known as the "indifferent stage" of genital development, during which both male and female fetuses have gonads with prominent cortical and medullary regions, dual sets of genital ducts, and external genitalia that appear similar. Male sexual differentiation is an "active" process requiring the presence of the SRY gene (gender-determining region), located on the short arm of the Y chromosome. Clinically, **gender is not apparent until about the 12th week of embryonic life and depends on the elaboration of testis-determining factor and, subsequently, androgens by the male gonad.** Female development is called the "basic developmental path of the human embryo," requiring not estrogen but the absence of testosterone.

Internal Reproductive Organs

The *primordial germ cells* migrate from the yolk sac through the mesentery of the hindgut to the posterior body wall mesenchyme at about the 10th thoracic level, which is the initial site of the future ovary (Figs. 5-1 and 5-2). When the germ cells reach this area, they induce proliferation of cells in the adjacent mesonephros and celomic epithelium to form a pair of *genital ridges* medial to the mesonephros. This occurs during the 5th week of gestation. The development of the gonad is absolutely dependent on this proliferation because these cells form a supporting aggregate of cells (the primitive sex cords) that invest the germ cells and without which the gonad would degenerate.

Müllerian Ducts

The *paramesonephric or müllerian ducts* form lateral to the mesonephric ducts; they grow caudally and then medially to fuse in the midline. They contact the urogenital sinus in the region of the posterior urethra at a slight thickening known as the *sinus tubercle.* Subsequent sexual development is controlled by the presence or absence of testis-determining factor, encoded on the Y chromosome and elaborated by the somatic sex cord cells. Testis-determining factor causes the degeneration of the gonadal cortex and differentiation of the medullary region of the gonad into Sertoli cells.

The Sertoli cells secrete a glycoprotein known as *anti-müllerian hormone* (AMH), which causes regression of the paramesonephric duct system in the male embryo and is the likely signal for differentiation of Leydig cells from the surrounding mesenchyme. The Leydig cells produce testosterone and, with the converting enzyme 5α-reductase, dihydrotestosterone. Testosterone is responsible for evolution of the mesonephric duct system into the vas deferens, epididymis, ejaculatory ducts, and seminal vesicle. At puberty, testosterone leads to spermatogenesis and changes in primary and secondary sex characteristics. Dihydrotestosterone triggers the

development of the male external genitalia and the prostate and bulbourethral glands. In the absence of testis-determining factor, the medulla regresses, and the cortical sex cords break up into isolated cell clusters (the primordial follicles).

The germ cells differentiate into oogonia and enter the first meiotic division as primary oocytes, at which point development is arrested until puberty. In the absence of AMH, the mesonephric duct system degenerates, although in at least one-fourth of adult women, remnants may be found in the mesovarium (*epoophoron, paroophoron*) or along the lateral wall of the uterus or vagina (*Gartner duct cyst*) (5).

The paramesonephric duct system subsequently develops. The inferior fused portion becomes the *uterovaginal canal*, which later becomes the epithelium and glands of the uterus and the upper vagina. The endometrial stroma and myometrium differentiate from surrounding mesenchyme. The cranial unfused portions of the paramesonephric ducts open into the celomic (future peritoneal) cavity and become the *fallopian tubes*.

The fusion of the paramesonephric ducts brings together two folds of peritoneum, which become the broad ligament and divide the pelvic cavity into a posterior rectouterine and anterior vesicouterine pouch or cul-de-sac. Between the leaves of the broad ligament, mesenchyme proliferates and differentiates into loose areolar connective tissue and smooth muscle.

FIGURE 5-1 The comparative changes of the female and male during early embryonic development.

Vagina

The *vagina* forms in the 3rd month of embryonic life. While the uterovaginal canal is forming, the endodermal tissue of the sinusal tubercle begins to proliferate, forming a pair of *sinovaginal bulbs*, which become the inferior 20% of the vagina. The most inferior portion of the uterovaginal canal becomes occluded by a solid core of tissue (the *vaginal plate*), the origin of which is unclear. Over the subsequent 2 months, this tissue elongates and canalizes by a process of central desquamation, and the peripheral cells become the vaginal epithelium. The fibromuscular wall of the vagina originates from the mesoderm of the uterovaginal canal. The hymen is a thin fold of membrane that remains to a varying degree between the dilated, canalized, fused sinovaginal bulbs and the urogenital sinus.

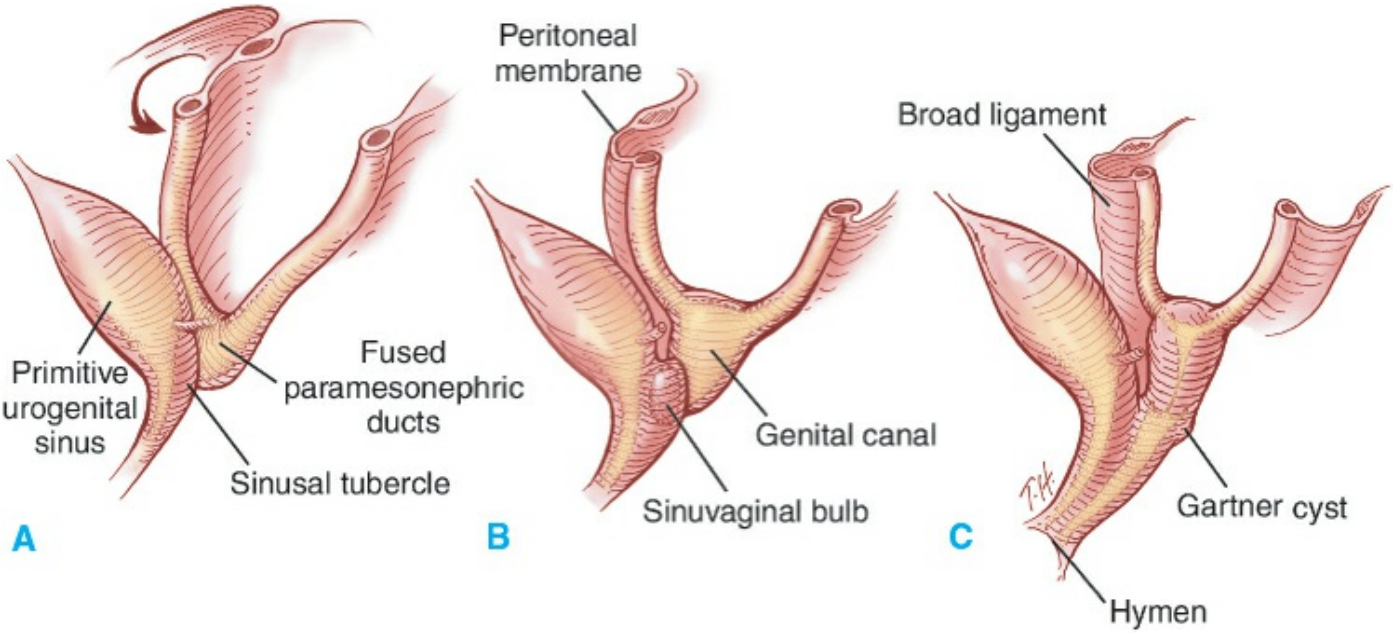

FIGURE 5-2 The embryonic development of the female genital tract. The formation of the uterus and vagina. **A:** The uterus and superior end of the vagina begin to form as the paramesonephric ducts fuse together near their attachment to the posterior wall of the primitive urogenital sinus. **B,C:** The ducts then zipper together in a superior direction between the 3rd and 5th months. As the paramesonephric ducts are pulled away from the posterior body wall, they drag a fold of peritoneal membrane with them, forming the broad ligaments of the uterus. **A–C:** The inferior end of the vagina forms from the sinovaginal bulbs on the posterior wall of the primitive urogenital sinus.

Accessory Genital Glands

The female accessory genital glands develop as outgrowths from the urethra (*paraurethral* or *Skene*) and the definitive urogenital sinus (*greater vestibular* or *Bartholin*). Although the ovaries first develop in the thoracic region, they ultimately arrive in the pelvis by a complicated process of descent. This descent by differential

growth is under the control of a ligamentous cord called the *gubernaculum*, which is attached to the ovary superiorly and to the fascia in the region of the future labia majora inferiorly. The gubernaculum becomes attached to the paramesonephric ducts at their point of superior fusion so that it becomes divided into two separate structures. As the ovary and its mesentery (the mesovarium) are brought into the superior portion of the broad ligament, the more proximal part of the gubernaculum becomes the *ovarian ligament*, and the distal gubernaculum becomes the *round ligament*.

External Genitalia

Early in the 5th week of embryonic life, folds of tissue form on each side of the cloaca and meet anteriorly in the midline to form the genital tubercle (Fig. 5-3). With the division of the cloaca by the urorectal septum and consequent formation of the perineum, these cloacal folds are known anteriorly as the *urogenital folds* and posteriorly as the *anal folds*. The genital tubercle begins to enlarge. In the female embryo, its growth gradually slows to form the clitoris, and the urogenital folds form the labia minora. In the male embryo, the genital tubercle continues to grow to form the penis, and the urogenital folds are believed to fuse to enclose the penile urethra. Lateral to the urogenital folds, another pair of swellings develops, known in the indifferent stage as *labioscrotal swellings*. In the absence of androgens, they remain largely unfused to become the labia majora. The definitive urogenital sinus gives rise to the vaginal vestibule, into which open the urethra, vagina, and greater vestibular glands.

Clinical Correlations

Developmental abnormalities of the urinary and genital systems can be explained and understood by a consideration of female and male embryologic development. [1] The intertwined development of these two systems may cause abnormalities in one to be associated with abnormalities in the other (6).

Urinary System

Urinary tract anomalies arise from defects in the ureteric bud, the metanephric blastema, or their inductive interaction with each other.

Renal Agenesis

Renal agenesis occurs when one or both ureteric buds fail to form or degenerate, and the metanephric blastema is therefore not induced to differentiate into nephrons. Bilateral renal agenesis is incompatible with postnatal survival, but infants with only one kidney usually survive, and the single kidney undergoes compensatory hypertrophy. **Unilateral renal agenesis is often associated with absence or abnormality of fallopian tubes, uterus, or vagina—the paramesonephric duct derivatives**.

Abnormalities of Renal Position

Abnormalities of renal position result from disturbance in the normal ascent of the kidneys. A malrotated pelvic kidney is the most common result; a horseshoe kidney, in which the kidneys are fused across the midline, occurs in about 1 in 600 individuals and has a final position lower than usual because its normal ascent is prevented by the root of the inferior mesenteric artery.

Duplication of the Upper Ureter and Renal Pelvis

Duplication of the upper ureter and renal pelvis is relatively common and results from premature bifurcation of the ureteric bud. If two ureteric buds develop, there will be complete duplication of the collecting system. In this situation, one ureteric bud will open normally into the posterior bladder wall, and the second bud will be carried more distally within the mesonephric duct to form an ectopic ureteral orifice into the urethra, vagina, or vaginal vestibule; incontinence is the primary presenting symptom. Most of the aforementioned urinary abnormalities remain asymptomatic unless obstruction or infection supervenes. In that case, anomalous embryologic development must be included in the differential diagnosis.

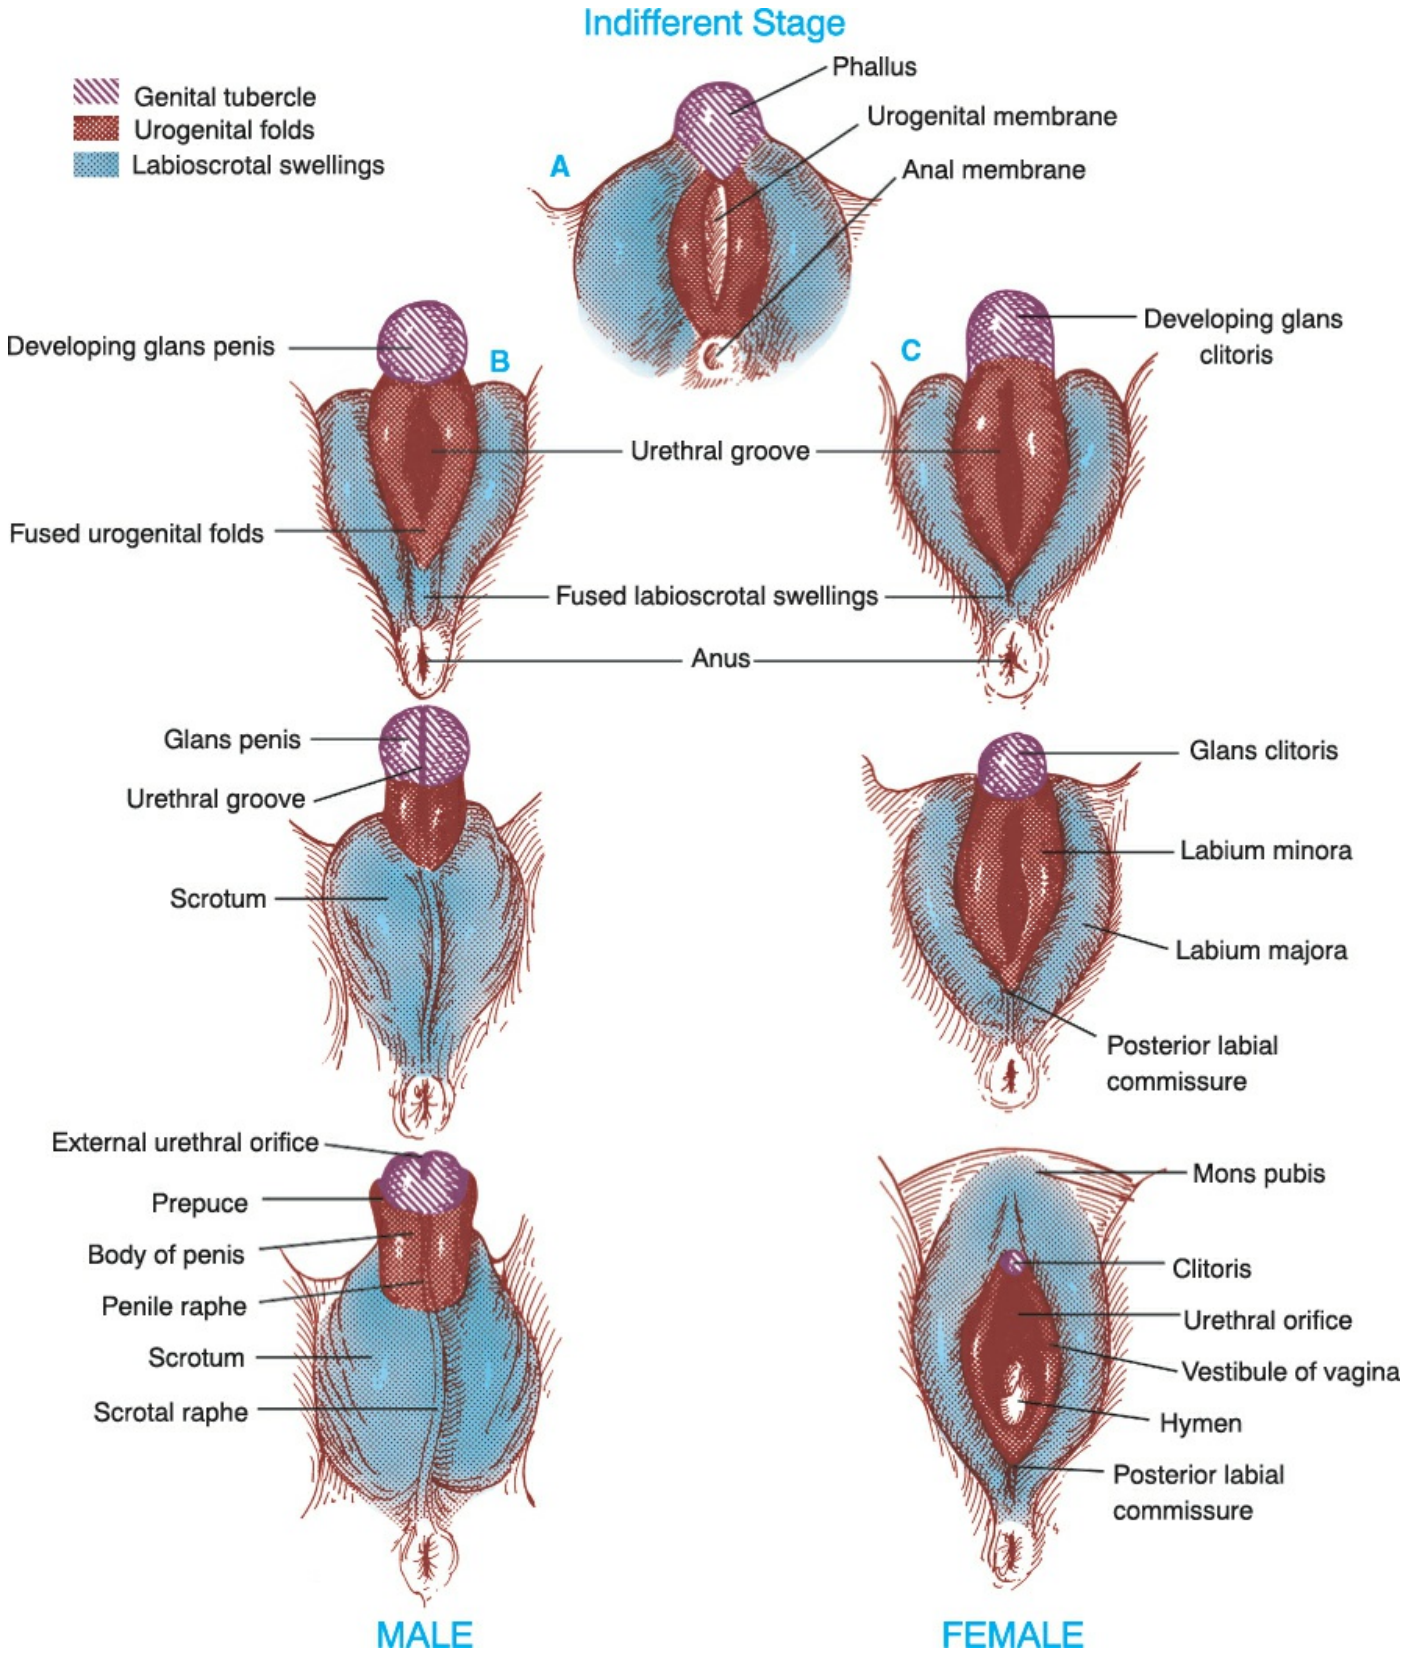

FIGURE 5-3 The comparative development of the female and male external genitalia. **A:** In both sexes, the development follows a uniform pattern through the 7th week and thereafter begins to differentiate. **B:** The male external genitalia. **C:** The female external genitalia.

Because the early development of the genital system is similar in both sexes, congenital defects in sexual development, usually arising from a variety of chromosomal abnormalities, tend to present clinically with ambiguous external genitalia. These conditions are known as *intersex conditions* or *hermaphroditism* and are classified according to the histologic appearance of the gonads.

True Hermaphroditism

Individuals with true hermaphroditism have both ovarian and testicular tissue, most commonly as composite ovotestes but occasionally with an ovary on one side and a testis on the other. In the latter case, a fallopian tube and a single uterine horn may develop on the side with the ovary because of the absence of local AMH. True hermaphroditism is an extremely rare condition associated with chromosomal mosaicism, mutation, or abnormal cleavage involving the X and Y chromosomes.

Pseudohermaphroditism

In individuals with pseudohermaphroditism, the genetic gender indicates one gender, whereas the external genitalia have characteristics of the other gender. Males with pseudohermaphroditism are genetic males with feminized external genitalia, most commonly manifesting as hypospadias (urethral opening on the ventral surface of the penis) or incomplete fusion of the urogenital or labioscrotal folds. Females with pseudohermaphroditism are genetic females with virilized external genitalia, including clitoral hypertrophy and some degree of fusion of the urogenital or labioscrotal folds. Both types of pseudohermaphroditism are caused either by abnormal levels of sex hormones or abnormalities in the sex hormone receptors.

Another major category of genital tract abnormalities involves various types of uterovaginal malformations, which occur in 0.16% of women (Fig. 5-4) (7). These malformations are believed to result from one or more of the following situations:

1. Improper fusion of the paramesonephric ducts
2. Incomplete development of one paramesonephric duct
3. Failure of part of the paramesonephric duct on one or both sides to develop
4. Absent or incomplete canalization of the vaginal plate

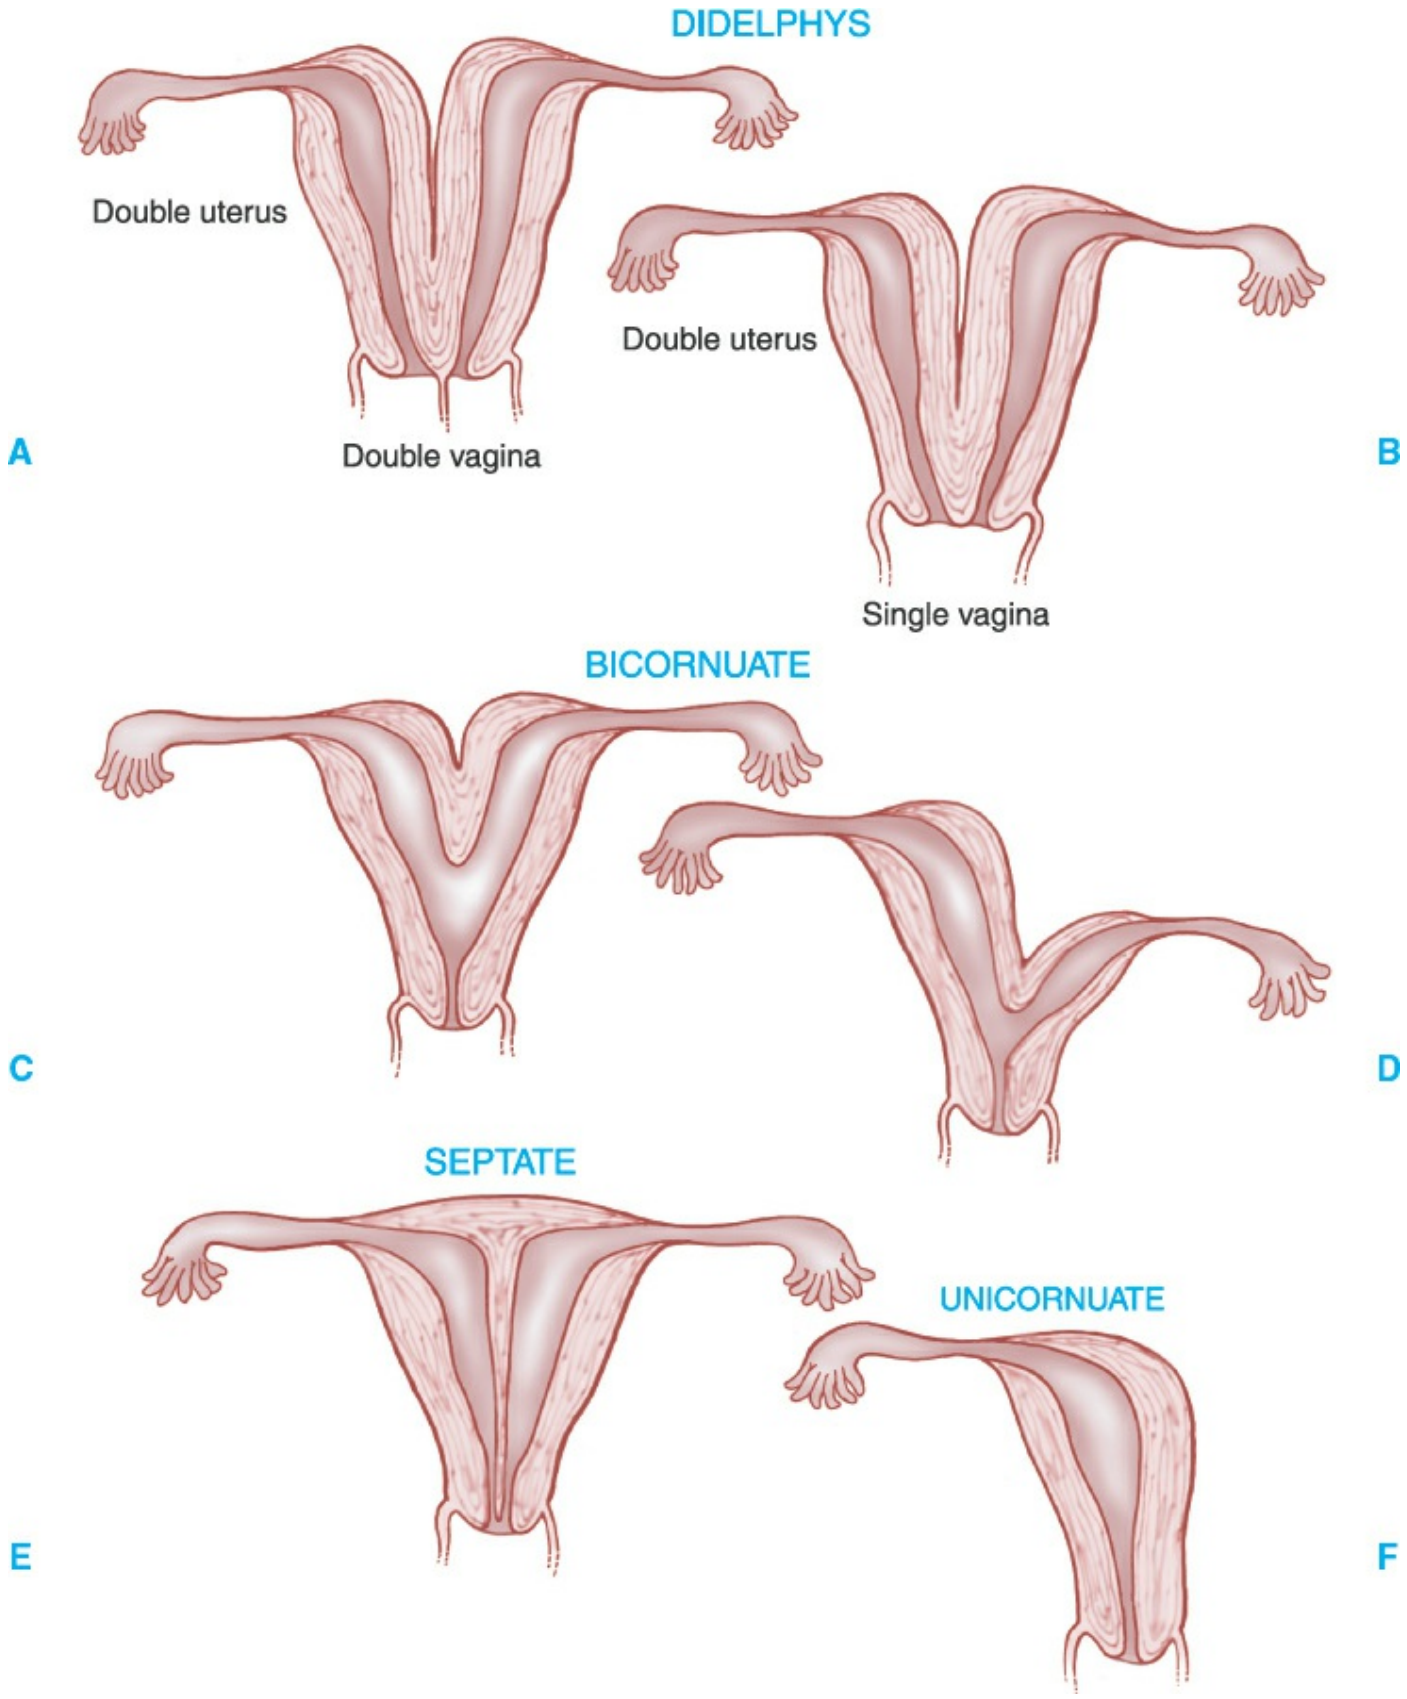

FIGURE 5-4 Types of congenital abnormalities. **A:** Double uterus (uterus didelphys) and double vagina. **B:** Double uterus with single vagina. **C:** Bicornuate uterus. **D:** Bicornuate uterus with a rudimentary left horn. **E:** Septate uterus. **F:** Unicornuate uterus.

PELVIC STRUCTURE

Bony Pelvis

The skeleton of the pelvis is formed by the sacrum and coccyx and the paired hip bones (coxal, innominate), which fuse anteriorly to form the symphysis pubis. Figure 5-5 illustrates the bony pelvis as well as its ligaments and foramina.

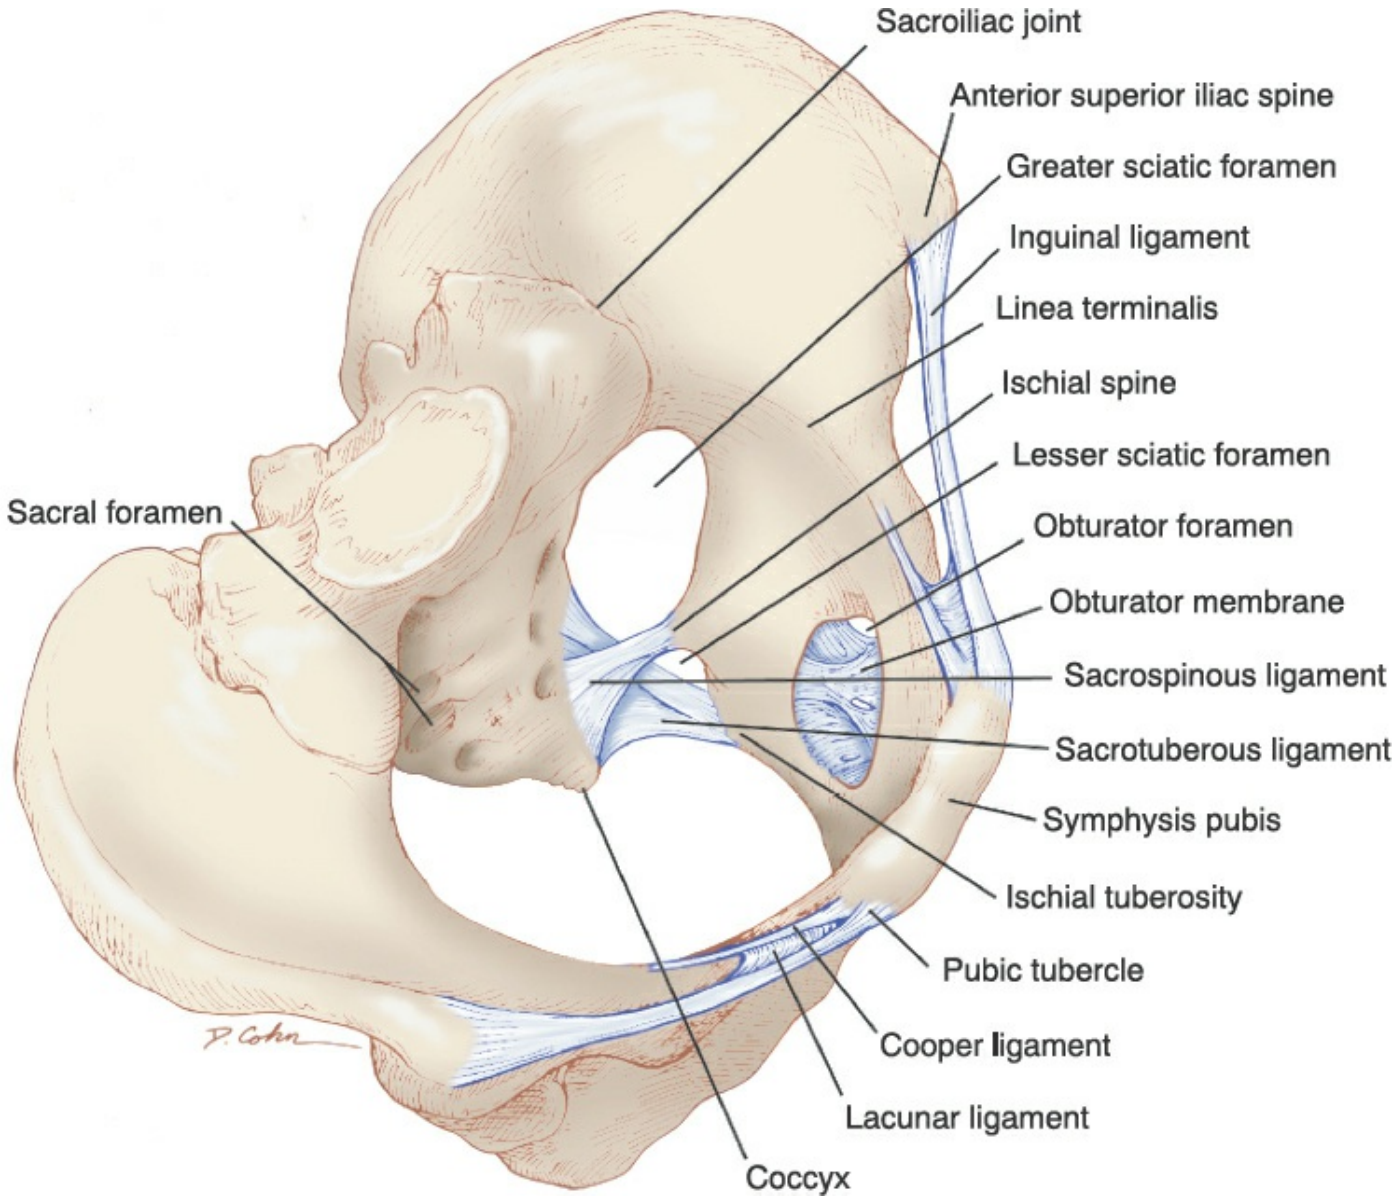

FIGURE 5-5 The female pelvis. The pelvic bones (the innominate bone, sacrum, and coccyx) and their joints, ligaments, and foramina.

Sacrum and Coccyx

The sacrum and coccyx are an extension of the vertebral column resulting from the five fused sacral vertebrae and the four fused coccygeal vertebrae. They are joined by a symphyseal articulation (sacrococcygeal joint), which allows some movement.

The essential features of the sacrum and coccyx are as follows:

1. **Sacral promontory**—the most prominent and anterior projection of the sacrum; this is an important landmark for insertion of a laparoscope and for sacrocolpopexy. It is located just below the level of bifurcation of the common iliac arteries.
2. **Four paired anterior and posterior sacral foramina—**exit sites for the anterior and posterior rami of the corresponding sacral nerves; the lateral sacral vessels also traverse the anterior foramina.
3. **Sacral hiatus—**results from incomplete fusion of the posterior lamina of the fifth sacral vertebra, offering access to the sacral canal, which is clinically important for caudal anesthesia.

Laterally, the alae ("wings") of the sacrum offer auricular surfaces that articulate with the hip bones to form synovial sacroiliac joints.

Os Coxae

The paired *os coxae*, or hip bones, have three components: the ilium, the ischium, and the pubis. These components meet to form the acetabulum, a cup-shaped cavity that accommodates the femoral head.

Ilium

1. **Iliac crest**—provides attachments to the iliac fascia, abdominal muscles, and fascia lata.
2. **Anterior superior and inferior spine**—superior spine provides the point of fixation of the inguinal ligament and is clinically important as a lateral landmark for laparoscopic entry.
3. **Posterior superior and inferior spine**—superior spine is the point of attachment for the sacrotuberous ligament and the posterior sacroiliac ligament.
4. **Arcuate line**—marks the pelvic brim and lies between the first two segments of the sacrum.
5. **Iliopectineal eminence (linea terminalis)**—the junction line of the ilium and the pubis.
6. **Iliac fossa**—the smooth anterior concavity of the ilium, covered by the iliacus muscle.

Ischium

1. **Ischial spine**—delineates the greater and lesser sciatic notch above and below it. It is the point of fixation for the sacrospinous ligament and the arcus tendineus fasciae pelvis (white line); the ischial spine represents an important landmark in the performance of pudendal nerve block and sacrospinous ligament vaginal suspension;

vaginal palpation during labor allows detection of progressive fetal descent.

2. **Ischial ramus**—joins the pubic rami to encircle the obturator foramen; provides the attachment for the inferior fascia of the urogenital diaphragm and the perineal musculofascial attachments.
3. **Ischial tuberosity**—the rounded bony prominence upon which the body rests in the sitting position; a clinical landmark for the passage of the inferior arm of anterior vaginal mesh kit systems.

Pubis

1. **Body**—formed by the midline fusion of the superior and inferior pubic rami.
2. **Symphysis pubis**—a fibrocartilaginous symphyseal joint where the bodies of the pubis meet in the midline, allows for some resilience and flexibility, which is critical during parturition.
3. **Superior and inferior pubic rami**—join the ischial rami to encircle the obturator foramen; provide the origin for the muscles of the thigh and leg; provide the attachment for the inferior layer of the urogenital diaphragm; the inferior rami is a clinical landmark for transobturator incontinence sling passage.
4. **Pubic tubercle**—a lateral projection from the superior pubic ramus, to which the inguinal ligament, rectus abdominis, and pyramidalis attach.

Clinical Considerations

[2] Studies using magnetic resonance imaging (MRI) or computed tomography (CT) pelvimetry found an association between the architecture of the bony pelvis, specifically a wider transverse inlet (distance between the most superior aspects of the iliopectineal line), a shorter obstetric conjugate (shortest distance between the sacral promontory and the pubic symphysis), a larger pelvic floor area, and the occurrence of pelvic floor disorders (8,9). Pelvic dimensions can increase the likelihood of pelvic floor damage during childbirth and predispose some women to structural failure later in life. It is theorized that women with a wide pelvic inlet may be more likely to suffer neuromuscular and connective tissue injuries during labor and delivery, increasing the risk of developing pelvic neuropathy, pelvic organ prolapse, or both (8,9). A loss of lumbar lordosis and a pelvic inlet that is less vertically oriented are more common in women who develop genital prolapse than in those who do not (10,11). A less vertical orientation of the pelvic inlet is thought to result in an alteration of the intra-abdominal forces that are normally directed anteriorly to the pubic symphysis such that a greater proportion is directed toward the pelvic viscera and their connective tissue and muscular supports. Recent studies have shown that a larger pelvis with a larger cross-sectional area is subject to more downward intra-abdominal force (12,13). This research complements previous theories that smaller pelvises may be protective (8).

Studies have demonstrated a decreased risk of pelvic floor disorders for African American women, which may be mediated by their relatively narrower pelvises (14). However, the understanding of pelvic shape is still rudimentary. One MRI study, in which only white women were enrolled to remove race as a potential confounder, found that bony pelvis dimensions were similar at the level of the muscular pelvic floor with and without pelvic organ prolapse (15).

Pelvic Bone Articulations

The pelvic bones are joined by four articulations (two pairs):

1. **Two cartilaginous symphyseal joints—the sacrococcygeal joint and the symphysis pubis**—these joints are surrounded by strong ligaments anteriorly and posteriorly, which are responsive to the effect of relaxin and facilitate parturition.
2. **Two synovial joints—the sacroiliac joints**—these joints are stabilized by the sacroiliac ligaments, the iliolumbar ligament, the lateral lumbosacral ligament, the sacrotuberous ligament, and the sacrospinous ligament.

The pelvis is divided into the *greater* and *lesser pelvis* by an oblique plane passing through the sacral promontory, the *linea terminalis* (*arcuate line of the ilium*), the pectineal line of the pubis, the pubic crest, and the upper margin of the symphysis pubis. This plane lies at the level of the superior pelvic aperture (*pelvic inlet*) or pelvic brim. The inferior pelvic aperture or *pelvic outlet* is irregularly bound by the tip of the coccyx, the symphysis pubis, and the ischial tuberosities. The dimensions of the superior and inferior pelvic apertures have important obstetric implications.

Ligaments

Four ligaments—inguinal, Cooper's, sacrospinous, and sacrotuberous—of the bony pelvis are of special importance to the gynecologic surgeon.

Inguinal Ligament

The inguinal ligament is important surgically in the repair of inguinal hernia. The inguinal ligament:

1. Is formed by the lower border of the aponeurosis of the external oblique muscle folded back upon itself.
2. Is fused laterally to the iliacus fascia and inferiorly to the fascia lata.
3. Flattens medially into the lacunar ligament, which forms the medial border of the femoral ring.

Cooper Ligament

Cooper ligament is used in bladder suspension procedures. Cooper ligament:

1. **Is a strong ridge of fibrous tissue extending along the pectineal line—also known as the pectineal ligament.**
2. **Merges laterally with the iliopectineal ligament and medially with the lacunar ligament.**

Sacrospinous Ligament

The sacrospinous ligament is often used for vaginal suspension. This ligament offers the advantage of a vaginal surgical route. The sacrospinous ligament:

1. **Extends from the ischial spine to the lateral aspect of the sacrum.**
2. **Is separated from the rectovaginal space by the rectal pillars.**
3. **Lies anterior to the pudendal nerve and the internal pudendal vessels at its attachment to the ischial spine.**

The inferior gluteal artery, with extensive collateral circulation, is found between the sacrospinous and sacrotuberous ligaments and may be injured during sacrospinous suspension (Fig. 5-6) (16). **[2]** Injury to the inferior gluteal artery, and to the pudendal nerve and internal pudendal vessels, during sacrospinous ligament suspension may be minimized by careful and controlled retraction and suture placement, at least two fingerbreadths medial to the ischial spine.

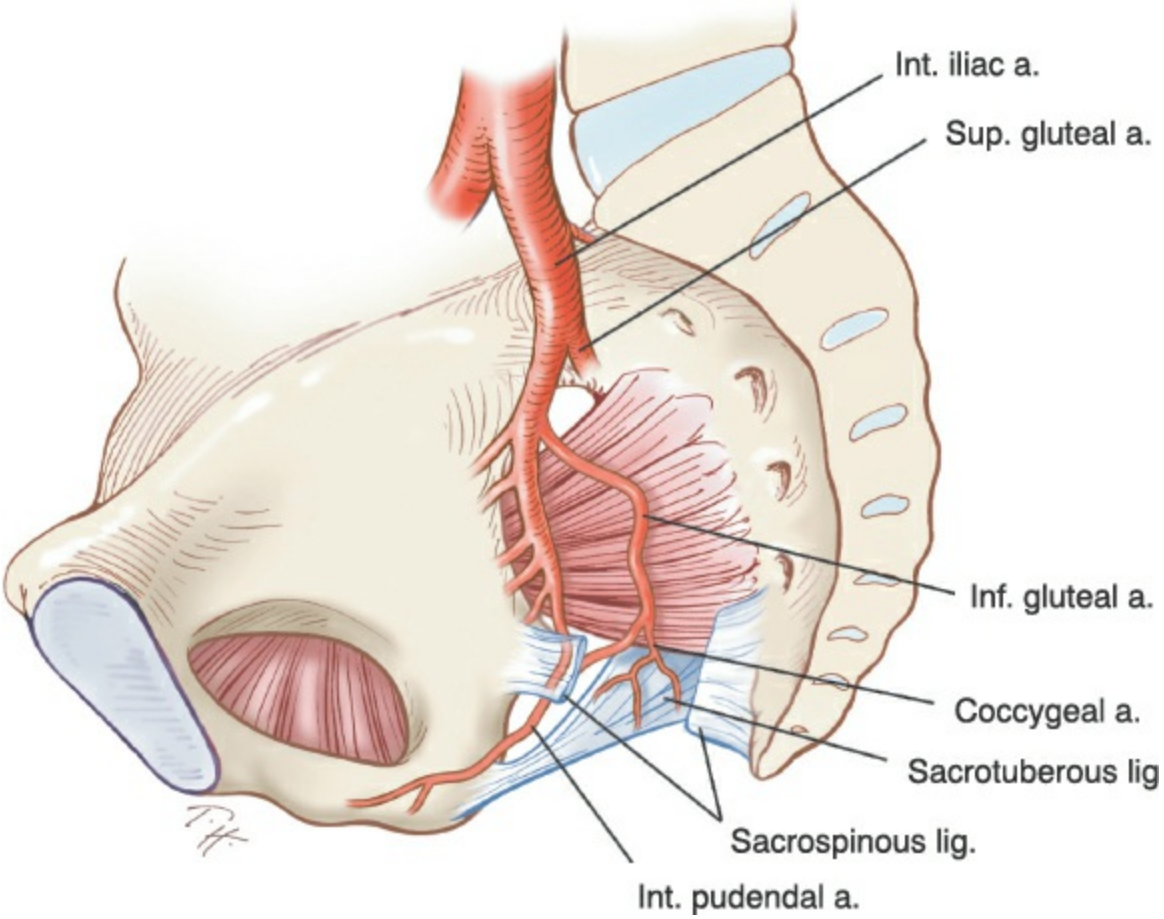

FIGURE 5-6 Tone drawing of left hemipelvis with sacrospinous ligament reflected. a., artery; Inf., inferior; lig., ligament; n., nerve; Sacrosp., sacrospinous; Sacrotub., sacrotuberous. (Redrawn from **Thompson JR, Gibbs JS, Genadry R, et al**. Anatomy of pelvic arteries adjacent to the sacrospinous ligament: importance of the coccygeal branch of the inferior gluteal artery. *Obstet Gynecol* 1999;94:973–977, with permission.)

Sacrotuberous Ligament

The sacrotuberous ligament is occasionally used as a point of fixation for vaginal vault suspension, sometimes inadvertently during attempted sacrospinous suspension. The sacrotuberous ligament:

1. **Extends from the ischial tuberosity to the lateral aspect of the sacrum**
2. **Merges medially with the sacrospinous ligament**
3. **Lies posterior to the pudendal nerve and the internal pudendal vessels**

Foramina

The bony pelvis and its ligaments delineate three important foramina that allow the passage of the various muscles, nerves, and vessels to the lower extremities.

Greater Sciatic Foramen

The greater sciatic foramen transmits the following structures: the piriformis muscle, the

superior gluteal nerves and vessels, the sciatic nerve along with the nerves of the quadratus femoris, the inferior gluteal nerves and vessels, the posterior cutaneous nerve of the thigh, the nerves of the obturator internus, and the internal pudendal nerves and vessels.

Lesser Sciatic Foramen

The lesser sciatic foramen transmits the tendon of the obturator internus to its insertion on the greater trochanter of the femur. The nerve of the obturator internus and the pudendal vessels and nerves reenter the pelvis through the lesser sciatic foramen.

Obturator Foramen

[3] The obturator foramen transmits the obturator nerves and vessels. The obturator neurovascular bundle can be injured during transobturator tape placement, a procedure for treatment of urinary incontinence. Older trocar-based mesh kits for anterior and apical vaginal prolapse were often passed through the obturator membrane, just lateral to the descending ischiopubic ramus but medial to the obturator foramen. Injury to the obturator nerves and vessels can be prevented during these procedures by careful identification of anatomic landmarks and placement away from the obturator foramen.

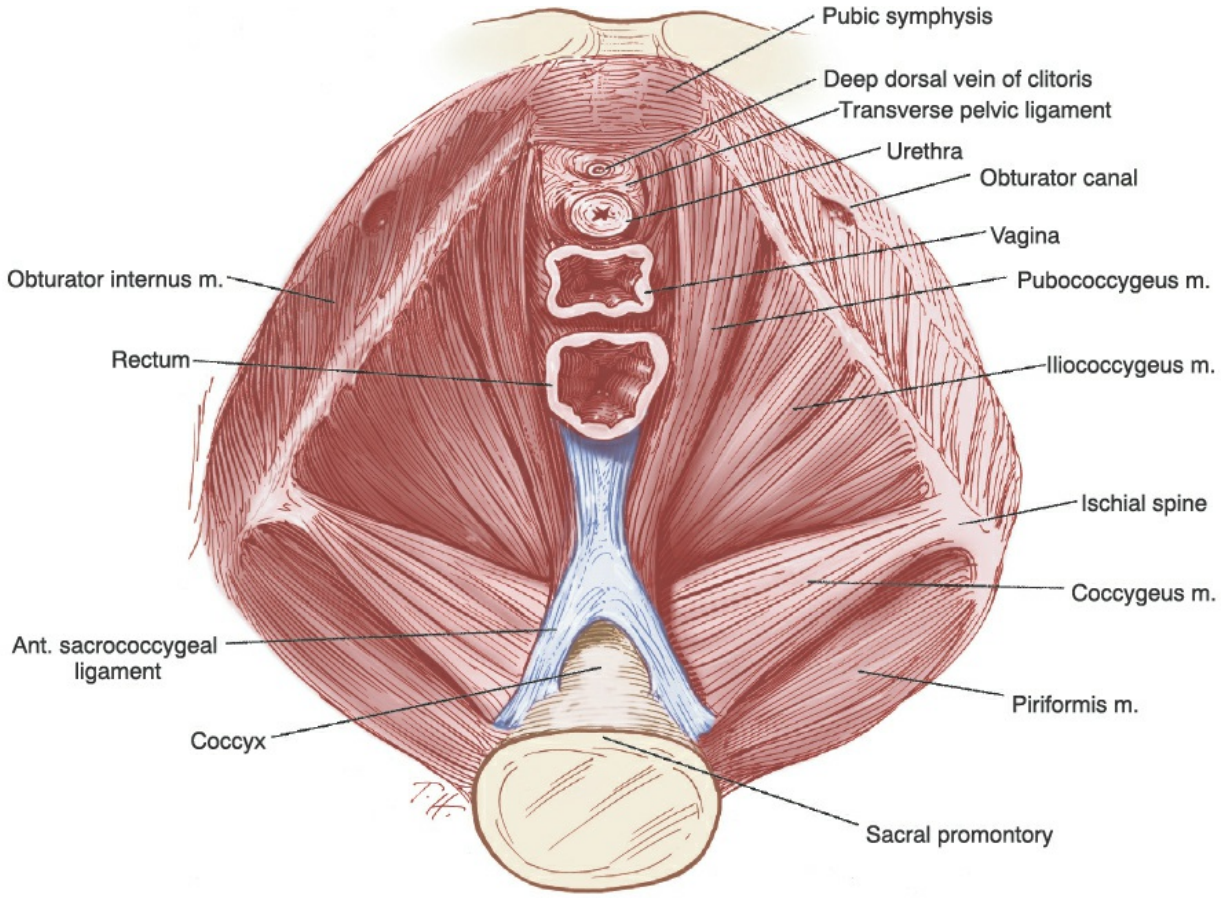
Muscles

The muscles of the pelvis include those of the lateral wall and those of the pelvic floor (Fig. 5-7; Table 5-2).

Lateral Wall

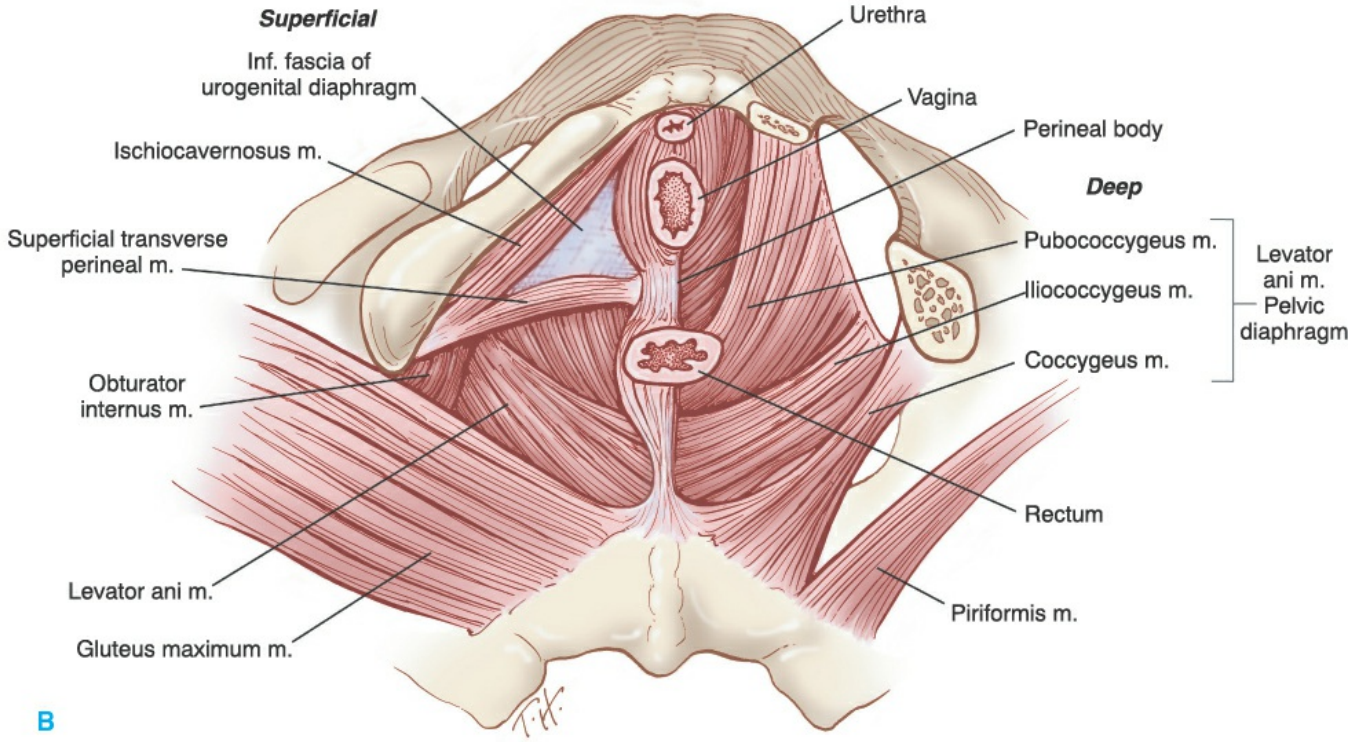
The muscles of the lateral pelvic wall pass into the gluteal region to assist in thigh rotation and adduction. They include the piriformis, the obturator internus, and the iliopsoas.

Pelvic Floor



Pelvic Diaphragm

The pelvic diaphragm is a funnel-shaped fibromuscular partition that forms the primary supporting structure for the pelvic contents (Fig. 5-8). It is composed of the levator ani (pubococcygeus, puborectalis, iliococcygeus) and the coccygeus muscles, along with their superior and inferior fasciae (Table 5-2 on page 61). It forms the ceiling of the ischiorectal fossa.



Levator Ani

The levator ani muscles are composed of the pubococcygeus (including the pubovaginalis and pubourethralis), puborectalis, and the iliococcygeus. The levator

ani is a broad, curved sheet of muscle stretching anteriorly from the pubis and posteriorly from the coccyx and from one side of the pelvis to the other. It is perforated by the urethra, vagina, and anal canal. Its origin is from the tendinous arch extending from the body of the pubis to the ischial spine. **This tendinous arch, called the *arcus tendineus levator ani*, is formed by a thickening of the obturator fascia and serves as a lateral landmark and point of attachment for some vaginal suspension procedures**. The levator ani is inserted into the central tendon of the perineum, the wall of the anal canal, the anococcygeal ligament, the coccyx, and the vaginal wall.

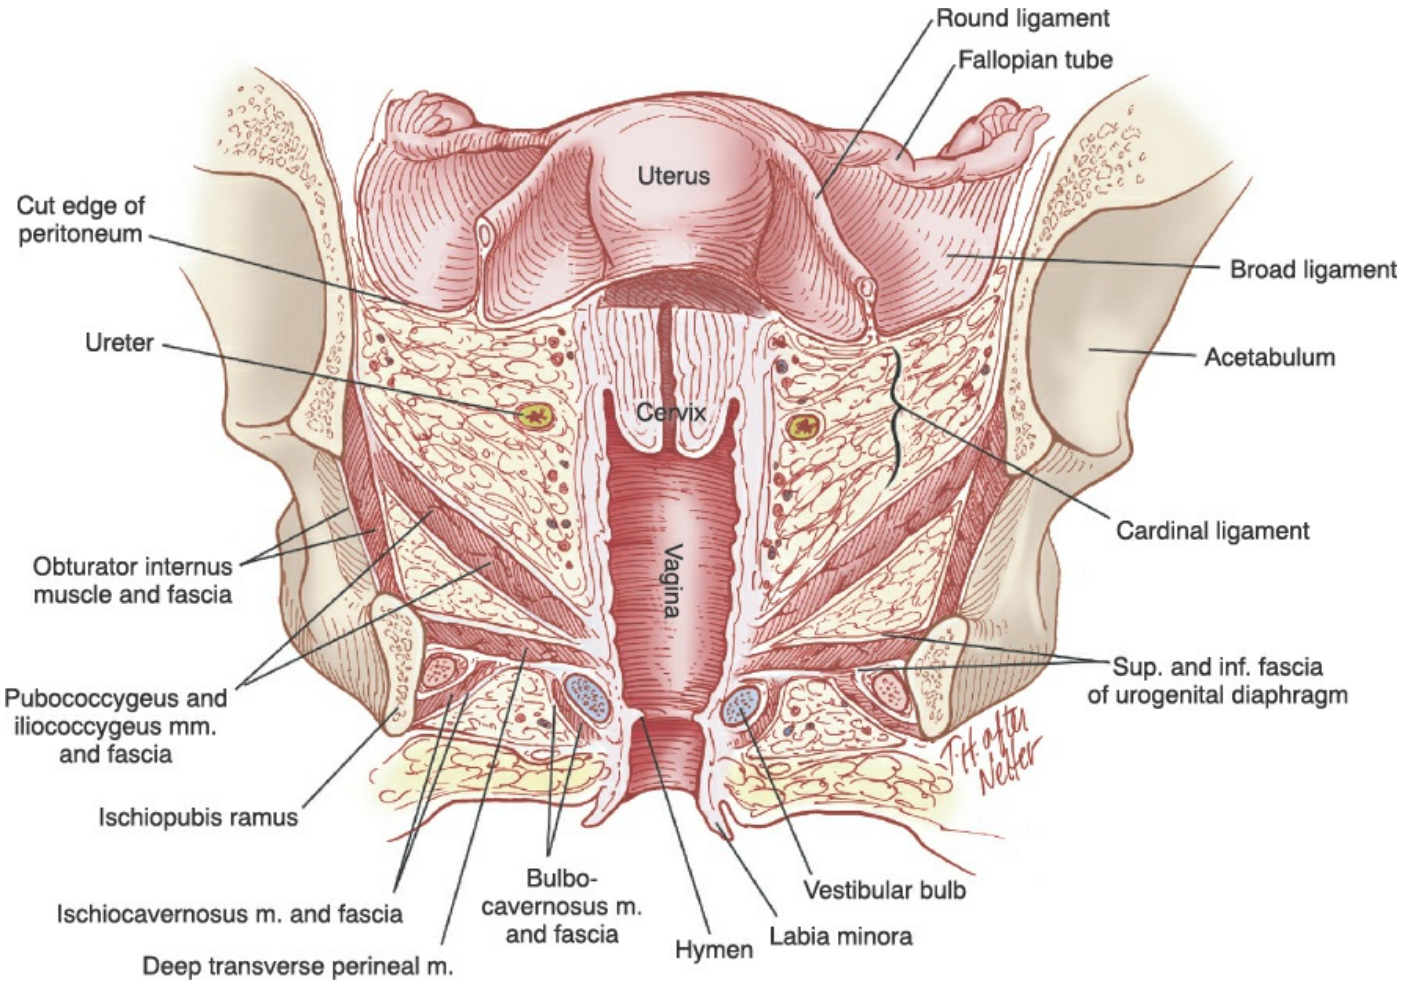

FIGURE 5-8 The ligaments and fascial support of the pelvic viscera.

Table 5-2 Muscles of the Pelvic Floor

	Origin	Insertion	Action	Innervation
Lateral Pelvic Wall				
Piriformis	Anterior aspect of S2–S4 and sacrotuberous ligament	Greater trochanter of the femur	Lateral rotation, abduction of thigh in flexion; holds head of femur in acetabulum	S1–S2; forms a muscular bed for the sacral plexus
Obturator internus	Superior and inferior pubic rami	Greater trochanter of the femur	Lateral rotation of thigh in flexion; assists in holding head of femur in acetabulum	(L5, S1) Obturator internus nerve
Iliopsoas	Psoas from the lateral margin of the lumbar vertebrae; iliacus from the iliac fossa	Lesser trochanter of the femur	Flexes thigh and stabilizes trunk on thigh; flexes vertebral column or bends it unilaterally	(L1–L3) Psoas–ventral rami of lumbar nerve (L2–L3) Iliacus–femoral nerve contains the lumbar plexus within its muscle body
Pelvic Floor				
Pelvic Diaphragm				
Levator ani Pubococcygeus Pubovaginalis Puborectalis	From the tendinous arch, extending from the body of the pubis to the ischial spine	Central tendon of the perineum; wall of the anal canal; anococcygeal ligament; coccyx; vaginal wall	Assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents; supports the posterior wall of the vagina; facilitates defecation; aids in fecal continence; during parturition, supports the fetal head during cervical dilation	S3–S4; the inferior rectal nerve
Coccygeus	Ischial spine and sacrospinous ligament	Lateral margin of the fifth sacral vertebra and coccyx	Supports the coccyx and pulls it anteriorly	S4–S5
Urogenital Diaphragm				
Deep transverse perineal	Medial aspect of the ischiopubic rami	Lower part of the vaginal wall; anterior fibers blend with those of the sphincter urethrae	Steadies the central perineal tendon	S2–S4; perineal nerve
Sphincter urethrae	Medial aspect of the ischiopubic rami	Urethra and vagina	Compresses the urethra	S2–S4; perineal nerve

The levator ani assists the anterior abdominal wall muscles in containing the abdominal and pelvic contents. It supports the vagina, facilitates defecation, and aids in maintaining fecal continence. During parturition, the levator ani supports the fetal head while the cervix dilates. A simulated vaginal delivery model demonstrated that the pubococcygeus muscle stretches more than three times its original length (17). The anterior portion of the levator ani complex serves to close the urogenital hiatus and pull the urethra, vagina, perineum, and anorectum toward the pubic bone, whereas the horizontally oriented posterior portion (levator plate) serves as a supportive diaphragm or "backstop" behind the pelvic viscera. Loss of normal levator ani tone, through denervation or direct muscle trauma, results in laxity of the urogenital hiatus, loss of the horizontal orientation of the levator plate, and a more bowl-like configuration. These

changes can be bilateral or asymmetric (18). Such configurations are seen more often in women with pelvic organ prolapse than in those with normal pelvic organ support (19).

The levator ani is composed of striated muscle fibers with predominantly type I (slow-twitch) fibers that maintain a constant state of resting contraction. The baseline activity of the levator ani keeps the urogenital hiatus narrowed and draws the distal parts of the urethra, vagina, and rectum toward the pubic bones. Type II (fast-twitch) muscle fibers allow for involuntary reflex muscle contraction elicited by sudden increase in abdominal pressure and for voluntary contractions, as with Kegel exercises. Relaxation of these muscles occurs only briefly and intermittently during the process of evacuation (voiding, defecation, and during parturition).

Traditional teaching is that the levator ani muscles are innervated by the pudendal nerve on the perineal surface and direct branches of the sacral nerves on the pelvic surface. Evidence indicates that the levator ani muscles are innervated solely by a nerve traveling on the superior (intrapelvic) surface of the muscles without the contribution of the pudendal nerve (20–25). This nerve, referred to as the *levator ani nerve*, originates from S3, S4, and/or S5 and innervates both the coccygeus and the levator ani muscle complex (20). After exiting the sacral foramina, it travels 2 to 3 cm medial to the ischial spine and arcus tendineus levator ani across the coccygeus, iliococcygeus, pubococcygeus, and puborectalis. Occasionally, a separate nerve comes directly from S5 to innervate the puborectalis muscle independently. Given its location, the levator ani nerve is susceptible to injury through parturition and pelvic surgery, such as during sacrospinous or iliococcygeus vaginal vault suspensions.

Urogenital Diaphragm

The muscles of the urogenital diaphragm anteriorly reinforce the pelvic diaphragm and are intimately related to the vagina and the urethra. They are enclosed between the inferior and superior fascia of the urogenital diaphragm. The muscles include the deep transverse perineal and sphincter urethrae **(Table 5-2)**.

Blood Vessels

The pelvic blood vessels supply genital structures and the following:

- Urinary and gastrointestinal tracts
- Muscles of the abdominal wall, pelvic floor and perineum, buttocks, and upper thighs
- Fasciae, other connective tissue, and bones
- Skin and other superficial structures

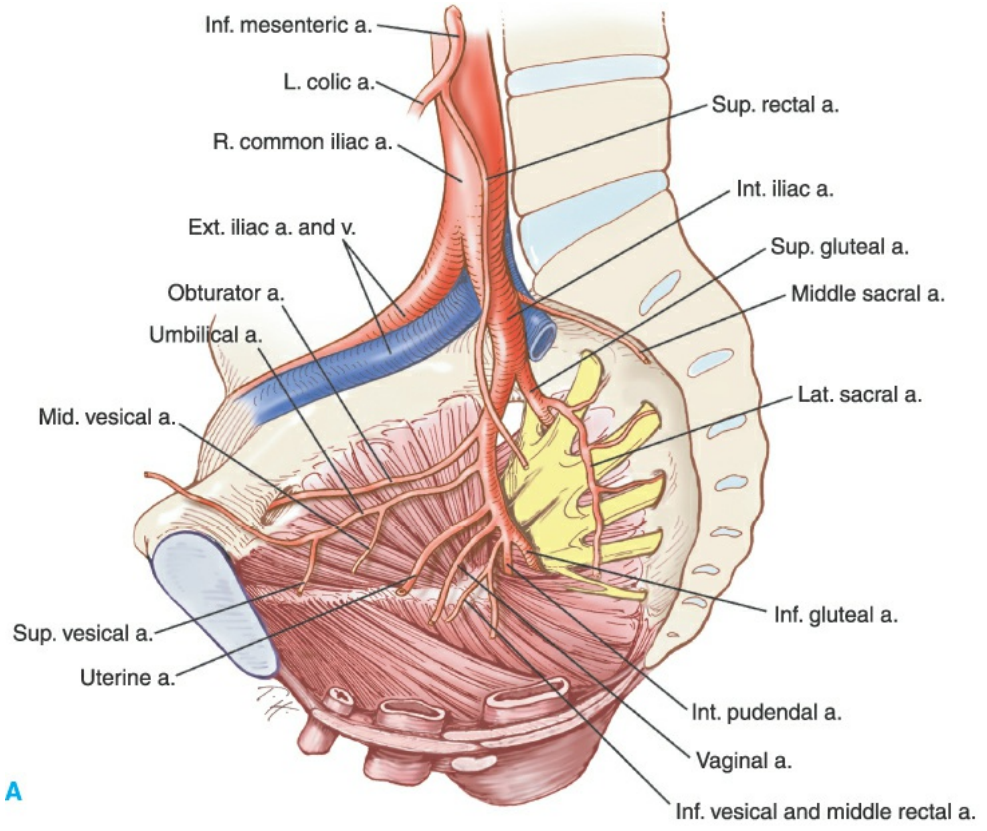
Classically, vessels supplying organs are known as *visceral vessels* and those supplying supporting structures are called *parietal vessels*.

Major Blood Vessels

The course of the major vessels supplying the pelvis is illustrated in Figure 5-9; their origin, course, branches, and venous drainage are presented in Table 5-3. In general, the venous system draining the pelvis closely follows the arterial supply and is named accordingly. Not infrequently, a vein draining a particular area may form a plexus with multiple channels. Venous systems, which are paired, mirror each other in their drainage patterns, with the notable exception of the ovarian veins. Unusual features of venous drainage are also listed in Table 5-3.

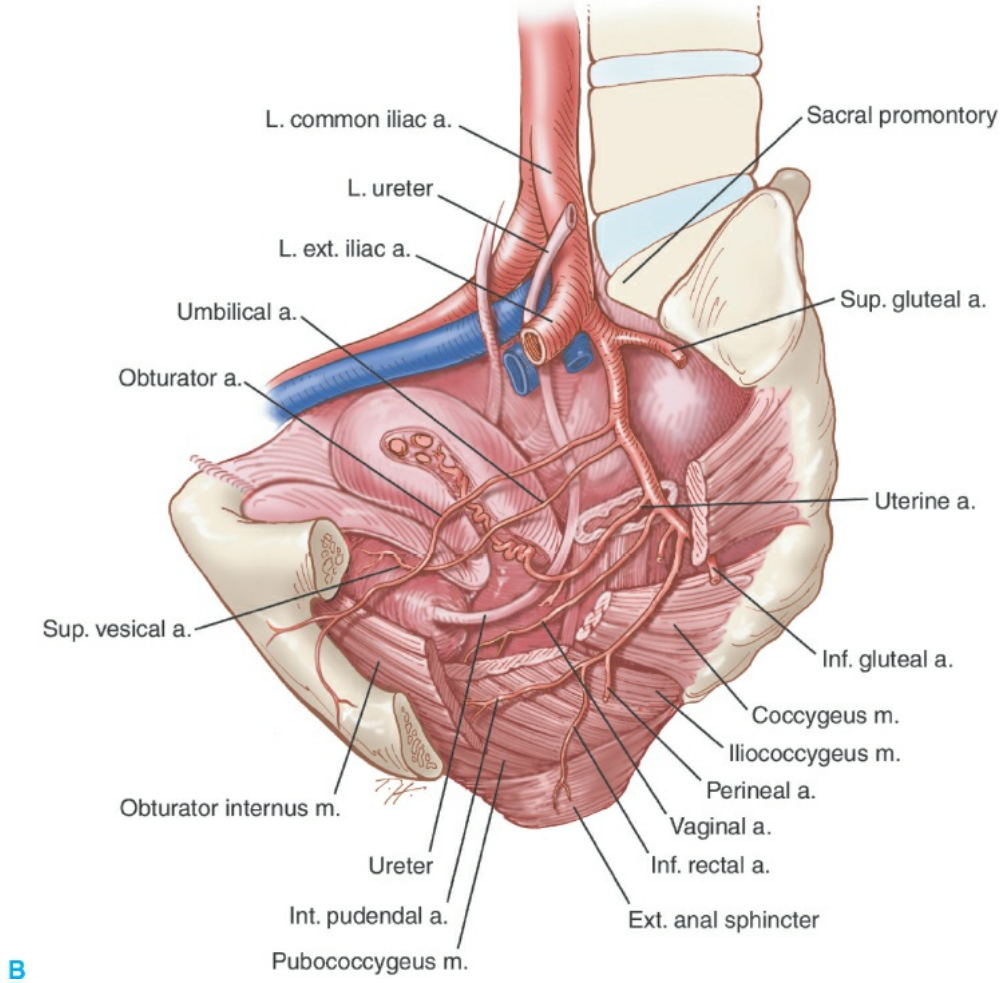
General Principles

"Control blood supply" and "maintain meticulous hemostasis" are two of the most common exhortations to young surgeons. In developing familiarity with the pattern of blood flow in the pelvis, several unique characteristics of this vasculature should be understood because of their potential implications for surgical practice:



1. **The pelvic vessels play an important role in pelvic support.** They provide condensations of endopelvic fascia that act to reinforce the normal position of pelvic organs (26).
2. **[4] There is significant anatomic variation between individuals in the branching pattern of the internal iliac vessels.** There is no constant order in which branches divide from the parent vessel; some branches may arise as common trunks or may spring from other branches rather than from the internal iliac. Occasionally, a branch may arise from another vessel entirely (e.g., the obturator artery may arise from the external iliac or inferior epigastric artery). This variation may be found in the branches of other major vessels; the ovarian arteries are reported to arise from the renal arteries or as a common trunk from the front of the aorta on occasion. The inferior gluteal artery may originate from the posterior or the anterior branch of the internal iliac (hypogastric) artery. Patterns of blood flow may be asymmetric from side to side, and structures supplied by anastomoses of different vessels may show variation from person to person in the proportion of vascular support provided by the vessels involved (26). The pelvic surgeon must be prepared for deviations from "textbook" vascular patterns.
3. **The pelvic vasculature is a high-volume, high-flow system with enormous expansive capabilities throughout reproductive life.** Blood flow through the uterine arteries increases to about 500 mL/min in late pregnancy. In nonpregnant women, certain conditions, such as uterine fibroids or malignant neoplasms, may be associated with neovascularization and hypertrophy of existing vessels and a corresponding increase in pelvic blood flow. Understanding the volume and flow characteristics of the pelvic vasculature in different clinical situations will enable the surgeon to anticipate problems and take appropriate pre- and intraoperative

measures (including blood and blood product availability) to prevent or manage hemorrhage.



4. **[4] The pelvic vasculature is supplied with an extensive network of collateral connections that provides a rich anastomotic communication between different major vessel systems (Fig. 5-10 on page 66).** This degree of redundancy is important to ensure adequate supply of oxygen and nutrients in the event of major trauma or other vascular compromise. Hypogastric artery ligation continues to be used as a strategy for management of massive pelvic hemorrhage when other measures have failed. Bilateral hypogastric artery ligation, particularly when combined with ovarian artery ligation, dramatically reduces pulse pressure in the pelvis, converting flow characteristics from that of an arterial system to a venous system and allowing use of collateral channels of circulation to continue blood supply to pelvic structures. The significance of collateral blood flow is demonstrated by reports of successful pregnancies occurring after bilateral ligation of both hypogastric and ovarian arteries (27). **Table 5-4 on page 67** lists the collateral channels of circulation in the pelvis.

Special Vascular Considerations

During laparoscopy, vascular injury most commonly occurs during abdominal entry. To avoid injury to vascular structures and resultant hemorrhage while inserting a trocar into the anterior abdominal wall, the surgeon should keep in mind certain anatomic relationships. The most common vascular injury is laceration of the inferior epigastric artery during placement of lateral trocars. The inferior epigastric artery is a branch of the external iliac artery, arising from the parent vessel at the medial border of the inguinal ligament and coursing cephalad lateral to and posterior to the rectus sheath at the level of the arcuate line. It lies about 1.5 cm lateral to the medial umbilical fold, which marks the site of the obliterated umbilical artery. **During laparoscopy, the inferior epigastric artery almost always can be visualized between the obliterated umbilical artery medially and the insertion of the round ligament through the inguinal canal laterally**. This artery can be traced visually cephalad under transillumination, allowing for safe insertion of the lateral port site. The distal aorta, which lies directly underneath the umbilicus, and the right common iliac artery, which crosses the midline, are particularly prone to injury during umbilical laparoscopic trocar insertion. The aortic bifurcation occurs at the level of L4 to L5, just above the sacral promontory. Palpation of the sacral promontory to guide trocar insertion allows the surgeon to avoid the major vascular structures in this area (see **Fig. 26-11** in Chapter 26). **[3] The left common iliac vein lies medial to the artery and is at risk of injury during dissection for sacrocolpopexy.**

Table 5-3 The Major Blood Vessels of the Pelvis

Artery	Origin	Course	Branches	Venous Drainage
Ovarian	Arises from ventral surface of aorta just below the origin of the renal vessels	Crosses over common iliac vessels; in proximity to ureter over much of its course, crosses over ureter while superficial to the psoas muscle and runs just lateral to the ureter when entering the pelvis as part of the infundibulopelvic ligament	To ovaries, fallopian tubes, broad ligament; often small branches to ureter	Right side drains into the inferior vena cava; left drains into the left renal vein
Inferior mesenteric artery (IMA)	Unpaired left-sided retroperitoneal artery arising from the aorta 2–5 cm proximal to its bifurcation	IMA and its branches pass over the left psoas muscle and common iliac vessels; IMA courses anterior to the ureter and ovarian vessels above the pelvic brim	1. *Left colic*—originates above pelvic brim; supplies left transverse colon, splenic flexure, descending colon 2. *Sigmoid*—several branches; supply sigmoid colon 3. *Superior rectal (hemorrhoidal)*—divides into two terminal branches to supply rectum	Inferior mesenteric vein empties into the splenic vein
Common iliac artery	Terminal division of the aorta at fourth lumbar vertebra	Oblique and lateral course, about 5 cm in length	1. *External iliac* 2. *Internal iliac*	Lie posterior and slightly medial to arteries; drain into inferior vena cava
External iliac femoral artery	Lateral bifurcation of common iliac, begins opposite the lumbosacral joint	Along the medial border of the psoas muscle and lateral pelvic side wall; becomes femoral artery after passing under the inguinal ligament to supply lower extremities	1. *Superficial epigastric*—supplies skin and subcutaneous tissue of lower anterior abdominal wall 2. *External pudendal*—supplies skin and subcutaneous tissue of mons pubis and anterior vulva 3. *Superficial circumflex iliac*—supplies skin/subcutaneous tissues of the flank 4. *Inferior epigastric*—supplies musculofascial layer of lower anterior abdominal wall 5. *Deep circumflex iliac*—supplies musculofascial layer of lower abdominal wall	Lie posterior and then medial to the artery as it enters the anterior thigh; drain into common iliac veins
Internal iliac (hypogastric) artery	Medial bifurcation of common iliac artery, begins opposite the lumbosacral joint; is major blood supply to the pelvis	Descends sharply into the pelvis; divides into an anterior and posterior division 3–4 cm after origin	*Posterior division:* 1. *Iliolumbar*—anastomoses with lumbar and deep circumflex iliac arteries; helps supply lower abdominal wall, iliac fossa 2. *Lateral sacral*—supplies contents of sacral canal, piriformis muscle 3. *Superior gluteal*—supplies gluteal muscles *Anterior division:* 1. *Obturator*—supplies iliac fossa, posterior pubis, obturator internus muscle 2. *Internal pudendal* 3. *Umbilical*—remnant of fetal umbilical artery; after giving off branches, as the medial umbilical ligament 4. *Superior, middle, inferior vesical*—supply bladder and one or more branches to the ureter 5. *Middle rectal (hemorrhoidal)*—supplies rectum, branches to midvagina 6. *Uterine*—supplies uterine corpus and cervix, with branches to upper vagina, tube, round ligament, and ovary 7. *Vaginal*—supplies vagina 8. *Inferior gluteal*—supplies gluteal muscles, muscles of posterior thigh	Deep to arteries, from complex plexus; drain into common iliac veins
Internal pudendal artery	Internal iliac artery; provides the major blood supply to the perineum	Leaves the pelvis through the greater sciatic foramen, courses around the ischial spine, and enters the ischiorectal fossa through the lesser sciatic foramen. In its path to the perineum, lies with the pudendal nerve within Alcock canal, a fascial tunnel over the obturator internus muscle	1. *Inferior rectal (hemorrhoids)*—supplies anal canal, external anal sphincter, perianal skin, with branches to levator ani 2. *Perineal*—supplies perineal skin, muscles of superficial perineal compartment (bulbocavernosus, ischiocavernosus, superficial transverse perineal) 3. *Clitoral*—supplies clitoris, vestibular bulb, Bartholin gland, and urethra	Drain into internal iliac veins
Middle sacral artery	Midline unpaired vessel arising from posterior terminal aorta	Courses over lower lumbar vertebrae, sacrum, and coccyx	Supplies bony and muscular structures of posterior pelvic wall	Paired middle sacral veins usually drain into left common iliac vein
Lumbar arteries	Segmental branches arising at each lumbar level from posterior aorta	Pass around the side of the four superior lumbar vertebrae, divide into anterior and posterior branches	Supplies abdominal wall musculature (external/internal oblique, transversus abdominis)	Drains into inferior vena cava

Lymphatics

The lymphatic system absorbs and transports interstitial fluid from tissues, including larger molecules like protein and cellular debris. Small lymphatic capillaries drain organs and form larger vessels that drain into lymph nodes. **The pelvic lymph nodes are generally arranged in groups or chains and follow the course of the larger pelvic vessels, for which they are usually named. Smaller nodes that lie close to the visceral structures are usually named for those organs.** Lymph nodes in the pelvis receive afferent lymphatic vessels from pelvic and perineal visceral and parietal structures and send efferent lymphatics to more proximal nodal groups. The number of lymph nodes and their exact location are variable; however, certain nodes tend to be relatively constant:

1. Obturator nodes in the obturator foramen, close to the obturator vessels and nerve
2. Nodes at the junction of the internal and external iliac veins
3. Ureteral nodes in the broad ligament near the cervix, where the uterine artery crosses over the ureter
4. The *Cloquet* or Rosenmüller node—the highest of the deep inguinal nodes that lies within the opening of the femoral canal

Figure 5-11 illustrates the pelvic lymphatic system. Table 5-5 outlines the major lymphatic chains of relevance to the pelvis and their primary afferent connections from major pelvic and perineal structures. There are extensive interconnections between lymph vessels and nodes; usually more than one lymphatic pathway is available for drainage of each pelvic site. Bilateral and crossed extension of lymphatic flow may occur, and entire groups of nodes may be bypassed to reach more proximal chains.

The natural history of most genital tract malignancies directly reflects the lymphatic drainage of those structures, although the various interconnections, different lymphatic paths, and individual variability make the spread of malignancy somewhat unpredictable. Regional lymph node metastasis is one of the most important factors in formulation of treatment plans for gynecologic malignancies and prediction of eventual outcome.

Nerves

The pelvis is innervated by both the autonomic and somatic nervous systems. The autonomic nerves include both *sympathetic* (adrenergic) and *parasympathetic* (cholinergic) fibers and provide the primary innervation for genital, urinary, and gastrointestinal visceral structures and blood vessels.

Somatic Innervation

The *lumbosacral plexus* and its branches provide motor and sensory somatic innervation to the lower abdominal wall, the pelvic and urogenital diaphragms, the perineum, and the hips and lower extremities (Fig. 5-12). The nerves originating from the muscles, the lumbosacral trunk, the anterior divisions of the upper four sacral nerves (*sacral plexus*), and the anterior division of the coccygeal nerve and fibers from the fourth and fifth sacral nerves (*coccygeal plexus*) are found on the anterior surface of the piriformis muscle and lateral to the coccyx, respectively, deep in the posterior pelvis. In Table 5-6 each major branch is listed by spinal segment and structures innervated. In addition to these branches, the lumbosacral plexus includes nerves that innervate muscles of the lateral pelvic wall (obturator internus, piriformis), posterior hip muscles, and the pelvic diaphragm. A visceral component, the pelvic splanchnic nerve, is included.

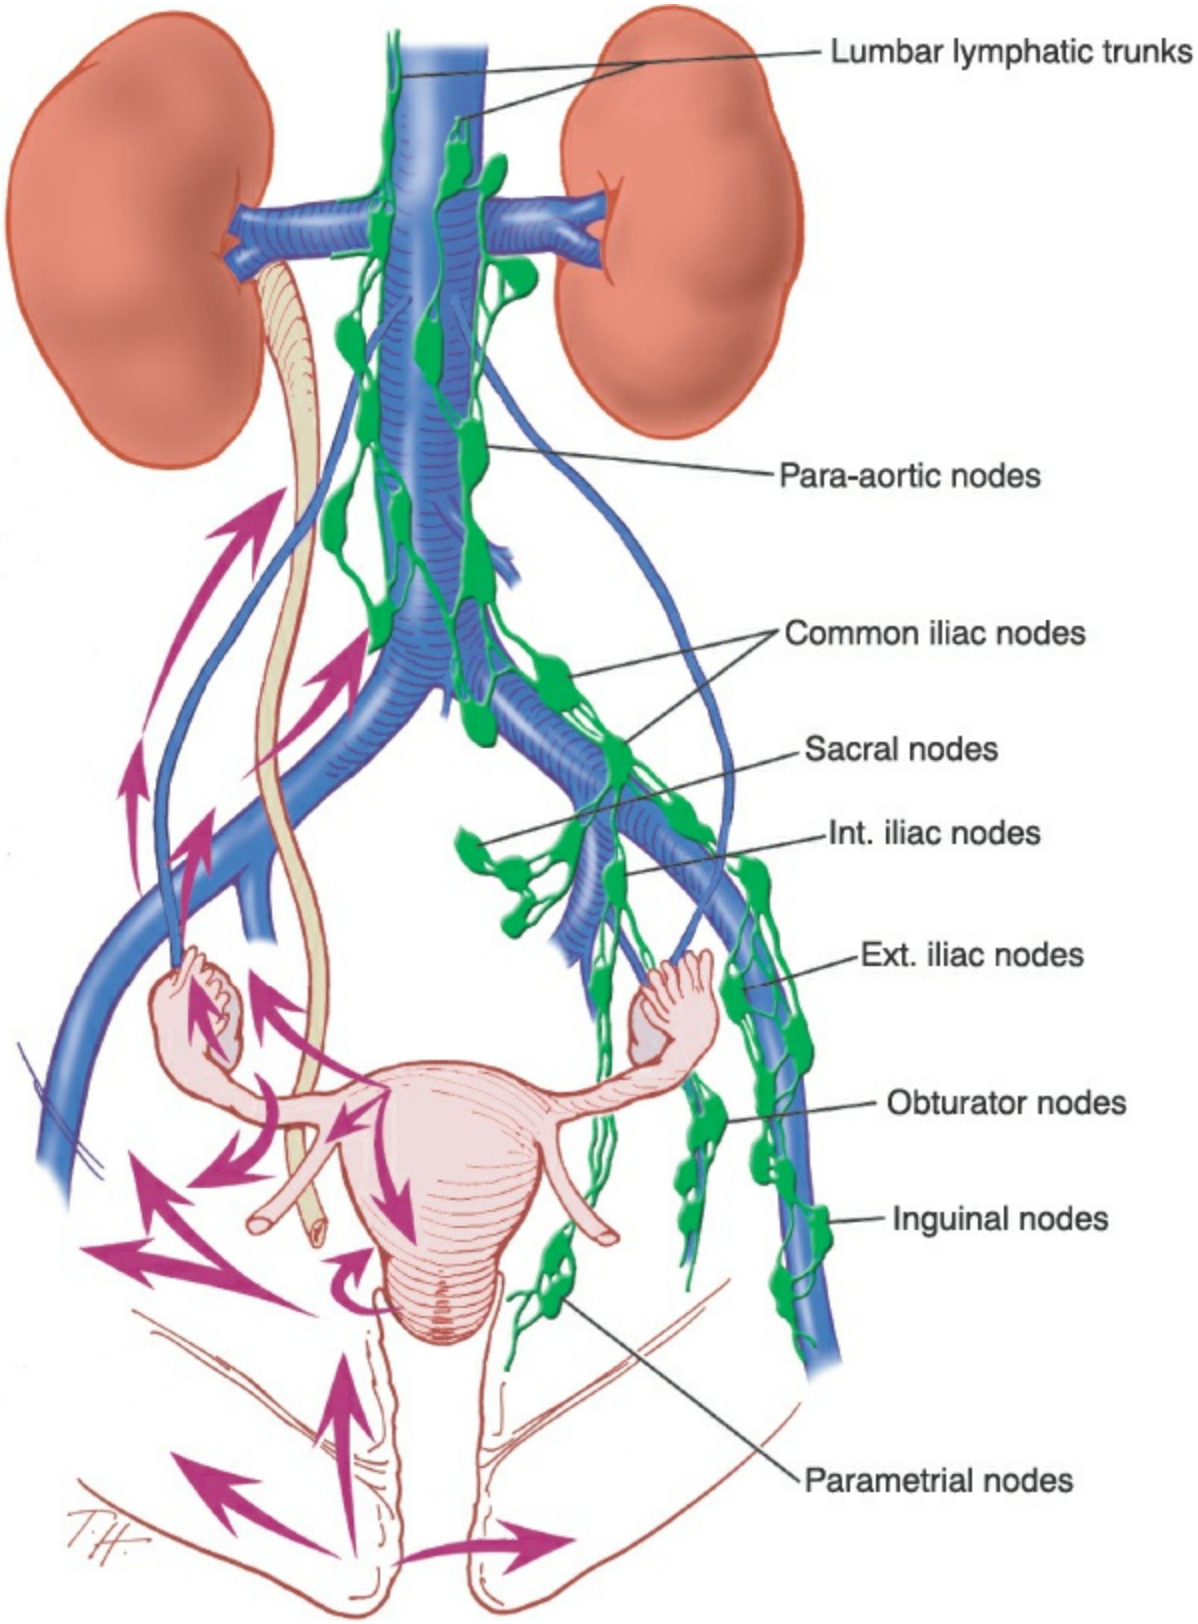

FIGURE 5-11 The lymphatic drainage of the female pelvis. The vulva and lower vagina drain to the superficial and deep inguinal nodes, sometimes directly to the iliac nodes (along the dorsal vein of the clitoris) and to the other side. The cervix and upper vagina drain laterally to the parametrial, obturator, and external iliac nodes and posteriorly along the uterosacral ligaments to the sacral nodes. Drainage from these primary lymph node groups is upward along the infundibulopelvic ligament, similar to drainage of the

ovary and fallopian tubes to the para-aortic nodes. The lower uterine body drains in the same manner as the cervix. Rarely, drainage occurs along the round ligament to the inguinal nodes.

Table 5-5 Primary Lymph Node Groups Providing Drainage to Genital Structures

Nodes	Primary Afferent Connections
Aortic/para-aortic	Ovary, fallopian tube, uterine corpus (upper); drainage from common iliac nodes
Common iliac	Drainage from external and internal iliac nodes
External iliac	Upper vagina, cervix, uterine corpus (upper); drainage from inguinal
Internal iliac	Upper vagina, cervix, uterine corpus (lower)
Lateral sacral	
Superior gluteal	
Inferior gluteal	
Obturator	
Vesical	
Rectal	
Parauterine	
Inguinal	Vulva, lower vagina (rare: uterus, tube, ovary)
Superficial	
Deep	

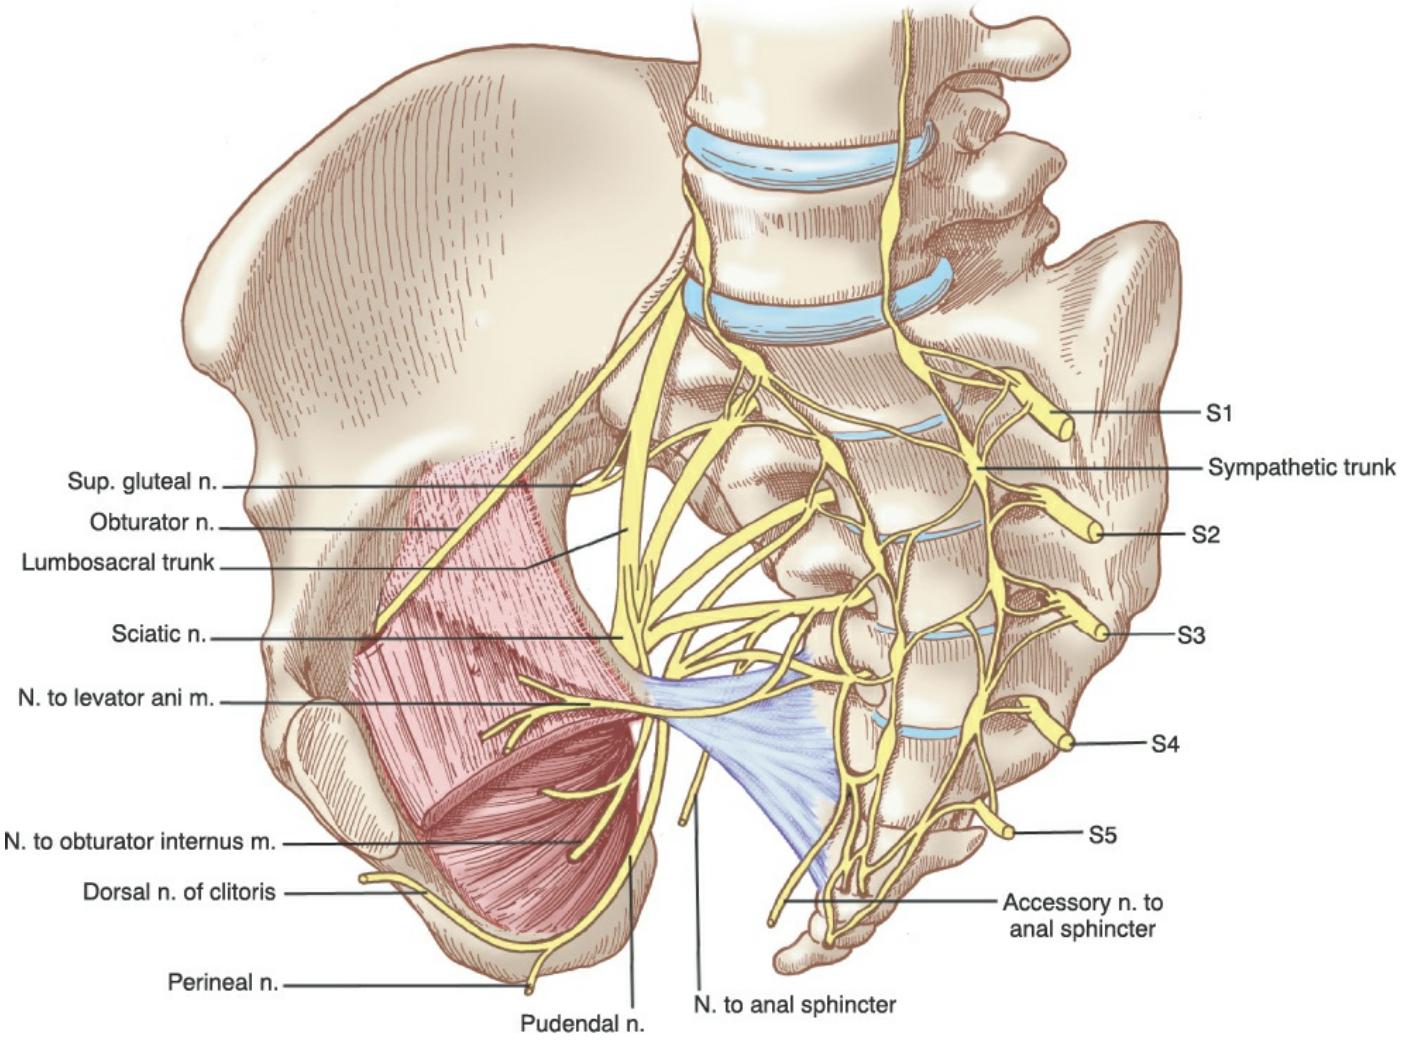

FIGURE 5-12 The sacral plexus. (Modified from **Kamina P**. *Anatomie Gynécologique et Obstétricale*. Paris, France: Maloine Sa Éditeur; 1984:90.)

Table 5-6 Lumbosacral Plexus

Nerve	Spinal Segment	Innervation
Iliohypogastric	T12, L1	Sensory—skin near iliac crest, just above symphysis pubis
Ilioinguinal	L1	Sensory—upper medial thigh, mons, labia majora
Lateral femoral cutaneous	L2, L3	Sensory—lateral thigh to level of knee
Femoral	L2, L3, L4	Sensory—anterior and medial thigh, medial leg and foot, hip and knee joints Motor—iliacus, anterior thigh muscles
Genitofemoral	L1, L2	Sensory—anterior vulva (genital branch), middle/upper anterior thigh (femoral branch)

Obturator	L2, L3, L4	Sensory—medial thigh and leg, hip and knee joints Motor—adductor muscles of thigh
Superior gluteal	L4, L5, S1	Motor—gluteal muscles
Inferior gluteal	L4, L5, S1, S2	Motor—gluteal muscles
Posterior femoral cutaneous	S1, S2, S3	Sensory—vulva, perineum, posterior thigh
Sciatic	L4, L5, S1, S2, S3	Sensory—much of leg, foot, lower extremity joints Motor—posterior thigh muscle, leg and foot muscles
Pudendal	S2, S3, S4	Sensory—perianal skin, vulva and perineum, clitoris, urethra, vaginal vestibule Motor—external anal sphincter, perineal muscles, urogenital diaphragm

Nerves supplying the cutaneous aspects of the anterior, medial, and lateral lower extremities, and the deep muscles of the anterior thigh, primarily leave the pelvis by passing beneath the inguinal ligament. Nerves supporting the posterior cutaneous and deep structures of the hip, thigh, and leg lie deep in the pelvis and should not be vulnerable to injury during pelvic surgery. [3] **The obturator nerve travels along the lateral pelvic wall to pass through the obturator foramen into the upper thigh, and it may be encountered in more radical dissections involving the lateral pelvic wall, in paravaginal repairs, or in trocar-based incontinence and prolapse procedures. Obturator nerve injury results in pain, sensory loss to the medial thigh, and motor loss to the adductor muscle group.**

The pudendal nerve innervates the striated urethral and anal sphincters and the deep and superficial perineal muscles and provides sensory innervation to the external genitalia. This nerve originates from S2–S4, crosses over the piriformis to travel with the internal pudendal vessels into the ischiorectal fossa through the lesser sciatic foramen, and travels through the pudendal canal (Alcock canal) on the medial aspect of the obturator internus muscles, where it divides into its three terminal branches to provide the primary innervation to the perineum. As the pudendal nerve passes posteriorly to the ischial spine and behind the lateral third of the sacrospinous ligament, pudendal nerve entrapment or injury can occur with suture placement into the sacrospinous ligament or arcus tendineus fasciae causing gluteal, perineal, and vulvar

pain. Other nerves contribute to the cutaneous innervation of the perineum:

1. **The anterior labial nerve branches of the ilioinguinal nerve**—these nerves emerge from within the inguinal canal and through the superficial inguinal ring to the mons and upper labia majora.
2. **The genital branch of the genitofemoral nerve**—this branch enters the inguinal canal with the round ligament and passes through the superficial inguinal ring to the anterior vulva.
3. **The perineal branches of the posterior femoral cutaneous nerve**—after leaving the pelvis through the greater sciatic foramen, these branches run in front of the ischial tuberosity to the lateral perineum and labia majora.
4. **Perforating cutaneous branches of the second and third sacral nerves**—these branches perforate the sacrotuberous ligament to supply the buttocks and contiguous perineum.
5. **The anococcygeal nerves**—these nerves arise from S4 to S5 and also perforate the sacrotuberous ligament to supply the skin overlying the coccyx.

Autonomic Innervation

Functionally, the innervation of the pelvic viscera may be divided into an *efferent* component and an *afferent*, or sensory, component. In reality, afferent and efferent fibers are closely associated in a complex interlacing network and cannot be separated anatomically.

Efferent Innervation

***Efferent* fibers of the autonomic nervous system, unlike motor fibers in the somatic system, involve one synapse outside the central nervous system, with two neurons required to carry each impulse. In the *sympathetic* (*thoracolumbar*) *division*, this synapse is generally at some distance from the organ being innervated; conversely, the synapse is on or near the organ of innervation in the *parasympathetic* (*craniosacral*) *division*. In general, the two systems innervate the same target organs but have opposing effects on them to maintain homeostasis. The parasympathetic division has a calming effect on body functions and can be thought of as the "resting and digesting" state. The sympathetic division prepares the body for physical activity and can be thought of as the "fight or flight" reaction**.

Axons from preganglionic neurons emerge from the spinal cord to make contact with peripheral neurons arranged in aggregates known as *autonomic ganglia*. Some of these ganglia, along with interconnecting nerve fibers, form a pair of longitudinal cords called the *sympathetic trunks*. Located lateral to the spinal column from the base of the cranium to the coccyx, the sympathetic trunks lie along the medial border of the psoas

muscle from T12 to the sacral prominence and then pass behind the common iliac vessels to continue into the pelvis on the anterior surface of the sacrum. On the anterolateral surface of the aorta, the *aortic plexus* forms a lacy network of nerve fibers with interspersed ganglia. Rami arising from or traversing the sympathetic trunks join this plexus and its subsidiaries.

The ovaries, part of the fallopian tubes, and broad ligament are innervated by the *ovarian plexus*, a network of nerve fibers accompanying the ovarian vessels and derived from the aortic and renal plexuses. The *inferior mesenteric plexus* is a subsidiary of the *celiac plexus* and *aortic plexus* and is located along the inferior mesenteric artery and its branches, providing innervation to the left colon, sigmoid, and rectum.

The *superior hypogastric plexus* (*presacral nerve*) is the continuation of the aortic plexus beneath the peritoneum in front of the terminal aorta, the fifth lumbar vertebra, and the sacral promontory, medial to the ureters **(Fig. 5-13)**. Embedded in loose areolar tissue, the plexus overlies the middle sacral vessels and is usually composed of two or three incompletely fused trunks. It contains preganglionic fibers from lumbar nerves, postganglionic fibers from higher sympathetic ganglia and the sacral sympathetic trunks, and visceral afferent fibers. Just below the sacral promontory, the superior hypogastric plexus divides into two loosely arranged nerve trunks, the *hypogastric nerves*. These nerves course inferiorly and laterally to connect with the inferior *hypogastric plexuses* (*pelvic plexuses*), which are a dense network of nerves and ganglia that lie along the lateral pelvic sidewall overlying branches of the internal iliac vessels **(Fig. 5-13)**.

The inferior hypogastric plexus includes efferent sympathetic fibers, afferent (sensory) fibers, and parasympathetic fibers arising from the pelvic splanchnic nerves (*S2 to S4, nervi erigentes*).

This paired plexus is the final common pathway of the pelvic visceral nervous system and is divided into three portions, representing distribution of innervation to the viscera:

1. **Vesical plexus**
   - Innervation: bladder and urethra
   - Course: along vesical vessels
2. **Middle rectal plexus (hemorrhoidal)**
   - Innervation: rectum
   - Course: along middle rectal vessels
3. **Uterovaginal plexus (Frankenhäuser ganglion)**
   - Innervation: uterus, vagina, clitoris, vestibular bulbs
   - Course: along uterine vessels and through cardinal and uterosacral ligaments; sympathetic and sensory fibers derive from T10, L1; parasympathetic fibers derive from S2 to S4

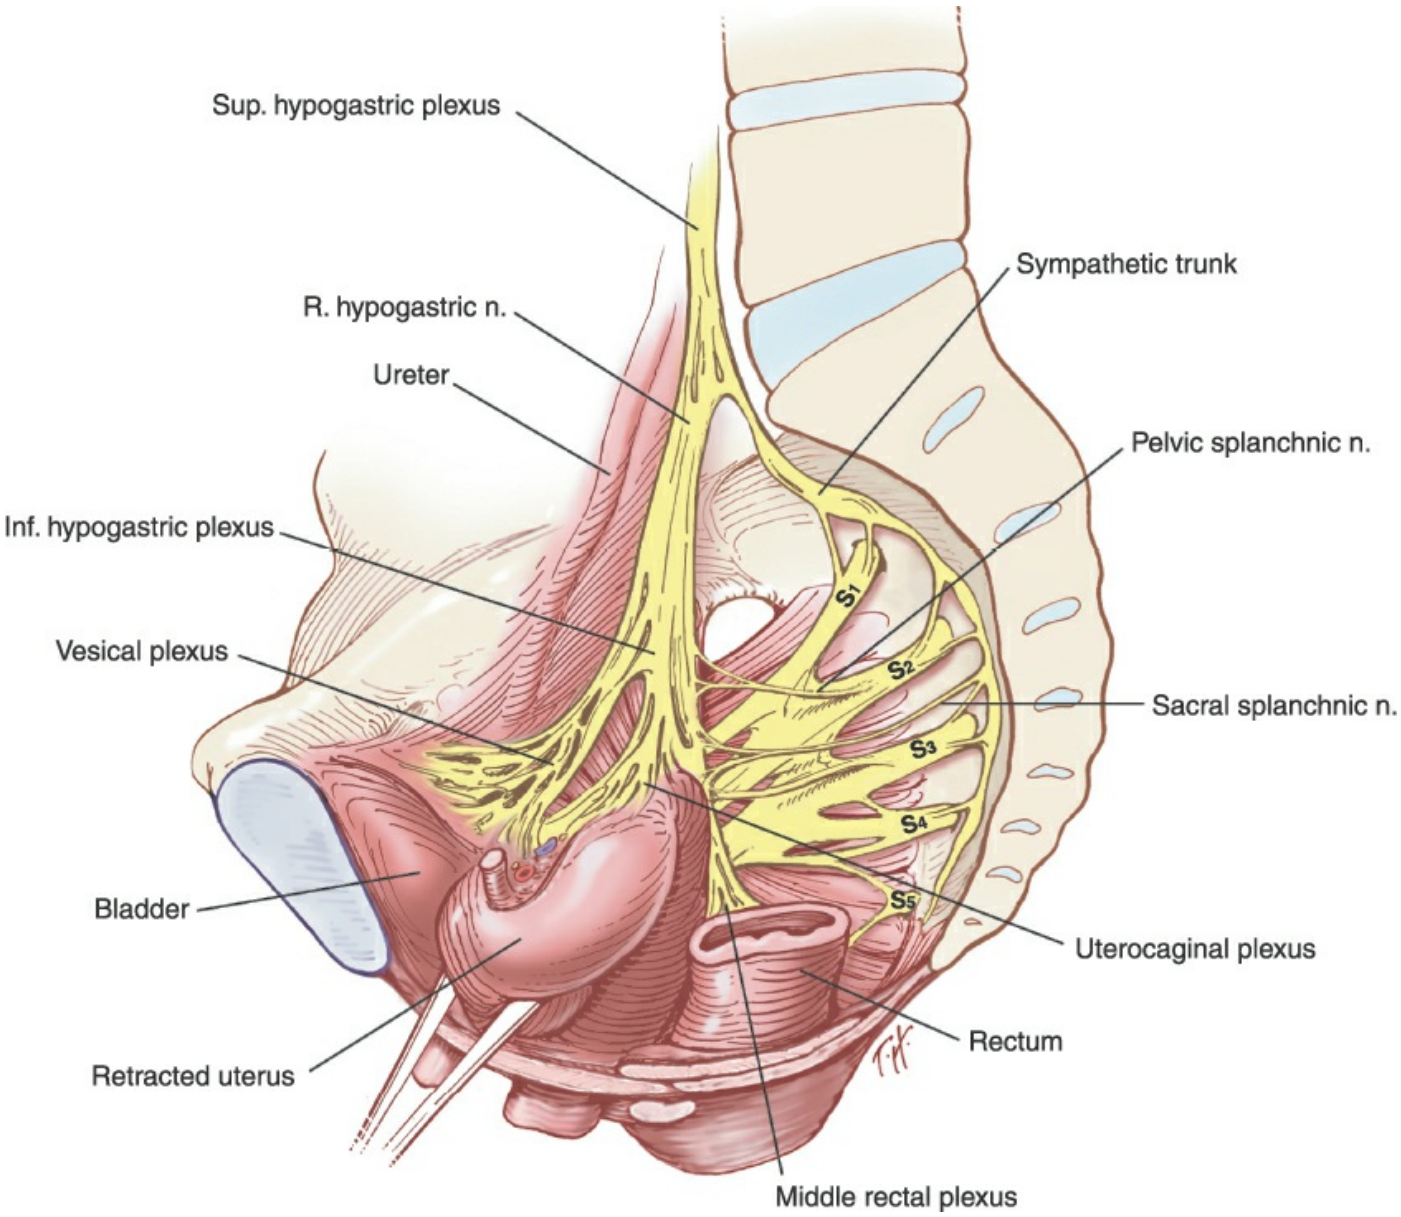

FIGURE 5-13 The presacral nerves.

Disruption of the superior hypogastric plexus or hypogastric nerves can cause de novo bladder, bowel, or sexual dysfunction postoperatively. Radical hysterectomy, where portions of this system are removed, can lead to significant visceral and/or sexual dysfunction (28,29). The sacral hypogastric plexus may be injured during dissection of deep pelvic retroperitoneal spaces for deep infiltrating endometriosis or during exposure of the anterior surface of S1 for mesh fixation during sacrocolpopexy. The hypogastric nerves extend from the superior hypogastric plexus and course through the lateral walls into the peritoneum of the posterior cul-de-sac and uterosacral ligaments. **[3]** Urinary, bowel, and sexual dysfunction have been reported after benign hysterectomy or vaginal apical suspension procedures where the inferior hypogastric nerve is interrupted during transection or securing of the uterosacral ligament (30,31).

Afferent Innervation

Afferent **fibers from the pelvic viscera and blood vessels traverse the same pathways to provide sensory input to the central nervous system**. They are involved in reflex arcs needed for bladder, bowel, and genital tract function. The afferent fibers reach the central nervous system to have their first synapse within the posterior spinal nerve ganglia.

Presacral neurectomy, in which a segment of the superior hypogastric plexus is divided and resected in order to interrupt sensory fibers from the uterus and cervix, is associated with relief of dysmenorrhea secondary to endometriosis in about 50% to 75% of cases in which it was used (32,33). Efferent fibers from the adnexa travel with the ovarian plexus. Pain originating from the ovary or tube is not relieved by resection of the presacral nerve. Disturbance in bowel or bladder function may result because this plexus contains efferent sympathetic and parasympathetic nerve fibers intermixed with afferent fibers. An alternative surgical procedure is resection of the uterosacral ligaments, which is also associated with urinary dysfunction including urinary retention (34).

An anesthetic block of the pudendal nerve is performed most often for pain relief with uncomplicated vaginal deliveries but may provide useful anesthesia for minor perineal surgical procedures. This nerve block may be accomplished transvaginally or through the perineum. A needle is inserted toward the ischial spine with the tip directed slightly posteriorly and through the sacrospinous ligament. As the anesthetic agent is injected, frequent aspiration is required to avoid injection into the pudendal vessels, which travel with the nerve.

PELVIC VISCERA

Genital Structures

Vagina

A sagittal section of the female pelvis is presented in Figure 5-14.

The vagina is a hollow fibromuscular tube extending from the vulvar vestibule to the uterus. In the dorsal lithotomy position, the vagina is directed posteriorly toward the sacrum, but its axis is almost horizontal in the upright position. It is attached at its upper end to the uterus just above the cervix. The spaces between the cervix and vagina are known as the *anterior*, *posterior*, and *lateral vaginal fornices*. **Because the vagina is attached at a higher point posteriorly than anteriorly, the posterior vaginal wall is about 3 cm longer than the anterior wall.**

The posterior vaginal fornix is separated from the posterior cul-de-sac and peritoneal cavity by the vaginal wall and peritoneum. This proximity is clinically

useful, both diagnostically and therapeutically. *Culdocentesis*, a technique in which a needle is inserted just posterior to the cervix through the vaginal wall into the peritoneal cavity, is used to evaluate intraperitoneal hemorrhage (e.g., ruptured ectopic pregnancy, hemorrhagic corpus luteum, other intra-abdominal bleeding), pus (e.g., pelvic inflammatory disease, ruptured intra-abdominal abscess), or other intra-abdominal fluid (e.g., ascites). Incision into the peritoneal cavity from this location in the vagina, known as a *posterior colpotomy*, can be used as an adjunct to laparoscopic excision of adnexal masses, with removal of the mass intact through the posterior vagina.

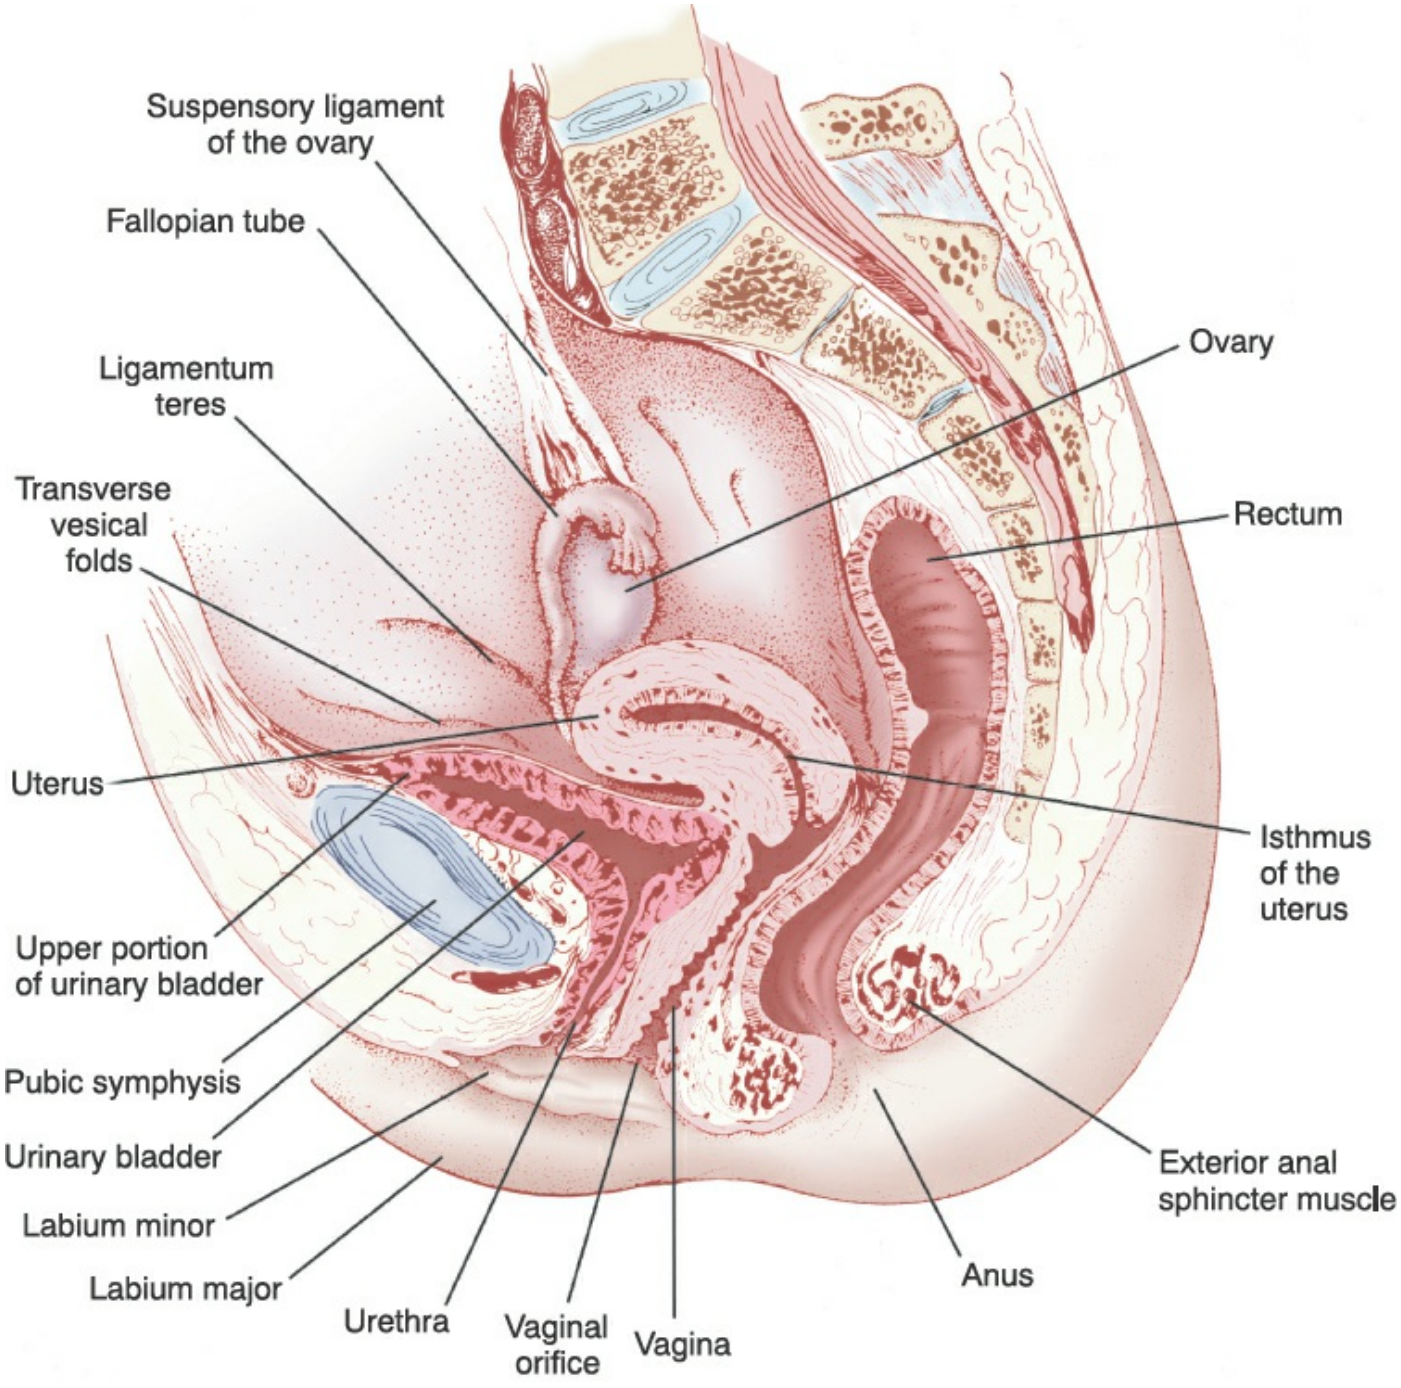

FIGURE 5-14 The pelvic viscera. A sagittal section of the female pelvis with the pelvic viscera and their

relationships.

The vagina is attached to the lateral pelvic wall with endopelvic fascial connections to the *arcus tendineus* (white line), which extends from the pubic bone to the ischial spine. This connection converts the vaginal lumen into a transverse slit with the anterior and posterior walls in apposition; the lateral space where the two walls meet is the *vaginal sulcus*. Lateral detachments of the vagina are recognized in some cystocele formations (lateral cystoceles or paravaginal defects).

The opening of the vagina may be covered by a membrane or surrounded by a fold of connective tissue called the *hymen.* This tissue is usually replaced by irregular tissue tags after sexual activity and childbirth occur. The lower vagina is somewhat constricted as it passes through the urogenital hiatus in the pelvic diaphragm; the upper vagina is more spacious. The entire vagina is characterized by its distensibility, which is most evident during childbirth.

The vagina is closely applied anteriorly to the urethra, bladder neck and trigonal region, and posterior bladder; posteriorly, the vagina lies in association with the perineal body, anal canal, lower rectum, and posterior cul-de-sac. **It is separated from the lower urinary and gastrointestinal tracts by their investing layers of fibromuscular elements known as the *endopelvic fascia.***

The vagina is composed of three layers:

1. **Mucosa**—nonkeratinized stratified squamous epithelium, without glands. Vaginal lubrication occurs primarily by transudation, with contributions from cervical and Bartholin gland secretions. The mucosa has a characteristic pattern of transverse ridges and furrows known as *rugae*. It is hormonally sensitive, responding to stimulation by estrogen with proliferation and maturation. The mucosa is colonized by mixed bacterial flora with *Lactobacillus* predominant; normal pH is 3.5 to 4.5.
2. **Muscularis**—connective tissue and smooth muscle, loosely arranged in inner circular and outer longitudinal layers.
3. **Adventitia**—endopelvic fascia, adherent to the underlying muscularis.

Blood Supply

The blood supply of the vagina includes the vaginal artery and branches from the uterine, middle rectal, and internal pudendal arteries.

Innervation

The innervation of the vagina is as follows: the upper vagina—uterovaginal plexus; the distal vagina—pudendal nerve.

Uterus

The uterus is a fibromuscular organ usually divided into a lower cervix and an

upper corpus or uterine body (Fig. 5-15).

Cervix

The portion of cervix exposed to the vagina is the exocervix or portio vaginalis. It has a convex round surface with a circular or slitlike opening (the external os) into the endocervical canal. **The endocervical canal is about 2 to 3 cm in length and opens proximally into the endometrial cavity at the internal os.**

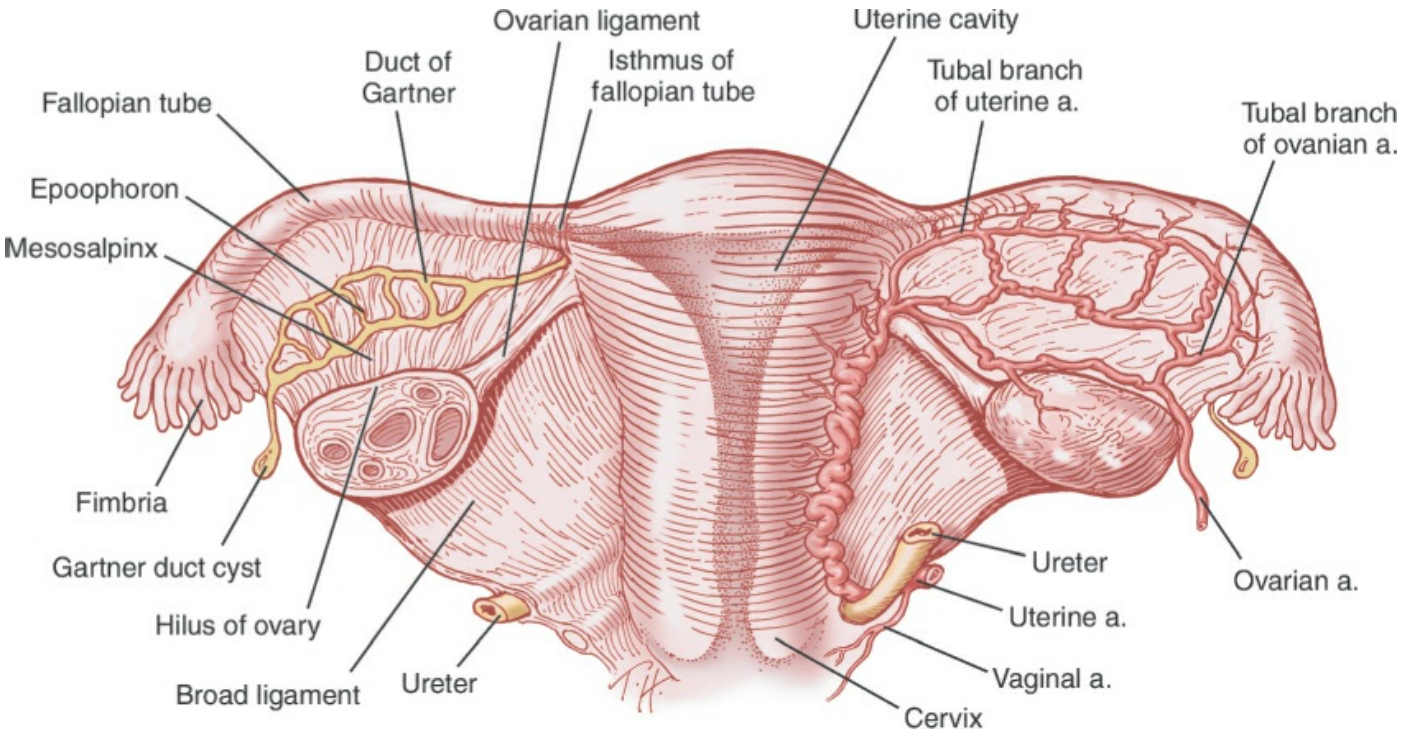

FIGURE 5-15 The uterus, fallopian tubes, and ovaries.

The cervical mucosa contains both stratified squamous epithelium, characteristic of the exocervix, and mucus-secreting columnar epithelium, characteristic of the endocervical canal. The intersection where these two epithelia meet—the squamocolumnar junction—is geographically variable and dependent on hormonal stimulation. It is this dynamic interface, the transformation zone, which is most vulnerable to the development of squamous neoplasia.

In early childhood, during pregnancy, or with oral contraceptive use, columnar epithelium may extend from the endocervical canal onto the exocervix, a condition known as *eversion* or *ectopy.* After menopause, the transformation zone usually recedes entirely into the endocervical canal.

Production of cervical mucus is under hormonal influence. It varies from profuse, clear, and thin mucus around the time of ovulation to scant and thick mucus in the postovulatory phase of the cycle. Deep in the mucosa and submucosa, the cervix is composed of fibrous connective tissue and a small amount of smooth muscle in a

circular arrangement.

Corpus

The body of the uterus varies in size and shape, depending on hormonal and childbearing status. **At birth, the cervix and corpus are about equal in size; in adult women, the corpus has grown to two to three times the size of the cervix**. The position of the uterus in relation to other pelvic structures is variable and is generally described in terms of positioning—anterior, midposition, or posterior; flexion; and version. ***Flexion* is the angle between the long axis of the uterine corpus and the cervix, whereas *version* is the angle of the junction of the uterus with the upper vagina**. Occasionally, abnormal positioning may occur secondary to associated pelvic pathology, such as endometriosis or adhesions.

The uterine corpus is divided into several different regions. The area where the endocervical canal opens into the endometrial cavity is known as the *isthmus or lower uterine segment.* On each side of the upper uterine body, a funnel-shaped area receives the insertion of the fallopian tubes and is called the *uterine cornu*; the uterus above this area is the fundus.

The endometrial cavity is triangular in shape and represents the mucosal surface of the uterine corpus. The epithelium is columnar and gland forming with a specialized stroma. It undergoes cyclic structural and functional change during the reproductive years, with regular shedding of the superficial endometrium and regeneration from the basal layer.

The muscular layer of the uterus, the *myometrium*, consists of interlacing smooth muscle fibers and ranges in thickness from 1.5 to 2.5 cm. Some outer fibers are continuous with those of the tube and round ligament.

Peritoneum covers most of the corpus of the uterus and the posterior cervix and is known as the *serosa.* Laterally, the broad ligament, a double layer of peritoneum covering the neurovascular supply to the uterus, inserts into the cervix and corpus. Anteriorly, the bladder lies over the isthmic and cervical region of the uterus.

Blood Supply

The blood supply to the uterus is the uterine artery, which anastomoses with the ovarian and vaginal arteries. Uterine artery embolization can block the blood supply to the uterine body to treat adenomyosis and control heavy uterine bleeding from fibroids or obstetrical hemorrhage.

Innervation

The nerve supply to the uterus is the uterovaginal plexus.

Fallopian Tubes

The fallopian tubes and ovaries collectively are referred to as the *adnexa.* The

fallopian tubes are paired hollow structures representing the proximal unfused ends of the müllerian duct. They vary in length from 7 to 12 cm, and their function includes ovum pickup, provision of physical environment for conception, and transport and nourishment of the fertilized ovum.

The tubes are divided into several regions:

1. **Interstitial**—narrowest portion of the tube, lies within the uterine wall and forms the tubal ostia at the endometrial cavity.
2. **Isthmus**—narrow segment closest to the uterine wall.
3. **Ampulla**—larger-diameter segment lateral to the isthmus.
4. **Fimbria (infundibulum)**—funnel-shaped abdominal ostia of the tubes, opening into the peritoneal cavity; this opening is fringed with numerous fingerlike projections that provide a wide surface for ovum pickup. The fimbria ovarica is a connection between the end of the tube and ovary, bringing the two closer.

The tubal mucosa is ciliated columnar epithelium, which becomes progressively more architecturally complex as the fimbriated end is approached. The muscularis consists of an inner circular and outer longitudinal layer of smooth muscle. The tube is covered by peritoneum and, through its mesentery (mesosalpinx), which is situated dorsal to the round ligament, is connected to the upper margin of the broad ligament.

Blood Supply

The vascular supply to the fallopian tubes is the uterine and ovarian arteries.

Innervation

The innervation to the fallopian tubes is the uterovaginal plexus and the ovarian plexus.

Ovaries

The ovaries are paired gonadal structures that lie suspended between the pelvic wall and the uterus by the infundibulopelvic ligament laterally and the utero-ovarian ligament medially. Inferiorly, the hilar surface of each ovary is attached to the broad ligament by its mesentery (mesovarium), which is dorsal to the mesosalpinx and fallopian tube. Primary neurovascular structures reach the ovary through the infundibulopelvic ligament and enter through the mesovarium. **The normal ovary varies in size, with measurements up to 5 × 3 × 3 cm.** Variation in dimension results from endogenous hormonal production, which varies with age and with each menstrual cycle. Exogenous substances, including oral contraceptives, gonadotropin-releasing hormone agonists, or ovulation-inducing medication, may either stimulate or suppress ovarian activity and affect size.

Each ovary consists of a cortex and medulla and is covered by a single layer of flattened cuboidal to low columnar epithelium that is continuous with the peritoneum at

the mesovarium. The cortex is composed of a specialized stroma and follicles in various stages of development or attrition. The medulla occupies a small portion of the ovary in its hilar region and is composed primarily of fibromuscular tissue and blood vessels.

Blood Supply

The blood supply to the ovary is the ovarian artery, which anastomoses with the uterine artery.

Innervation

The innervation to the ovary is the ovarian plexus and the uterovaginal plexus.

Urinary Tract

Ureters

The ureter is the urinary conduit leading from the kidney to the bladder; it measures about 25 cm in length and is totally retroperitoneal in location.

The lower half of each ureter traverses the pelvis after crossing the common iliac vessels at their bifurcation, just medial to the ovarian vessels. It descends into the pelvis adherent to the peritoneum of the lateral pelvic wall and the medial leaf of the broad ligament and enters the bladder base anterior to the upper vagina, traveling obliquely through the bladder wall to terminate in the bladder trigone.

The ureteral mucosa is a transitional epithelium. The muscularis consists of an inner longitudinal and outer circular layer of smooth muscle. A protective connective tissue sheath, which is adherent to the peritoneum, encloses the ureter.

Blood Supply

The blood supply is variable, with contributions from the renal, ovarian, common iliac, internal iliac, uterine, and vesical arteries.

Innervation

The innervation is through the ovarian plexus and the vesical plexus.

Bladder and Urethra

Bladder

The bladder is a hollow organ, spherically shaped when full, that stores urine. Its size varies with urine volume, normally reaching a maximum volume of at least 300 mL. The bladder is often divided into two areas, which are of physiologic significance:

1. The **base of the bladder** consists of the urinary trigone posteriorly and a thickened area of detrusor anteriorly. The three corners of the trigone are formed by the two ureteral orifices and the opening of the urethra into the bladder. The bladder base receives α-adrenergic sympathetic innervation and is the area responsible for

maintaining continence.

2. The **dome of the bladder** is the remaining bladder area above the bladder base. It has parasympathetic innervation and is responsible for micturition.

The bladder is positioned posterior to the pubis and lower abdominal wall and anterior to the cervix, upper vagina, and part of the cardinal ligament. Laterally, it is bounded by the pelvic diaphragm and obturator internus muscle.

The bladder wall has four layers—the urothelium, lamina propria, muscularis propria, and serosa. The urothelium is the innermost epithelial lining of the bladder and is composed of transitional cell epithelium. Covering the uroepithelium is a glycosaminoglycan (GAG) layer, which acts as an impermeable protective barrier to prohibit bacterial adherence and prevent urothelial damage from urinary proteases and ions. The lamina propria and muscularis propria (detrusor muscle) are composed of intermeshing muscle fibers, which allow for rapid expansion during bladder filling.

The bladder mucosa is transitional cell epithelium. The muscle wall (detrusor), rather than being arranged in layers, is composed of intermeshing muscle fibers.

Blood Supply

The blood supply to the bladder is from the superior, middle, and inferior vesical arteries, with contribution from the uterine and vaginal vessels.

Innervation

The innervation to the bladder is from the vesical plexus, with contribution from the uterovaginal plexus.

Urethra

The vesical neck is the region of the bladder that receives and incorporates the urethral lumen. The female urethra is about 3 to 4 cm in length and extends from the bladder to the vestibule, traveling just anterior to the vagina.

The urethra is lined by nonkeratinized squamous epithelium that is responsive to estrogen stimulation. Within the submucosa, on the dorsal surface of the urethra, are the paraurethral or Skene glands, which empty through ducts into the urethral lumen. Distally, these glands empty into the vestibule on either side of the external urethral orifice. **Chronic infection of Skene glands, with obstruction of their ducts and cystic dilation, is believed to be an inciting factor in the development of suburethral diverticula. Symptomatic patients can complain of urinary outflow obstruction (e.g., hesitancy, dribbling, lateral spraying, retention, or urinary tract infection).**

The urethra contains an inner longitudinal layer of smooth muscle and outer circularly oriented smooth muscle fibers. The inferior fascia of the urogenital diaphragm or perineal membrane begins at the junction of the middle and distal thirds of the urethra. Proximal to the middle and distal parts of the urethra, voluntary muscle fibers derived

from the urogenital diaphragm intermix with the outer layer of smooth muscle, increasing urethral resistance and contributing to continence. At the level of the urogenital diaphragm, the skeletal muscle fibers leave the wall of the urethra to form the sphincter urethrae and deep transverse perineal muscles. In the coronal plane on MRI studies, the ventral urogenital diaphragm forms an interconnected complex with the compressor urethrae, vestibular bulb, and levator ani. The dorsal part connects the levator ani and vaginal sidewall via a distinct band to the ischiopubic ramus. In the sagittal plane the parallel position of urogenital diaphragm and levator ani can be seen (35).

Blood Supply

The vascular supply to the urethra is from the vesical and vaginal arteries and the internal pudendal branches.

Innervation

The innervation to the urethra is from the vesical plexus and the pudendal nerve.

The lower urinary and genital tracts are intimately connected anatomically and functionally. In the midline, the bladder and proximal urethra can be dissected easily from the underlying lower uterine segment, cervix, and vagina through a loose avascular plane. The distal urethra is essentially inseparable from the vagina. Of surgical significance is the location of the bladder trigone immediately over the middle third of the vagina. Unrecognized injury to the bladder during pelvic surgery may result in development of a vesicovaginal fistula.

Dissection to the level of the trigone is rarely required, and damage to this critical area is unusual.

Lower Gastrointestinal Tract

Sigmoid Colon

The sigmoid colon begins its characteristic S-shaped curve as it enters the pelvis at the left pelvic brim (Fig. 5-16). The columnar mucosa and richly vascularized submucosa are surrounded by an inner circular layer of smooth muscle and three overlying longitudinal bands of muscle called teniae coli. A mesentery of varying length attaches the sigmoid to the posterior abdominal wall.

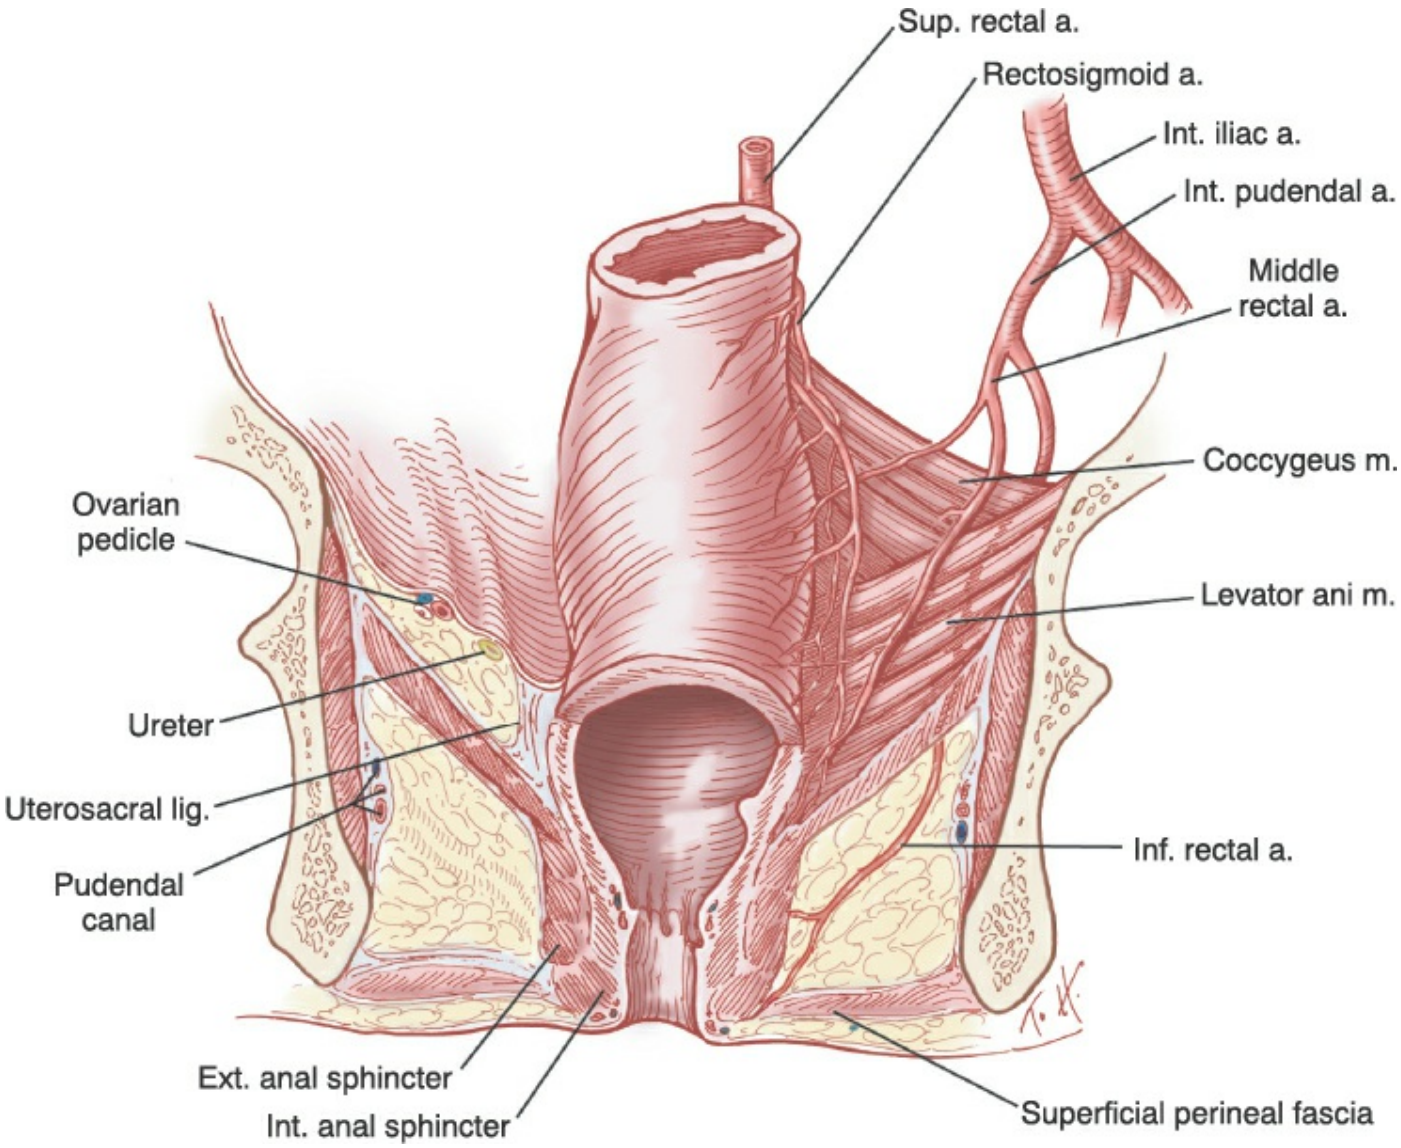

FIGURE 5-16 The rectosigmoid colon, its vascular supply, and muscular support (coronal view: peritoneum removed on right).

Blood Supply

The blood supply to the sigmoid colon is from the sigmoid arteries.

Innervation

The nerves to the sigmoid colon are derived from the inferior mesenteric plexus.

Rectum

The sigmoid colon loses its mesentery in the midsacral region and becomes the rectum about 15 to 20 cm above the anal opening. The rectum follows the curve of the lower sacrum and coccyx and becomes entirely retroperitoneal at the level of the rectouterine pouch or posterior cul-de-sac. It continues along the pelvic curve just posterior to the vagina until the level of the anal hiatus of the pelvic diaphragm, at which point it takes a sharp 90-degree turn posteriorly and becomes the anal canal,

separated from the vagina by the perineal body.

The rectal mucosa is lined by a columnar epithelium and characterized by three transverse folds that contain mucosa, submucosa, and the inner circular layer of smooth muscle. The teniae of the sigmoid wall broaden and fuse over the rectum to form a continuous longitudinal external layer of smooth muscle to the level of the anal canal.

Anal Canal

The anal canal begins at the level of the sharp turn in the direction of the distal colon and is 2 to 3 cm in length. At the anorectal junction, the mucosa changes to stratified squamous epithelium (the pectinate line), which continues until the termination of the anus at the anal verge, where there is a transition to perianal skin with typical skin appendages. It is surrounded by a thickened ring of circular muscle fibers that are a continuation of the circular muscle of the rectum, the internal anal sphincter. Its lower part is surrounded by bundles of striated muscle fibers, the external anal sphincter (36).

The internal anal sphincter maintains a steady state of tonic contraction, transiently relaxes in response to rectal distension, and does not appear to be solely essential for continence. Fecal continence is provided primarily by the puborectalis muscle and internal anal sphincter, which work in conjunction with the external anal sphincter. The puborectalis surrounds the anal hiatus in the pelvic diaphragm and interdigitates posterior to the rectum to form a rectal sling. Its constant tone contributes to the anorectal angle, which prevents stool from entering the anus from the rectum. The external anal sphincter surrounds the terminal anal canal below the level of the levator ani. **[3]** A growing body of literature suggests that both external anal sphincter and levator ani muscles are important for fecal continence and that multiple injuries contribute to pelvic floor dysfunction (37,38). One such MRI study showed that major levator ani muscle injuries were observed in 19.1% women who delivered vaginally with external anal sphincter injuries, 3.5% who delivered vaginally without external anal sphincter injury, and none of the women who delivered by cesarean section before labor. Among women with external anal sphincter injuries, those with major levator ani muscle injuries trended more toward fecal incontinence (37). Patients with chronic fourth-degree lacerations who have absence of the anterior portions of the external anal sphincter and internal anal sphincter can still maintain continence with an intact puborectalis muscle (39). Further studies suggest that thickening of the internal anal sphincter occurs with aging, and that thinning of the external anal sphincter and a corresponding drop in squeeze pressure correlated with fecal incontinence, but not aging (40).

The anatomic proximity of the lower gastrointestinal tract to the lower genital tract is particularly important during surgery of the vulva and vagina. Lack of attention to this proximity during repair of vaginal lacerations or episiotomies can lead to damage of the rectum and fistula formation or injury to the external anal

sphincter, resulting in fecal incontinence. Because of the avascular nature of the rectovaginal space, it is relatively easy to dissect the rectum from the vagina in the midline, which is routinely done in the repair of rectoceles.

Blood Supply

The vascular supply to the rectum and anal canal is from the superior, middle, and inferior rectal arteries. The venous drainage is a complex submucosal plexus of vessels that, under conditions of increased intra-abdominal pressure (pregnancy, pelvic mass, chronic constipation, ascites), may dilate and become symptomatic with rectal bleeding or pain as hemorrhoids.

Innervation

The nerve supply to the anal canal is from the middle rectal plexus, the inferior mesenteric plexus, and the pudendal nerve.

THE GENITAL TRACT AND ITS RELATIONS

The genital tract is situated at the bottom of the intraabdominal cavity and is related to the intraperitoneal cavity and its contents, the retroperitoneal spaces, and the pelvic floor. Accessing it through the abdominal wall or the perineum requires a thorough knowledge of the anatomy of these areas and their relationships.

The Abdominal Wall

The anterior abdominal wall is bounded superiorly by the xiphoid process and the costal cartilage of the 7th to 10th ribs and inferiorly by the iliac crest, anterosuperior iliac spine, inguinal ligament, and pubic bone. It consists of skin, muscle, fascia, nerves, and vessels.

Skin

The lower abdominal skin may exhibit striae, or "stretch marks," and increased pigmentation in the midline in parous women. The subcutaneous tissue contains a variable amount of fat.

Muscles

Five muscles and their aponeuroses contribute to the structure and strength of the anterolateral abdominal wall (Fig. 5-17; Table 5-7).

Fascia

Superficial Fascia

The superficial fascia consists of two layers:

1. **Camper fascia**—the most superficial layer, which contains a variable amount of fat and is continuous with the superficial fatty layer of the perineum
2. **Scarpa fascia**—a deeper membranous layer continuous in the perineum with Colles fascia (superficial perineal fascia) and with the deep fascia of the thigh (fascia lata)

Rectus Sheath

The aponeuroses of the external and internal oblique and the transverse abdominis combine to form a sheath for the rectus abdominis and pyramidalis, fusing medially in the midline at the linea alba and laterally at the semilunar line (Fig. 5-18). Above the arcuate line, the aponeurosis of the internal oblique muscle splits into anterior and posterior lamella (Fig. 5-18A). Below this line, all three layers are anterior to the body of the rectus muscle (Fig. 5-18B). The rectus is covered posteriorly by the transversalis fascia, providing access to the muscle for the inferior epigastric vessels.

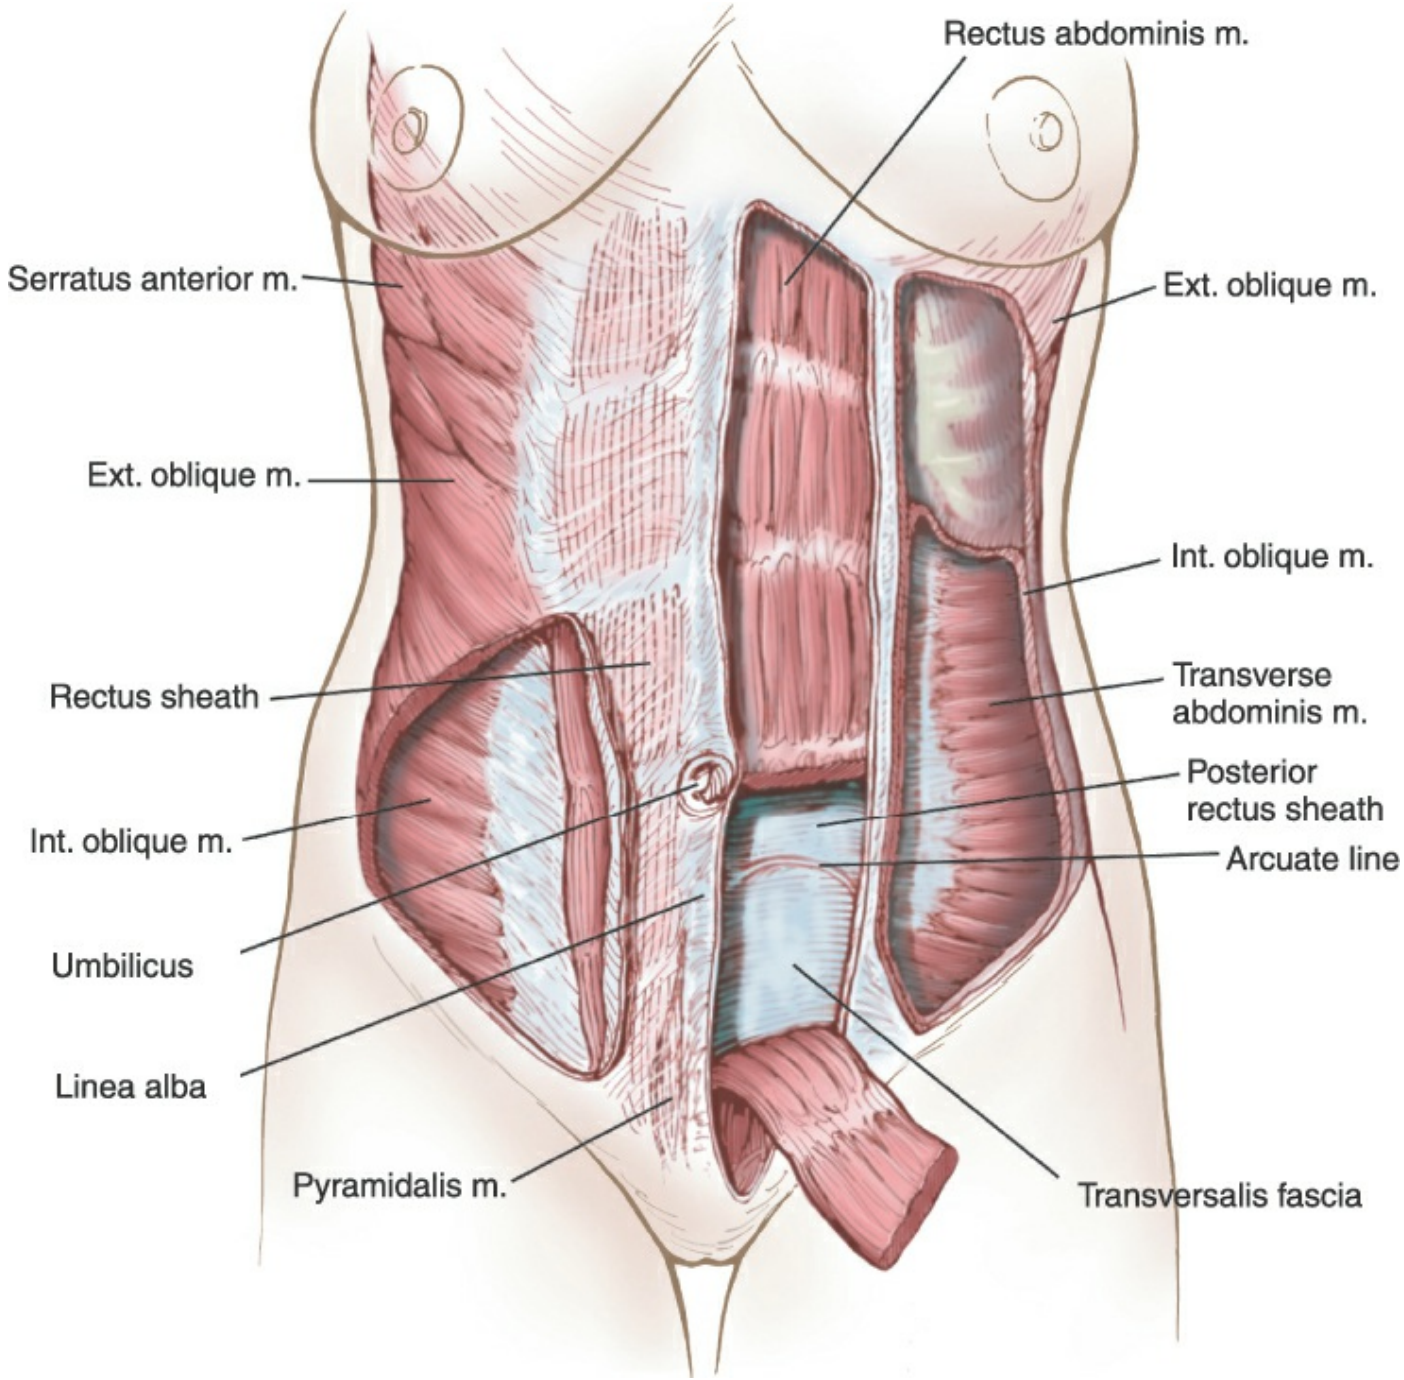

FIGURE 5-17 The abdominal wall muscles.

Table 5-7 Muscles Contributing to the Structure and Strength of the Anterolateral Abdominal Wall

Muscle	Origin	Insertion	Action
External oblique	Fleshy digitations from the outer surfaces of ribs 5–12	Fibers radiate inferiorly, anteriorly, and medially, in most cases ending in the aponeurosis of the external muscle and inserting into the anterior half of the iliac crest, the pubic tubercle, and the linea alba. The superficial inguinal ring is located above and lateral to the pubic tubercle at the end of a triangular cleft in the external oblique muscle, bordered by strong fibrous bands that transmit the round ligament	Compresses and supports abdominal viscera; flexes and rotates vertebral column
Internal oblique	Posterior layer of the thoracolumbar fascia, the anterior two-thirds of the iliac crest, and the lateral two-thirds of the inguinal ligament	Inferior border of ribs 10–12. The superior fibers of the aponeurosis split to enclose the rectus abdominis muscle and join at the linea alba above the arcuate line. The most inferior fibers join with those of the transverse abdominis muscle to insert into the pubic crest and pecten pubis via the conjoint tendon	Compresses and supports abdominal viscera
Transversus abdominis	Inner aspect of the inferior six costal cartilages, the thoracolumbar fascia, the iliac crest, and the lateral one-third of the inguinal ligament	Linea alba with the aponeurosis of the internal oblique, the pubic crest and the pecten pubis through the conjoint tendon	Compresses and supports abdominal viscera
Rectus abdominis	Superior pubic ramus and the ligaments of the symphysis pubis	Anterior surface of the xiphoid process and the cartilage of ribs 5–7	Tenses anterior abdominal wall and flexes trunk
Pyramidalis	Small triangular muscle contained within the rectus sheath, anterior to the lower part of the rectus muscle	On the linea alba, easily recognizable shape, used to locate the midline, particularly in a patient with previous abdominal surgery and scarring of the abdominal wall	Tenses the linea alba, insignificant in terms of function, and is frequently absent

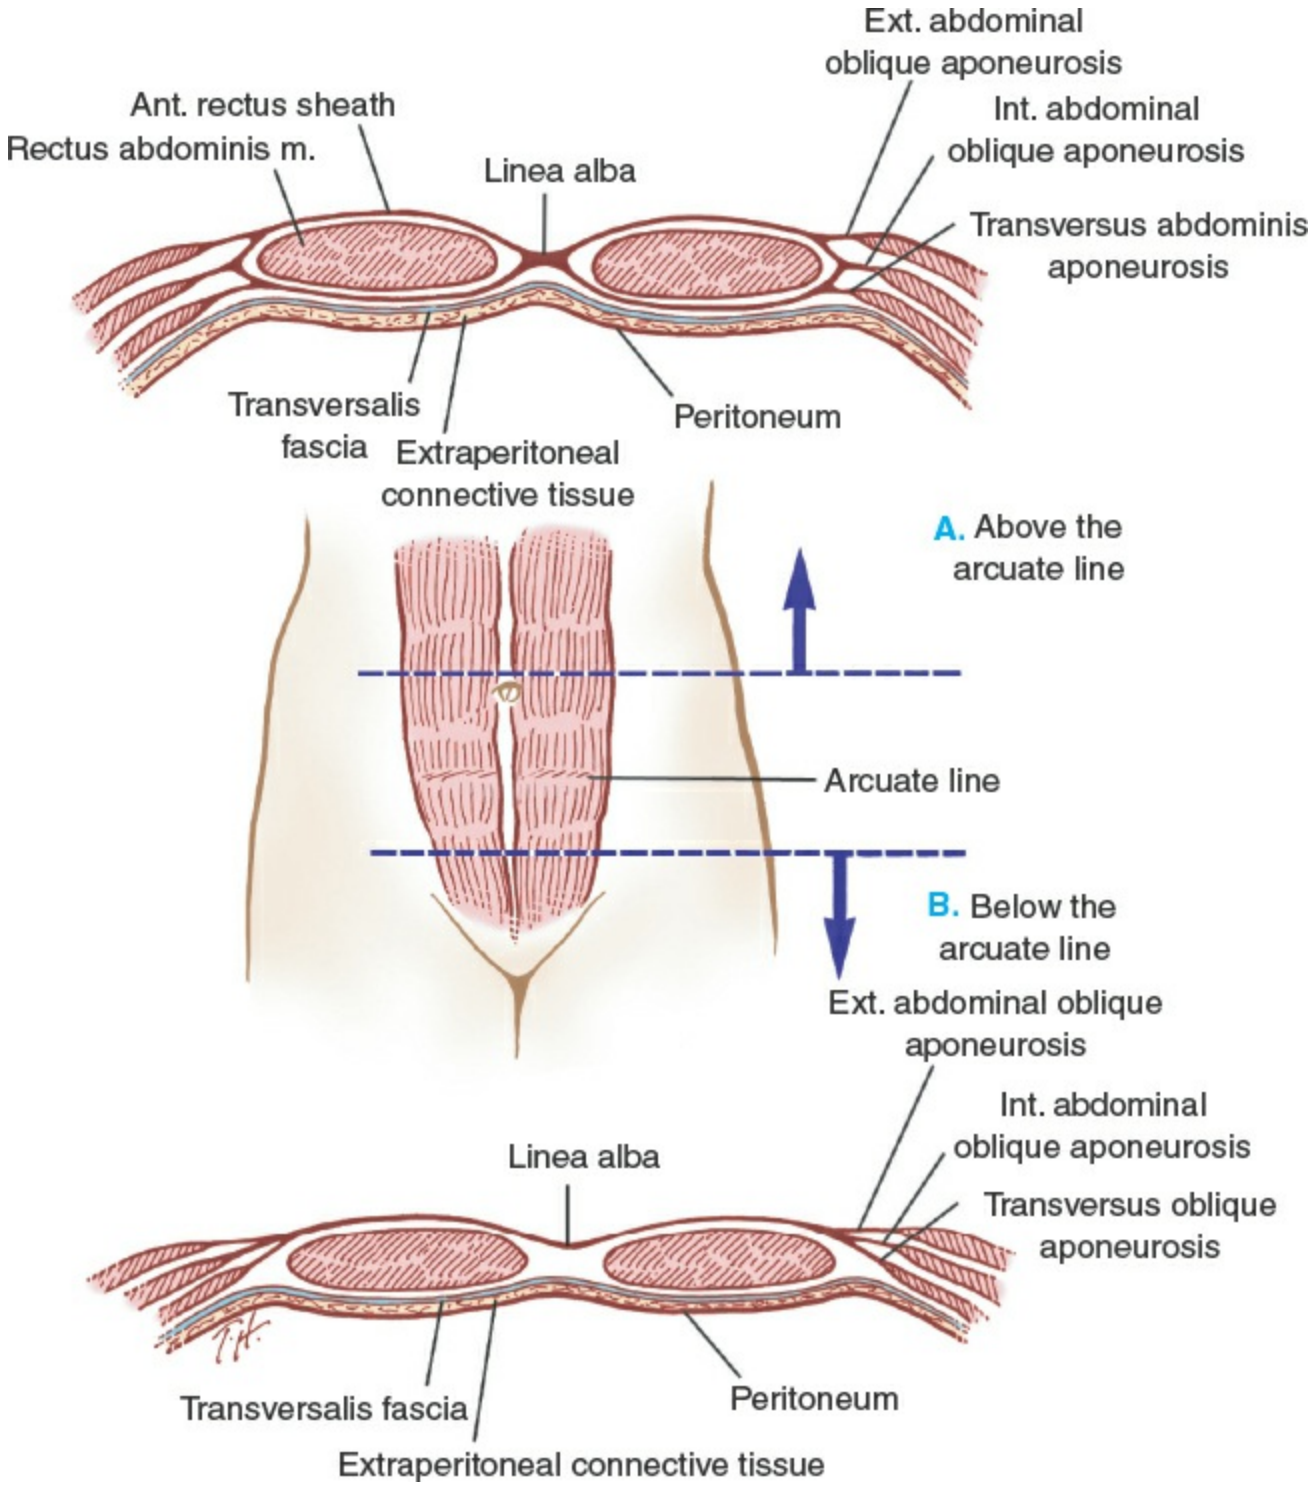

FIGURE 5-18 A transverse section of the rectus abdominis. The aponeurosis of the external and internal oblique and the transversus abdominis from the rectus abdominis. **A:** Above the arcuate line. **B:** Below the arcuate line.

Transversalis Fascia and Endopelvic Fascia

[2] The transversalis fascia is a firm membranous sheet on the internal surface of the transversus abdominis muscle that extends beyond the muscle and forms a fascia lining the entire abdominopelvic cavity. Like the peritoneum, it is divided into a

parietal and a visceral component. It is continuous from side to side across the linea alba and covers the posterior aspect of the rectus abdominis muscle below the arcuate line. Superiorly, it becomes the inferior fascia of the diaphragm. Inferiorly, it is attached to the iliac crest, covers the iliac fascia and the obturator internus fascia, and extends downward and medially to form the superior fascia of the pelvic diaphragm.

[2] Characteristically, the transversalis fascia continues along blood vessels and other structures leaving and entering the abdominopelvic cavity and contributes to the formation of the visceral (*endopelvic*) pelvic fascia (41)**. The pelvic fascia invests the pelvic organs and attaches them to the pelvic sidewalls, thereby playing a critical role in *pelvic support.*** In the inguinal region, the fascial relationships result in the development of the inguinal canal, through which the round ligament exits into the perineum. The fascia is separated from the peritoneum by a layer of preperitoneal fat. Areas of fascial weakness or congenital or posttraumatic and surgical injuries result in herniation of the underlying structures through a defective abdominal wall. The incisions least likely to result in damage to the integrity and innervation of the abdominal wall muscles include a midline incision through the linea alba and a transverse incision through the recti muscle fibers that respects the integrity of its innervation (42).

Nerves and Vessels

The tissues of the abdominal wall are innervated by the continuation of the inferior intercostal nerves T4 to T11 and the subcostal nerve T12. The inferior part of the abdominal wall is supplied by the first lumbar nerve through the iliohypogastric and the ilioinguinal nerves. **Abdominal wall surgical sites below the level of the anterior superior iliac spine have the potential for ilioinguinal or iliohypogastric nerve injury**. Injury to these nerves occurs in approximately 4% of Pfannenstiel incisions (43,44). The primary blood supply to the anterior lateral abdominal wall includes the following:

1. The **inferior epigastric and deep circumflex iliac arteries,** branches of the external iliac artery
2. The **superior epigastric artery,** a terminal branch of the internal thoracic artery

The inferior epigastric artery runs superiorly in the transverse fascia to reach the arcuate line, where it enters the rectus sheath. It is vulnerable to damage by abdominal incisions in which the rectus muscle is completely or partially transected, during placement of lateral laparoscopic ports, or by excessive lateral traction on the rectus. The deep circumflex artery runs on the deep aspect of the anterior abdominal wall parallel to the inguinal ligament and along the iliac crest between the transverse abdominis muscle and the internal oblique muscle. The superior epigastric

vessels enter the rectus sheath superiorly just below the seventh costal cartilage.

The venous system drains into the saphenous vein, and the lymphatics drain to the axillary chain above the umbilicus and to the inguinal nodes below it. The subcutaneous tissues drain to the lumbar chain.

Abdominal Anatomy

Greater Omentum

When the abdomen and peritoneum are opened, the first structure encountered is the greater omentum. The greater omentum is a fold of visceral peritoneum that hangs like an apron over the small and large intestines. It is attached cranially to the greater curvature of the stomach and doubles back to attach to the transverse colon. Lifting the omentum reveals the large intestine on the periphery surrounding coils of small bowel. The blood supply is provided by the right and left gastroepiploic arteries, which anastomose within the anterior greater omentum.

Lesser Omentum

The lesser omentum arises from the lesser curvature of the stomach and extends to the liver. The hepatic artery, the common bile duct, the portal vein, the hepatic plexus of nerves, and lymphatics run in between the two layers of the lesser omentum. An arterial loop formed by the anastomosis of the left gastric artery and right gastric branch of the hepatic artery runs along the attachment to the stomach.

Small Intestine

The small intestine is a convoluted tube measuring approximately 6 m long, which extends from the suspensory ligament of the duodenum (ligament of Treitz) to the ileocecal valve. The small intestine is divided into three portions: the duodenum, jejunum, and the ileum. The shortest portion of the bowel is the duodenum (25 cm), which consists of four parts. The major portion of the small intestine consists of the jejunum and ileum. The jejunum and ileum are attached to the posterior abdominal wall by a mesentery that allows each coil to accommodate itself to changes in form and position. The root of the mesentery is about 15 to 20 cm long and extends obliquely from the duodenojejunal flexure to the right colon.

Blood Supply

The duodenum is supplied by branches originating from the celiac trunk. The jejunum and ileum are supplied by branches of the superior mesenteric artery. Venous drainage occurs via the superior mesenteric vein to the portal vein.

Large Intestine

The large intestine extends from the end of the ileum to the anus and consists of the

cecum, ascending colon, transverse colon, descending colon, sigmoid colon, rectum, and anus. It is about 1.5 m long and is anchored to the parietal peritoneum along the right and left gutters. The cecum is situated in the right iliac fossa above the lateral half of the inguinal ligament. The vermiform appendix is found off the inferior side of the cecum. The ascending colon passes upward, opposite the colic valve to the undersurface of the right lobe of the liver, on the right side of the gallbladder. It abruptly bends forward and to the left, forming the right colic flexure. The transverse colon is the longest and most moveable part of the colon. It curves sharply on itself beneath the lower end of the spleen, forming the left colic flexure. The descending colon passes downward along the lateral border of the left kidney and then descends to the crest of the ileum where it ends in the iliac colon.

Blood Supply

The blood supply to the large intestine is derived from the colic and sigmoid branches of the mesenteric arteries. The superior mesenteric artery supplies the right colon and transverse colon; the inferior mesenteric artery supplies the left flexure, left sigmoid colon, and the upper two-thirds of rectum; and the internal pudendal artery supplies the anus and lower rectum. The venous drainage mirrors the colonic arterial supply with the inferior mesenteric vein draining into the splenic vein and the superior mesenteric vein joining the splenic vein to form the hepatic portal vein.

Perineum

The perineum is situated at the lower end of the trunk between the buttocks. Its bony boundaries include the lower margin of the pubic symphysis anteriorly, the tip of the coccyx posteriorly, and the ischial tuberosities laterally. These landmarks correspond to the boundaries of the pelvic outlet. The diamond shape of the perineum is customarily divided by an imaginary line joining the ischial tuberosities immediately in front of the anus, at the level of the perineal body, into an anterior urogenital and a posterior anal triangle **(Fig. 5-19)**.

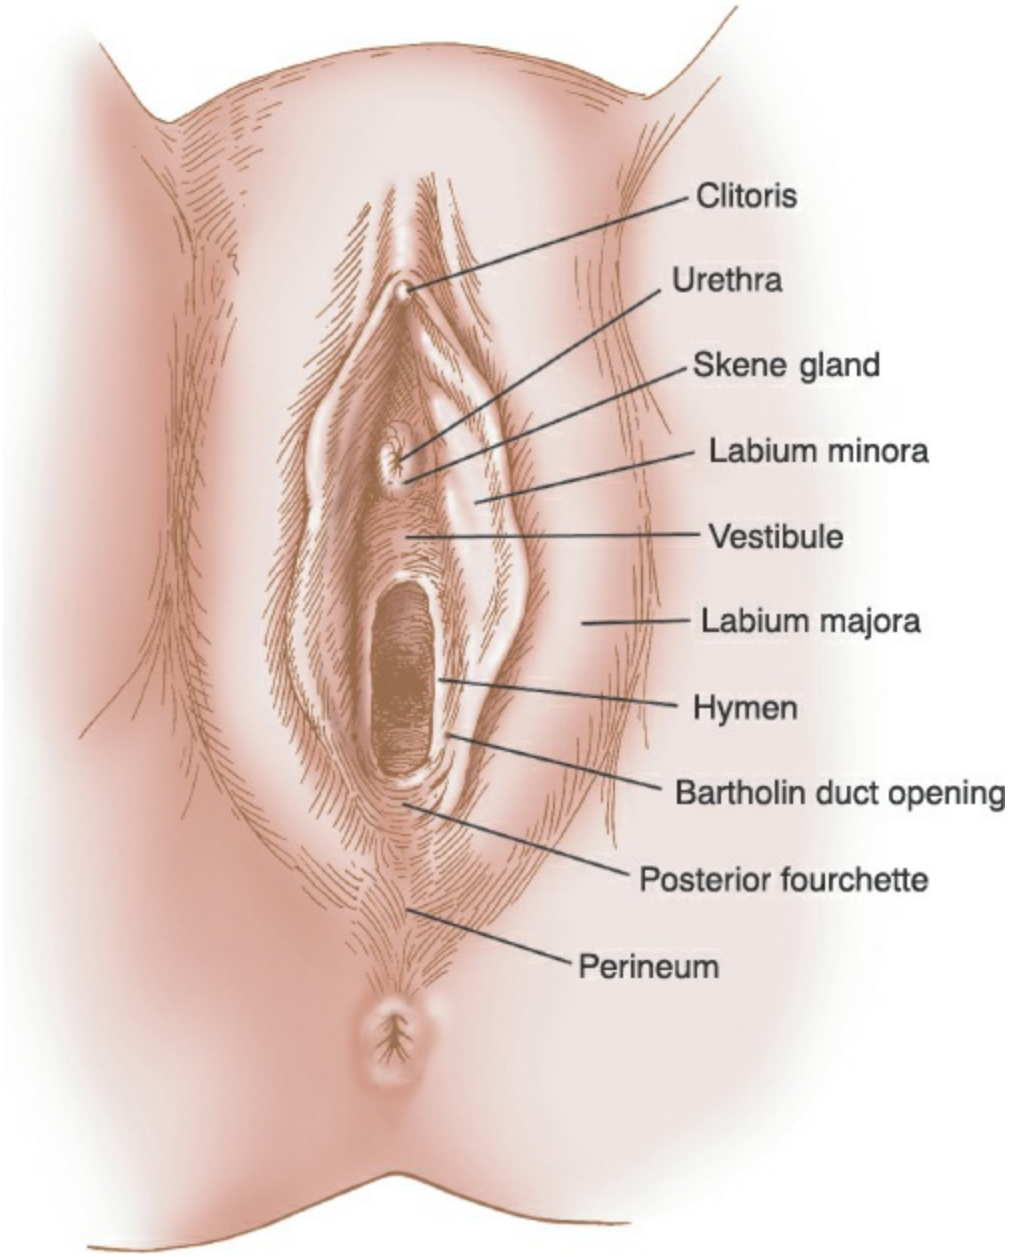

FIGURE 5-19 Vulva and perineum.

Urogenital Triangle

The urogenital triangle includes the external genital structures and the urethral opening (Fig. 5-19). These external structures cover the superficial and deep perineal compartments and are known as the *vulva* (Figs. 5-20 and 5-21).

Vulva

Mons Pubis

The mons pubis is a triangular eminence in front of the pubic bones that consists of adipose tissue covered by hair-bearing skin up to its junction with the abdominal

wall.

Labia Majora

The labia majora are a pair of fibroadipose folds of skin that extend from the mons pubis downward and backward to meet in the midline in front of the anus at the posterior fourchette. They include the terminal extension of the round ligament and occasionally a peritoneal diverticulum, the *canal of Nuck.* They are covered by skin with scattered hairs laterally and are rich in sebaceous, apocrine, and eccrine glands.

Labia Minora

The labia minora lie between the labia majora, with which they merge posteriorly, and are separated into two folds anteriorly as they approach the clitoris. The anterior folds unite to form the prepuce or hood of the clitoris. The posterior folds form the frenulum of the clitoris as they attach to its inferior surface. The labia minora are covered by hairless skin overlying a fibroelastic stroma rich in neural and vascular elements. The area between the posterior labia minora forms the vestibule of the vagina.

Clitoris

The clitoris is an erectile organ that is 2 to 3 cm in length. It consists of two crura and two corpora cavernosa and is covered by a sensitive rounded tubercle (the glans).

Vaginal Orifice

The vaginal orifice is surrounded by the *hymen*, a variable crescentic mucous membrane that is replaced by rounded caruncles after its rupture. The opening of the duct of the *greater vestibular* (*Bartholin*) *glands* is located on each side of the vestibule. Numerous lesser vestibular glands are scattered posteriorly and between the urethral and vaginal orifices.

Urethral Orifice

The urethral orifice is immediately anterior to the vaginal orifice and about 2 to 3 cm beneath the clitoris. The *Skene* (*paraurethral*) *gland* duct presents an opening on its posterior surface.

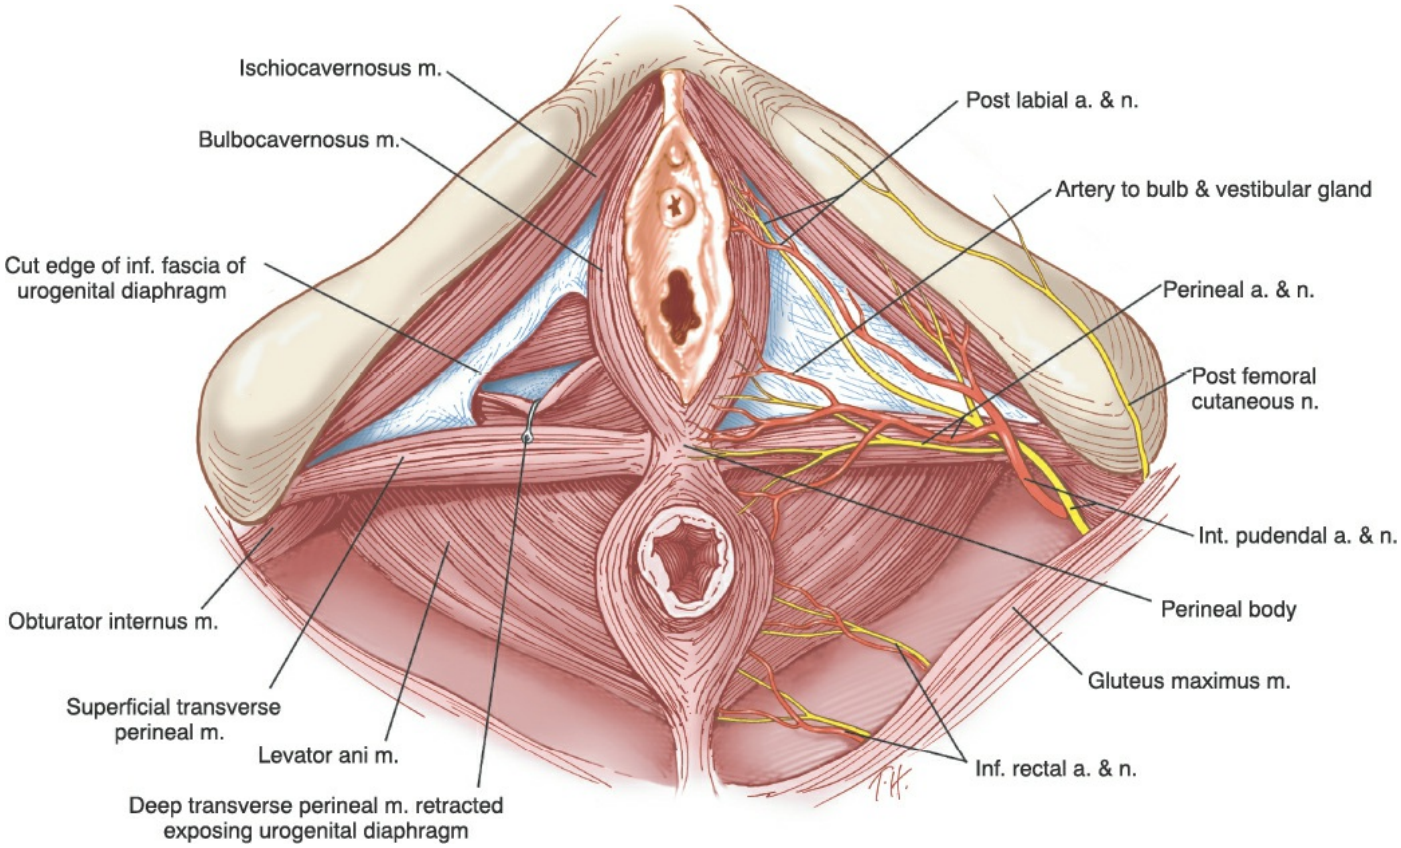

FIGURE 5-20 Superficial perineal compartment.

Superficial Perineal Compartment

The superficial perineal compartment lies between the superficial perineal fascia and the inferior fascia of the urogenital diaphragm (perineal membrane) (Fig. 5-20). The superficial perineal fascia has superficial and deep components. **The superficial layer is relatively thin and fatty and is continuous superiorly with the superficial fatty layer of the lower abdominal wall (*Camper fascia*)**. It continues laterally as the fatty layer of the thighs. The deep layer of the superficial perineal (*Colles*) fascia is continuous superiorly with the deep layer of the superficial abdominal fascia (*Scarpa fascia*), which attaches to the ischiopubic rami and ischial tuberosities. **The superficial perineal compartment is continuous superiorly with the superficial fascial spaces of the anterior abdominal wall, allowing spread of blood or infection along that route**. Such spread is limited laterally by the ischiopubic rami, anteriorly by the transverse ligament of the perineum, and posteriorly by the superficial transverse perineal muscle. The superficial perineal compartment includes the following:

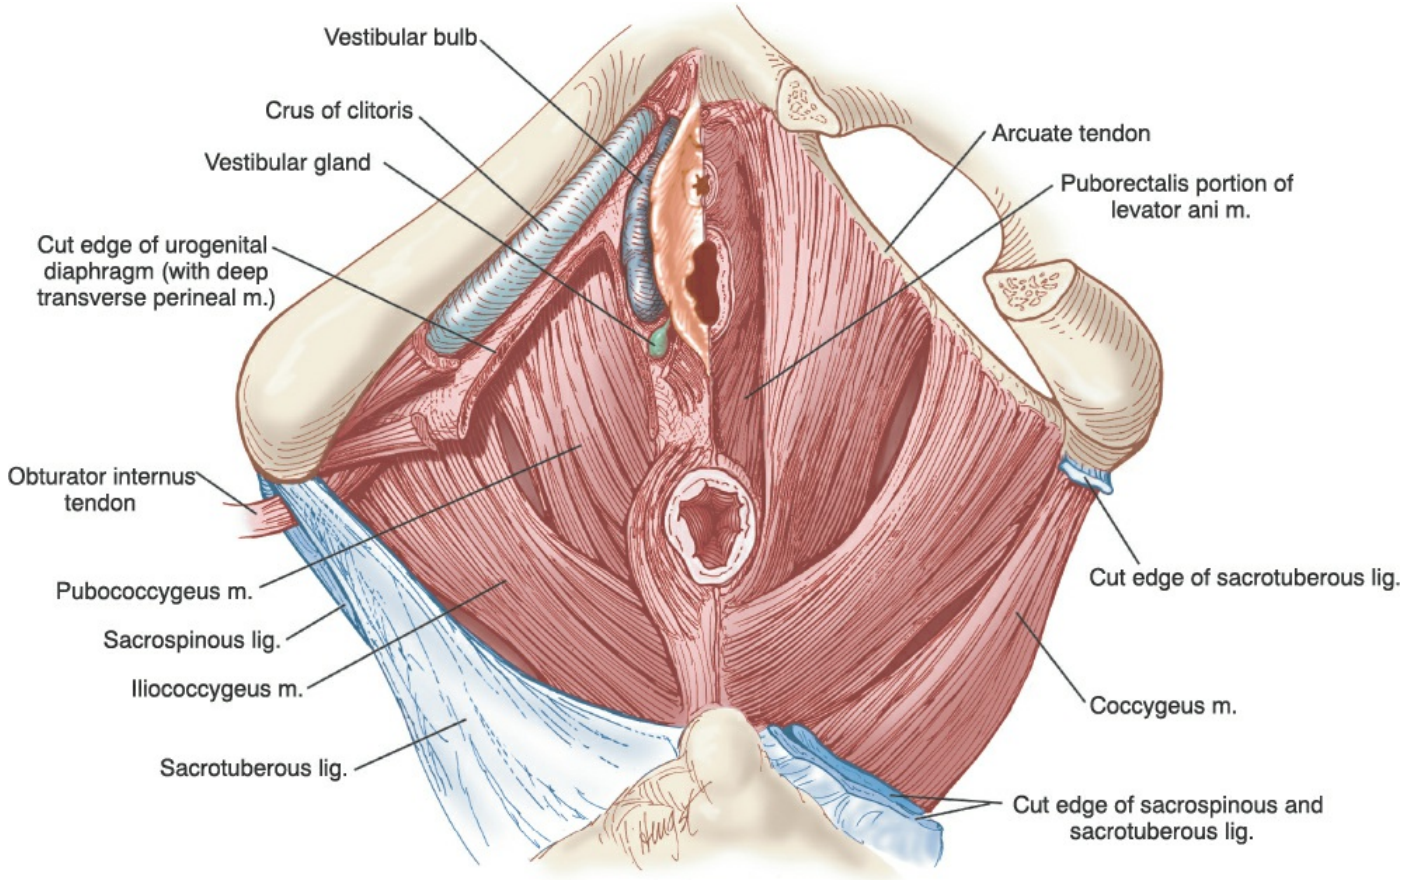

FIGURE 5-21 Deep perineal compartment.

Erectile Bodies

The vestibular bulbs are 3-cm, highly vascular structures surrounding the vestibule and located under the bulbocavernosus muscle. The body of the clitoris is attached by two crura to the internal aspect of the ischiopubic rami. The crura are covered by the ischiocavernosus muscles.

Muscles

The muscles of the vulva are the ischiocavernosus, the bulbocavernosus, and superficial transverse perineal. They are included in the superficial perineal compartment as follows:

Ischiocavernosus

- Origin—ischial tuberosity
- Insertion—ischiopubic bone
- Action—compresses the crura and lowers the clitoris

Bulbocavernosus

- Origin—perineal body

- Insertion—posterior aspect of the clitoris; some fibers pass above the dorsal vein of the clitoris in a sling-like fashion
- Action—compresses the vestibular bulb and dorsal vein of the clitoris

Superficial Transverse Perineal

- Origin—ischial tuberosity
- Insertion—central perineal tendon
- Action—fixes the perineal body

Vestibular Glands

The vestibular glands are situated on either side of the vestibule under the posterior end of the vestibular bulb. They drain between the hymen and the labia minora. Their mucous secretion helps maintain adequate lubrication. Infection in these glands can result in an abscess.

Deep Perineal Compartment

The deep perineal compartment is a fascial space bound inferiorly by the perineal membrane and superiorly by a deep fascial layer that separates the urogenital diaphragm from the anterior recess of the ischiorectal fossa (Fig. 5-21). It is stretched across the anterior half of the pelvic outlet between the ischiopubic rami. The deep compartment may be directly continuous superiorly with the pelvic cavity (45). The posterior pubourethral ligaments, functioning as wing-like elevations of the fascia ascending from the pelvic floor to the posterior aspect of the symphysis pubis, provide a point of fixation to the urethra and support the concept of the continuity of the deep perineal compartment with the pelvic cavity.

The anterior pubourethral ligaments represent a similar elevation of the inferior fascia of the urogenital diaphragm and are joined by the intermediate pubourethral ligament, with the junction between the two fascial structures arcing under the pubic symphysis (46). The urogenital diaphragm includes the *sphincter urethrae* (*urogenital sphincter*) and the *deep transverse perineal* (*transversus vaginae*) muscle.

The urogenital diaphragm (perineal membrane) is composed of two regions: one dorsal and one ventral. The dorsal portion consists of bilateral transverse fibrous sheets that attach the lateral wall of the vagina and perineal body to the ischiopubic ramus. This portion is devoid of striated muscle. The ventral portion is part of a solid three-dimensional tissue mass in which several structures are embedded. It is intimately associated with the compressor urethrae and the urethrovaginal sphincter muscles of the distal uretha. In this region the perineal membrane is continuous with the insertion of the arcus tendineus fasciae pelvis. The levator ani muscles are connected with the cranial surface of the perineal membrane. The vestibular bulb and clitoral crus are fused with

the membrane's caudal surface (47).

The sphincter urethrae **(Fig. 5-22)** is a continuous muscle fanning out as it develops proximally and distally, including the following:

1. **External urethral sphincter**, which surrounds the middle third of the urethra
2. **Compressor urethrae**, arcing across the ventral side of the urethra
3. **Urethrovaginal sphincter**, which surrounds the ventral aspect of the urethra and terminates in the lateral vaginal wall

The deep transverse perineal muscle originates at the internal aspect of the ischial bone, parallels the muscle compressor urethrae, and attaches to the lateral vaginal wall along the perineal membrane. Studies show that a smaller striated urogenital sphincter is associated with stress incontinence and poorer pelvic floor muscle function (48).

The urinary and genital tracts have a common reliance on several interdependent structures for support. **The cardinal and uterosacral ligaments are condensations of endopelvic fascia that support the cervix and upper vagina over the levator plate. Laterally, endopelvic fascial condensations attach the midvagina to the pelvic walls at the arcus tendineus fasciae pelvis anteriorly and the arcus tendineus levator ani posteriorly. The distal anterior vagina and urethra are anchored to the urogenital diaphragm and the distal posterior vagina to the perineal body.**

Anteriorly, the pubourethral ligaments and pubovesical fascia and ligaments provide fixation and stabilization for the urethra and bladder. Posteriorly, they rely on the vagina and lower uterus for support. Partial resection or relaxation of the uterosacral ligaments often leads to relaxation of the genitourinary complex, resulting in the formation of a cystocele. Studies indicate that half of the observed variation in anterior compartment support may be explained by apical support (49). Various types and degrees of genital tract prolapse or relaxation are almost always associated with similar findings in the bladder, urethra, or both.

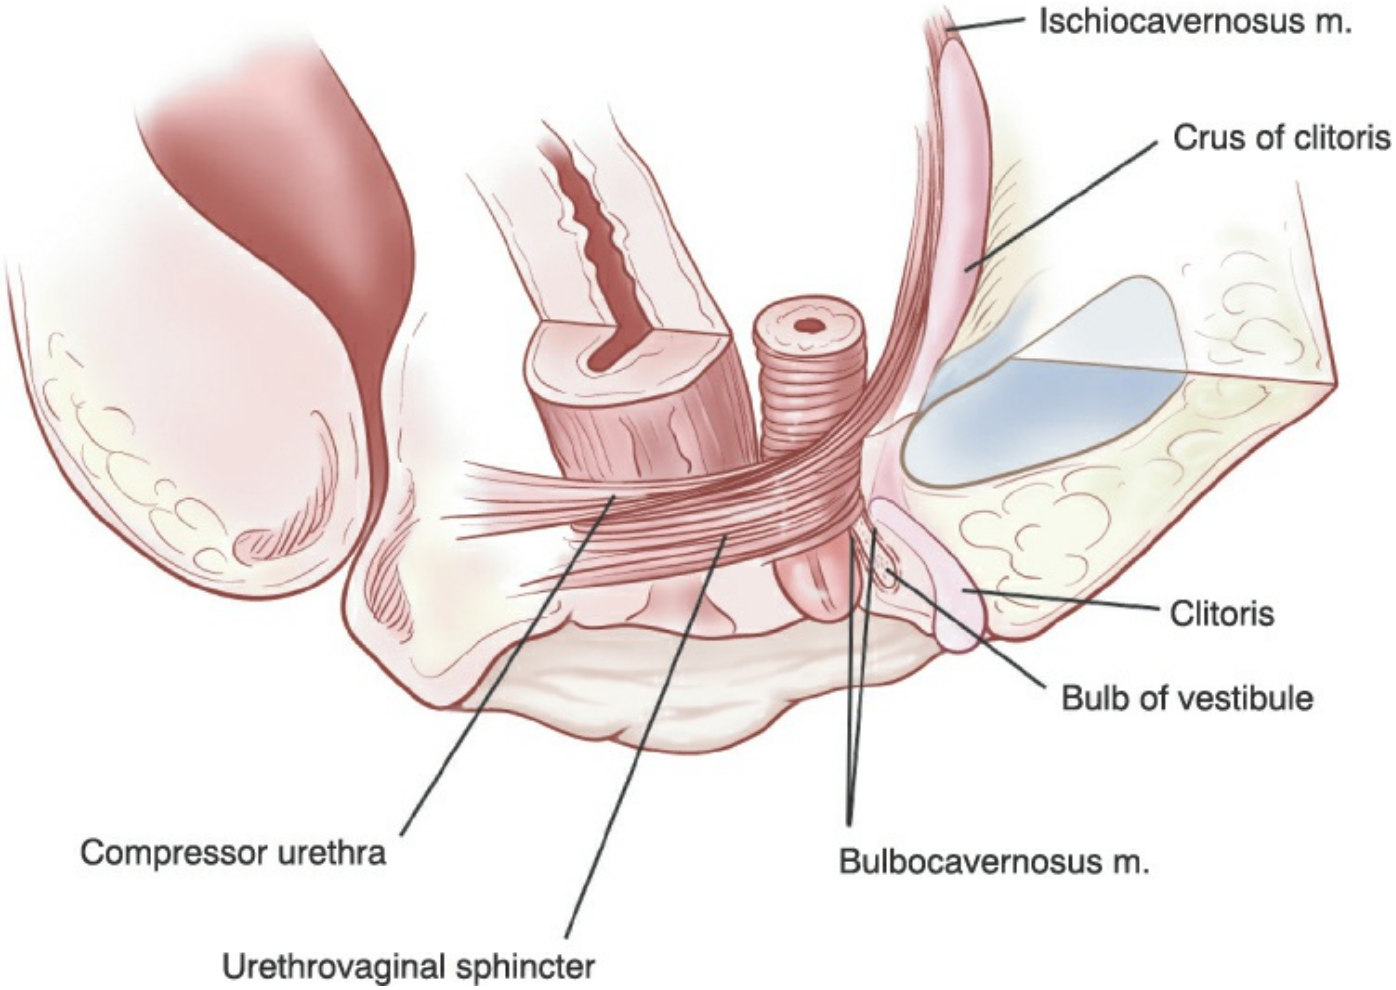

FIGURE 5-22 The complete urogenital sphincter musculature, bladder, and vagina. (Redrawn from **Haderer JM, Pannu HK, Genadry R, et al**. Controversies in female urethral anatomy and their significance for understanding urinary continence: observations and literature review. *Int Urogynecol J Pelvic Floor Dysfunct* 2002;13:236–252, with permission.)

[2] There are three levels of vaginal support as described by DeLancey (Fig. 5-23) (50). Level I support consists of paracolpium that suspends the apical portion of the vagina and is comprised of the cardinal–uterosacral ligament complex. Level II support comprises the paracolpium that is attached to the vagina laterally via the arcus tendineus fasciae pelvis and superior fascia of the levator ani. Level III support consists of the distal vaginal attachments: anteriorly, via fusion of the urethra to the vagina; laterally, to the levators; and posteriorly, with the perineal body.

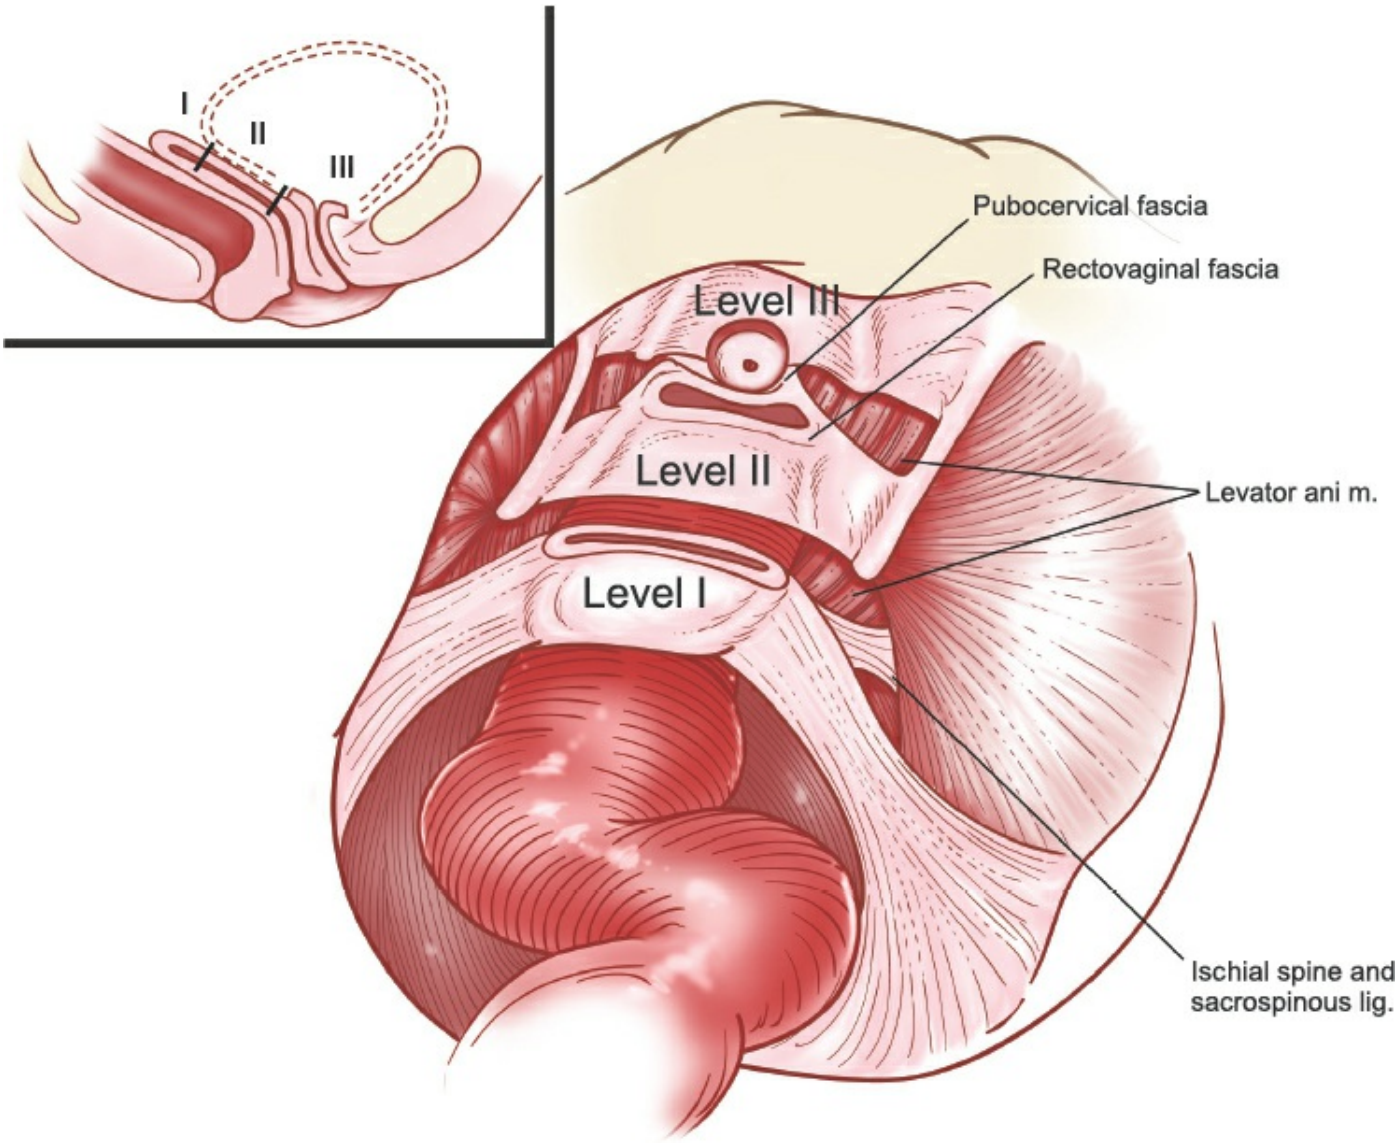

FIGURE 5-23 DeLancey levels of support. (Modified from **DeLancey JO**. Anatomic aspects of vaginal eversion after hysterectomy. *Am J Obstet Gynecol* 1992;166:17–28, with permission.)

Clinical Relevance

[2] Disruption of level I support may lead to prolapse of the uterus or vaginal vault, while damage to level II and III supports predispose to anterior and posterior vaginal prolapse. All levels of defective support should be repaired during reconstructive surgery.

Blood Supply

The blood supply to the vulva is as follows:

1. External pudendal artery (from femoral artery), internal pudendal artery
2. Venous drainage—internal pudendal veins

The blood supply to the superficial and deep perineal compartments is as follows:

1. Internal pudendal artery, dorsal artery of the clitoris
2. Venous drainage—internal pudendal veins, which are richly anastomotic
3. Lymphatic drainage—internal iliac chain

Innervation

The innervation to the vulva is from branches of the following nerves:

1. Ilioinguinal nerve
2. Genitofemoral nerve (genital branch)
3. Lateral femoral cutaneous nerve of the thigh (perineal branch)
4. Perineal nerve (branch of pudendal)
5. Superficial and deep perineal compartments, innervated by the perineal nerve

Perineal Body

The perineal body or central perineal tendon is critical to the posterior support of the lower aspect of the anterior vaginal wall. It is a triangle-shaped structure separating the distal portion of the anal and vaginal canals that is formed by the convergence of the tendinous attachments of the bulbocavernosus, the external anal sphincter, and the superficial transverse perineal muscle. Its superior border represents the point of insertion of the *rectovaginal* (*Denonvilliers*) *fascia*, which extends to the underside of the peritoneum covering the cul-de-sac of Douglas, separating the anorectal from the urogenital compartment (51). The perineal body plays an important anchoring role in the musculofascial support of the pelvic floor. It represents the central connection between the two layers of support of the pelvic floor—the pelvic and urogenital diaphragm. It also provides a posterior connection to the anococcygeal raphe. Thus, it is central to the definition of the bi-level support of the floor of the pelvis.

Anal Triangle

The anal triangle includes the lower end of the anal canal. The external anal sphincter surrounds the anal triangle, and the ischiorectal fossa is on each side. Posteriorly, the *anococcygeal body* lies between the anus and the tip of the coccyx and consists of thick fibromuscular tissue (of levator ani and external anal sphincter origin) giving support to the lower part of the rectum and the anal canal.

The *external anal sphincter* forms a thick band of muscular fibers arranged in three layers running from the perineal body to the anococcygeal ligament. The subcutaneous fibers are thin and surround the anus and, without bony attachment, decussate in front of it. The superficial fibers sweep forward from the anococcygeal ligament and tip of the coccyx, go around the anus, and insert into the perineal body. The deep fibers arise from the perineal body to encircle the lower half of the anal canal to form a true sphincter muscle, which fuses with the puborectalis portion of the levator

ani.

The *ischiorectal fossa* is mainly occupied by fat and separates the ischium laterally from the median structures of the anal triangle. It is a fascia-lined space located inferiorly between the perineal skin and the pelvic diaphragm superiorly; it communicates with the contralateral ischiorectal fossa over the anococcygeal ligament. Superiorly, its apex is at the origin of the levator ani muscle from the obturator fascia. It is bound medially by the levator ani and the external sphincter with their fascial covering, laterally by the obturator internus muscle with its fascia, posteriorly by the sacrotuberous ligament and the lower border of the gluteus maximus muscle, and anteriorly by the base of the urogenital diaphragm. It is widest and deepest posteriorly and weakest medially.

An ischiorectal abscess should be drained without delay, or it will extend into the anal canal. The cavity is filled with fat that cushions the anal canal and is traversed by many fibrous bands, vessels, and nerves, including the pudendal and the inferior rectal nerves. The perforating branch of S2 and S3 and the perineal branch of S4 run through this space.

The *pudendal (Alcock) canal* is a tunnel formed by a splitting of the inferior portion of the obturator fascia running anteromedially from the ischial spine to the posterior edge of the urogenital diaphragm. It contains the pudendal artery, vein, and nerve in their traverse from the *pelvic* cavity to the perineum.

Blood Supply

The blood supply to the anal triangle is from the inferior rectal (hemorrhoidal) artery and vein.

Innervation

The innervation to the anal triangle is from the perineal branch of the fourth sacral nerve and the inferior rectal (hemorrhoidal) nerve.

Retroperitoneum and Retroperitoneal Spaces

The subperitoneal area of the true pelvis is partitioned into potential spaces by the various organs and their respective fascial coverings and by the selective thickenings of the endopelvic fascia into ligaments and septa (Fig. 5-24). It is imperative that surgeons operating in the pelvis be familiar with these spaces, as discussed below.

Prevesical Space

The prevesical (Retzius) space is a fat-filled potential space bound anteriorly by the pubic bone, covered by the transversalis fascia, and extending to the umbilicus between the medial umbilical ligaments (obliterated umbilical arteries); posteriorly,

the space extends to the anterior wall of the bladder. It is separated from the paravesical space by the ascending bladder septum (bladder pillars).

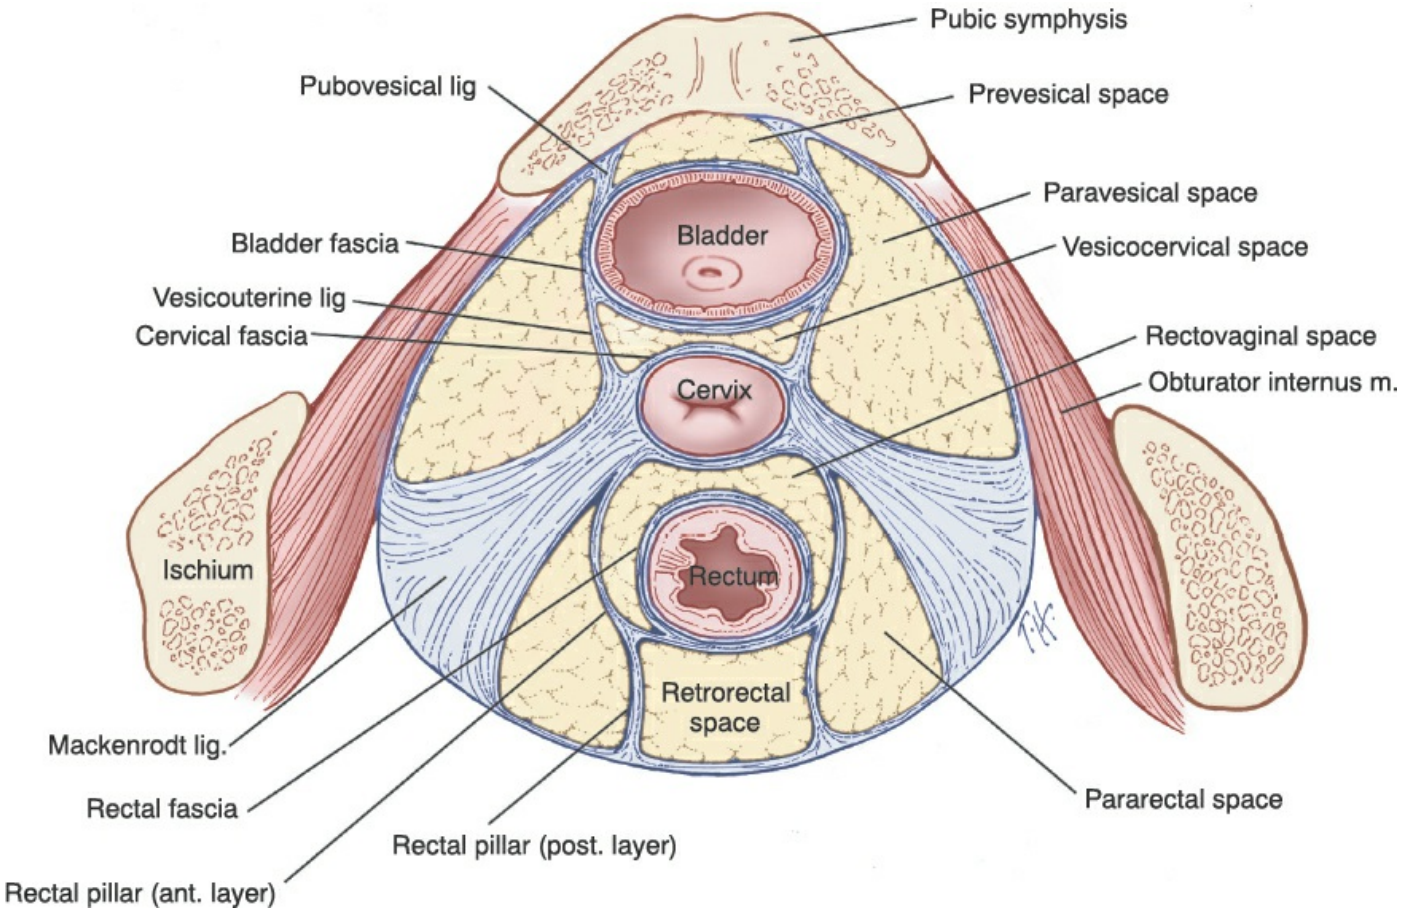

FIGURE 5-24 Schematic sectional drawing of the pelvis shows the firm connective tissue covering. The bladder, cervix, and rectum are surrounded by a connective tissue covering. The Mackenrodt ligament extends from the lateral cervix to the lateral abdominal pelvic wall. The vesicouterine ligament originating from the anterior edge of the Mackenrodt ligament leads to the covering of the bladder on the posterior side. The sagittal rectal column spreads both to the connective tissue of the rectum and the sacral vertebrae closely nestled against the back of the Mackenrodt ligament and lateral pelvic wall. Between the firm connective tissue bundles is loose connective tissue (paraspaces). (From **Von Peham H, Amreich JA.** *Gynaekologische Operationslehre*. Berlin, Germany: S Karger; 1930, with permission.)

[3] Upon entering the prevesical space, the pubourethral ligaments may be seen inserting into the posterior aspect of the symphysis pubis as a thickened prolongation of the arcus tendineus fasciae. With combined abdominal and vaginal bladder neck suspensory procedures, the point of entry is usually the Retzius space between the arcus tendineus and the pubourethral ligaments. During a Burch retropubic colposuspension, the sutures are placed into the iliopectineal line or Cooper ligament. The sutures should be carefully anchored to avoid bleeding from the venous plexus of Santorini, which lies in the space lateral to the bladder neck and urethra.

Paravesical Spaces

The paravesical spaces are fat filled and limited by the fascia of the obturator internus muscle and the pelvic diaphragm laterally, the bladder pillar medially, the endopelvic fascia inferiorly, the lateral umbilical ligament superiorly, the cardinal ligament posteriorly, and the pubic bone anteriorly. The paravesical spaces are developed by blunt dissection during a radical hysterectomy to access the parametria containing the cervical lymphatic system.

Vesicovaginal Space

The vesicovaginal space is separated from the Retzius space by the endopelvic fascia. This space is limited anteriorly by the bladder wall (from the proximal urethra to the upper vagina), posteriorly by the anterior vaginal wall, and laterally by the bladder septa (selective thickenings of the endopelvic fascia inserting laterally into the arcus tendineus). **A tear in these fascial investments and thickenings medially, transversely, or laterally allows herniation and development of a cystocele.**

Rectovaginal Space

The rectovaginal space extends between the vagina and the rectum from the superior border of the perineal body to the underside of the rectouterine Douglas pouch. It is bound anteriorly by the rectovaginal septum (firmly adherent to the posterior aspect of the vagina), posteriorly by the anterior rectal wall, and laterally by the descending rectal septa separating the rectovaginal space from the pararectal space on each side. The rectovaginal septum represents a firm membranous transverse septum dividing the pelvis into rectal and urogenital compartments, allowing the independent function of the vagina and rectum, and providing support for the rectum. It is fixed laterally to the pelvic sidewall by rectovaginal fascia (part of the endopelvic fascia) along a line extending from the posterior fourchette to the arcus tendineus fasciae pelvis, midway between the pubis and the ischial spine (52). An anterior rectocele often results from a defective *septum* or an avulsion of the septum from the perineal body. Reconstruction of the perineum is critical for the restoration of this important compartmental separation and for the support of the anterior vaginal wall (53). **[2] Lateral detachment of the rectovaginal fascia from the pelvic sidewall may constitute a "pararectal" defect analogous to anterior paravaginal defects.**

Pararectal Space

The pararectal space is bound laterally by the levator ani, medially by the rectal pillars, and posteriorly above the ischial spine by the anterolateral aspect of the sacrum. It is separated from the retrorectal space by the posterior extension of the descending rectal septa.

Retrorectal Space

The retrorectal space is limited by the rectum anteriorly and the anterior aspect of the sacrum posteriorly. It communicates with the pararectal spaces laterally above the uterosacral ligaments and extends superiorly into the presacral space.

Presacral Space

The presacral space is the superior extension of the retrorectal space and is limited by the deep parietal peritoneum anteriorly and the anterior aspect of the sacrum posteriorly. It harbors the middle sacral vessels and the hypogastric plexuses between the bifurcation of the aorta invested by loose areolar tissue. Presacral neurectomy requires familiarity with and working knowledge of this space. **[3] Abdominal sacrocolpopexy involves dissection in the presacral space down to the anterior longitudinal ligament, which is the point of fixation for the tail of the Y-shaped mesh graft. The surgical space is bound superiorly by the bifurcation of the great vessels and laterally by the ureter on the right and the mesentery of the sigmoid colon and the left common iliac vein on the left. The presacral venous plexus covers the anterior aspect of the sacrum and can bleed profusely if lacerated during dissection. The middle sacral artery often lies just to the left of the midsacral promontory and is most likely to be injured as the needle exits the tissue. The left iliac vein lies medial to the left iliac artery bounding this space and is more prone to injury during laparoscopic entry or presacral dissection.**

Peritoneal Cavity

The female pelvic organs lie at the bottom of the abdominopelvic cavity covered superiorly and posteriorly by the small and large bowel. Anteriorly, the uterine wall is in contact with the posterosuperior aspect of the bladder. The uterus is held in position by the following structures:

1. The **round ligaments** coursing inferolaterally toward the internal inguinal ring
2. The **uterosacral ligaments**, which provide support to the cervix and upper vagina and interdigitate with fibers from the cardinal ligament near the cervix
3. The **cardinal ligaments**, which provide support to the cervix and upper vagina and contribute to the support of the bladder

Anteriorly, the uterus is separated from the bladder by the vesicouterine pouch and from the rectum posteriorly by the rectouterine pouch or Douglas cul-de-sac. Laterally, the bilateral broad ligaments carry the neurovascular pedicles and their respective fascial coverings, attaching the uterus to the lateral pelvic sidewall.

The broad ligament is in contact inferiorly with the paravesical space, the obturator fossa, the pelvic extension of the iliac fossa to which it provides a

peritoneal covering, and the uterosacral ligament. Superiorly, it extends into the infundibulopelvic ligament.

Ureter

In its pelvic path in the retroperitoneum, several relationships are of significance and identify areas of greatest vulnerability to injury of the ureter (Fig. 5-25):

1. **The ovarian vessels cross over the ureter as it approaches the pelvic brim and lie in lateral proximity to the ureter as it enters the pelvis.**
2. **As the ureter descends into the pelvis, it runs within the broad ligament just lateral to the uterosacral ligament, separating the uterosacral ligament from the mesosalpinx, mesovarium, and ovarian fossa.**
3. **At the approximate level of the ischial spine, the ureter crosses under the uterine artery in its course through the cardinal ligament ("bridge over water" relationship); the ureter divides this area into the supraureteric parametrium surrounding the uterine vessels and the infraureteric paracervix molded around the vaginal vessels and extending posteriorly into the uterosacral ligament. In this location, the ureter lies 2 to 3 cm lateral to the cervix and in proximity to the insertion of the uterosacral ligament at the cervix. This proximity warrants caution when using the uterosacral ligament for vaginal vault suspension** (54,55).
4. **The ureter turns medially here to cross the anterior upper vagina as it traverses the bladder wall.**

[5] About 75% of all iatrogenic injuries to the ureter result from gynecologic procedures (56,57). Laparoscopic hysterectomies have the highest rate of ureteral injuries and vaginal hysterectomies the lowest (58,59). Distortions of pelvic anatomy, including adnexal masses, endometriosis, other pelvic adhesive disease, or fibroids, may increase susceptibility to injury by displacement or alteration of usual anatomy. Ninety-one percent of injuries occur at the level of the pelvic ureter and only 2% and 7% occur at the upper and middle ureteral thirds, respectively (60). **Careful identification of the course of the ureter before securing the infundibulopelvic ligament and uterine artery is the best protection against ureteric injury during hysterectomy or adnexectomy. Even with severe intraperitoneal disease, the ureter can always be identified using a retroperitoneal approach and noting fundamental landmarks and relationships.**

Pelvic Floor

The pelvic floor includes all of the structures closing the pelvic outlet from the skin inferiorly to the peritoneum superiorly. It is commonly divided by the pelvic diaphragm into a pelvic and a perineal portion (61). The pelvic diaphragm is spread transversely in a hammock-like fashion across the true pelvis, with a central hiatus for the urethra, vagina, and rectum. Anatomically and physiologically, the pelvic diaphragm can be divided into two components: the internal and external components.

The *external component* originates from the arcus tendineus, extending from the pubic bone to the ischial spine. It gives rise to fibers of differing directions, including the *pubococcygeus*, the *iliococcygeus*, and the *coccygeus*.

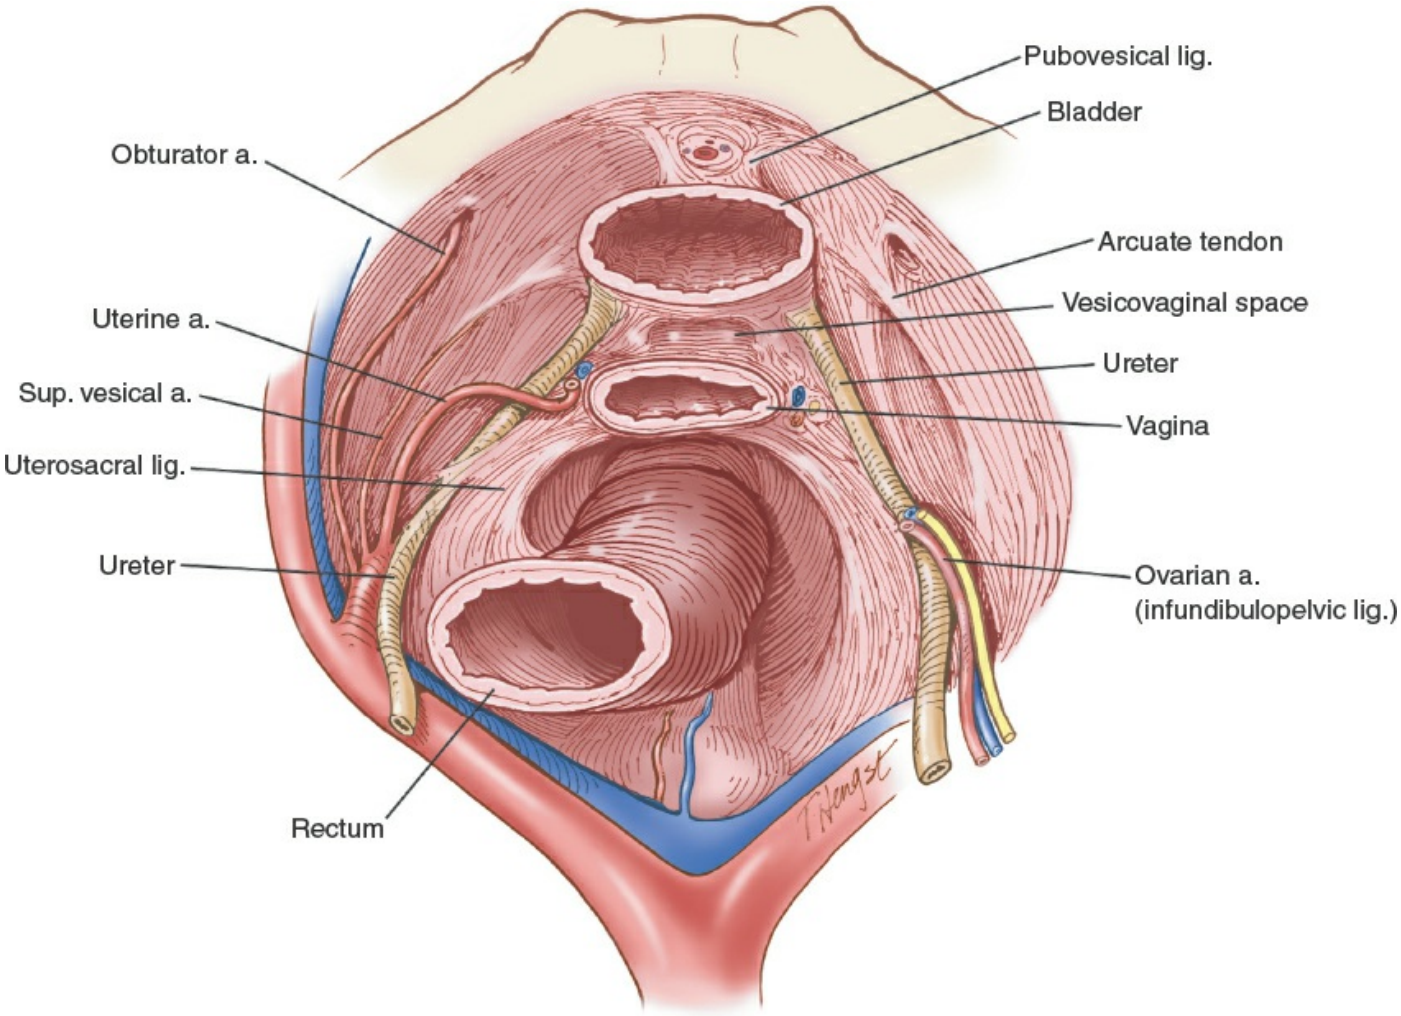

FIGURE 5-25 The course of the ureter and its relationship to the sites of greatest vulnerability.

The *internal component* originates from the pubic bone above and medial to the origin of the pubococcygeus and is smaller but thicker and stronger (61). Its fibers run in a sagittal direction and are divided into the following two portions:

1. *Pubovaginalis* fibers run in a perpendicular direction to the urethra, crossing the lateral vaginal wall at the junction of its lower one-third and upper two-thirds to

insert into the perineal body. The intervening anterior interlevator space is covered by the urogenital diaphragm.
2. *Puborectalis* superior fibers sling around the rectum to the symphysis pubis; its inferior fibers insert into the lateral rectal wall between the internal and external sphincter.

The pelvic diaphragm is covered superiorly by fascia, which includes a parietal and a visceral component and is a continuation of the transversalis fascia (Fig. 5-26). The parietal fascia has areas of thickening (ligaments, septa) that provide reinforcement and fixation for the pelvic floor. **The visceral (*endopelvic*) fascia extends medially to invest the pelvic viscera, resulting in a fascial covering to the bladder, vagina, uterus, and rectum. It becomes attenuated where the peritoneal covering is well defined and continues laterally with the pelvic cellular tissue and neurovascular pedicles**.

Musculofascial elements (the hypogastric sheath) extend along the vessels originating from the internal iliac artery. Following these vessels to their respective organs, the hypogastric sheath extends perivascular investments that contribute to the formation of the endopelvic fascia so critical for the support of the pelvic organs.

Thus, the parietal fascia anchors the visceral fascia, which defines the relationship of the various viscera and provides them with significant fixation (uterosacral and cardinal ligaments), septation (vesicovaginal and rectovaginal), and definition of pelvic spaces (prevesical, vesicovaginal, rectovaginal, paravesical, pararectal, and retrorectal).

For its support, the pelvic floor relies on the complementary role of the pelvic diaphragm and its fascia resting on the perineal fibromuscular complex. It is composed of the perineal membrane (urogenital diaphragm) anteriorly and the perineal body joined to the anococcygeal raphe by the external anal sphincter posteriorly. This double-layered arrangement, when intact, provides optimal support for the pelvic organs and counterbalances the forces pushing them downward with gravity and with any increase in intra-abdominal pressure **(Fig. 5-27)**. Dynamic imaging techniques, such as MRI, CT, and ultrasonography, increasingly are used to provide additional information in the evaluation of pelvic floor problems by visualizing anatomic landmarks during different functional phases.

Endopelvic Fascia

Controversy exists surrounding the use of the term "fascia" as it applies to the pelvis. Histologic studies reveal that the linings of the levator ani, piriformis, and obturator internus are skeletal ligamental connective tissue and genuine examples of pelvic fascia. One example in which the term "fascia" is incorrectly used is in reference to the tissue that is plicated in an anterior colporrhaphy. Histologically, it is the muscular lining of

the vagina that is plicated. There are no discrete capsules of fascia that separate the bladder and vagina from each other.

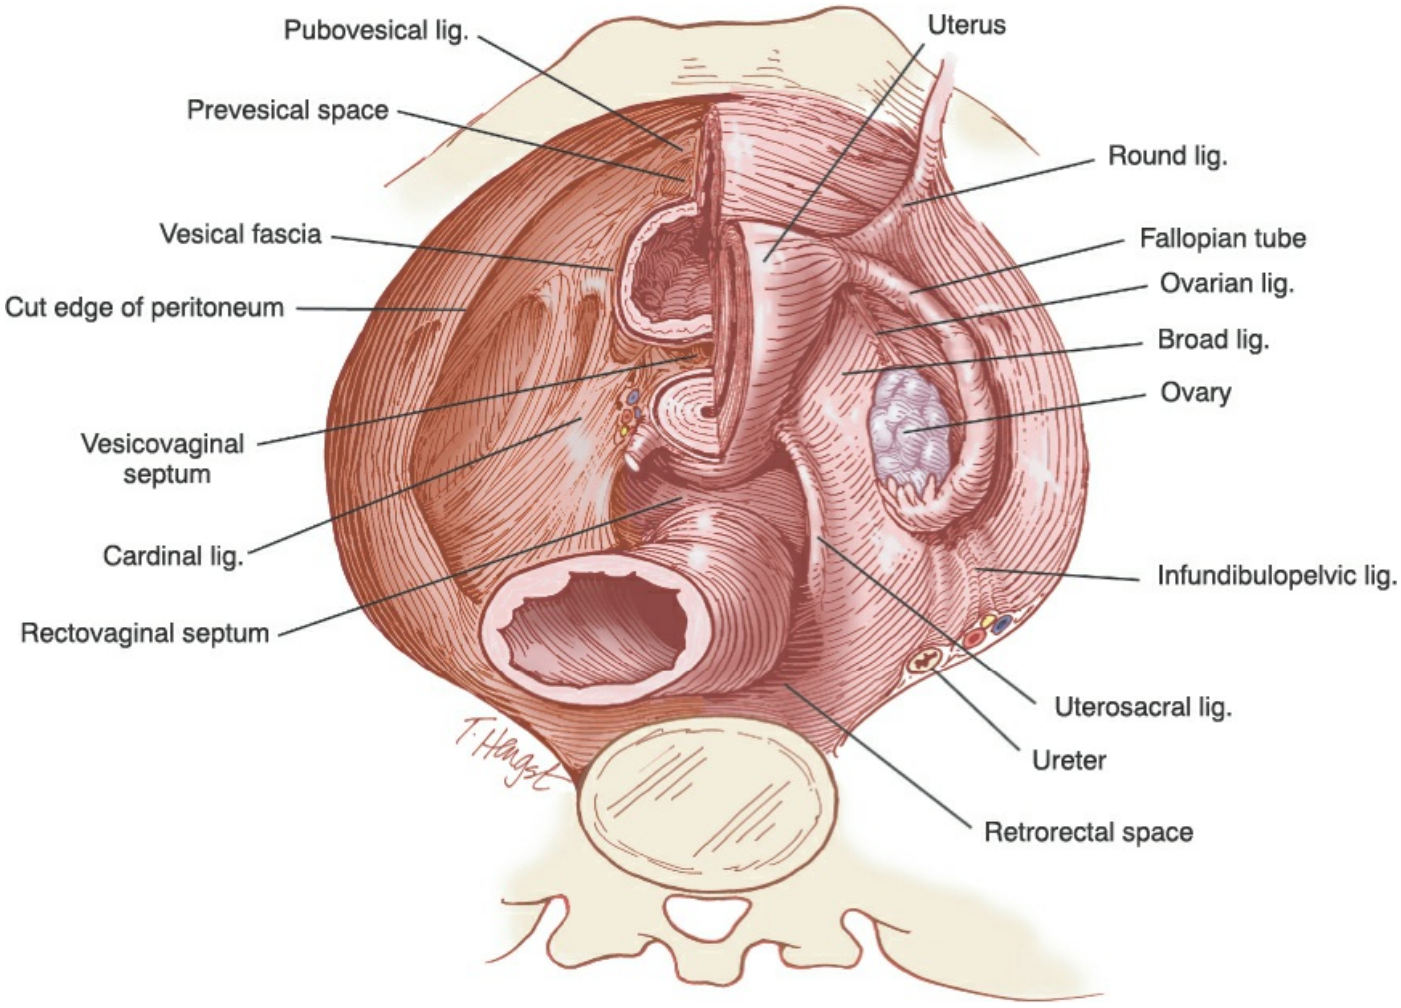

FIGURE 5-26 The fascial components of the pelvic diaphragm.

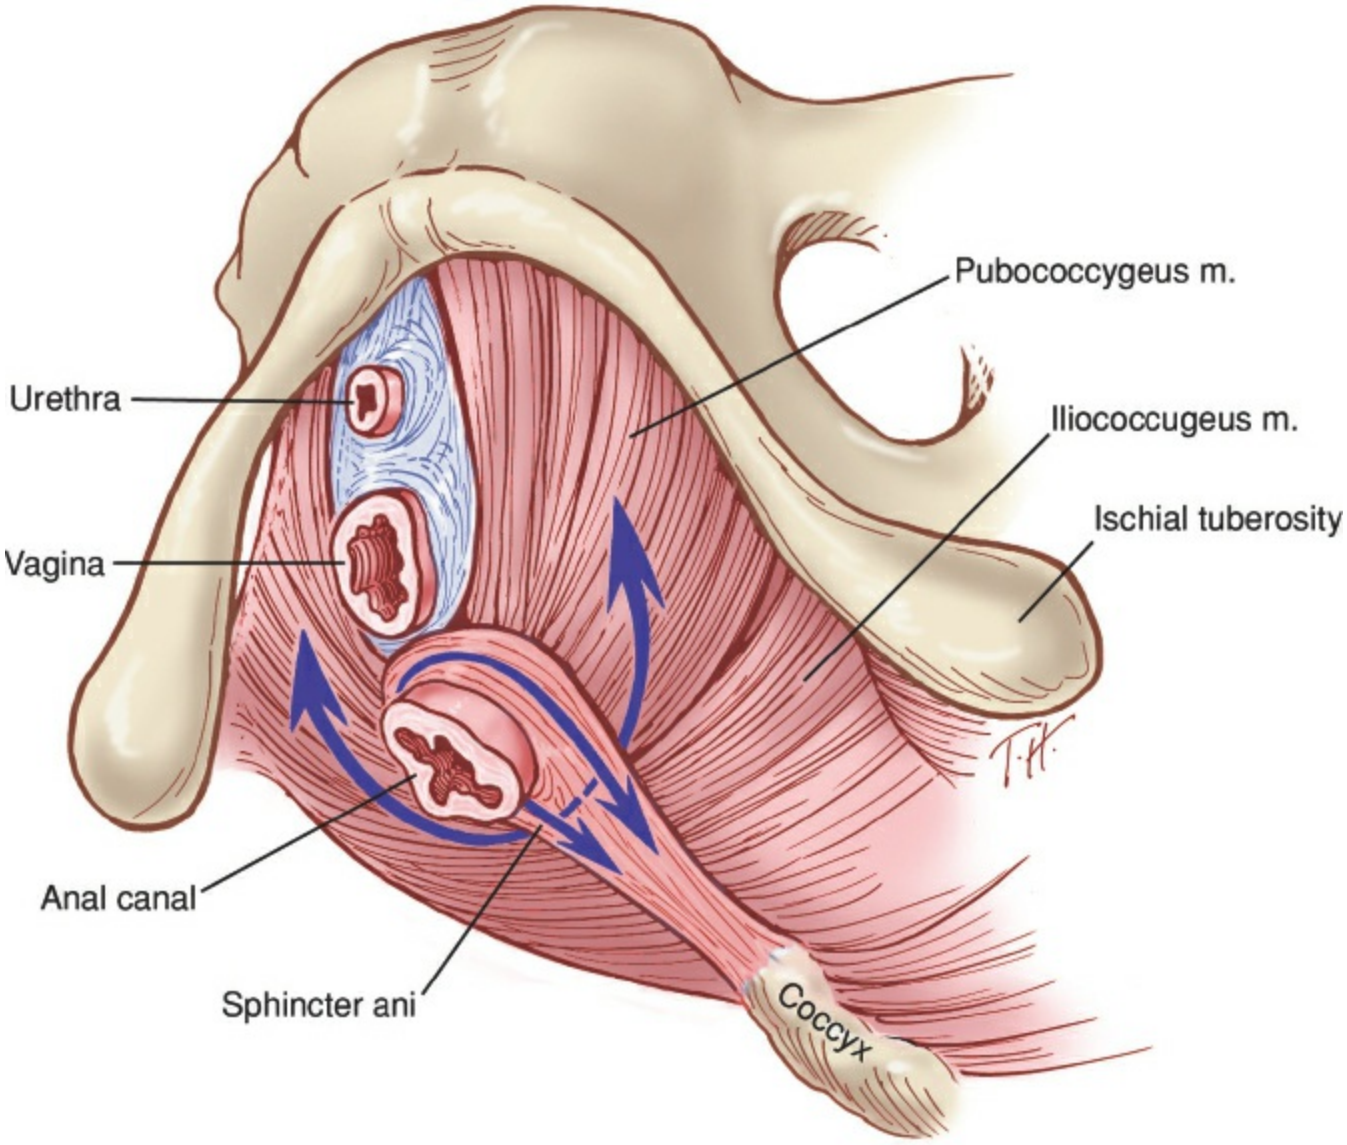

FIGURE 5-27 The double-layered muscular support of the pelvic diaphragm.

The endopelvic fascia is a sheet of fibroareolar tissue following the blood supply to the visceral organs and acts as a retroperitoneal mesentery. The fascia divides the retroperitoneal space into avascular planes. The endopelvic or pubocervical fascia attaches the cervix and vagina to the lateral pelvic sidewall. It is composed of two parts: the parametrium, which is that part connected to the uterus (i.e., the uterosacral and cardinal ligaments), and the paracolpium, which is that part connected to the vagina. The parametrium and cardinal ligaments continue to the vaginal introitus and fuse directly to the supporting tissues associated with the vagina. The uterine and vaginal arteries travel in these structures. The uterosacral ligaments are the posterior components of the cardinal ligaments, extending from the cervix and upper vagina to the lateral sacrum. Lateral pelvic support is provided by linear condensations of obturator and levator ani fascia termed the arcus tendineus fasciae pelvis and the arcus tendineus levator ani, respectively. The arcus tendineus levator ani serves as a point of attachment

for the pubococcygeus and iliococcygeus muscles and lies on the fascia of the obturator internus muscle. It runs from the posterolateral pubic ramus to the ischial spine. The arcus tendineus fasciae pelvis runs from the anterior pubis to the ischial spine as it joins with the arcus tendineus levator ani. It provides lateral (paravaginal) support to the anterior vagina. Detachment of the pubocervical fascia and pubourethral fascia from the arcus tendineus fasciae pelvis may lead to a lateral cystocele.

Obturator Space

The obturator *membrane* is a fibrous sheath that spans the obturator *foramen* through which the obturator neurovascular bundle penetrates via the obturator *canal*. The obturator internus muscle lies on the superior (intrapelvic) side of the obturator membrane. The origin of the obturator internus is on the inferior margin of the superior pubic ramus and the pelvic surface of the obturator membrane. Its tendon passes through the lesser sciatic foramen to insert onto the greater trochanter of the femur to laterally rotate the thigh. The obturator artery and vein originate as branches of the internal iliac vessels. As they emerge from the cranial side of the obturator membrane via the obturator canal and enter the obturator space, they divide into many small branches, supplying blood to the muscles of the adductor compartment of the thigh. Cadaver work contradicted previous reports that the obturator vessels bifurcate into medial and lateral branches (62). Rather, the vessels are predominantly small (<5 mm in diameter) and splinter into variable courses. The muscles of the medial thigh and adductor compartment are (from superficial to deep) the gracilis, adductor longus, adductor brevis, adductor magnus, obturator externus, and obturator internus. In contrast to the vessels, the obturator nerve emerges from the obturator membrane and bifurcates into anterior and posterior divisions, traveling distally down the thigh to supply the muscles of the adductor compartment. With the patient in the dorsal lithotomy position, the nerves and vessels follow the thigh and course laterally away from the ischiopubic ramus. **[3] Transobturator incontinence slings are often placed beneath the adductor longus tendon and just lateral to the descending ischiopubic ramus in order to avoid the obturator neurovascular bundle, which lies lateral and superior to this relatively safe point of entry through the obturator membrane.**

SUMMARY

New surgical approaches are being developed to solve old problems and often require surgeons to revisit familiar anatomy from an unfamiliar perspective or with a different understanding of complex anatomic relationships. Examples of innovative surgical approaches that require renewed understanding of anatomic relationships include laparoscopic or robotic surgery, midurethral incontinence slings that traverse

the obturator or retropubic spaces, and prolapse kits that traverse pararectal and paravesical spaces. Anatomic alterations secondary to disease, congenital variation, or intraoperative complications may make familiar surgical territory suddenly seem foreign. All of these situations require surgeons to be perpetual students of anatomy, regardless of their breadth or depth of experience.

Several strategies for continuing education in anatomy are suggested:

1. **Review relevant anatomy before each surgical procedure.**
2. **Study the gynecologic literature on an ongoing basis—numerous publications document the evolution of newer concepts regarding anatomic issues such as pelvic support.**
3. **Operate with more experienced pelvic surgeons, particularly when incorporating new surgical procedures.**
4. **Periodically dissect fresh or fixed cadaveric specimens; this practice may be arranged through local or regional anatomy boards or medical schools or by special arrangement at the time of autopsy.**
5. **Take advantage of newer computer-generated three-dimensional pelvic models and virtual reality interactive surgical simulators to better understand functional anatomy and to help plan complicated surgical procedures** (63,64).

KEY POINTS

1 The regulation and maintenance of normal tissue requires a balance between cell proliferation and programmed cell death, or *apoptosis*.

2 Among the genes that participate in the control of cell growth and function, *proto-oncogenes* and *tumor suppressor genes* are particularly important.

3 Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are *protein kinases* that convert an extracellular signal into an intracellular signal. Many of the proteins that participate in the intracellular signal transduction system are encoded by *proto-oncogenes* that are divided into subgroups based on their cellular location or enzymatic function.

4 Oncogenes comprise a family of genes that result from gain of function mutations of their normal counterparts, proto-oncogenes. The normal function of proto-oncogenes is to stimulate proliferation in a controlled context. Activation of oncogenes can lead to stimulation of cell proliferation and development of a malignant phenotype.

5 Tumor suppressor genes are involved in the development of most cancers and are usually inactivated in a two-step process in which both copies of the tumor suppressor gene are mutated or inactivated by epigenetic mechanisms like methylation. The most commonly mutated tumor suppressor gene in human cancers is *p53.*

2 T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses. T cells can be distinguished from other types of lymphocytes by their cell surface phenotype, based on the pattern of expression of various molecules, and by differences in their biologic functions.

2 There are two major subsets of mature T cells that are phenotypically and functionally distinct: *T-helper/inducer cells*, which express the CD4 cell surface marker, and the *T-suppressor/cytotoxic cells*, which express the CD8 marker. T_H1 and T_H2 are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: Clones of T_H1 produce interleukin-2 (IL-2) and interferon-γ (IFN-γ), whereas T_H2 clones produce IL-4, IL-5, IL-6, and IL-10.

Advances in molecular biology and genetics have improved our understanding of basic biologic concepts and disease development. The knowledge acquired with the completion of the human genome project, the data available through The Cancer Genome Atlas (TCGA), the development of novel diagnostic modalities, such as the microarray technology for the analysis of DNA and proteins, and the emergence of treatment strategies that target specific disease mechanisms all have an increasing impact on the specialty of obstetrics and gynecology.

Normal cells are characterized by discrete metabolic, biochemical, and physiologic mechanisms. Specific cell types differ with respect to their mainly genetically determined responses to external influences (Fig. 6-1). An external stimulus is converted to an intracellular signal, for example, via a cell membrane receptor. The intracellular signal is transferred to the nucleus and generates certain genetic responses that lead to changes in cellular function, differentiation, and proliferation. Although specific cell types and tissues exhibit unique functions and responses, many basic aspects of cell biology and genetics are common to all eukaryotic cells.

CELL CYCLE

Normal Cell Cycle

Adult eukaryotic cells possess a well-balanced system of continuous production of DNA (transcription) and proteins (translation). Proteins are constantly degraded and replaced depending on the specific cellular requirements. Cells proceed through a sequence of phases called the cell cycle, during which the DNA is distributed to two daughter cells (*mitosis*) and subsequently duplicated (*synthesis phase*). This process is controlled at key checkpoints that monitor the status of cells, for example, the amount of DNA present in each cell. The cell cycle is regulated by a small number of heterodimeric protein kinases that consist of a regulatory subunit (cyclin) and a catalytic subunit (cyclin-dependent kinase). Association of a cyclin with a cyclin-dependent kinase (CdkC) determines which proteins will be phosphorylated at a specific point during the cell cycle.

The cell cycle is divided into four major phases: M phase (mitosis), G_1 phase (period between mitosis and initiation of DNA replication), S phase (DNA synthesis), and G_2 phase (period between completion of DNA synthesis and mitosis) (Fig. 6-2). Post-mitotic cells can "exit" the cell cycle into the so-called G_0 phase and remain for days, weeks, or even a lifetime without further proliferation. The duration of the cell cycle may be highly variable, although most human cells complete the cell cycle within approximately 24 hours. During a typical cell cycle, mitosis lasts about 30 to 60 minutes, the G_1 phase 7 to 10 hours, S phase 10 hours, and

G_2 phase 5 hours. With respect to the cell cycle, there are three subpopulations of cells:

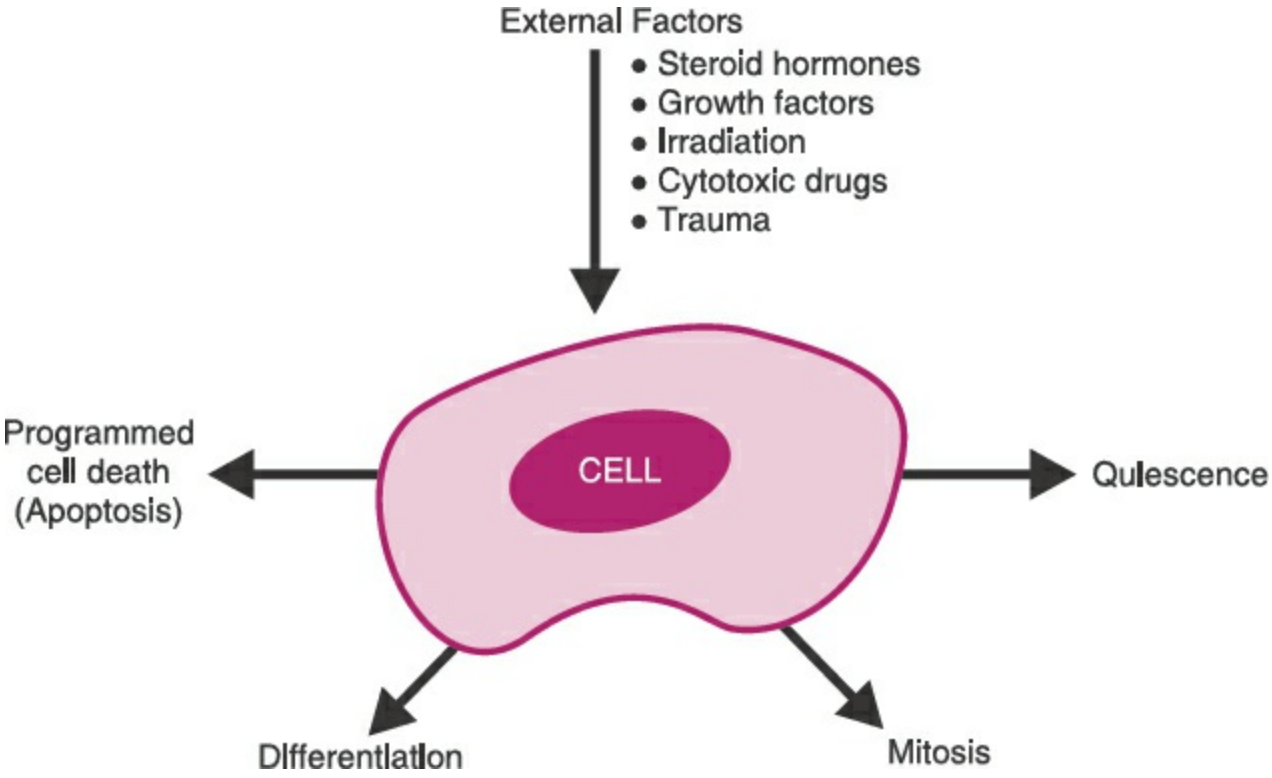

FIGURE 6-1 External stimuli affect the cell, which has a specific coordinated response.

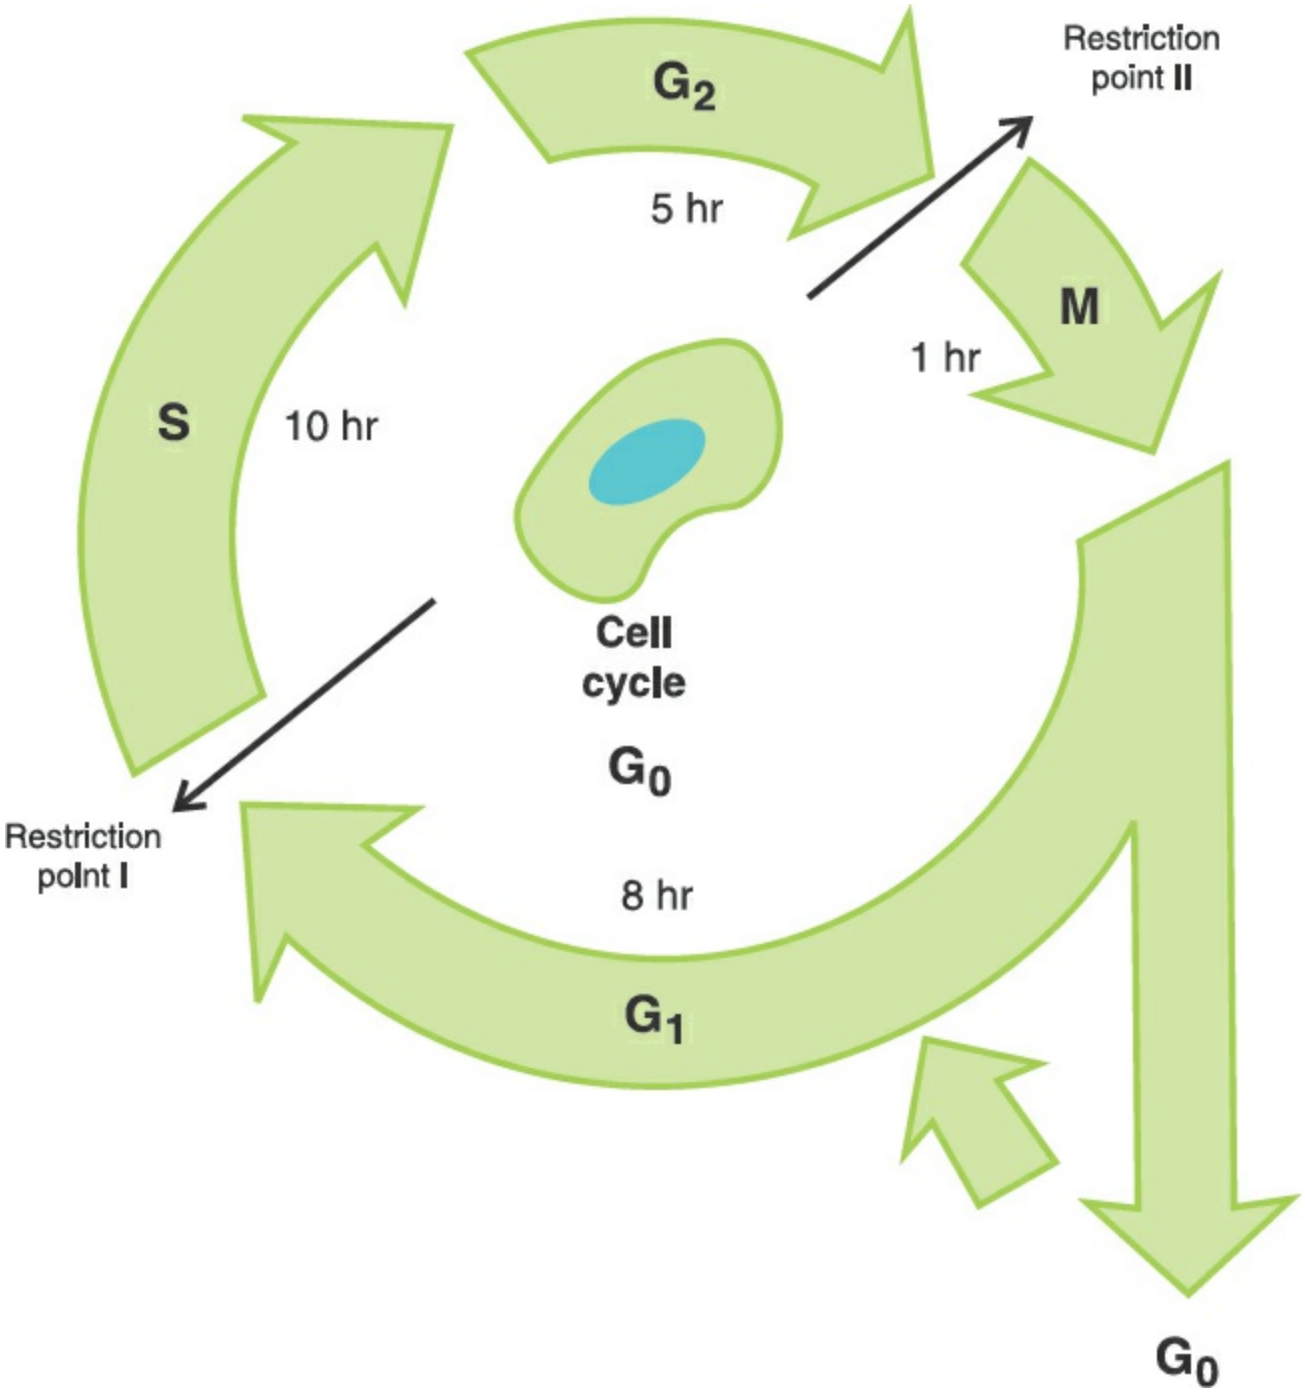

FIGURE 6-2 The cell cycle.

1. ***Terminally differentiated cells*** cannot reenter the cell cycle.
2. ***Quiescent (G0) cells*** can enter the cell cycle if appropriately stimulated.
3. ***Dividing cells*** are currently in the cell cycle.

Red blood cells, striated muscle cells, uterine smooth muscle cells, and nerve cells are terminally differentiated. Other cells, such as fibroblasts, exit from the G_1 phase into the G_0 phase and are considered to be out of the cell cycle. These cells enter the cell

cycle following exposure to specific stimuli, such as growth factors and steroid hormones. Dividing cells are found in the gastrointestinal tract, the skin, and the cervix.

G_1 Phase

In response to specific external stimuli, cells enter the cell cycle by moving from the G_0 phase into the G_1 phase. The processes during G_1 phase lead to the synthesis of enzymes and regulatory proteins necessary for DNA synthesis during S phase and are mainly regulated by G_1 cyclin-dependent kinase–cyclin complexes (G_1CdkC). Complexes of G_1CdkC induce degradation of the S phase inhibitors in late G_1. Release of the S phase CdkC complex subsequently stimulates entry into the S phase. **Variations in the duration of the G_1 phase of the cell cycle, ranging from less than 8 hours to longer than 100 hours, account for the different generation times exhibited by different types of cells.**

S Phase

The nuclear DNA content of the cell is duplicated during the S phase of the cell cycle. The S-phase CdkC complex activates proteins of the DNA prereplication complexes that assemble on DNA replication origins during G_1. The prereplication complex activates initiation of DNA replication and inhibits the assembly of new prereplication complexes. This inhibition ascertains that each chromosome is replicated only once during the S phase.

G_2 Phase

RNA and protein synthesis occurs during the G_2 phase of the cell cycle. The burst of biosynthetic activity provides the substrates and enzymes to meet the metabolic requirements of the two daughter cells. Another important event that occurs during the G_2 phase of the cell cycle is the repair of errors of DNA replication that may have occurred during the S phase. Failure to detect and correct these genetic errors can result in a broad spectrum of adverse consequences for the organism and the individual cell (1). Defects in the DNA repair mechanism are associated with an increased incidence of cancer. Mitotic CdkC complexes are synthesized during the S and G_2 phases, but are inactive until DNA synthesis is completed.

M Phase

Nuclear–chromosomal division occurs during the mitosis or M phase. During this phase, the cellular DNA is equally distributed to each of the daughter cells. Mitosis provides a diploid (2n) DNA complement to each somatic daughter cell. Following mitosis, eukaryotic mammalian cells contain diploid DNA, reflecting a karyotype that includes 44 somatic chromosomes and an XX or XY sex chromosome complement.

Exceptions to the diploid cellular content include hepatocytes (4n) and the functional syncytium of the placenta.

Mitosis is divided into prophase, metaphase, anaphase, and telophase. Mitotic CdkC complexes induce chromosome condensation during the prophase, assembly of the mitotic spindle apparatus, and alignment of the chromosomes during the metaphase. Activation of the anaphase promoting complex (APC) leads to inactivation of the protein complexes that connect sister chromatids during metaphase, permitting the onset of anaphase. During anaphase, sister chromatids segregate to opposite spindle poles. The nuclear envelope breaks down into multiple small vesicles early in mitosis and reforms around the segregated chromosomes as they decondense during telophase. Cytokinesis is the process of division of the cytoplasm that segregates the endoplasmic reticulum and the Golgi apparatus during mitosis. After completion of mitosis, cells enter the G_1 phase and either reenter the cell cycle or remain in G_0.

Ploidy

After meiosis, germ cells contain a haploid (1n) genetic complement. After fertilization, a 46,XX or 46,XY diploid DNA complement is restored. Restoration of the normal cellular DNA content is crucial to normal function. Abnormalities of cellular DNA content cause distinct phenotypic abnormalities, as exemplified by a hydatidiform molar pregnancy (see Chapter 39). In a complete hydatidiform mole, an oocyte without any nuclear genetic material (e.g., an empty ovum) is fertilized by one sperm. The haploid genetic content of the fertilized ovum is duplicated, and the diploid cellular DNA content is restored, resulting in a homozygous 46,XX gamete. Less often, a complete hydatidiform mole results from the fertilization of an empty ovum by two sperm, resulting in a heterozygous 46,XX or 46,XY gamete. In complete molar pregnancies, the nuclear DNA is usually paternally derived, embryonic structures do not develop, and trophoblast hyperplasia occurs. Rarely, complete moles are biparental. This karyotype seems to be found in patients with recurrent hydatidiform moles and is associated with a higher risk of persistent trophoblastic disease.

A partial hydatidiform mole follows the fertilization of a haploid ovum by two sperm, resulting in a 69 XXX, 69 XXY, or 69 XYY karyotype. A partial mole contains paternal and maternal DNA, and both embryonic and placental development occur. Both the 69 YYY karyotype and the 46 YY karyotype are incompatible with embryonic and placental development. These observations demonstrate the importance of maternal genetic material, in particular the X chromosome, in normal embryonic and placental development.

In addition to total cellular DNA content, the chromosome number is an important determinant of cellular function. Abnormalities of chromosome number, which often are caused by nondisjunction during meiosis, result in well-characterized

clinical syndromes such as trisomy 21 (Down syndrome), trisomy 18, and trisomy 13.

Genetic Control of the Cell Cycle

Cellular proliferation must occur to balance normal cell loss and maintain tissue and organ integrity. This process requires the coordinated expression of many genes at discrete times during the cell cycle. In the absence of growth factors, cultured mammalian cells are arrested in the G_0 phase. With the addition of growth factors, these quiescent cells pass through the so-called restriction point 14 to 16 hours later and enter the S phase 6 to 8 hours thereafter. **The restriction point or the G_1/S boundary marks the point at which a cell commits to proliferation. A second checkpoint is the G_2/M boundary, which marks the point at which repair of any DNA damage must be completed** (2). To successfully complete the cell cycle, a number of cell division cycle (*cdc*) genes are activated.

Cell Division Cycle Genes

Among the factors that regulate the cell cycle checkpoints, proteins encoded by the *cdc2* family of genes and the cyclin proteins appear to play particularly important roles (3). Growth factor–stimulated mammalian cells express early- or delayed-response genes, depending on the chronologic sequence of the appearance of specific RNAs. The early- and delayed-response genes act as nuclear transcription factors and stimulate the expression of a cascade of other genes. Early-response genes such as *c-Jun* and *c-Fos* enhance the transcription of delayed-response genes such as *E2Fs*. E2F transcription factors are required for the expression of various cell cycle genes and are functionally regulated by the retinoblastoma (*Rb*) protein. Binding of Rb to E2F converts E2F from a transcriptional activator to a repressor of transcription. Phosphorylation of Rb inhibits its repressing function and permits E2F-mediated activation of genes required for entry into the S phase. Cdk4-cyclin D, Cdk6-cyclin D, and Cdk2-cyclin E complexes cause phosphorylation of Rb, which remains phosphorylated throughout the S, G_2, and M phases of the cell cycle. After completion of mitosis, a decline of the level of Cdk-cyclins leads to dephosphorylation of Rb by phosphatases and, consequently, an inhibition of *E2F* in the early G_1 phase.

Cdks are under evaluation as targets for cancer treatments because they are frequently overactive in cancer disease and Cdk-inhibiting proteins are dysfunctional. The Cdk4 inhibitor P1446A-05, for example, specifically inhibits Cdk4-mediated G_1-S phase transition, arresting cell cycling and inhibiting cancer cell growth (4). SNS-032 selectively binds to Cdk2, -7, and -9, preventing their phosphorylation and activation and subsequently preventing cell proliferation.

As cells approach the G_1-S phase transition, synthesis of cyclin A is initiated. The

Cdk2-cyclin A complex can trigger initiation of DNA synthesis by supporting the prereplication complex. The cyclin-dependent kinase 1 (Cdk1) protein, formerly called *p34 cdc2*, and specific cyclins (namely cyclin B1) form a complex heterodimer referred to as *mitosis-promoting factor* (5), which catalyzes protein phosphorylation and drives the cell into mitosis. Cdk1 assembles with cyclin A and cyclin B in the G_2 phase and promotes the activity of the mitosis promoting factor (MPF). **Mitosis is initiated by activation of the *cdc* gene at the G_2-M checkpoint** (6). After the G_2-M checkpoint is passed, the cell undergoes mitosis. In the presence of abnormally replicated chromosomes, progression past the G_2-M checkpoint does not occur.

The *p53* tumor suppressor gene participates in cell cycle control. Cells exposed to radiation therapy exhibit an S-phase arrest that is accompanied by increased expression of p53. This delay permits the repair of radiation-induced DNA damage. In the presence of *p53* mutations, the S-phase arrest that normally follows radiation therapy does not occur (7). The wild type *p53* gene can be inactivated by the human papillomavirus (HPV) E6 protein, preventing S-phase arrest in response to DNA damage.

Apoptosis

[1] The regulation and maintenance of normal tissue requires a balance between cell proliferation and programmed cell death, or *apoptosis.* When proliferation exceeds programmed cell death, the result is hyperplasia. When programmed cell death exceeds proliferation, the result is atrophy. Programmed cell death is a crucial concomitant of normal embryologic development. This mechanism accounts for deletion of the interdigital webs, palatal fusion, and development of the intestinal mucosa (8). Programmed cell death is an important phenomenon in normal physiology. The reduction in the number of endometrial cells following alterations in steroid hormone levels during the menstrual cycle is, in part, a consequence of programmed cell death (9). In response to androgens, granulosa cells undergo programmed cell death (e.g., follicular atresia) (10).

Programmed cell death, or apoptosis, is an energy-dependent, active process that is initiated by the expression of specific genes. This process is distinct from cell necrosis, although both mechanisms result in a reduction in the total cell number. In programmed cell death, cells shrink and undergo phagocytosis. Conversely, groups of cells expand and lyse when undergoing cell necrosis. This process is energy independent and results from noxious stimuli. Programmed cell death is triggered by a variety of factors, including intracellular signals and exogenous stimuli such as radiation exposure, chemotherapy, and hormones. Cells undergoing programmed cell death may be identified on the basis of histologic, biochemical, and molecular biologic changes. Histologically, apoptotic cells exhibit cellular condensation and fragmentation of the nucleus. Biochemical correlates of impending programmed cell death include an

increase in transglutaminase expression and fluxes in intracellular calcium concentration (11).

Programmed cell death emerged as an important factor in the growth of neoplasms. Historically, neoplastic growth was characterized by uncontrolled cellular proliferation that resulted in a progressive increase in tumor burden. It is recognized that the **increase in tumor burden associated with progressive disease reflects an imbalance between cell proliferation and cell death**. Cancer cells fail to respond to the normal signals to stop proliferating, and they may fail to recognize the physiologic signals that trigger programmed cell death.

MODULATION OF CELL GROWTH AND FUNCTION

The normal cell exhibits an orchestrated response to the changing extracellular environment. The three groups of substances that signal these extracellular changes are steroid hormones, growth factors, and cytokines. The capability to respond to these stimuli requires a cell surface recognition system, intracellular signal transduction, and nuclear responses for the expression of specific genes in a coordinated fashion. **[2] Among the genes that participate in the control of cell growth and function, *proto-oncogenes and tumor suppressor genes* are particularly important.** More than 100 proto-oncogene products that contribute to growth regulation have been identified (Table 6-1) (12). As a group, proto-oncogenes exert positive effects upon cellular proliferation. In contrast, *tumor suppressor genes* exert inhibitory regulatory effects on cellular proliferation (Table 6-2).

Steroid Hormones

Steroid hormones play a crucial role in reproductive biology and in general physiology. Among the various functions, steroid hormones influence pregnancy, cardiovascular function, bone metabolism, and an individual's sense of well-being. The action of steroid hormones is mediated via extracellular signals to the nucleus to affect a physiologic response.

Estrogens exert a variety of effects on growth and development of different tissues. The effects of estrogens are mediated via estrogen receptors (ER), intracellular proteins that function as ligand-activated transcription factors and belong to the nuclear receptor superfamily (13). **Two mammalian ERs have been identified: ERα and ERβ**. The structure of both receptors is similar and consists of 6 domains named A through F from the N- to C-terminus, encoded by 8 to 9 exons (14). Domains A and B are located at the N-terminus and contain an agonist-independent transcriptional activation domain (activation function 1 [AF-1]). The C domain is a highly conserved central DNA-binding domain composed of two zinc fingers through

which ER interacts with the major groove and the phosphate backbone of the DNA helix. The C-terminus of the protein contains domains E and F and functions as ligand-binding domain (LBD–domain E) and AF-2–domain F **(Fig. 6-3)**.

Table 6-2 Tumor Suppressor Genes

p53	Mutated in as many as 50% of solid tumors
Rb	Deletions and mutations predispose to retinoblastoma
PTEN	Dual specificity phosphatase that represses PI3-kinase/Akt pathway activation with negative effect on cell growth
$P16^{INK4a}$	Binds to cyclin-CDK4 complex inhibiting cell cycle progression
FHIT	Fragile histidine triad gene with tumor suppressor function via unknown mechanisms
WT1	Mutations are correlated with the Wilms tumor
NF1	Neurofibromatosis gene
APC	Associated with colon cancer development in patients with familial adenomatous

Activation of transcription via the ER is a multistep process. The initial step requires activation of the ER via various mechanisms (Fig. 6-4). For example, estrogens such as 17β-estradiol can diffuse into the cell and bind to the LBD of the ER. Upon ligand binding, the ER undergoes conformational changes followed by a dissociation of various bound proteins, mainly heat shock proteins 90 and 70 (Hsp90 and Hsp70). Activation of the ER also requires phosphorylation by several protein kinases, including casein kinase II, PKA, and components of the Ras/MAPK (mitogen-activated protein kinase) pathway (14). Four phosphorylation sites of the ER are clustered in the NH_2 terminus with the AF-1 region.

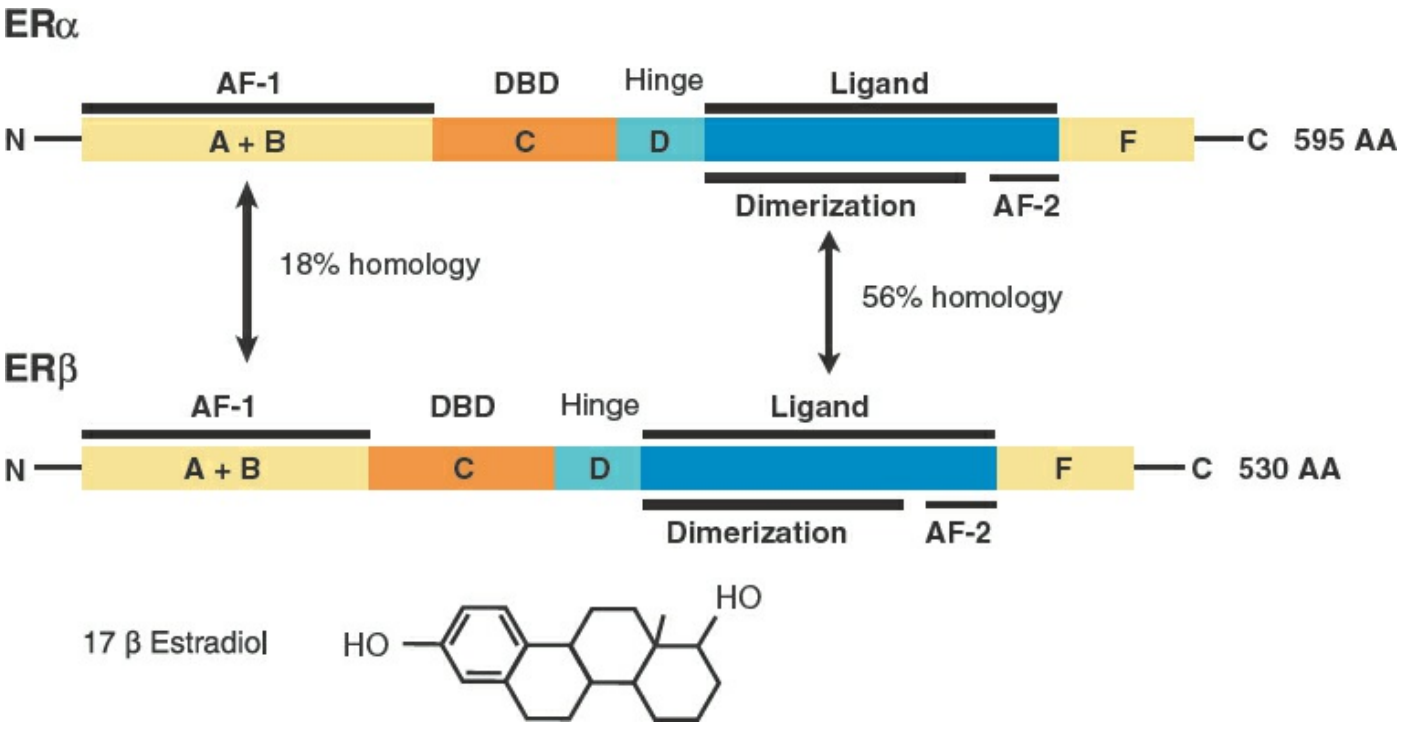

FIGURE 6-3 Structure of the two mammalian estrogen receptors. ERα (595 amino acids) and ERβ (530 amino acids) consist of six domains (A to F from the N- to C-terminus). Domains A and B at the N-terminus

contain an agonist-independent transcriptional activation domain (activation function 1, or AF-1). The C domain is the central DNA-binding sequence (DBD). Domains E and F function as the ligand-binding domain (LBD) and activation function 2 (AF-2). Also shown is the structure of the ER ligand 17β-estradiol.

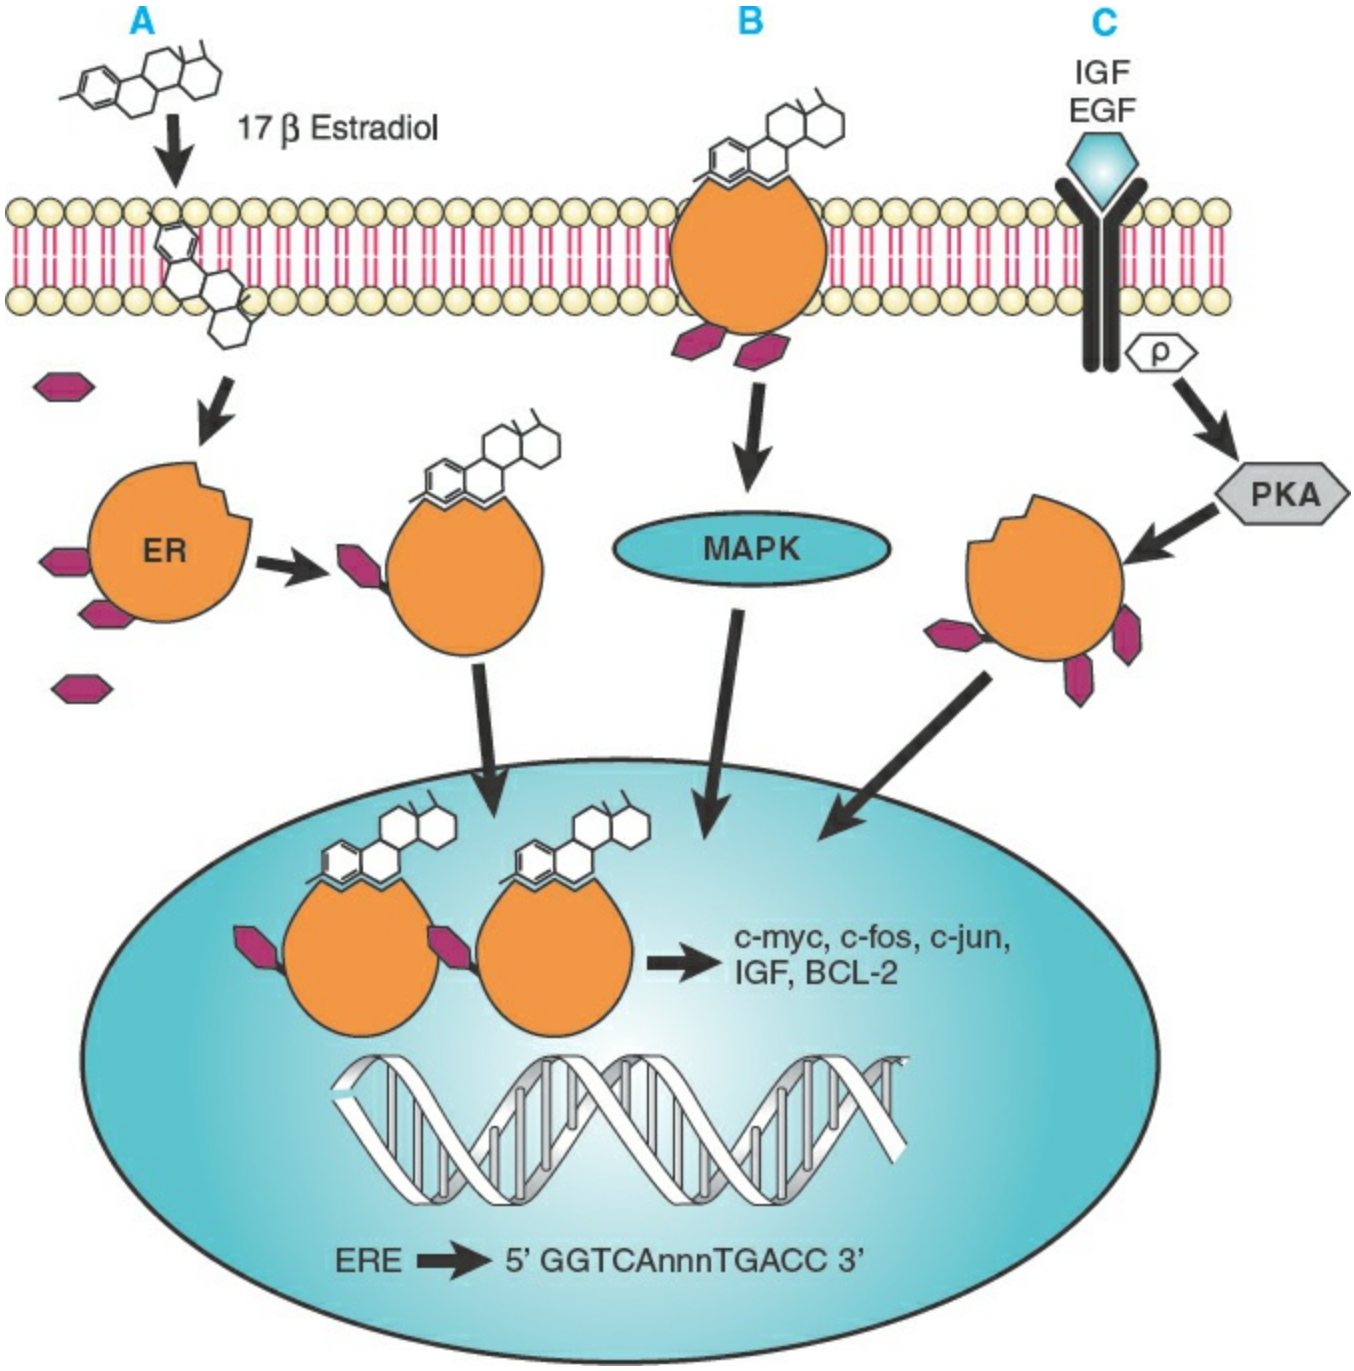

FIGURE 6-4 Activation of estrogen receptor–mediated transcription. Intracellular estrogen receptor signaling is mediated via different pathways. **A:** 17β-Estradiol diffuses through the cell membrane and binds to cytoplasmic ER. The ER is subsequently phosphorylated, undergoes dimerization, and binds to the estrogen response element (ERE) on the promoter of an estrogen responsive gene. **B:** Estrogen ligand binds to membrane-bound ER and activates the mitogen-activated protein kinase (MAPK) pathways that support ER-mediated transcription. **C:** Binding of cytokines such as insulinlike growth factor (IGF) or epidermal growth factor to their membrane receptor can cause activation of protein kinases like PKA, which subsequently activates ER by phosphorylation.

The activated ER elicits a number of different genomic as well as nongenomic effects on intracellular signaling pathways. The classical steroid signaling pathway involves binding of the activated ER to an estrogen responsive element (ERE) on the genome as homodimers and subsequent stimulation of transcription (15). The minimal consensus sequence for the ERE is a 13 bp palindromic inverted repeat (IR) and is defined as 5′-GGTCAnnnTGACC-3′. Genes that are regulated by activated ERs include early gene responses such as *c-myc, c-fos,* and *d-jun,* and genes encoding for growth factors such as insulin growth factor (IGF-1 and IGF-2), epidermal growth factor (EGF), transforming growth factor α (TGF-α), and colony-stimulating factor (CSF-1).

Various ligands with different affinities to the ER were developed and are called *selective estrogen receptor modulators* (*SERMs*). *Tamoxifen,* for example, is a mixed agonist/antagonist for ERα, but it is a pure antagonist for ERβ. The ERβ receptor is ubiquitously expressed in hormone-responsive tissues, whereas the expression of ERα fluctuates in response to the hormonal milieu. The cellular and tissue effects of an estrogenic compound appear to reflect a dynamic interplay between the actions of these ER isoforms. These observations underscore the complexity of estrogen interactions with both normal and neoplastic tissues. Mutations of hormone receptors and their functional consequences illustrate their important contributions to normal physiology.

Growth Factors

Growth factors are polypeptides that are produced by a variety of cell types and exhibit a wide range of overlapping biochemical actions. Growth factors bind to high-affinity cell membrane receptors and trigger complex positive and negative signaling pathways that regulate cell proliferation and differentiation (16). **In general, growth factors exert positive or negative effects upon the cell cycle by influencing gene expression related to events that occur at the G_1-S cell cycle boundary**.

Because of their short half-life in the extracellular space, growth factors act over limited distances through autocrine or paracrine mechanisms. In the autocrine loop, the growth factor acts on the cell that produced it. The paracrine mechanism of growth control involves the effect of growth factors on another cell in proximity. Growth factors that play an important role in female reproductive physiology are listed in Table 6-3. The biologic response of a cell to a specific growth factor depends on a variety of factors, including the cell type, the cellular microenvironment, and the cell cycle status.

The regulation of ovarian function occurs through *autocrine, paracrine,* and *endocrine* mechanisms. The growth and differentiation of ovarian cells are particularly influenced by the insulinlike growth factors (IGF) **(Fig. 6-5)**. IGFs amplify the actions

of gonadotropin hormones on autocrine and paracrine growth factors found in the ovary. IGF-1 acts on granulosa cells to cause an increase in cAMP, progesterone, oxytocin, proteoglycans, and inhibin. On theca cells, IGF-1 causes an increase in androgen production. Theca cells produce tumor necrosis factor α (TNF-α) and EGF, which are regulated by follicle-stimulating hormone (FSH). EGF acts on granulosa cells to stimulate mitogenesis. Follicular fluid contains IGF-1, IGF-2, TNF-α, TNF-β, and EGF. **Disruption of these autocrine and paracrine intraovarian pathways may be the basis of polycystic ovarian disease, disorders of ovulation, and ovarian neoplastic disease**.

TGF-β activates intracytoplasmic serine threonine kinases and inhibits cells in the late G_1 phase of the cell cycle (17). It appears to play an important role in embryonic remodeling. Mullerian-inhibiting substance (MIS), which is responsible for regression of the mullerian duct, is structurally and functionally related to TGF-β (18). TGF-α is an EGF homologue that binds to the EGF receptor and acts as an autocrine factor in normal cells. As with EGF, TGF-α promotes the entry of G_0 cells into the G_1 phase of the cell cycle. The role of growth factors in endometrial growth and function was the subject of several reviews (17,19). Similar to the ovary, autocrine, paracrine, and endocrine mechanisms of control also occur in the endometrial tissue.

Table 6-3 Growth Factors That Play Important Roles in Female Reproductive Physiology

Growth Factor	Sources	Targets	Actions
Platelet-derived growth factor (PDGF)	Placenta, platelets, preimplantation embryo, endothelial cells	Endothelial cells Trophoblasts	Mitogen
Epidermal growth factor (EGF)	Submaxillary gland, theca cells Granulosa cells Endometrium	Mitogen	
Transforming growth factor α (TGF-α)	Embryo, placenta, theca cell, ovarian stromal cell	Placenta Granulosa cells	Mitogen
Transforming growth factor β (TGF-β)	Embryo, theca cells Endometrium Granulosa cells Theca cells	Mitogen	
Insulinlike growth factor 1 (IGF-1)	Granulosa cells	Theca cells Granulosa cells	Mediates growth hormone activity
Insulinlike growth factor 2 (IGF-2)	Theca cells	Theca cells	Insulinlike
Fibroblast growth factor (FGF)	Granulosa cells	Granulosa cells Angiogenic Mitogen	

Intracellular Signal Transduction

[3] Growth factors trigger intracellular biochemical signals by binding to cell membrane receptors. In general, these membrane-bound receptors are *protein kinases* that convert an extracellular signal into an intracellular signal. The interaction between growth factor ligand and its receptor results in receptor dimerization, autophosphorylation, and tyrosine kinase activation. Activated receptors in turn phosphorylate substrates in the cytoplasm and trigger the intracellular signal transduction system **(Fig. 6-6)**. The intracellular signal transduction system relies on serine threonine kinases, *src*-related kinases, and G proteins. Intracellular signals activate nuclear factors that regulate gene expression. **Many of the proteins that participate in the intracellular signal transduction system are encoded by *proto-oncogenes* that are divided into subgroups based on their cellular location or enzymatic function (Fig. 6-7)** (20).

FIGURE 6-6 Pathways of intracellular signal transduction.

The *raf* and *mos* proto-oncogenes encode proteins with serine threonine kinase activity. These kinases integrate signals originating at the cell membrane with those that are forwarded to the nucleus (21). Protein kinase C (PKC) is an important component of a second messenger system that exhibits serine threonine kinase activity. This enzyme plays a central role in phosphorylation, which is a general mechanism for activating and deactivating proteins. It also plays an important role in cell metabolism and division (22).

The *Src* family of tyrosine kinases is related to PKC and includes protein products encoded by the *src*, *yes*, *fgr*, *hck*, *lyn*, *fyn*, *lck*, *alt*, and *fps/fes* proto-oncogenes. These proteins bind to the inner cell membrane surface.

The *G proteins* are guanyl nucleotide-binding proteins. The heterotrimeric, or large G proteins, link receptor activation with effector proteins such as adenyl cyclase, which activates the cAMP-dependent, kinase-signaling cascade (23). The monomeric or small G proteins, encoded by the *Ras* proto-oncogene family, are designated *p21* and are particularly important regulators of mitogenic signals. The *p21 Ras* protein exhibits guanyl triphosphate (GTP) binding and GTPase activity. Hydrolysis of GTP to guanyl diphosphate (GDP) terminates *p21 Ras* activity. The *p21 Ras* protein influences the production of deoxyguanosine and inositol phosphate (IP) 3, arachidonic acid production, and IP turnover.

The phosphoinositide 3 (PI3) kinase can be activated by various growth factors like platelet-derived growth factor (PDGF) or IGF results. Activation of PI3 kinase results in an increase of intracellular, membrane-bound lipids, phosphatidylinositol-(3),(4)-diphosphate (PIP2), and phosphatidylinositol-(3),(4),(5)-triphosphate (PIP3). The *Akt* protein is subsequently phosphorylated by PIP3-dependent kinases (PDK) for full activation. Activated *Akt* is released from the membrane and elicits downstream effects that lead to an increase in cell proliferation, prevention of apoptosis, invasiveness, drug resistance, and neoangiogenesis (24). The *PTEN* (phosphatase and chicken tensin homologue deleted on chromosome 10) protein is an important factor in the PI3 kinase pathway, because it counteracts the activation of *Akt* by dephosphorylating PIP3. Cells with mutated tumor suppressor gene *PTEN* and lack of functional *PTEN* expression display an increased proliferation rate and decreased apoptosis, possibly supporting the development of a malignant phenotype. *PTEN* frequently is mutated in endometrioid adenocarcinoma. Furthermore, lack of functional *PTEN* expression was described in endometriosis.

The mammalian target of rapamycin (mTOR) is regulated by the PI3 kinase pathway. mTOR is a serine/threonine protein kinase that regulates a variety of cellular processes, including proliferation, motility, and translation (25). mTOR integrates the input from various upstream pathways, including insulin and growth factors like IGF proteins. The

mTOR pathway provides important survival signals for cancer cells and therefore was one focus of targeted drug development (26). For example, *rapamycin* inhibits mTOR by associating with its intracellular receptor FKBP12. Derivatives of *rapamycin* like *everolimus* (RAD001) and *temsirolimus* (CCI779) showed promising results in clinical trials (27).

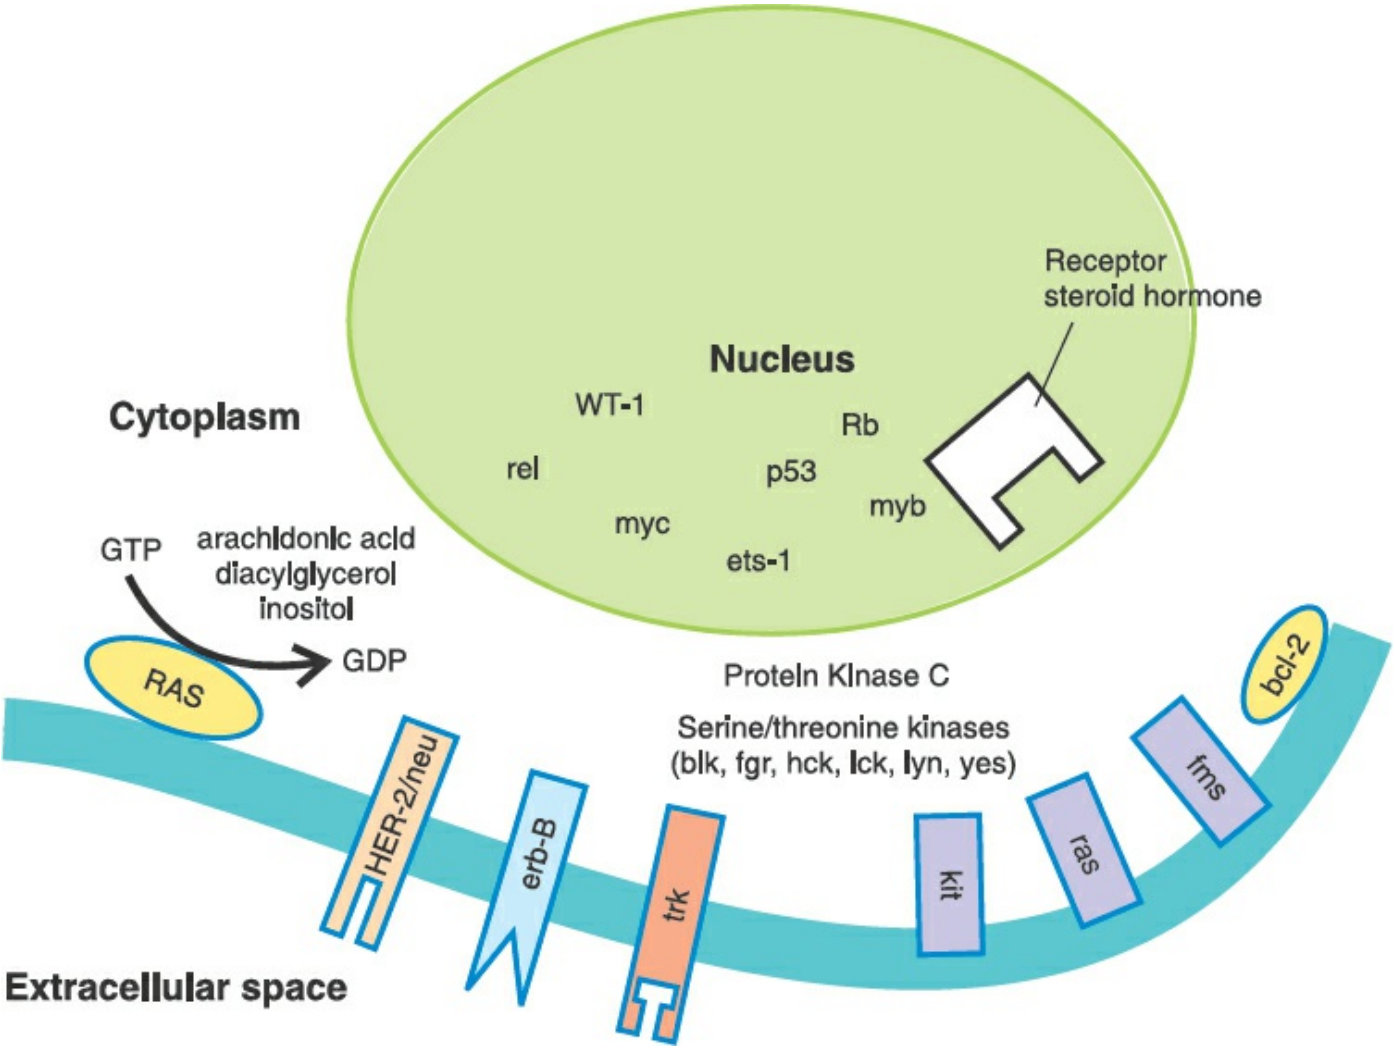

FIGURE 6-7 Proto-oncogenes are divided into subgroups based on their cellular location or enzymatic function.

mTOR functions as the catalytic subunit of two different protein complexes. Among the proteins associated with mTOR complex 1 (mTORC1) is mTOR, the regulatory associated protein of mTOR (Raptor), and PRAS40. This complex functions as a nutrient and energy sensor and controls protein synthesis (28). mTORC1 is activated by insulin, growth factors, amino acids and oxidative stress, low nutrient levels, reductive stress, and growth factor deprivation inhibit its activity. In contrast, the mTOR complex 2 (mTORC2) contains, among others, mTOR, the rapamycin-insensitive protein Rictor, and mammalian stress-activated protein kinase interacting protein 1 (mSIN1). mTORC2

regulates the cytoskeleton and phosphorylates Akt (29). Its regulation is complex, but involves insulin, growth factors, serum, and nutrient levels.

Expression of Genes and Proteins

Ovarian, endometrial, and cervical cancers have distinct molecular and genomic profiles. Ovarian carcinomas, in particular the high-grade serous histologic subtypes, are characterized by genomic instability with low frequencies of conserved mutations (30). Despite substantial differences between the gynecologic cancers, activation of the PI3K pathway is common.

Endometrial cancers demonstrate the highest frequency of PI3K pathway alterations (31). The rate of alterations in PIK3CA range from 25% to 40% and in the PIK3R1 from 15% to 25% (32). In addition to PI3K alterations, 30% to 90% of endometrial cancers have impaired PTEN function, most often identified in endometrioid histologies (33). PI3K inhibition may impair proliferation of endometrial cancer cells. In addition, loss of PTEN or PIK3CA mutation may serve as biomarkers associated with response to novel targeted agents that antagonize PI3K (34). Studies utilizing patient-derived xenograft (PDX) models of endometrial carcinomas, with and without alterations in PIK3CA, have suggested that pan-PI3K inhibition may produce significant anti-tumor responses. Most of the published data regarding PI3K pathway inhibitors in endometrial cancer have been based on mTOR inhibition. Rapalog inhibitors (everolimus, ridaforolimus, and temsirolimus) have been demonstrated to inhibit mTORC1 complex kinase activity. However, in clinical application, the response rates to monotherapy have been low, ranging from 4% to 25%; the higher response rates correlating with patients extensively pretreated with cytotoxic chemotherapy (35). Combination treatment of everolimus and letrozole showed a 32% response rate (11 of 35 patients) (36). These response rates and duration are similar to treatment with alternating courses of megestrol acetate and tamoxifen, with an overall RR of 27%. Based on these comparable response findings, a randomized study is underway comparing these two treatment strategies (GOG-3007) (36).

Genetic alterations of the PI3K pathway have been identified in up to 70% of ovarian cancers (37). Gain of function mutations in PIK3CA have been observed in 4% to 12% of ovarian cancers (38). Ovarian clear cell and endometrioid adenocarcinomas demonstrate a higher frequency of mutations with 33% to 40% activating mutations in PIK3CA in clear cell carcinomas, and 12% to 20% of endometrioid carcinomas (39).

In cervical cancer, amplifications and activating mutations of the PIK3CA gene have been demonstrated in 23% to 36% of cases, with the highest mutation rate found in PIK3CA gene (40). The HPV oncogenic proteins, namely E6, and E7 enhance PI3K pathway signaling via direct activation of PI3K, as well as downstream AKT and rpS6K. These proteins induce ligand-dependent signaling indirectly through epidermal

growth factor receptor (EGFR). Similar to ovarian cancer, data pertaining to the use of targeted PI3K pathway therapy in cervical carcinoma is limited, with studies underway.

Regulation of genetic transcription and replication is crucial to the normal function of the daughter cells, the tissues, and ultimately the organism. Transmission of external signals to the nucleus by way of the intracellular signal transduction cascade culminates in the transcription of specific genes and translation of the mRNA into proteins that ultimately affect the structure, function, and proliferation of the cell.

The human genome project resulted in the determination of the sequence of DNA of the entire human genome (41). **With the completion of this project, it appears that the human haploid genome contains 23,000 protein coding genes**. Sequencing the human genome is a major scientific achievement that has opened the door for more detailed studies of structural and functional genomics. **Structural genomics involves the study of three-dimensional structures of proteins based on their amino acid sequences. Functional genomics provides a way to correlate the structure and function. Proteomics involves the identification and cataloging of all proteins used by a cell, and cytomics involves the study of cellular dynamics, including intracellular system regulation and response to external stimuli**. The **transcriptome** is the set of all RNA molecules, including mRNA, rRNA, tRNA, and other noncoding RNA produced in one or a population of cells. The transcriptome varies with external environmental conditions and reflects the actively expressed genes. **The *metabolome* describes a set of small-molecule metabolites, including hormones and signaling molecules, that are found in a single organism. Similar to the transcriptome and proteome, the metabolome is subject to rapid changes** (42). **The *kinome* of an organism describes a set of protein kinases, enzymes that are crucial for phosphorylation reactions**.

Cancer Genetics

Cancer is a genetic disease that results from a series of mutations in various cancer genes. Uncontrolled cell growth occurs because of accumulation of somatic mutations or the inheritance of one or more mutations through the germline, followed by additional somatic mutations. The mutation in genes that are directly involved in normal cellular growth and proliferation can lead to the development of uncontrolled growth, invasion, and metastasis.

According to the Knudson hypothesis, which was first described in children with hereditary retinoblastoma, two hits or mutations within the genome of a cell are required for a malignant phenotype to develop (43). **In hereditary cancers, the first hit is present in the genome of every cell. Only one additional hit is necessary,**

therefore, to disrupt the correct function of the second cancer gene allele. In contrast, sporadic cancers develop in cells without hereditary mutations in the cancer predisposing alleles. In this case, both hits must occur in a single somatic cell to disrupt both cancer gene alleles (Fig. 6-8).

Most adult solid tumors require 5 to 10 rate-limiting mutations to acquire the malignant phenotype. Among these mutations, some are responsible for causing the cancer phenotype, whereas others might be considered bystander mutations, as with, for example, the amplification of genes that are adjacent to an oncogene. The most compelling evidence for the mutagenic tumor development process is that the age-specific incidence rates for most human epithelial tumors increase at roughly the fourth to eighth power of elapsed time.

Gatekeepers and Caretakers

[4] Cancer susceptibility genes are divided into "gatekeepers" and "caretakers" (44). Gatekeeper genes control cellular proliferation and are divided into oncogenes and tumor suppressor genes. In general, oncogenes stimulate cell growth and proliferation, and tumor suppressor genes reduce the rate of cell proliferation or induce apoptosis. Gatekeepers prevent the development of tumors by inhibiting growth or promoting cell death. Examples of gatekeeper genes include the tumor suppressor gene *p53* and the retinoblastoma gene.

Caretaker genes preserve the integrity of the genome and are involved in DNA repair (stability genes). The inactivation of caretakers increases the likelihood of persistent mutations in gatekeeper genes and other cancer-related genes. The DNA mismatch repair (MMR) genes, MLH1, MSH2, and MSH6, are examples of caretaker genes.

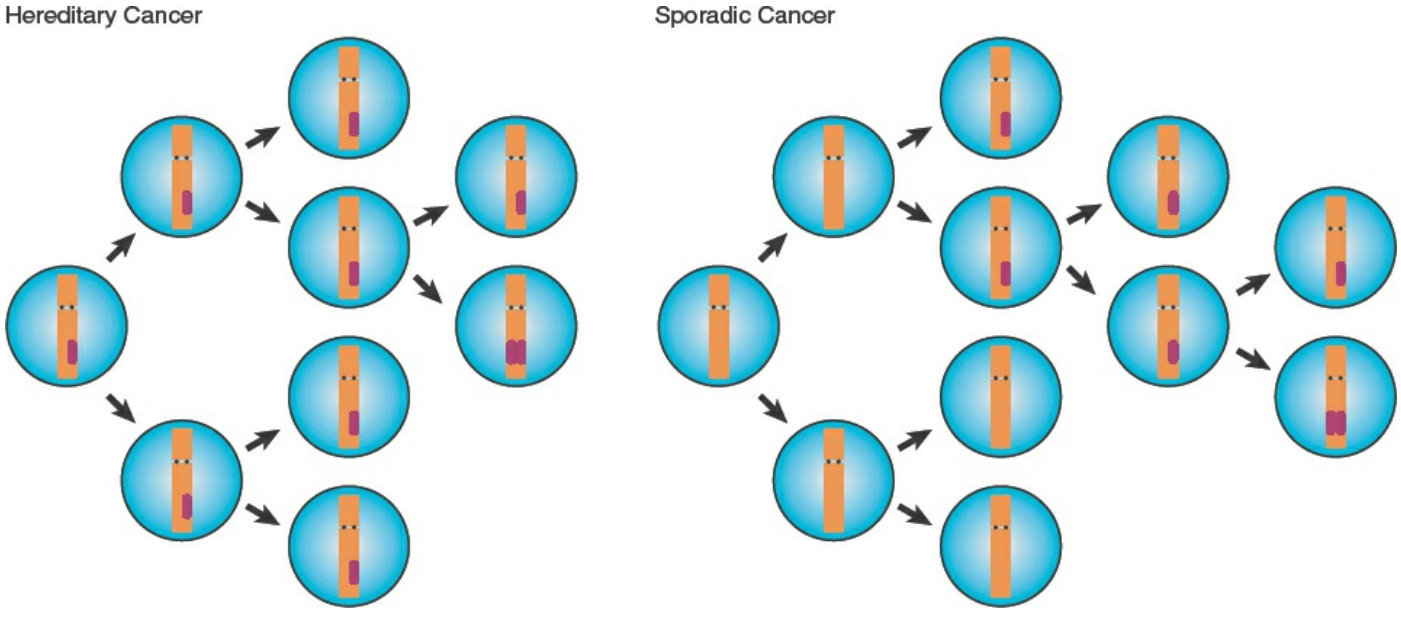

FIGURE 6-8 Hereditary and sporadic cancer development based on the Knudson "two-hit" genetic model.

All cells harbor one mutant tumor suppressor gene allele in hereditary cancer. The loss of the second allele results in the malignant phenotype. Sporadic cancers develop in cells with normal genome, therefore requiring both alleles to be inactivated (two hits).

Hereditary Cancer

Most cancers are caused by spontaneous somatic mutations. However, a small percentage of cancers arise on a heritable genomic background. About 12% of all ovarian cancers and about 5% of endometrial cancers are considered to be hereditary (45,46). Germline mutations require additional mutations at one or more loci for tumorigenesis to occur. These mutations occur via different mechanisms, for example, via environmental factors such as ionizing radiation or mutations of stability genes. **Characteristics of hereditary cancers include diagnosis at a relatively early age and a family history of cancer, usually of a specific cancer syndrome, in two or more relatives**. Hereditary cancer syndromes associated with gynecologic tumors are summarized in Table 6-4.

[4] Various cancer-causing genetic and epigenetic mechanisms are described. On the genomic level, gain of function gene mutations can lead to a conversion of proto-oncogenes into oncogenes, and loss of function gene mutations can inactivate tumor suppressor genes. Epigenetic changes include DNA methylation, which can cause inactivation of tumor suppressor gene expression by preventing the correct function of the associated promoter sequence. Collectively, these genetic and epigenetic changes are responsible for the development of cancer characterized by the ability of cells to invade and metastasize, grow independently of growth factor support, and escape from antitumor immune responses.

Oncogenes

Oncogenes comprise a family of genes that result from the gain of function mutations of their normal counterparts, proto-oncogenes. The normal function of proto-oncogenes is to stimulate proliferation in a controlled context. Activation of oncogenes can lead to stimulation of cell proliferation and development of a malignant phenotype. Oncogenes were initially discovered through retroviral tumorigenesis. Viral infection of mammalian cells can result in integration of the viral sequences into the proto-oncogene sequence of the host cell. The integrated viral promoter activates transcription from the surrounding DNA sequences, including the proto-oncogene. Enhanced transcription of the proto-oncogene sequences results in the overexpression of growth factors, growth factor receptors, and signal transduction proteins, which result in stimulation of cell proliferation. One of the most important group of viral oncogenes is the family of *ras* genes, which include *c-H*(*Harvey*)*-ras*, *c-K*(*Kirsten*)*-ras*, and *N*(*Neuroblastoma*)*-ras*.

Tumor Suppressor Genes

[5] Tumor suppressor genes are involved in the development of most cancers and are usually inactivated in a two-step process in which both copies of the tumor suppressor gene are mutated or inactivated by epigenetic mechanisms like methylation (47). **The most commonly mutated tumor suppressor gene in human cancers is *p53*** (48). The p53 protein regulates transcription of other genes involved in cell cycle arrest such as *p21*. Upregulation of p53 expression is induced by DNA damage and contributes to cell cycle arrest, allowing DNA repair to occur. p53 also plays an important role in the initiation of apoptosis. The most common mechanism of inactivation of p53 differs from the classic two-hit model. In most cases, missense mutations that change a single amino acid in the DNA-binding domain of p53 result in overexpression of nonfunctional p53 protein in the nucleus of the cell.

The identification of tumor suppressor genes was facilitated by positional cloning strategies. The main approaches are cytogenetic studies to identify chromosomal alterations in tumor specimens, DNA linkage techniques to localize genes involved in inherited predisposition to cancer, and examination for loss of heterozygosity (LOH) or allelic alterations among studies in sporadic tumors. Comparative genomic hybridization (CGH) allows fluorescence identification of chromosome gain and loss in human cancers within a similar experiment.

Table 6-4 Hereditary Cancer Syndromes Associated With Gynecologic Tumors

Hereditary Syndrome	Gene Mutation	Tumor Phenotype
Li–Fraumeni syndrome	TP53, CHEK2	Breast cancer, soft tissue sarcoma, adrenal cortical carcinoma, brain tumors
Cowden syndrome, Bannayan–Zonana syndrome	PTEN	Breast cancer, hamartoma, glioma, endometrial cancer
Hereditary breast and ovarian cancer	BRCA1, BRCA2	Cancer of breast, ovary, fallopian tube
Hereditary nonpolyposis colorectal cancer (HNPCC)	MLH1, MSH2, MSH3, MSH6, PMS2	Cancer of colon, endometrium, ovary, stomach, small bowel, urinary tract
Multiple endocrine neoplasia type I	Menin	Cancer of thyroid, pancreas, and pituitary, ovarian carcinoid
Multiple endocrine neoplasia type II	RET	Cancer of thyroid and parathyroid, pheochromocytoma, ovarian carcinoid
Peutz–Jeghers syndrome	STK11	Gastrointestinal hamartomatous polyps, tumors of the stomach, duodenum, colon, ovarian sex cord tumor with

		annular tubules (SCTAT)

Stability Genes

The third class of cancer genes is "stability genes," which promotes tumorigenesis in a different way from tumor suppressor genes or amplified oncogenes. The main function of stability genes is the preservation of the correct DNA sequence during DNA replication (caretaker function) (49). Mistakes that are made during normal DNA replication or induced by exposure to mutagens can be repaired by a variety of mechanisms that involve MMR genes, nuclear-type excision repair genes, and base excision repair genes. The inactivation of stability genes potentially leads to a higher mutation rate in all genes. However, only mutations in oncogenes and tumor suppressor genes influence cell proliferation and confer a selective growth advantage to the mutant cell. Similar to tumor suppressor genes, both alleles of stability genes must be activated to cause loss of function.

Genetic Aberrations

Gene replication, transcription, and translation are imperfect processes, and the fidelity is less than 100%. Genetic errors may result in abnormal structure and function of genes and proteins. Genomic alterations such as gene amplification, point mutations, and deletions or rearrangements were identified in premalignant, malignant, and benign neoplasms of the female genital tract **(Fig. 6-9)**.

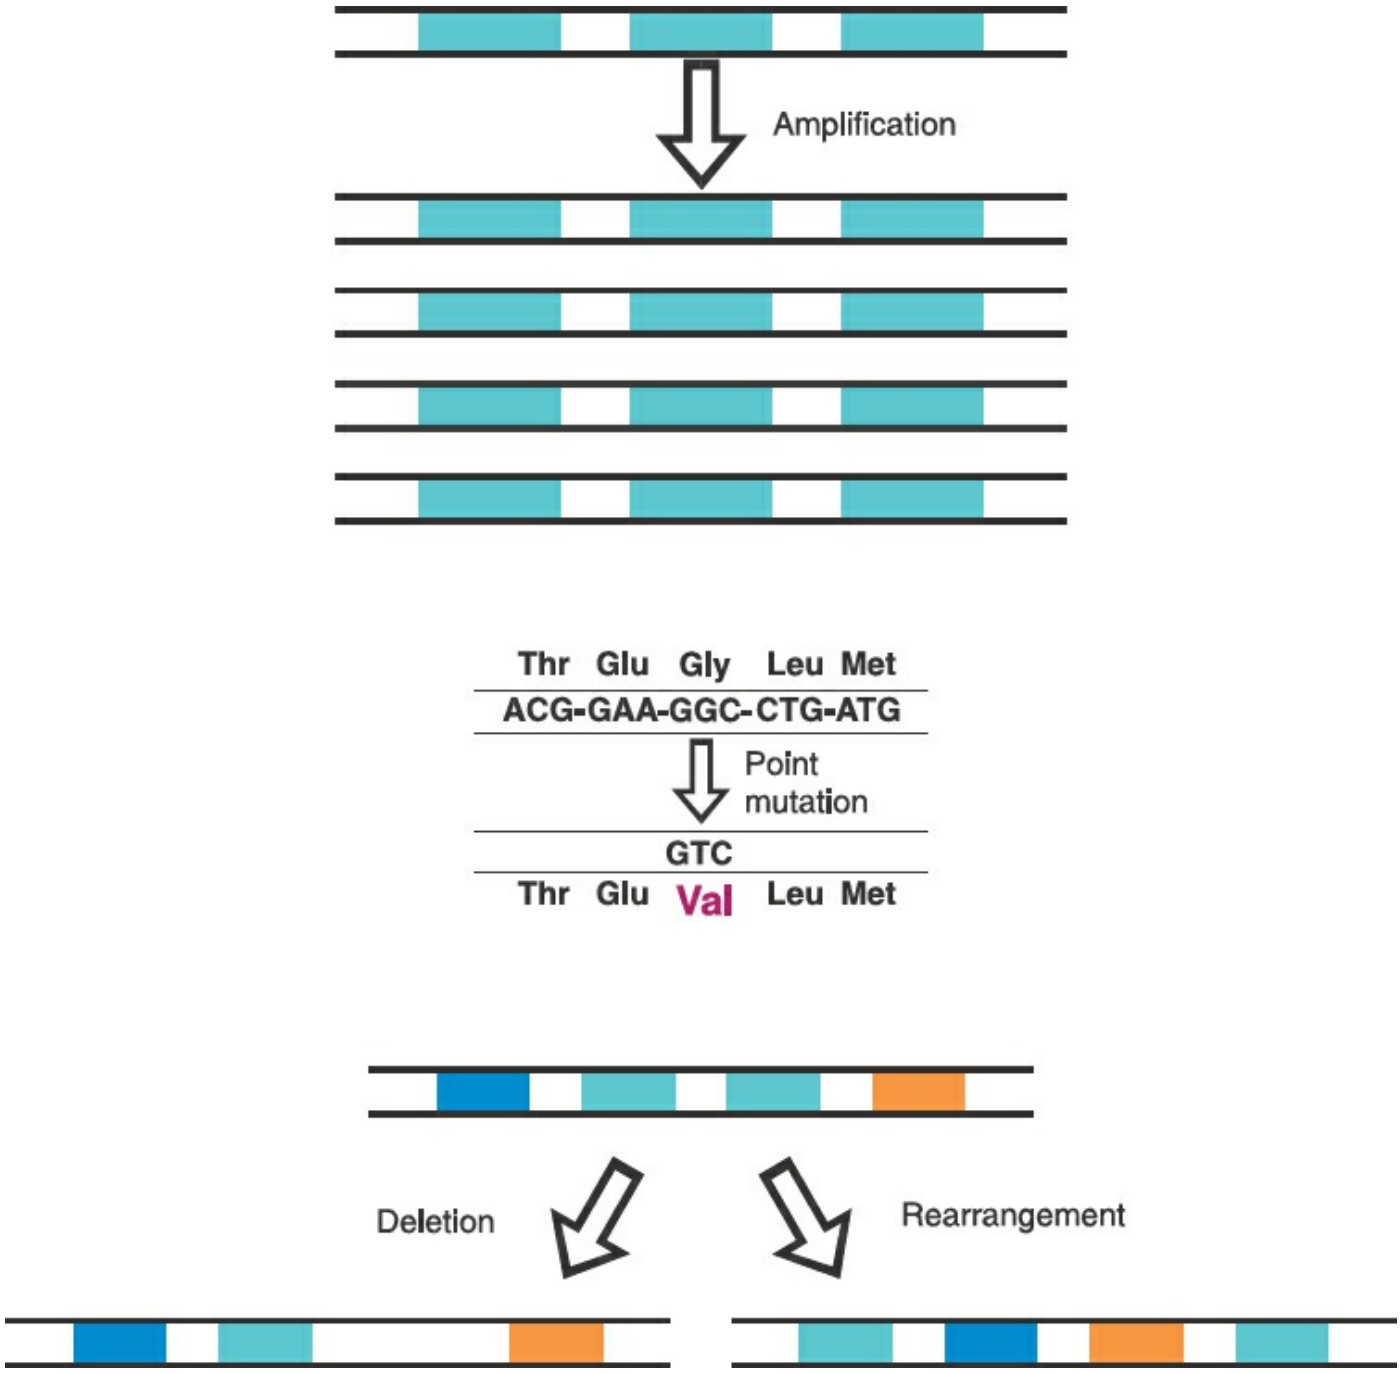

FIGURE 6-9 Genes can be amplified or undergo mutation, deletion, or rearrangement.

Amplification

Amplification refers to an increase in the copy number of a gene. Amplification results in enhanced gene expression by increasing the amount of template DNA that is available for transcription. Proto-oncogene amplification is a relatively common event in malignancies of the female genital tract. The *HER2/neu* proto-oncogene, also known as *c-erbB-2* and HER2, encodes a 185 *kDa* transmembrane glycoprotein with intrinsic tyrosine kinase activity. It belongs to a family of transmembrane receptor genes that includes the EGF receptors *erbB-1*, *erbB-3*, and *erbB-4*. *HER2/neu* interacts with a

variety of different cellular proteins that increase cell proliferation. Overexpression of *HER2/neu* was demonstrated in about 30% of breast cancers, 20% of advanced ovarian cancers, and as many as 50% of endometrial cancers (50). The GOG-177 study (a randomized prospective phase III study including patients with measurable stages III to IV, or recurrent endometrial carcinoma and randomly assigned treatment with either *doxorubicin* and *cisplatin* or *doxorubicin*, *cisplatin*, and *paclitaxel* with G-CSF) also included tumor collection within the study parameters. A review of the tumor specimens showed a 44% rate of HER2 overexpression (2+ or 3+ by immunohistochemical [IHC] staining) and 12% HER2 amplification by fluorescence in situ hybridization (FISH) (51). Morrison et al. investigated HER2 expression and amplification in women with endometrial cancer, including a wide variety of histologies. The investigation showed a correlation between HER2 expression and amplification and tumors of higher grade/stage, lymph node positivity, and survival outcomes. Overall survival was significantly shorter in patients with HER2 expression (median 5.2 years) and/or showed amplification (median 3.5 years) versus those that did not (median 13 years) (52). The clinical significance of HER2 overexpression or gene amplification continues to be debated.

Point Mutations

Point mutations of a gene may remain without any consequence for the expression and function of the protein (gene polymorphism). However, point mutations can alter a codon sequence and subsequently disrupt the normal function of a gene product. The *ras* gene family is an example of oncogene-encoded proteins that disrupt the intracellular signal transduction system following point mutations. Transforming Ras proteins contain point mutations in critical codons (i.e., codons [11, 12], [59], [61]) with decrease of GTPase activity and subsequent expression of constitutively active Ras. Point mutations of the *p53* gene are the most common genetic mutations described in solid tumors. These mutations occur at preferential "hot spots" that coincide with the most highly conserved regions of the gene. The *p53* tumor suppressor gene encodes for a phosphoprotein that is detectable in the nucleus of normal cells. When DNA damage occurs, *p53* can arrest cell cycle progression to allow the DNA to be repaired or undergo apoptosis. The lack of function of normal *p53* within a cancer cell results in a loss of control of cell proliferation with inefficient DNA repair and genetic instability. Somatic mutations of the *p53* gene occur in approximately 50% of advanced ovarian cancers and 30% to 40% of endometrial cancers (predominantly serous histology) but are uncommon in cervical cancer (53,54).

BRCA

Point mutations in the BRCA1 and BRCA2 genes can alter the activity of these genes and predispose to the development of breast and ovarian cancer(s) (55). The

frequency of BRCA1 and BRCA2 mutations in the general population in the United States is estimated at 1:250. Specific founder mutations were reported for various ethnic groups. For example, two BRCA1 mutations (185delAG and 5382insC) and one BRCA2 mutation (6174delT) are found in 2.5% of Ashkenazi Jews of Central and Eastern European descent. Additional founder mutations were described in other ethnic groups, including from the Netherlands (BRCA1, 2804delAA and several large deletion mutations), Iceland (BRCA2, 995del5), and Sweden (BRCA1, 3171ins5).

The BRCA proteins are involved in DNA repair. If DNA is damaged, for example, by ionizing radiation or chemotherapy, the BRCA2 protein binds to the RAD51 protein, which is central for the repair of double-stranded breaks via homologous recombination. BRCA2 regulates the availability and activity of RAD51 in this key reaction. Phosphorylation of the BRCA2/RAD51 complex allows RAD51 to bind to the site of DNA damage and, in conjunction with several other proteins, mediates repair of DNA by homologous recombination. BRCA1 functions within a complex network of protein–protein interactions, mediating DNA repair by homologous recombination and regulating transcription via the BRCA1-associated surveillance complex (BASC).

Deletions and Rearrangements

Individuals carrying a germline BRCA1 or BRCA2 pathogenic mutation have an elevated lifetime risk of developing breast and ovarian cancer(s). Based on a meta-analysis by Chen et al., the 70-year risk of developing ovarian cancer is 40% and 18% for BRCA1 and BRCA2, respectively, and breast cancer is 57% and 49% for BRCA1 and BRCA2, respectively (56). These germline mutations are inherited in an autosomal-dominant fashion. Approximately 5% of breast and 20% of ovarian cancers arise in women carrying heterozygous germline mutations in BRCA1 or BRCA2 (57). BRCA1 and BRCA2 are tumor suppressor genes. Loss of nonmutated (wild-type) allele at either BRCA1 or BRCA2 locus, termed locus-specific LOH, can be observed in tumors. Cells with loss of BRCA function and resultant homologous recombination (HR)–based DNA repair deficiency have enhanced sensitivity to DNA-damaging agents, namely cytotoxic platinum-based chemotherapies and targeted therapies (specifically inhibition of poly [ADP-ribose] polymerases [PARPs]) (58). Although much research has demonstrated that germline pathogenic mutations in BRCA1 or BRCA2 in ovarian cancer can downregulate HR, and thereby increase a patient's sensitivity and response to platinum-based chemotherapy and PARP inhibition, there is less evidence to support the potential impact of somatic sequence variants of BRCA function. Published studies have demonstrated that germline and somatic pathogenic mutations in HR genes (BRCA1, BRCA2, *ATM, BARD1, BRIP1, CHEK1, CHEK2, FAM175A, MRE11A, NBN, PALB2, RAD51C,* and *RAD51D*) occur in 31% of patients with serous or nonserous ovarian cancer (59). Of these, 75% of germline HR mutations and 71% of somatic HR mutations were in BRCA (60). The role of somatic pathogenic BRCA mutations in platinum-based

chemotherapy and PARP inhibitor sensitivity indicates that the number of individuals with ovarian cancer who may benefit from such treatments are greater than predicted by the frequency of germline pathogenic mutations alone.

Poly (ADP-Ribose) Polymerases

PARPs are vital components of DNA damage and repair pathways. The concept of synthetic lethality is based on the idea that simultaneous loss of function of two or more gene products can cause cell death, even if a deficiency in one is not lethal (61). For example, a tumor cell without a lethal inactivating mutation of BRCA DNA repair genes, might still be destroyed if also exposed to effects of PARP inhibition. Given that HGSCs are associated with germline BRCA1 or BRCA2 mutations, they remain the most suitable candidates for PARP inhibition. DNA repair function is inherently decreased in tumor cells, compared with normal cells. This discrepancy contributes to the high selectivity of PARP inhibitors (61).

Three different PARP inhibitors have been approved by the FDA for the treatment of ovarian cancer patients, each with a different clinical indication. *Olaparib* and *niraparib* are indicated in patients with platinum-sensitive ovarian cancer as maintenance therapy following response to platinum-based chemotherapy for recurrent disease. Neither drug requires the presence of germline or somatic mutations in BRCA1 or BRCA2 genes for this indication. For the treatment of recurrent ovarian cancer with *olaparib*, patients must have had three or more lines of chemotherapy and have a germline mutation in BRCA1 or BRCA2. Response rates in this patient population is about 30% based on clinical trial data (62). *Rucaparib* is likewise approved for maintenance therapy in patients with recurrent, platinum-sensitive ovarian cancer but requires the presence of a germline or somatic BRCA1 or BRCA2 mutation (63). The most common side effects with PARP inhibitors include hematologic toxicities including thrombocytopenia and anemia, gastrointestinal side effects, in particular nausea and fatigue.

Lynch Syndrome (Hereditary Nonpolyposis Colorectal Cancer Syndrome, HNPCC)

Lynch syndrome (LS) is an autosomal-dominant inherited disorder caused by germline mutations in DNA MMR genes. Mutations are characterized by predisposition for cancers arising from the colon, rectum, small bowel, endometrium, ovary, stomach, pancreas, renal pelvis, ureter, and brain (64). This syndrome was first identified in patients with familial predisposition to gastrointestinal cancers. Endometrial cancer often precedes colorectal and other LS-associated malignancies. Women with LS have a 15% to 70% lifetime risk of endometrial cancer and a 6% to 8% lifetime risk of ovarian cancer, with this wide range accounting for a variety of histopathologic subtypes (65,66). Such a high incidence has led to increased screening of endometrial carcinoma specimens for abnormalities in the DNA MMR pathway. The most common and convincing method of germline mutation analysis is focused on the four primary MMR

genes associated in LS, including MLH1, MSH2, MSH6, and PMS1. Mutations in MSH2 and/or MLH1 account for 90% of heterozygous mutations, while MSH6 mutations account for most of the remaining cases (67). A smaller subset of patients may carry mutations in the EPCAM gene, which can lead to Lynch phenotype by way of hypermethylation and inactivation of MSH2 promoter. IHC staining for loss of expression serves as the standard screening approach. Microsatellite instability (MSI) testing is available as a substitute or additional modality for abnormalities of the MMR system; however, this testing has been shown to be less sensitive than IHC, primarily because of a failure to detect several MSH6 germline mutation carriers (64).

Deletions and rearrangements reflect gross changes in the DNA template that may result in the synthesis of a markedly altered protein product. Somatic mutations may involve chromosomal translocations that result in chimeric transcripts with juxtaposition of one gene to the regulatory region of another gene. This mutation type is most commonly reported in leukemias, lymphomas, and mesenchymal tumors. The Philadelphia chromosome in chronic myeloid leukemia (CML), for example, is the result of a reciprocal translocation between one chromosome 9 and one chromosome 22. The DNA sequence removed from chromosome 9 contains the proto-oncogene *c-ABL* and inserts into the *BCR* gene sequence on chromosome 22 (Philadelphia chromosome). The resulting chimeric *BCR-ABL* gene product functions as a constitutively active tyrosine kinase and stimulates cellular proliferation by such mechanisms as an increase of growth factors.

Single-nucleotide polymorphism (SNP) describes a variation in the DNA sequence (68). Single nucleotides in the genome differ between paired chromosomes in either one individual or between two individuals. For example, the sequences T**G**ACTA and T**C**ACTA contain one single change in the second nucleotide from guanine (G) to cytosine (C). This results in a G and C allele for this particular gene sequence. SNPs can occur within coding or noncoding sequences of genes or in the intergenic regions. SNPs might not change the amino acid sequence of the protein that is produced (synonymous SNP) or produce a different peptide (nonsynonymous SNPs). If SNPs are located in noncoding regions, various other processes like gene splicing or transcription factor binding might be affected.

The frequency of SNPs in a given population is provided by the minor allele frequency. This frequency differs between ethnic groups and geographic locations. SNPs were associated with various human diseases including cancer. They influence the effect of drug treatment and responses to pathogens and chemicals (69). SNPs are important for the comparison between genomes of different populations, for example, providing information about the susceptibility of a certain population to develop specific cancers (70).

THE CANCER GENOME ATLAS PROJECT

In 2006, the National Cancer Institute and the National Human Genome Research Institute initiated TCGA project. The goal of the project is to provide a comprehensive genomic characterization and sequence analysis of cancer diseases. The initial phase included glioblastoma multiforme, lung, and ovarian cancers (71,72).

TCGA is taking advantage of high-throughput genome analysis techniques, including gene expression profiling, SNP genotyping, copy number variation profiling, genomewide methylation profiling, microRNA profiling, and exon sequencing (73). These data are accessible for researchers via TCGA webpage (https://gdc.cancer.gov). The findings as pertaining to gynecologic malignancies are summarized below.

Endometrial Carcinoma

An integrated genomic, transcriptomic, and proteomic characterization of 373 endometrial carcinomas (tumor samples and corresponding germline DNA) using array- and sequencing-based technologies was performed (74). Uterine serous tumors and 25% of high-grade endometrioid tumors exhibited extensive copy number alterations, few DNA methylation changes, low ER and progesterone receptor levels, and frequent TP53 mutations. The majority of endometrioid tumors were identified as having frequent mutations in PTEN, CTNNB1, PIK3CA, ARID1A, and KRAS, novel mutations in SWI/SNF chromatin remodeling complex gene ARID5B, and few copy number alterations or TP53 mutations. In addition, 10% of endometrioid tumors were identified to have markedly increased transversion mutation frequency and a newly identified mutation in POLE. *POLE* is a catalytic subunit of DNA polymerase epsilon involved in nuclear DNA replication and repair (75). These new findings classify endometrial carcinomas into four distinct categories: POLE ultramutated, MSI hypermutated, copy-number low, and copy-number high. Somatic copy number alterations (SCNAs) showed that most endometrioid tumors have few SCNAs, most serous and serous-like tumors exhibit extensive SCNAs, and the extent of SCNA roughly correlates with progression-free survival (74).

According to TCGA data, endometrial cancer has higher-frequency mutations in the PI(3)K/AKT pathway than any other tumor type that has been studied. Endometrioid endometrial carcinomas demonstrate parallels with characteristics of colorectal carcinoma, specifically high frequency of MSI (40% and 11%, respectively), *POLE* mutations (7% and 3%, respectively) which lends to ultrahigh mutation rates, and frequent activation of WNT/CTNNB1 signaling. Yet, endometrial carcinomas are unlike those of colorectal carcinomas as they have unique *KRAS* and *CTNNB1* mutations and a distinct means by which pathway activation is achieved. Data pertaining to molecular characterization showed 25% of tumors classified as high-grade endometrioid have a molecular phenotype similar to uterine serous carcinomas, including frequent *TP53*

mutations and extensive SCNA.

Ovarian Carcinoma

TCGA review for ovarian cancer included 489 clinically annotated stages II to IV high-grade serous ovarian cancer (HGSC) samples and corresponding normal DNA. The summary of mutational spectrum includes high prevalence of mutations in TP53 (present in at least 96% of samples), BRCA1, and BRCA2 (including both germline and somatic mutations) in 22% of the tumors (76). HGSC demonstrates a high frequency of mutations in genes involved in homologous recombination, and is hence considered a disease of high genomic instability. The mutation spectrum in HGSC differs from those in other histologic subtypes of ovarian cancer. Clear-cell ovarian cancer tumors have few *TP53* mutations, yet frequent *ARID1A* and *PIK3CA* mutations (39). Endometrioid ovarian cancers carry frequent *CTNNB1*, *ARID1A*, and *PIK3CA* mutations and a lower rate of *TP53*; and mucinous ovarian cancer tumors have prevalent *KRAS* mutations (77). Such differences between ovarian cancer subtypes demonstrate the ongoing need for subtype-specific targeted therapeutic modalities.

Cervical Carcinoma

TCGA study collection included primary frozen cervical cancer tumor tissue and blood samples from patients who had not previously received chemotherapy or radiotherapy. Whole exome sequencing demonstrated the following significantly mutated genes: *ERBB3*, *CASP8*, *HLA-A*, *SHKBP1,* and *TGFBR2* (78). Amplifications and fusion events were reported involving the *BCAR4* gene, a metastasis-promoting lncRNA that enhances cell proliferation in estrogen-resistant breast cancer by activating the HER2/3 pathway, which can be targeted indirectly by *lapatinib* (a dual tyrosine kinase inhibitor that interrupts the HER2 and EGFR pathways) (78,79). Amplifications in *CD274* and *PDCD1LG2* were identified, both of which have been associated with response to *lapatinib*. Another identified novel genomic characteristic that further subclassifies cervical cancers is a group of endometrial-like cervical cancers involved predominantly with HPV-negative tumors and characterized by mutations in *KRAS*, *ARID1A*, and PTEN. These proteins may serve as therapeutic targets.

IMMUNOLOGY

The immune system plays an essential part in host defense mechanisms, in particular the response to infections and neoplastic transformation. Our increased understanding of immune system regulation provides opportunities for the development of novel immunotherapeutic and immunodiagnostic approaches.

Immunologic Mechanisms

The human immune system has the potential to respond to abnormal or tumor cells in various ways. Some of these immune responses occur in an innate or antigen-nonspecific manner, whereas others are adaptive or antigen specific. Adaptive responses are specific to a given antigen. The establishment of a memory response allows a more rapid and vigorous response to the same antigen in future encounters. Various innate and adaptive immune mechanisms are involved in responses to tumors, including cytotoxicity directed to tumor cells mediated by cytotoxic T cells (CTLs), natural killer (NK) cells, macrophages, and antibody-dependent cytotoxicity mediated by complementation activation (80).

Adaptive or specific immune responses include humoral and cellular responses. *Humoral immune responses* refer to the production of antibodies. Antibodies are bifunctional molecules composed of a variable region with specific antigen-binding sites, combined with a constant region that directs the biologic activities of the antibody, such as binding to phagocytic cells or activation of complement. ***Cellular immune responses* are antigen-specific immune responses mediated directly by activated immune cells rather than by the production of antibodies**. The distinction between humoral and cellular responses is historical and originates from the experimental observation that humoral immune function can be transferred by serum, whereas cellular immune function requires the transfer of cells. Most immune responses include both humoral and cellular components. Several types of cells, including cells from both the myeloid and lymphoid lineages, make up the immune system. Specific humoral and cellular immune responses to foreign antigens involve the coordinated action of populations of lymphocytes operating in concert with one another and with phagocytic cells (macrophages). These cellular interactions include direct cognate interactions involving cell-to-cell contact and cellular interactions involving the secretion of and response to cytokines or lymphokines. Lymphoid cells are found in lymphoid tissues, such as lymph nodes or spleen, or in the peripheral circulation. The cells that make up the immune system originate from stem cells in the bone marrow.

B Cells, Hormonal Immunity, and Monoclonal Antibodies

B lymphocytes synthesize and secrete antibodies. Mature, antigen-responsive B cells develop from pre-B cells (committed B-cell progenitors) and differentiate to become plasma cells, which produce large quantities of antibodies. Pre-B cells originate from bone marrow stem cells in adults after rearrangement of immunoglobulin genes from their germ cell configuration. Mature B cells express cell surface immunoglobulin molecules that function as receptors for antigen.

Upon interaction with antigen, mature B cells respond to become antibody-producing cells. The process requires the presence of appropriate cell–cell stimulatory

signals and cytokines. Monoclonal antibodies are directed against a specific antigenic determinant. In contrast, polyclonal antibodies detect multiple epitopes that might be presented by just one or a panel of proteins. The in vitro production of monoclonal antibodies, pioneered by Kohler and Milstein in the 1970s, has become an invaluable diagnostic and therapeutic tool, particularly for the management of malignancies (81). The tumor antigen CA125, for example, was detected in a screen of antibodies generated against ovarian cancer cell lines. A radioimmunoassay is widely used to measure CA125 in the serum of patients with ovarian cancer and guide treatment decisions. Therapeutic approaches utilized immunotoxin-conjugated monoclonal antibodies directed to human ovarian adenocarcinoma antigens. These antibodies induce tumor cell killing and can prolong survival in mice implanted with a human ovarian cancer cell line. However, some obstacles limit the clinical use of monoclonal antibodies, including tumor cell antigenic heterogeneity, modulation of tumor-associated antigens, and cross-reactivity of normal host and tumor-associated antigens. Unique tumor-specific antigens have not been identified. All tumor antigens have to be considered as tumor-related antigens because they are expressed on malignant and nonmalignant tissues. Because most monoclonal antibodies are murine, the host's immune system can recognize and respond to these foreign mouse proteins. The use of the genetically engineered monoclonal antibodies composed of human-constant regions with specific antigen-reactive murine variable regions can result in reduced antigenicity.

T Lymphocytes and Cellular Immunity

[6] T lymphocytes have a central role in the generation of immune responses by acting as helper cells in both humoral and cellular immune responses and by acting as effector cells in cellular responses. T-cell precursors originate in the bone marrow and move to the thymus, where they mature into functional T cells. During their thymic maturation, T cells that can recognize antigens in the context of the *major histocompatibility complex* (MHC) molecules are selected, while self-responding T cells are removed (82).

T cells can be distinguished from other types of lymphocytes by their cell surface phenotype, based on the pattern of expression of various molecules, and by differences in their biologic functions. All mature T cells express certain cell surface molecules, such as the cluster determinant 3 (CD3) molecular complex and the T-cell antigen receptor (TCR), found in close association with the CD3 complex. **T cells recognize antigens through the cell surface T-cell antigen receptor**. The structure and organization of this molecule are similar to those of antibody molecules, which are the B-cell receptors for the antigen. During T-cell development, the T-cell receptor gene undergoes gene arrangements similar to those seen in B cells, but there are important differences between the antigen receptors on B cells and T cells. The T-cell receptor is

not secreted, and its structure is somewhat different from that of antibody molecules. The way in which the B-cell and T-cell receptors interact with antigens is quite different. T cells can respond to antigens only when these antigens are presented in association with MHC molecules on antigen-presenting cells. Effective antigen presentation involves the processing of the antigen into small fragments of peptide within the antigen-presenting cell and the subsequent presentation of these fragments of antigen in association with MHC molecules expressed on the surface of the antigen-presenting cell. T cells can respond to antigens only when presented in this manner, unlike B cells, which can bind antigens directly, without processing and presentation by antigen-presenting cells.

[7] **There are two major subsets of mature T cells that are phenotypically and functionally distinct: *T-helper/inducer cells*, which express the CD4 cell surface marker, and the *CTLs*, which express the CD8 marker.** The expression of these markers is acquired during the passage of T cells through the thymus. CD4 T cells can provide help to B cells, resulting in the production of antibodies by B cells, and interact with antigen presented by antigen-presenting cells in association with MHC class II molecules. CD4 T cells can act as helper cells for other T cells. CD8 T cells include cells that are cytotoxic (cells that can kill target cells bearing appropriate antigens), and they interact with an antigen presented on target cells in association with MHC class I molecules. These T cells can inhibit the biologic functions of B cells or other T cells (80). Although the primary biologic role of *CTLs* seems to be lysis of virus-infected autologous cells, cytotoxic immune T cells can mediate the lysis of tumor cells directly. Presumably, CTLs recognize antigens associated with MHC class I molecules on tumor cells through their antigen-specific T-cell receptor, setting off a series of events that ultimately results in the lysis of the target cell.

Monocytes and Macrophages

Monocytes and macrophages, which are myeloid cells, have important roles in innate and adaptive immune responses; macrophages play a key part in the generation of immune responses. T cells do not respond to foreign antigens unless those antigens are processed and presented by antigen-presenting cells. **Macrophages (and B cells and dendritic cells) express MHC class II molecules and are effective antigen-presenting cells for CD4 T cells.** Helper-inducer (CD4) T cells that bear a T-cell receptor of appropriate antigen and self-specificity are activated by this antigen-presenting cell to provide help (various factors—lymphokines—that induce the activation of other lymphocytes). In addition to their role as antigen-presenting cells, macrophages play an important part in innate responses by ingesting and killing microorganisms. Activated macrophages, besides their many other functional capabilities, can act as cytotoxic, antitumor killer cells.

Natural Killer Cells

NK cells are effector cells in an innate type of immune response: the nonspecific killing of tumor cells and virus-infected cells. Therefore, **NK activity represents an innate form of immunity that does not require an adaptive, memory response for optimal biologic function, but the antitumor activity can be increased by exposure to several agents, particularly cytokines such as interleukin-2 (IL-2).** Characteristically, NK cells have a large granular lymphocyte morphology. NK cells display a pattern of cell surface markers that differs from those characteristic of T or B cells. NK cells can express a receptor for the crystallizable fragment (Fc) portion of antibodies, and other NK-associated markers. NK cells appear to be functionally and phenotypically heterogeneous, when compared with T or B cells. The cells that can carry out antibody-dependent cellular cytotoxicity, or antibody-targeted cytotoxicity, are NK-like cells. Antibody-dependent cellular cytotoxicity by NK-like cells resulted in the lysis of tumor cells in vitro. The mechanisms of this tumor cell killing are not clearly understood, although close cellular contact between the effector cell and the target cell seems to be required.

Cytokines, Lymphokines, and Immune Mediators

Many events in the generation of immune responses (and during the effector phase of immune responses) require or are enhanced by cytokines, which are soluble mediator molecules (Table 6-5) (83,84). Cytokines are pleiotropic in that they have multiple biologic functions that depend on the type of target cell or its maturational state. Cytokines are heterogeneous in the sense that most cytokines share little structural or amino acid homology. ***Cytokines*** **are called** ***monokines*** **if they are derived from monocytes,** ***lymphokines*** **if they are derived from lymphocytes,** ***interleukins*** **if they exert their actions on leukocytes, or** ***interferons*** **(IFNs) if they have antiviral effects.** They are produced by a wide variety of cell types and seem to have important roles in many biologic responses outside the immune response, such as inflammation or hematopoiesis. They may be involved in the pathophysiology of a wide range of diseases and show great potential as therapeutic agents in immunotherapy for cancer. Although cytokines are a heterogeneous group of proteins, they share some characteristics. For instance, most cytokines are low- to intermediate-molecular-weight (10 to 60 kDa) glycosylated-secreted proteins. They are involved in immunity and inflammation, are produced transiently and locally (they act in an autocrine and paracrine rather than an endocrine manner), are extremely potent in small concentrations, and interact with high-affinity cellular receptors that are specific for each cytokine. The cell surface binding of cytokines by specific receptors results in signal transduction followed by changes in gene expression and, ultimately, by changes in cellular proliferation or altered cell behavior, or both. Their biologic actions overlap, and exposure of responsive cells to multiple cytokines can result in synergistic or antagonistic biologic effects.

T-cell subsets characterized by the secretion of distinct patterns of cytokines were identified. **T_H1 and T_H2 are two helper T-cell subpopulations that control the nature of an immune response by secreting a characteristic and mutually antagonistic set of cytokines: clones of T_H1 produce IL-2 and IFN-γ, whereas T_H2 clones produce IL-4, IL-5, and IL-10** (85). A similar dichotomy between T_H1- and T_H2-type responses was reported in humans. Human IL-10 inhibits the production of IFN-γ and other cytokines by human peripheral blood mononuclear cells and by suppressing the release of cytokines (IL-1, IL-6, IL-8, and TNF-α) by activated monocytes (84). IL-10 downregulates class II MHC expression on monocytes, resulting in a strong reduction in the antigen-presenting capacity of these cells. Together, these observations support the concept that IL-10 has an important role as an immune-inhibitory cytokine. Additional T-cell subsets were identified, including Th17 cells and regulatory T cells (Treg). Th17 cells are a distinct, pro-inflammatory T-cell subset, which is functionally characterized by mediating protection against extracellular bacteria and by its pathogenic role in autoimmune disorders (86,87). Th17 cells characteristically produce IL-17, CXCL13 (a B-cell stimulatory chemokine), IL-6, and TNF-α, in contrast to Th2 cells, which characteristically produce IL-4, IL-5, IL-9, and IL-13, or Th1 cells, which produce IFN-γ **(Fig. 6-2)**. Treg cells constitute another subset of CD4-positive T cells that participates in the maintenance of immunologic self-tolerance by actively suppressing the activation and expansion of self-reactive lymphocytes. Treg cells are characterized by the expression of CD25 (the IL-2 receptor chain) and the transcription factor FoxP3 (88,89). Treg cell activity is thought to be important in preventing the development of autoimmune diseases. Removal of Treg may enhance immune responses against infectious agents or cancer. Although much remains to be learned about the role of Treg activity in antitumor immunity, it is clear that such cells may play a role in modulating host responses to cancer. Much of the recent research has been directed at the tumor microenvironment. Specifically, the tumor microenvironment consists of several varieties of cell types that interact with tumor cells to influence tumor initiation, growth, and metastasis (90). The tumor microenvironment plays a key role in allowing tumor cells to evade immune recognition and destruction.

Because epithelial cancers of the ovary usually remain confined to the peritoneal cavity, even in the advanced stages of the disease, it was suggested that the growth of ovarian cancer intraperitoneally could be related to a local deficiency of antitumor immune effector mechanisms (91). Studies showed that ascitic fluid from patients with ovarian cancer contained increased concentrations of IL-10. Various other cytokines are seen in ascitic fluid obtained from women with ovarian cancer, including IL-6, IL-10, TNF-α, *granulocyte colony-stimulating factor* (G-CSF), and *granulocyte-macrophage colony-stimulating factor* (GM-CSF). A similar pattern was seen in serum

samples from women with ovarian cancer with elevations of IL-6 and IL-10.

TNF-α is a cytokine that can be directly cytotoxic for tumor cells, increase immune cell–mediated cellular cytotoxicity, activate macrophages, and induce secretion of monokines. Other biologic activities of TNF-α include the induction of cachexia, inflammation, and fever; it is an important mediator of endotoxic shock.

Cytokines in Cancer Therapy

Cytokines are exceptionally pleiotropic with a wide array of biologic activities, including some outside the immune system (92). Because some cytokines have direct or indirect antitumor and immune-enhancing effects, several of these factors are used in the experimental treatment of cancer.

The precise roles of cytokines in antitumor responses have not been elucidated. Cytokines can exert antitumor effects by many different direct or indirect activities. It is possible that a single cytokine could increase tumor growth directly by acting as a growth factor while at the same time increasing immune responses directed toward the tumor. The potential of cytokines to increase antitumor immune responses was tested in experimental adoptive immunotherapy by exposing the patient's peripheral blood cells or tumor-infiltrating lymphocytes to cytokines such as IL-2 in vitro, thus generating activated cells with antitumor effects that can be given back to the patient (93). Some cytokines can exert direct antitumor effects. TNF can induce cell death in sensitive tumor cells.

The effects of cytokines on patients with cancer might be modulated by soluble receptors or blocking factors. For instance, blocking factors for TNF and for lymphotoxin were found in ascitic fluid from patients with ovarian cancer (93). Such factors could inhibit the cytolytic effects of TNF or lymphotoxin and should be taken into account in the design of clinical trials of intraperitoneal infusion of these cytokines.

Table 6-5 Sources, Target Cells, and Biologic Activities of Cytokines Involved in Immune Responses

Cytokine	Cellular Source	Target Cells	Biologic Effects
IL-1	Monocytes and macrophages	T cells, B cells Neurons	Costimulator Pyrogen
IL-2	Tumor cells	Endothelial cells	
	T cells	T cells	Activation and growth
		B cells	Activation and antibody production
		NK cells	Activation and growth
IL-3	T cells	Immature hemopoietic stem cells	Growth and differentiation
IL-4	T cells (T_H2)	B cells	Activation and growth; isotype switch to IgE; increased MHCII expression
		T cells	Growth
IL-6	Monocytes and macrophages	B cells	Differentiation, antibody production
	T cells (T_H17), B cells	T cells	Costimulator
	Ovarian cancer cells	Hepatocytes	Induction of acute-phase response
	Other tumors	Stem cells	Growth and differentiation
	Tumor cells	Autocrine/paracrine growth and viability-enhancing factor	
IL-10	T cells (Treg, T_H2)	T cells	Inhibition of cytokine synthesis
	Monocytes and macrophages	Monocytes and macrophages	Inhibition of Ag presentation and cytokine production
		B cells	Activation
IL-12	Monocytes	NK cells, T cells	Promotes T_H1 cells
IL-13	T cells (T_H2), mast cells, NK cells	B cells, T_H2 cells, macrophages	Regulates IgE secretion by B cell T_H2 development Macrophage activity
IL-15	Dendritic cells, monocytes, placenta, kidney, lung, heart, T cells	Mast cells	NK cell development and function Mast cell proliferation
IL-17	T cells (T_H17)	T cells, fibroblasts	T-cell activation Induces secretion of cytokines by fibroblasts
IL-23	Monocytes, macrophages	CD4+ T cells	Promotes T_H17 cells
IFN-γ	T cells (T_H1)	Monocytes/macrophages	Activation
	NK cells	NK cells, T cells, B cells	Activation Enhances responses
TNF-α	Monocytes and macrophages	Monocytes/macrophages	
	T cells (T_H17)	T cells, B cells	
		Neurons	
	Monokine production		
	Costimulator		
	Pyrogen		
		Endothelial cells Muscle and fat cells	Activation, inflammation Catabolism/cachexia

IL-1, interleukin-1; Treg, regulatory T cells; T_H1, type 1 T-helper lymphocyte; NK cells, natural killer cells; T_H2, type 2 T-helper lymphocyte; IgE, immunoglobulin E; MHCII, major histocompatibility complex class II; Ag, antigen; IFN, interferon; TNF, tumor necrosis factor.

Modified from **Berek JS, Martinez-Maza O.** *Immunology and immunotherapy.* In: **Lawton FG, Neijt JP, Swenerton KD,** eds. *Epithelial Cancer of the Ovary. London: BMJ; 1995:224,* with permission.

Cytokines have growth-increasing effects on tumor cells in addition to inducing antitumor effects. They can act as autocrine or paracrine growth factors for human tumor cells, including those of nonlymphoid origin. For instance, IL-6 (which is produced by various types of human tumor cells) can act as a growth factor for human myeloma, Kaposi sarcoma, renal carcinoma, and epithelial ovarian cancer cells (94).

Cytokines are of great potential value in the treatment of cancer, but because of their

multiple, even conflicting, biologic effects, a thorough understanding of cytokine biology is essential for their successful use (93).

FACTORS THAT TRIGGER NEOPLASIA

Cell biology is characterized by considerable redundancy and functional overlap, so a defect in one mechanism does not invariably jeopardize the function of the cell. When a sufficient number of abnormalities in structure and function occur, normal cell activity is jeopardized, and uncontrolled cell growth or cell death results. Either end point may result from accumulated genetic mutations. Factors are identified that enhance the likelihood of genetic mutations, jeopardize normal cell biology, and may increase the risk of cancer.

Increased Age

Increasing age is considered the single most important risk factor for the development of cancer (95). Cancer is diagnosed in as much as 50% of the population by 75 years of age. It was suggested that the increasing risk of cancer with age reflects the accumulation of critical genetic mutations over time, which ultimately culminates in neoplastic transformation. The basic premise of the multistep somatic mutation theory of carcinogenesis is that genetic or epigenetic alterations of numerous independent genes result in cancer. Factors that are associated with an increased likelihood of cancer include exposure to exogenous mutagens, altered host immune function, and certain inherited genetic syndromes and disorders.

Environmental Factors

A mutagen is a compound that results in a genetic mutation. A number of environmental pollutants act as mutagens when tested in vitro. Environmental mutagens usually produce specific types of mutations that can be differentiated from spontaneous mutations. A carcinogen is a compound that can produce cancer. It is important to recognize that all carcinogens are not mutagens and that all mutagens are not necessarily carcinogens.

Smoking

Cigarette smoking is perhaps the most well-known example of mutagen exposure that is associated with the development of lung cancer when the exposure is of sufficient duration and quantity in a susceptible individual. An association between cigarette smoking and cervical cancer has been recognized for decades. **It was determined that the mutagens in cigarette smoke are selectively concentrated in**

cervical mucus (96). It was hypothesized that cigarette smoke acted as a mutagen when exposed to the proliferating epithelial cells of the transformation zone, thus increasing the likelihood of DNA damage and subsequent cellular transformation.

Others observed that HPV DNA is frequently inserted into the fragile histidine triad (*FHIT*) gene in cervical cancer specimens. The *FHIT* is an important tumor suppressor gene. Cigarette smoking might facilitate the incorporation of HPV DNA into the *FHIT* gene with subsequent disruption of correct tumor suppressor gene function.

Radiation

Radiation exposure can increase the risk of cancer. The biologic effects of ionization surpass those of x-rays and gamma rays. Ionization of water molecules creates hydroxyl radicals, which cause DNA strand breaks or base damage. Most radiation-induced damage is repaired precipitously. However, misrepair may cause point mutations, chromosome translocations, and gene fusions associated with cancer initiation (97). Normally, radiation damage prompts an S-phase arrest so that DNA damage is repaired. This requires normal *p53* gene function. If DNA repair fails, the damaged DNA is propagated to daughter cells following mitosis. If a sufficient number of critical genes are mutated, cellular transformation may result (98).

Immune Function

Systemic immune dysfunction was recognized for decades as a risk factor for cancer. Patients infected with HIV who have a depressed CD4 cell count are reported to be at increased risk of cervical dysplasia (99). Individuals who underwent high-dose chemotherapy with stem cell support may be at increased risk of developing a variety of solid neoplasms. These examples illustrate the importance of immune function in host surveillance for transformed cells. Another example of altered immune function that may be related to the development of cervical dysplasia is the alteration in mucosal immune function that occurs in women who smoke cigarettes (100). The Langerhans cell population of the cervix is decreased in women who smoke. Langerhans cells are responsible for antigen processing. It is postulated that a reduction in these cells increases the likelihood of successful HPV infection of the cervix.

Summary of Menstrual Cycle Regulation

KEY POINTS

1 The female reproductive process involves the central nervous system (primarily hypothalamus), the pituitary gland, the ovary, and the uterus (endometrium). All must function appropriately for normal reproduction to occur.

2 Hypothalamic gonadotropin-releasing hormone (GnRH) simultaneously regulates the luteinizing hormone (LH) and follicle-stimulating hormone (FSH) in the pituitary through pulsatile secretions. The pulse frequency determines the relative amounts of LH and FSH secretion.

3 The ovary responds to FSH and LH in a defined, sequential manner to produce follicular growth, ovulation, and corpus luteum formation. The cycle is designed to produce an optimal environment for pregnancy; if pregnancy does not occur, the cycle begins again.

4 In the early menstrual cycle the ovary produces estrogen, which is responsible for endometrial growth. After ovulation, progesterone is produced in significant quantities, which transforms the endometrium into a form ideal for implantation of the embryo. If no pregnancy occurs, the ovary ceases to produce estrogen and progesterone, the endometrium is sloughed, and the cycle repeats.

[1] The reproductive process in women is a complex and highly evolved interaction of many components. The carefully orchestrated series of events that contributes to a normal ovulatory menstrual cycle requires precise timing and regulation of hormonal input from the central nervous system (CNS), pituitary gland, and ovary. This delicately balanced process can be disrupted easily and result in reproductive failure, which is a major clinical issue confronting gynecologists. To manage such conditions effectively, it is critical that gynecologists understand the normal physiology of the menstrual cycle. The anatomic structures, hormonal components, and their interactions, play a vital role in the function of the reproductive system. Fitting together the various pieces of this intricate puzzle creates “the big picture”: an overview of how the reproductive system of women is designed to function.

NEUROENDOCRINOLOGY

Neuroendocrinology represents facets of two traditional fields of medicine: endocrinology, which is the study of hormones (i.e., substances secreted into the bloodstream that have diverse actions at sites remote from the point of secretion); and neuroscience, which is the study of the action of neurons. The discovery of neurons that transmit impulses and secrete their products into the vascular system to function as hormones, a process known as neurosecretion, demonstrates that the two systems are intimately linked. For instance, the menstrual cycle is regulated through the feedback of hormones on the neural tissue of the CNS.

ANATOMY

Hypothalamus

The hypothalamus is a small neural structure situated at the base of the brain above the optic chiasm and below the third ventricle (Fig. 7-1). It is connected

directly to the pituitary gland and is the part of the brain that is the source of many pituitary secretions. Anatomically, the hypothalamus is divided into three zones: *periventricular* (adjacent to the third ventricle); *medial* (primarily cell bodies); and *lateral* (primarily axonal). Each zone is further subdivided into structures known as nuclei, which represent locations of concentrations of similar types of neuronal cell bodies **(Fig. 7-2)**.

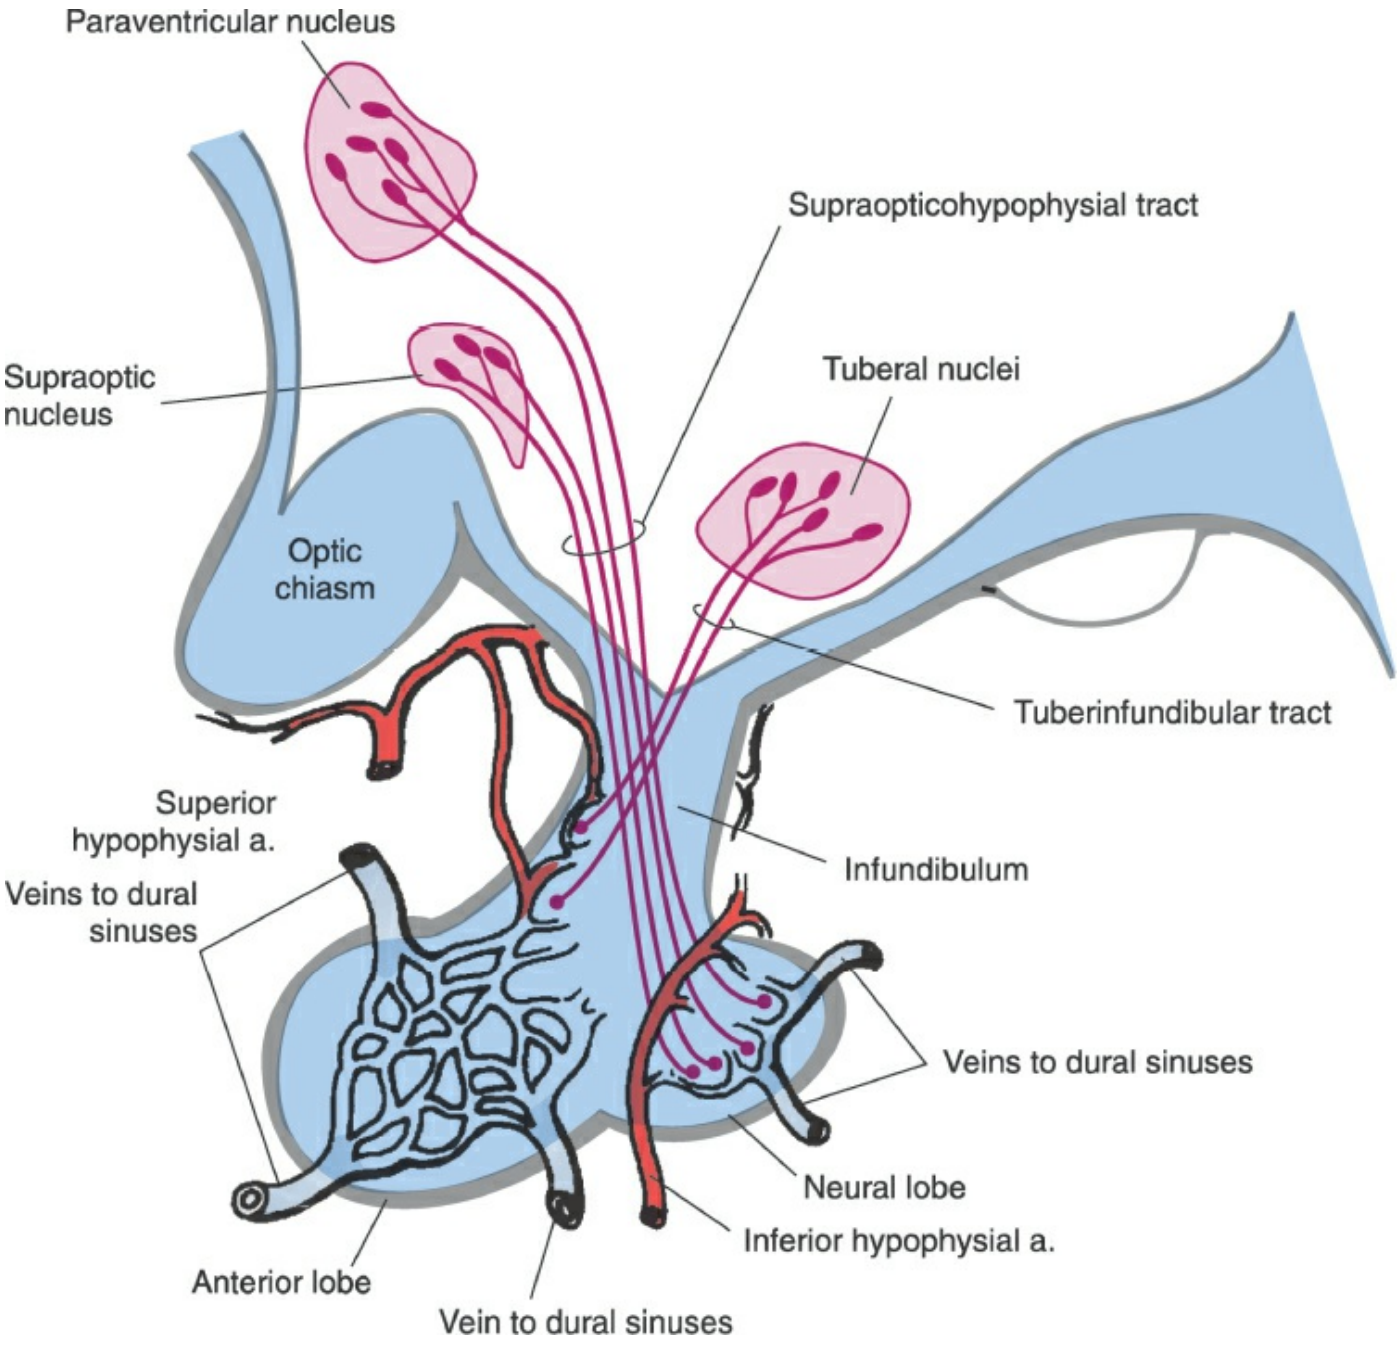

FIGURE 7-1 The hypothalamus and its neurologic connections to the pituitary.

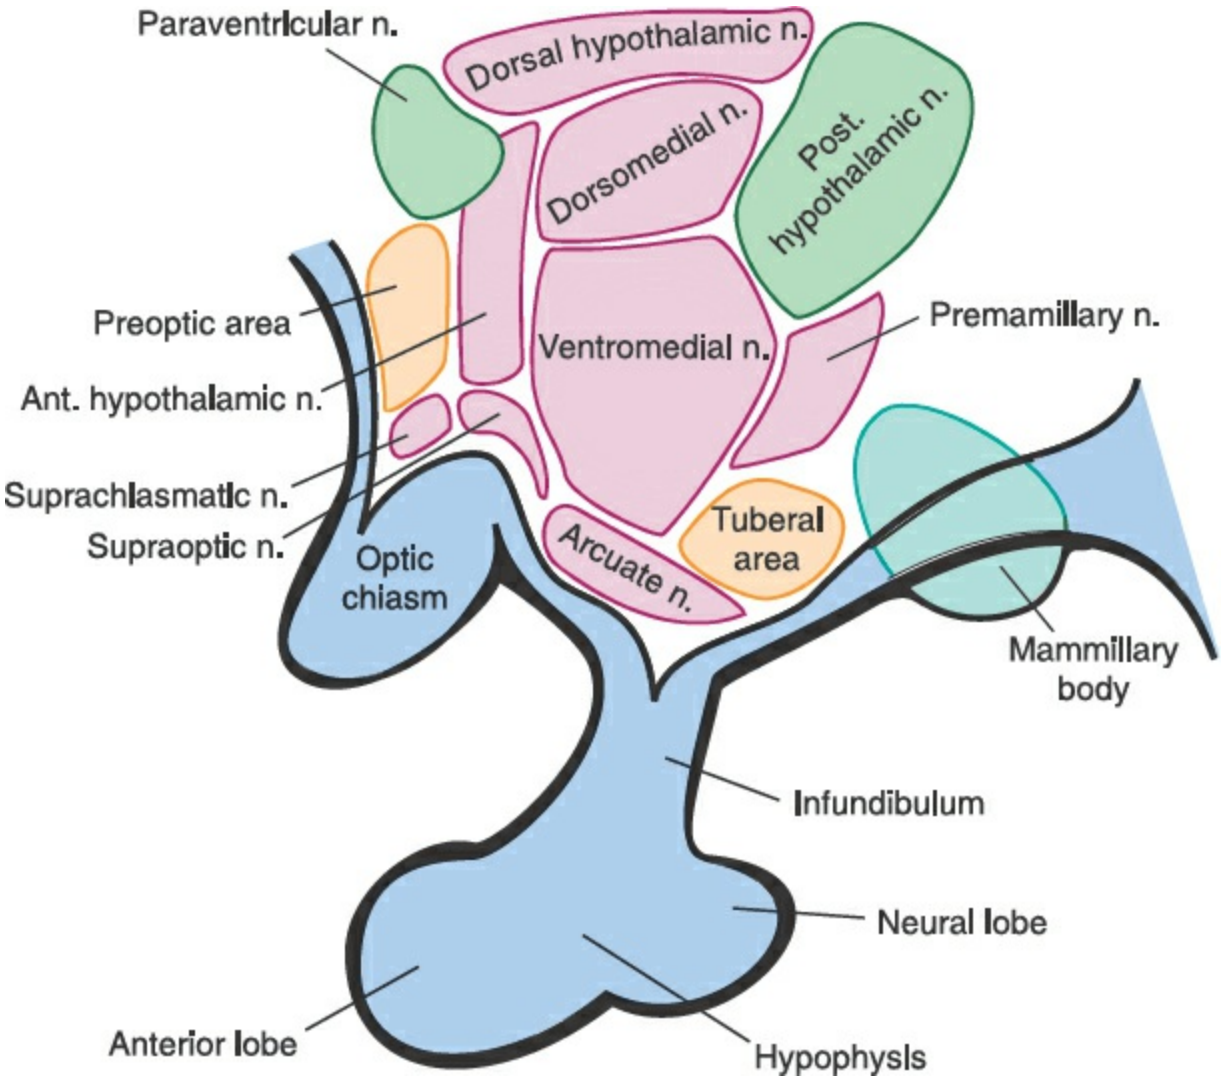

FIGURE 7-2 The neuronal cell bodies of the hypothalamus.

The hypothalamus is not an isolated structure within the CNS; instead, it has multiple interconnections with other regions in the brain. In addition to the well-known pathways of hypothalamic output to the pituitary, there are numerous less well-characterized pathways of output to diverse regions of the brain, including the limbic system (amygdala and hippocampus), the thalamus, and the pons (1). Many of these pathways form feedback loops to areas supplying neural input to the hypothalamus.

FIGURE 7-3 The hypothalamic secretory products function as pituitary-releasing factors that control the endocrine function of the ovaries, the thyroid, and the adrenal glands. CRH, corticotropin releasing hormone; TRH, thyrotropin releasing hormone; GnRH, gonadotropin releasing hormone; FSH, follicle stimulating hormone; LH, leutinizing hormone; T4, thyroxine; ACTH, adrenocorticotropic hormone; TSH, thyroid stimulating hormone; and E_2, estradiol.

Several levels of feedback to the hypothalamus exist and are known as the long, short, and ultrashort feedback loops. The **long feedback loop** is composed of endocrine input from circulating hormones, just as is the feedback of androgens and estrogens onto steroid receptors in the hypothalamus (2,3). Similarly, pituitary hormones may feed back to the hypothalamus and serve important regulatory functions in **short-loop feedback.** Finally, hypothalamic secretions may directly feed back to the hypothalamus itself in an **ultrashort feedback loop.**

The major secretory products of the hypothalamus are the pituitary-releasing factors (Fig. 7-3):

1. ***Gonadotropin-releasing hormone* (*GnRH*), which controls the secretion of *luteinizing hormone* (*LH*) and *follicle-stimulating hormone* (*FSH*)**
2. ***Corticotropin-releasing hormone* (*CRH*), which controls the release of *adrenocorticotrophic hormone* (*ACTH*)**
3. ***Growth hormone–releasing hormone* (*GHRH*), which regulates the release of *growth hormone* (*GH*)**
4. ***Thyrotropin-releasing hormone* (*TRH*), which regulates the secretion of *thyroid-stimulating hormone* (*TSH*)**

The hypothalamus is the source of all neurohypophyseal hormone production. The neural posterior pituitary can be viewed as a direct extension of the hypothalamus connected by the finger-like infundibular stalk. The capillaries in the median eminence differ from those in other regions of the brain. Unlike the usual tight junctions that exist between adjacent capillary endothelial lining cells, the capillaries in this region are fenestrated in the same manner as capillaries outside the CNS. As a result, there is no blood–brain barrier in the median eminence.

Pituitary

The pituitary is divided into three regions or lobes: *anterior*, *intermediate*, and *posterior*. The *anterior pituitary* (*adenohypophysis*) is quite different structurally from the *posterior neural pituitary* (*neurohypophysis*), which is a direct physical extension of the hypothalamus. The adenohypophysis is derived embryologically from epidermal ectoderm from an infolding of Rathke pouch. Therefore, it is not composed of neural

tissue, as is the posterior pituitary, and does not have direct neural connections to the hypothalamus. Instead, a unique anatomic relationship exists that combines elements of neural production and endocrine secretion.

The adenohypophysis itself has no direct arterial blood supply. Its major source of blood flow is also its source of hypothalamic input—the portal vessels. Blood flow in these portal vessels is primarily from the hypothalamus to the pituitary. Blood is supplied to the posterior pituitary via the superior, middle, and inferior hypophyseal arteries. In contrast, the anterior pituitary has no direct arterial blood supply. Instead, it receives blood via a rich capillary plexus of the portal vessels that originates in the median eminence of the hypothalamus and descends along the pituitary stalk. This pattern is not absolute, however, and retrograde blood flow has occurred (4). This blood flow, combined with the location of the median eminence outside the blood–brain barrier, permits bidirectional feedback control between the two structures.

The specific secretory cells of the anterior pituitary are classified based on their hematoxylin- and eosin-staining patterns. Acidophilic-staining cells primarily secrete GH and prolactin and, to a variable degree, ACTH (5). The gonadotropins are secreted by basophilic cells, and TSH is secreted by the neutral-staining chromophobes.

REPRODUCTIVE HORMONES

Hypothalamus

Gonadotropin-Releasing Hormone

***GnRH* (*also called luteinizing hormone–releasing hormone, or LHRH*) is the controlling factor for gonadotropin secretion** (6). It is a decapeptide produced by neurons with cell bodies primarily in the arcuate nucleus of the hypothalamus (7–9) **(Fig. 7-4)**. Embryologically, these neurons originate in the olfactory pit and migrate to their adult locations (10). These GnRH-secreting neurons project axons that terminate on the portal vessels at the median eminence where GnRH is secreted for delivery to the anterior pituitary. Less clear in function are multiple other secondary projections of GnRH neurons to locations within the CNS.

The gene that encodes GnRH produces a 92-amino-acid precursor protein, which contains the GnRH decapeptide and a 56 amino acid peptide known as GnRH-associated peptide (GAP). The GAP is a potent inhibitor of prolactin secretion and a stimulator of gonadotropin release.

Pulsatile Secretion

[2] GnRH is unique among releasing hormones in that it simultaneously regulates the secretion of two hormones—FSH and LH. It is unique among the body's

hormones because it must be secreted in a pulsatile fashion to be effective, and the pulsatile release of GnRH influences the release of the two gonadotropins (11–13). Using animals that had undergone electrical destruction of the arcuate nucleus and had no detectable levels of gonadotropins, a series of experiments were performed with varying dosages and intervals of GnRH infusion (13,14). Continual infusions did not result in gonadotropin secretion, whereas a pulsatile pattern led to physiologic secretion patterns and follicular growth. Continual exposure of the pituitary gonadotroph to GnRH results in a phenomenon called *downregulation*, through which the number of gonadotroph cell surface GnRH receptors is decreased (15). Similarly, intermittent exposure to GnRH will "upregulate" or "autoprime" the gonadotroph to increase its number of GnRH receptors (16). This allows the cell to have a greater response to subsequent GnRH exposure. Similar to the intrinsic electrical pacemaker cells of the heart, this action most likely represents an intrinsic property of the GnRH-secreting neuron, although it is subject to modulation by various neuronal and hormonal inputs to the hypothalamus.

The continual pulsatile secretion of GnRH is necessary because GnRH has an extremely short half-life (only 2 to 4 minutes) as a result of rapid proteolytic cleavage. The pulsatile secretion of GnRH varies in frequency and amplitude throughout the menstrual cycle and is tightly regulated **(Fig. 7-5)** (17,18).

The **follicular phase** is characterized by frequent, small-amplitude pulses of GnRH secretion. In the late follicular phase, there is an increase in frequency and amplitude of pulses. During **the luteal phase**, however, there is a progressive lengthening of the interval between pulses. The amplitude in the luteal phase is higher than that in the follicular phase, but it declines progressively over the 2 weeks. This variation in pulse frequency allows for variation in LH and FSH throughout the menstrual cycle. For example, decreasing the pulse frequency of GnRH decreases LH secretion but increases FSH, an important aspect of enhancing FSH availability in the late luteal phase. The pulse frequency is not the sole determinant of pituitary response; additional hormonal influences, such as those exerted by ovarian peptides and sex steroids, can modulate the GnRH effect.

FIGURE 7-4 Gonadotropin-releasing hormone is a decapeptide.

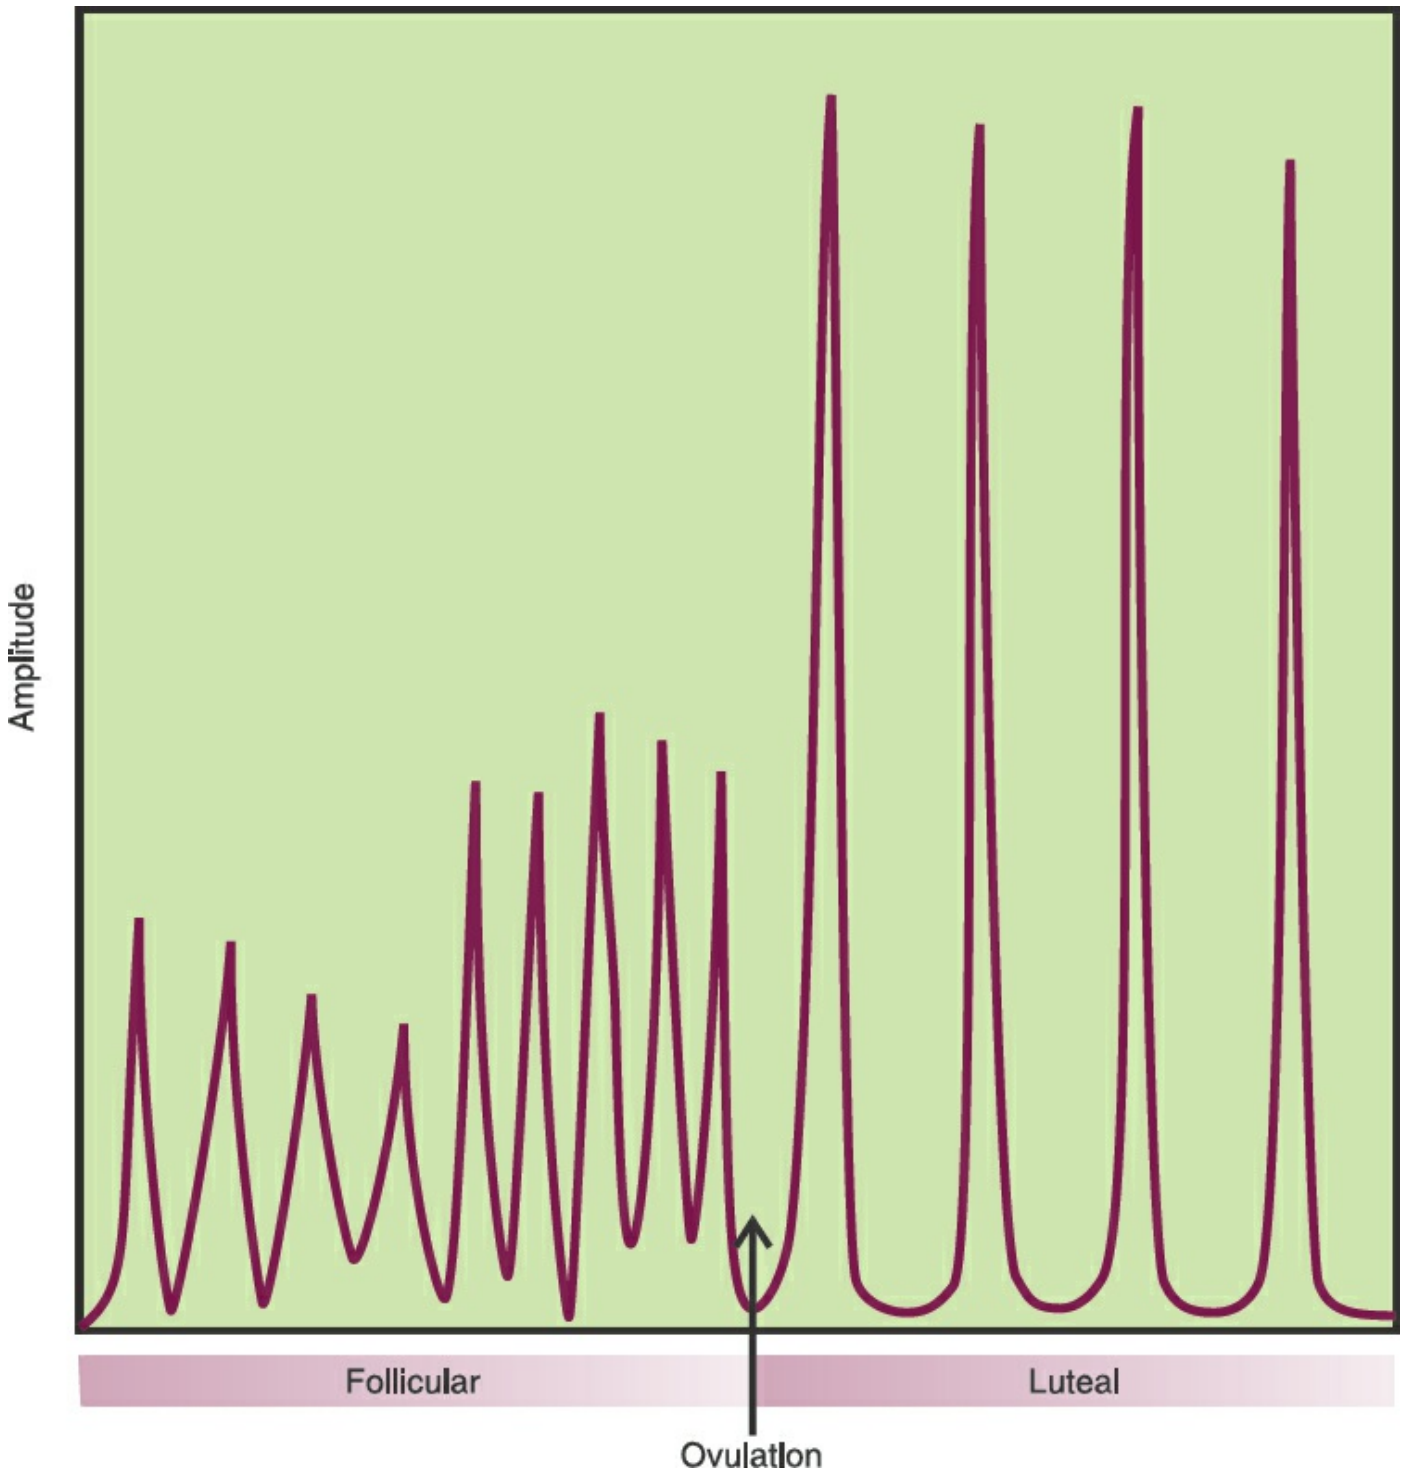

FIGURE 7-5 The pulsatile secretion of gonadotropin-releasing hormone in the follicular and luteal phases of the cycle.

Although GnRH is primarily involved in endocrine regulation of gonadotropin secretion from the pituitary, it is apparent that this molecule has autocrine and paracrine functions throughout the body. The decapeptide is found in neural and nonneural tissues; receptors are present in many extrapituitary structures, including the ovary and placenta. Data suggest that GnRH may be involved in regulating human

chorionic gonadotropin (hCG) secretion and implantation, and in decreasing cell proliferation and mediating apoptosis in tumor cells (19). The role of GnRH in the extrapituitary sites remains to be fully elucidated.

Gonadotropin-Releasing Hormone Agonists

Mechanism of Action

Used clinically, GnRH agonists are modifications of the native molecule to either increase receptor affinity or decrease degradation (20). Their use leads to a persistent activation of GnRH receptors, as if continuous GnRH exposure existed. As would be predicted by the constant GnRH infusion experiments, this leads to suppression of gonadotropin secretion. An initial release of gonadotropins is followed by a profound suppression of secretion. The initial release of gonadotropins represents the secretion of pituitary stores in response to receptor binding and activation. With continued activation of the gonadotroph GnRH receptor, however, there is a downregulation effect and a decrease in the concentration of GnRH receptors. As a result, gonadotropin secretion decreases and sex steroid production falls to castrate levels (21).

Additional modification of the GnRH molecule results in an analogue that has no intrinsic activity but competes with GnRH for the same receptor site (22). **These GnRH antagonists produce a competitive blockade of GnRH receptors, preventing stimulation by endogenous GnRH and causing an immediate fall in gonadotropin and sex steroid secretion** (23). The clinical effect is observed within 24 to 72 hours. Moreover, antagonists may not function solely as competitive inhibitors; evidence suggests they may also produce downregulation of GnRH receptors, further contributing to the loss of gonadotropin activity (24).

Structure—Agonists and Antagonists

As a peptide hormone, GnRH is degraded by enzymatic cleavage of bonds between its amino acids. Pharmacologic alterations of the structure of GnRH led to the creation of agonists and antagonists **(Fig. 7-4)**. The primary sites of enzymatic cleavage are between amino acids 5 and 6, 6 and 7, and 9 and 10. Substitution of the position-6 amino acid glycine with large bulky amino acid analogues makes degradation more difficult and creates a form of GnRH with a relatively long half-life. Substitution at the carboxyl terminus produces a form of GnRH with increased receptor affinity. The resulting high affinity and slow degradation produces a molecule that mimics continuous exposure to native GnRH (20). Thus, as with constant GnRH exposure, downregulation occurs. GnRH agonists are widely used to treat disorders that are dependent on ovarian hormones (21). They are used to control ovulation induction cycles and treat precocious puberty, ovarian hyperandrogenism, leiomyomas, endometriosis, and hormonally dependent cancers. The development of GnRH antagonists proved more difficult because a molecule was needed that maintained the binding and degradation resistance

of agonists but failed to activate the receptor. Early attempts involved modification of amino acids 1 and 2, as well as those previously utilized for agonists. Commercial antagonists have structural modifications at amino acids 1, 2, 3, 6, 8, and 10. The treatment spectrum is expected to be similar to that of GnRH agonists, but with a more rapid onset of action.

Nonpeptide, small molecule structures with high affinity for the GnRH receptor were developed (25). These compounds demonstrated the ability to suppress the reproductive axis in a dose-related manner via oral administration, unlike the parenteral approach required with traditional peptide analogues (26). Investigation may elucidate an expanded therapeutic role for these antagonists.

Endogenous Opioids and Effects on GnRH

The endogenous opioids are three related families of naturally occurring substances produced in the CNS that represent the natural ligands for the opioid receptors (27–29). **There are three major classes of endogenous opioids**, each derived from precursor molecules:

1. ***Endorphins*** are named for their endogenous morphine-like activity. These substances are produced in the hypothalamus from the precursor proopiomelanocortin (POMC) and have diverse activities, including regulation of temperature, appetite, mood, and behavior (30).
2. ***Enkephalins*** are the most widely distributed opioid peptides in the brain, and they function primarily in regulation of the autonomic nervous system. Proenkephalin A is the precursor for the two enkephalins of primary importance: methionine–enkephalin and leucine–enkephalin.
3. ***Dynorphins*** are endogenous opioids produced from the precursor proenkephalin B that serve a function similar to that of the endorphins, producing behavioral effects and exhibiting a high analgesic potency.

The endogenous opioids play a significant role in the regulation of hypothalamic–pituitary function. Endorphins appear to inhibit GnRH release within the hypothalamus, resulting in inhibition of gonadotropin secretion (31). Ovarian sex steroids can increase the secretion of central endorphins, further depressing gonadotropin levels (32).

Endorphin levels vary significantly throughout the menstrual cycle, with peak levels in the luteal phase and a nadir during menses (33). This inherent variability, although helping to regulate gonadotropin levels, may contribute to cycle-specific symptoms experienced by ovulatory women. For example, the dysphoria experienced by some women in the premenstrual phase of the cycle may be related to a withdrawal of endogenous opiates (34). This theory is bolstered by the finding that inhibition of opiate

withdrawal by naltrexone alleviates many premenstrual symptoms (35).

Pituitary Hormone Secretion

Anterior Pituitary

The anterior pituitary is responsible for the secretion of the major hormone-releasing factors—FSH, LH, TSH, and ACTH—and GH and prolactin. Each hormone is released by a specific pituitary cell type.

Gonadotropins

The gonadotropins FSH and LH are produced by the anterior pituitary gonadotroph cells and are responsible for ovarian follicular stimulation. Structurally, there is great similarity between FSH and LH (Fig. 7-6). They are glycoproteins that share identical α subunits and differ only in the structure of their β subunits, which confer receptor specificity (36,37). The synthesis of the β subunits is the rate-regulating step in gonadotropin biosynthesis (38). TSH and placental hCG share identical α subunits with the gonadotropins. There are several forms of each gonadotropin, which differ in carbohydrate content as a result of posttranslation modification. The degree of modification varies with steroid levels and is an important regulator of gonadotropin bioactivity.

Prolactin

***Prolactin,* a 198-amino-acid polypeptide secreted by the anterior pituitary lactotroph, is the primary trophic factor responsible for the synthesis of milk by the breast** (39). Several forms of this hormone, which are named according to their size and bioactivity, are normally secreted (40). Prolactin gene transcription is principally stimulated by estrogen; other hormones promoting transcription are TRH and a variety of growth factors.

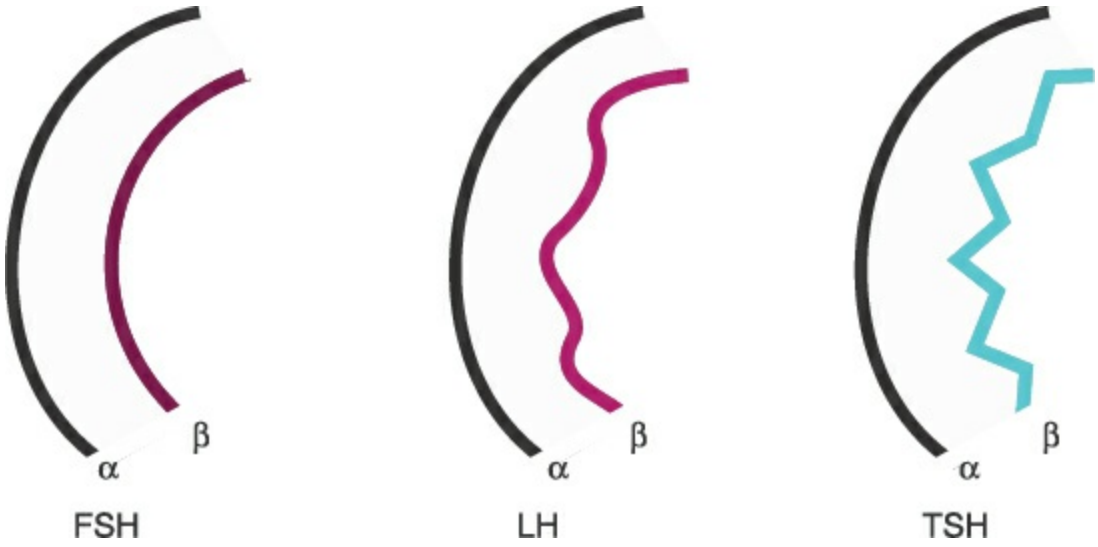

FIGURE 7-6 The structural similarity between follicle-stimulating hormone (FSH), luteinizing hormone (LH), and thyroid-stimulating hormone (TSH). The α subunits are identical, and the β subunits differ.

Prolactin secretion is under tonic inhibitory control by the hypothalamic secretion of dopamine (41). Therefore, disease states characterized by decreased dopamine secretion or any condition that interrupts transport of dopamine down the infundibular stalk to the pituitary gland will result in increased synthesis of prolactin. In this respect, prolactin is unique in comparison with all other pituitary hormones: It is predominantly under tonic inhibition, and release of control produces an increase in secretion. **Clinically, increased prolactin levels are associated with amenorrhea and galactorrhea, and hyperprolactinemia should be suspected in any individual with symptoms of either of these conditions.**

Although prolactin appears to be primarily under inhibitory control, many stimuli can elicit its release, including breast manipulation, drugs, stress, exercise, and certain foods. Hormones that may stimulate prolactin release include TRH, vasopressin, γ-aminobutyric acid (GABA), dopamine, β-endorphin, vasoactive intestinal peptide (VIP), epidermal growth factor (EGF), angiotensin II, estrogens, and possibly GnRH (42–46). The relative contributions of these substances under normal conditions remain to be determined.

Thyroid-Stimulating Hormone, Adrenocorticotropic Hormone, and Growth Hormone

The other hormones produced by the anterior pituitary are TSH, ACTH, and GH. TSH is secreted by the pituitary thyrotrophs in response to TRH. As with GnRH, TRH is synthesized primarily in the arcuate nucleus of the hypothalamus and is secreted into the portal circulation for transport to the pituitary. In addition to stimulating TSH release, TRH is a major stimulus for the release of prolactin. TSH stimulates release of T_3 and T_4 from the thyroid gland, which in turn has a negative feedback effect on pituitary TSH secretion. Abnormalities of thyroid secretion (hyper- and hypothyroidism) are frequently associated with ovulatory dysfunction as a result of diverse actions on the hypothalamic–pituitary–ovarian axis (47).

Adrenocorticotrophic hormone is secreted by the anterior pituitary in response to another hypothalamic-releasing factor, CRH, and stimulates the release of adrenal glucocorticoids. Unlike the other anterior pituitary products, ACTH secretion has a diurnal variation with an early morning peak and a late evening nadir. As with the other pituitary hormones, ACTH secretion is negatively regulated by feedback from its primary end product, which in this case is cortisol.

The anterior pituitary hormone that is secreted in the greatest absolute amount is GH. It is secreted in response to the hypothalamic-releasing factor, GHRH, and by thyroid hormone and glucocorticoids. This hormone is secreted in a pulsatile fashion but with peak release occurring during sleep. In addition to its vital role in the stimulation

of linear growth, GH plays a diverse role in physiologic homeostasis. The hormone plays a role in bone mitogenesis, CNS function (improved memory, cognition, and mood), body composition, breast development, and cardiovascular function. It also affects insulin regulation and acts anabolically. GH appears to have a role in the regulation of ovarian function, although the degree to which it serves this role in normal physiology is unclear (48).

Posterior Pituitary

Structure and Function

The posterior pituitary (neurohypophysis) is composed exclusively of neural tissue and is a direct extension of the hypothalamus. It lies directly adjacent to the adenohypophysis but is embryologically distinct, derived from an invagination of neuroectodermal tissue in the third ventricle. Axons in the posterior pituitary originate from neurons with cell bodies in two distinct regions of the hypothalamus, the supraoptic and paraventricular nuclei, named for their anatomic relationship to the optic chiasm and the third ventricle. Together these two nuclei compose the hypothalamic magnocellular system. These neurons can secrete their synthetic products directly from axonal boutons into the general circulation to act as hormones. This is the mechanism of secretion of the hormones of the posterior pituitary, oxytocin and arginine vasopressin (AVP). Although this is the primary mode of release for these hormones, numerous other secondary pathways were identified, including secretion into the portal circulation, intrahypothalamic secretion, and secretion into other regions of the CNS (49).

In addition to the established functions of oxytocin and vasopressin, several other diverse roles were suggested in animal models. These functions include modulation of sexual activity and appetite, learning and memory consolidation, temperature regulation, and regulation of maternal behaviors (50). In the human, these neuropeptides were linked to social attachment (51–53). Receptor variants for these two molecules were linked to the spectrum of autistic disorders, suggesting that proper function of these two neuropeptides with their receptors is required for positive group interactive behavior. This relationship is strengthened by a strong association between altruistic behavior and the length of the AVP-1a receptor promoter region (52,54). Complex human behaviors may be partially governed by a relatively simple neuropeptide system. Continuing investigation should help elucidate this physiology and potential therapeutic interventions.

Oxytocin

Oxytocin is a 9-amino-acid peptide primarily produced by the paraventricular nucleus of the hypothalamus **(Fig. 7-7)**. The primary function of this hormone in humans is the stimulation of two specific types of muscular contractions **(Fig. 7-8)**. The first type, uterine muscular contraction, occurs during parturition. The second type of

muscular contraction regulated by oxytocin is breast lactiferous duct myoepithelial contractions, which occur during the milk letdown reflex. Oxytocin release may be stimulated by suckling, triggered by a signal from nipple stimulation transmitted via thoracic nerves to the spinal cord and then to the hypothalamus, where oxytocin is released in an episodic fashion (48). Oxytocin release may be triggered by olfactory, auditory, and visual clues, and may play a role in the conditioned reflex in nursing animals. Stimulation of the cervix and vagina can cause significant release of oxytocin, which may trigger reflex ovulation (the Ferguson reflex) in some species.

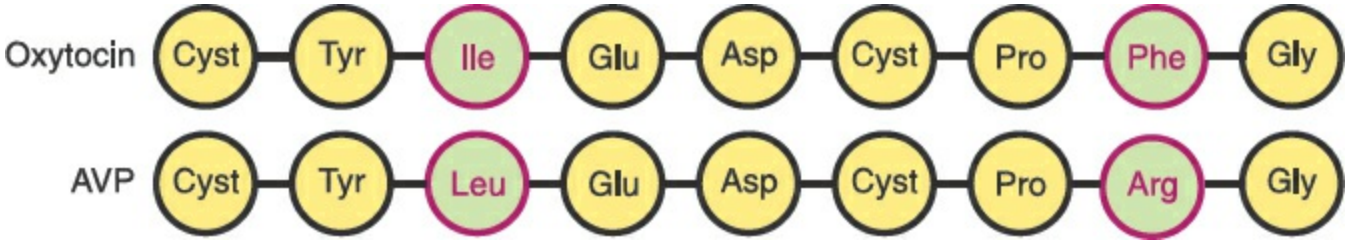

FIGURE 7-7 Oxytocin and arginine vasopressin (AVP) are 9-amino-acid peptides produced by the hypothalamus. They differ in only two amino acids.

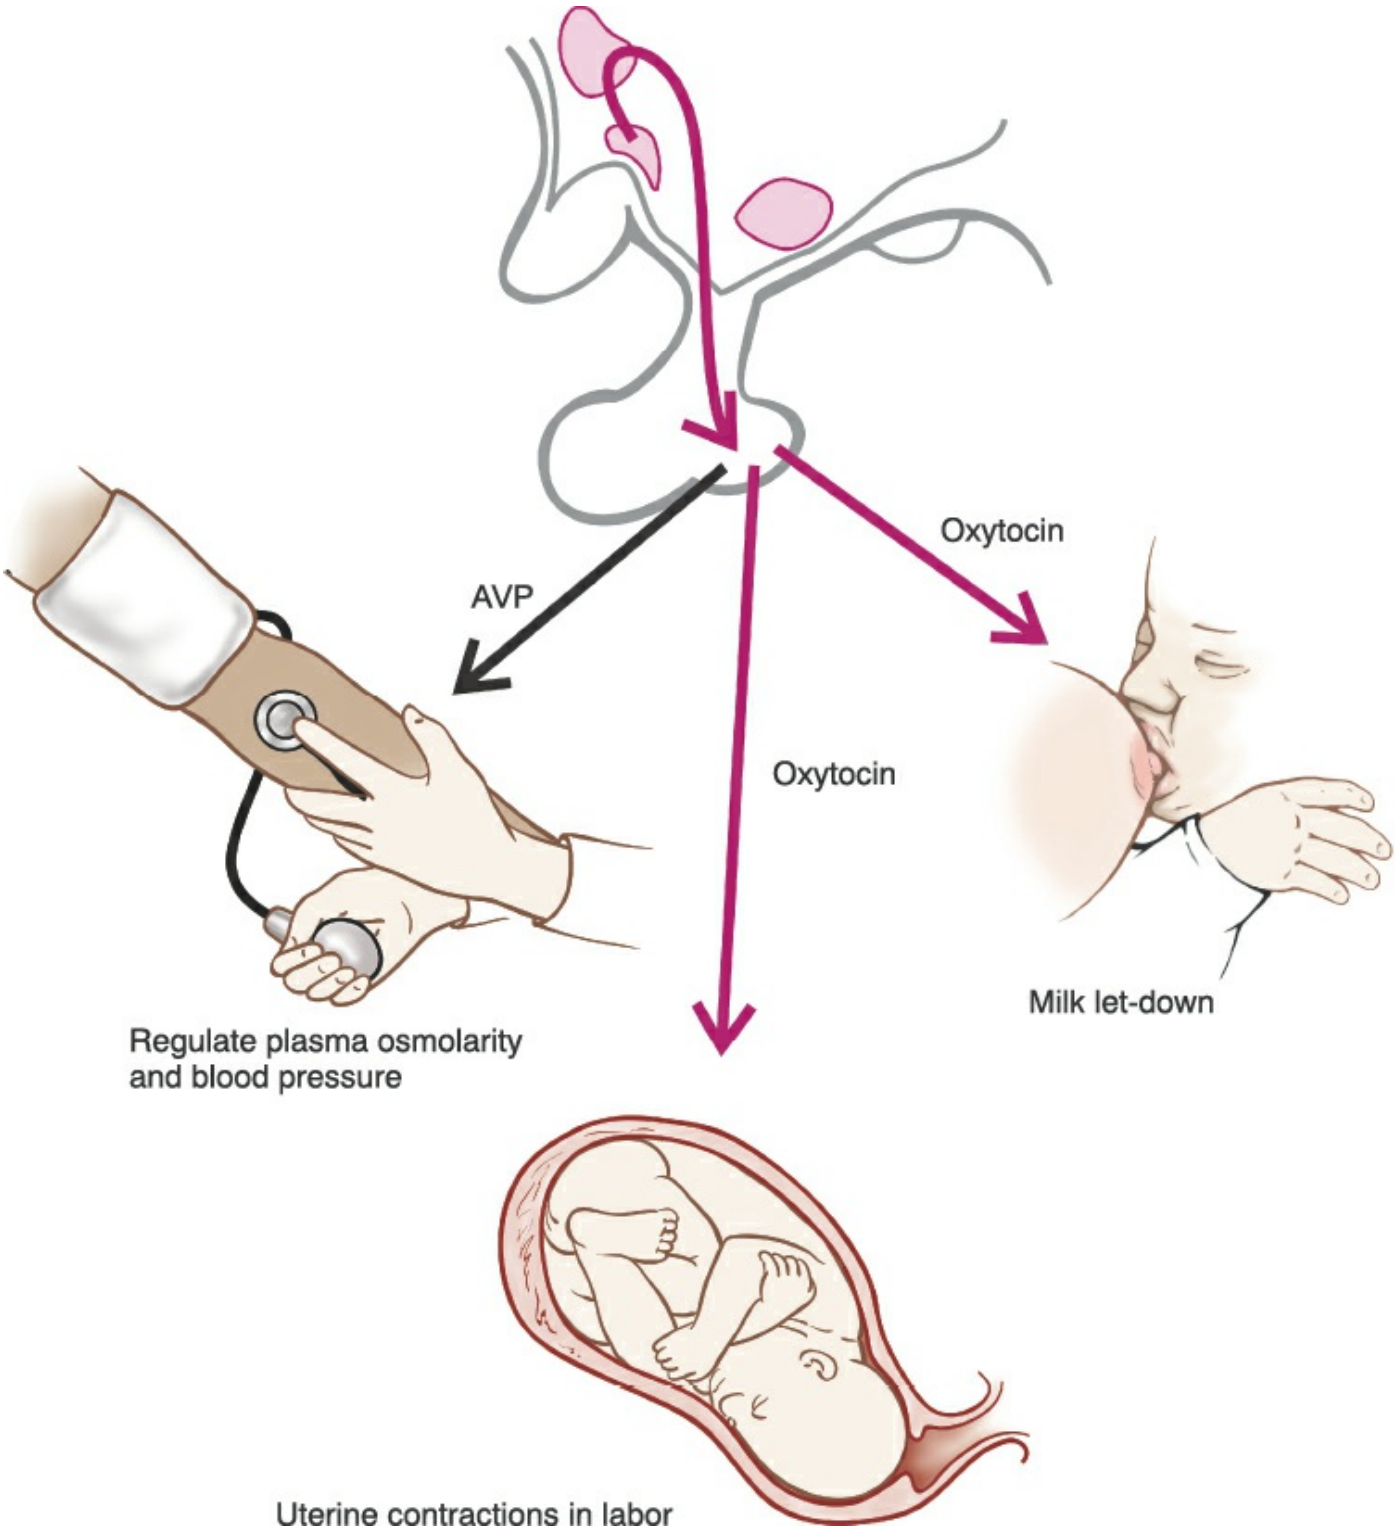

FIGURE 7-8 Oxytocin stimulates muscular contractions of the uterus during parturition and the breast lactiferous duct during the milk letdown reflex. Arginine vasopressin (AVP) regulates circulating blood volume, pressure, and osmolality.

Arginine Vasopressin

Also known as antidiuretic hormone (ADH), AVP is the second major secretory product of the posterior pituitary (Fig. 7-7). It is synthesized primarily by neurons

with cell bodies in the supraoptic nuclei (Fig. 7-8). Its major function is the regulation of circulating blood volume, pressure, and osmolality (55). Specific receptors throughout the body can trigger the release of AVP. Osmoreceptors located in the hypothalamus sense changes in blood osmolality from a mean of 285 mOsm/kg. Baroreceptors sense changes in blood pressure caused by alterations in blood volume and are peripherally located in the walls of the left atrium, carotid sinus, and aortic arch (56). These receptors can respond to changes in blood volume of more than 10%. In response to decreases in blood pressure or volume, AVP is released and causes arteriolar vasoconstriction and renal free–water conservation. This leads to a decrease in blood osmolality and an increase in blood pressure. Activation of the renal renin–angiotensin system can also activate AVP release.

MENSTRUAL CYCLE PHYSIOLOGY

[3] In the normal menstrual cycle, orderly cyclic hormone production and parallel proliferation of the uterine lining prepare for implantation of the embryo. Disorders of the menstrual cycle and, likewise, disorders of menstrual physiology, may lead to various pathologic states, including infertility, recurrent miscarriage, and malignancy.

Normal Menstrual Cycle

The normal human menstrual cycle can be divided into two segments: the ovarian cycle and the uterine cycle, based on the organ under examination. The ovarian cycle may be further divided into follicular and luteal phases, whereas the uterine cycle is divided into corresponding proliferative and secretory phases (Fig. 7-9). The phases of the ovarian cycle are characterized as follows:

1. **Follicular phase—hormonal feedback promotes the orderly development of a single dominant follicle, which should be mature at midcycle and prepared for ovulation. The average length of the human follicular phase ranges from 10 to 14 days, and variability in this length is responsible for most variations in total cycle length.**
2. **Luteal phase—the time from ovulation to the onset of menses has an average length of 14 days.**

A normal menstrual cycle lasts from 21 to 35 days, with 2 to 6 days of flow and an average blood loss of 20 to 60 mL. However, studies of large numbers of women with normal menstrual cycles showed that approximately two-thirds of adult women have cycles lasting 21 to 35 days (57). The extremes of reproductive life

(after menarche and perimenopause) are characterized by a higher percentage of anovulatory or irregularly timed cycles (58,59).

Hormonal Variations

The relative pattern of ovarian, uterine, and hormonal variation along the normal menstrual cycle is shown in Figure 7-9.

1. At the beginning of each monthly menstrual cycle, levels of gonadal steroids are low and have been decreasing since the end of the luteal phase of the previous cycle.
2. With the demise of the corpus luteum, FSH levels begin to rise, and a cohort of growing follicles is recruited. These follicles each secrete increasing levels of estrogen as they grow in the follicular phase. The increase in estrogen is the stimulus for uterine endometrial proliferation.
3. Rising estrogen levels provide negative feedback on pituitary FSH secretion, which begins to wane by the midpoint of the follicular phase. In addition, the growing follicles produce inhibin B, which suppresses FSH secretion by the pituitary. Conversely, LH initially decreases in response to rising estradiol levels, but late in the follicular phase the LH level is increased dramatically (biphasic response).
4. At the end of the follicular phase (just before ovulation), FSH-induced LH receptors are present on granulosa cells and, with LH stimulation, modulate the secretion of progesterone. Progesterone secretion is responsible for the FSH midcycle surge.
5. After a sufficient degree of estrogenic stimulation, the pituitary LH surge is triggered, which is the proximate cause of ovulation that occurs 24 to 36 hours later. Ovulation heralds the transition to the luteal–secretory phase.
6. The estrogen level decreases through the early luteal phase from just before ovulation until the midluteal phase, when it begins to rise again as a result of corpus luteum secretion. Similarly, inhibin A is secreted by the corpus luteum.
7. Progesterone levels rise precipitously after ovulation and can be used as a presumptive sign that ovulation has occurred.
8. Progesterone, estrogen, and inhibin A act centrally to suppress gonadotropin secretion and new follicular growth. These hormones remain elevated through the lifespan of the corpus luteum and wane with its demise, thereby setting the stage for the next cycle.

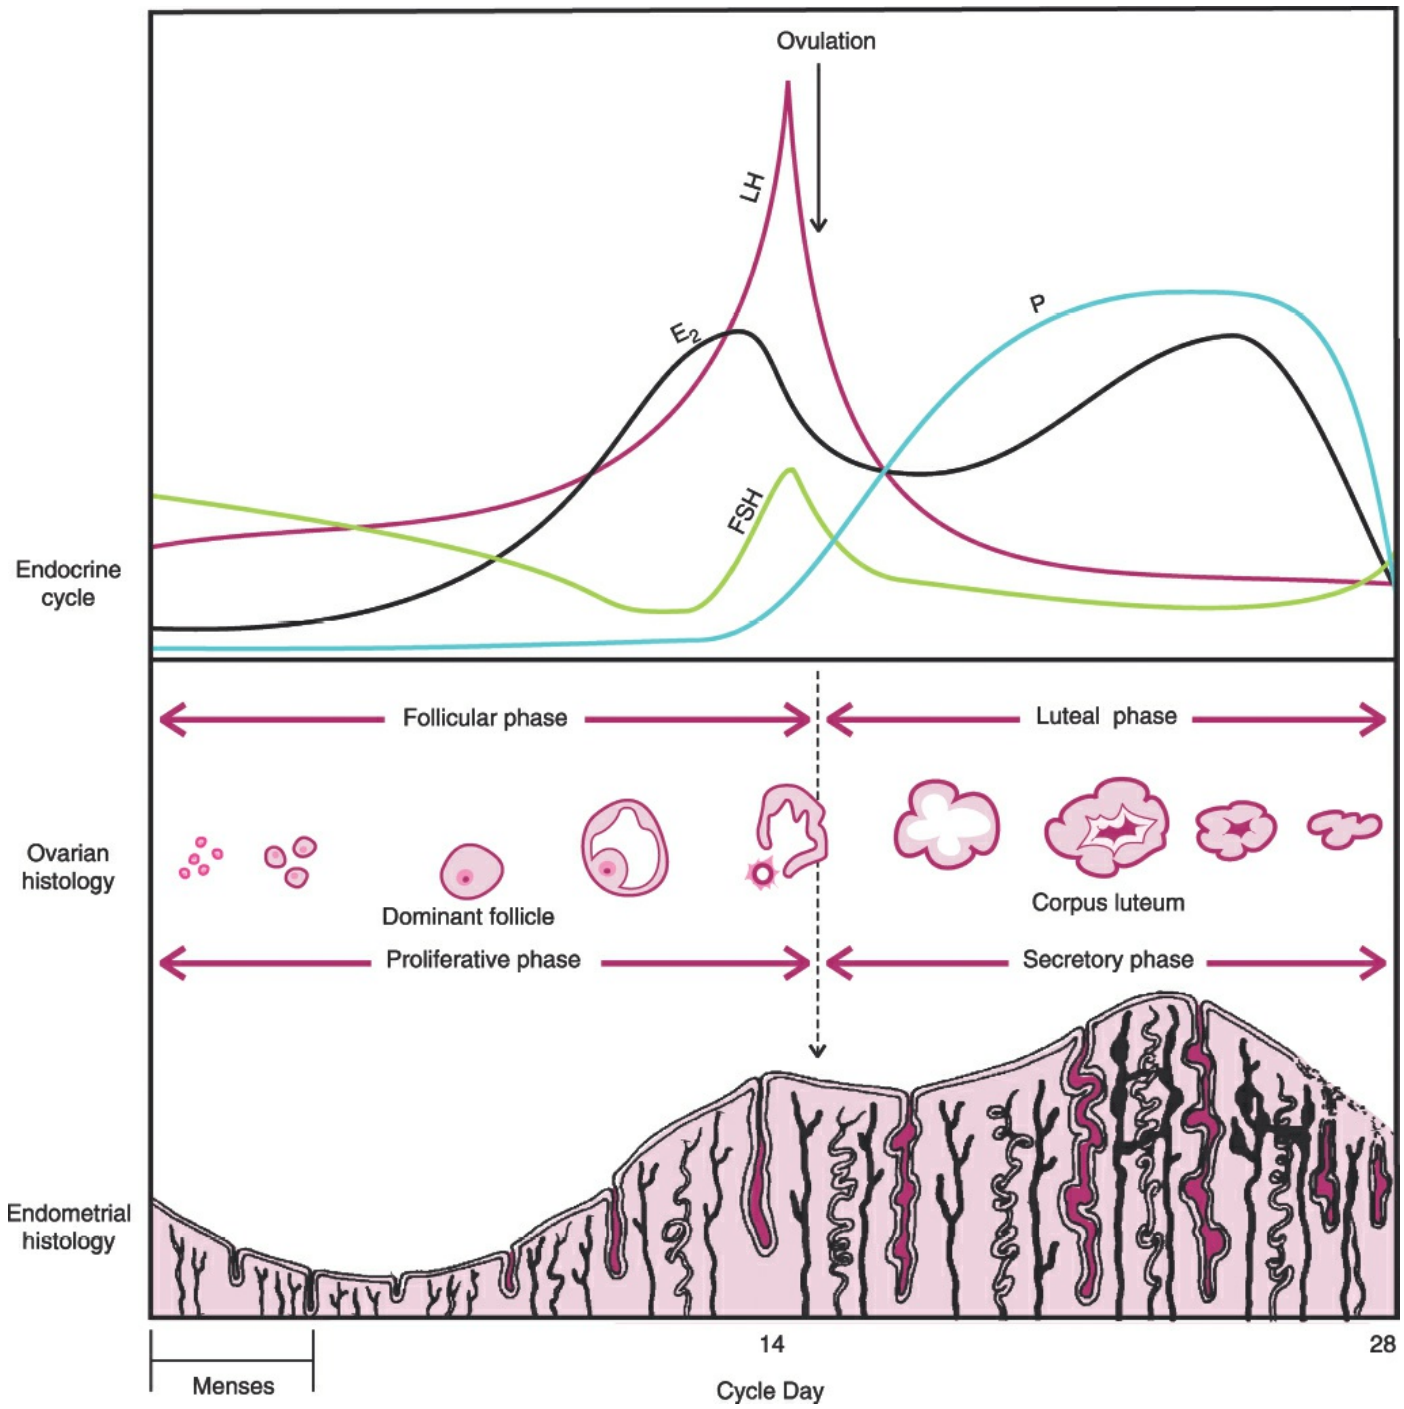

FIGURE 7-9 The menstrual cycle. The ***top panel*** shows the cyclic changes of follicle-stimulating hormone (FSH), luteinizing hormone (LH), estradiol (E_2), and progesterone (P) relative to the time of ovulation. The ***bottom panel*** correlates the ovarian cycle in the follicular and luteal phases and the endometrial cycle in the proliferative and secretory phases.

Uterus

Cyclic Changes of the Endometrium

In 1950, Noyes, Hertig, and Rock described the cyclic histologic changes in the adult

human endometrium **(Fig. 7-10)** (60). These changes proceed in an orderly fashion in response to cyclic hormonal production by the ovaries **(Fig. 7-9)**. Histologic cycling of the endometrium can best be viewed in two parts: the endometrial glands and the surrounding stroma. **The superficial two-thirds of the endometrium is the zone that proliferates and is ultimately shed with each cycle if pregnancy does not occur. This cycling portion of the endometrium is known as the *decidua functionalis* and is composed of a deeply situated intermediate zone (stratum spongiosum) and a superficial compact zone (stratum compactum). The *decidua basalis* is the deepest region of the endometrium. It does not undergo significant monthly proliferation but, instead, is the source of endometrial regeneration after each menses** (61).

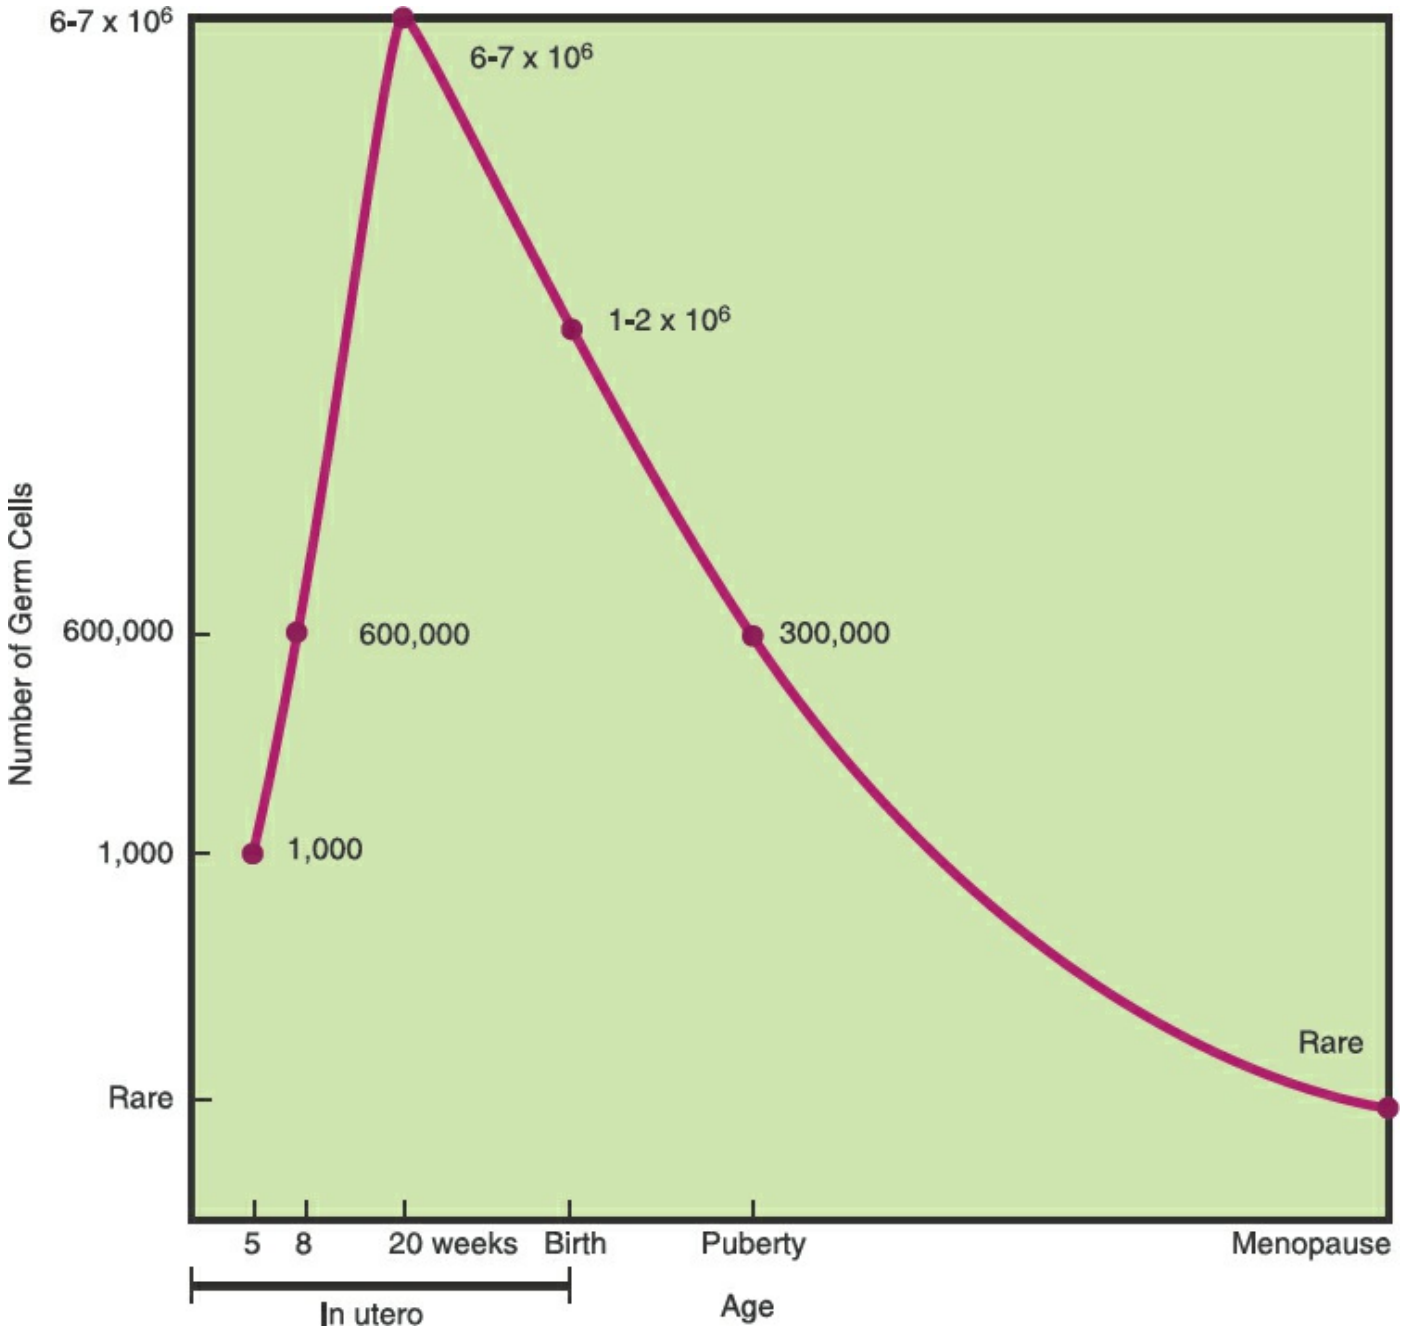

FIGURE 7-10 The number of oocytes in the ovary before and after birth and through menopause.

The existence of endometrial stem cells was assumed but difficult to document. Researchers found a small population of human epithelial and stromal cells that possess clonogenicity, suggesting that they represent the putative endometrial stem cells (62). Further evidence of the existence of such cells, and their source, was provided by another study that showed endometrial glandular epithelial cells, obtained from endometrial biopsies of women undergoing bone marrow transplants, express the HLA type of the donor bone marrow (63). This finding suggests that endometrial stem cells exist, reside in bone marrow, and migrate to the basalis of the endometrium. Furthermore, the timing of the appearance of these cells following the transplant was as long as several years. This experiment has been duplicated using autologous bone marrow–derived stem cells and placing them in the spiral arterioles of patients with intrauterine synechiae (64). Animal models suggest this approach may be of value in regenerating damaged or absent endometrium (65,66). It is likely that this treatment will prove to be of clinical importance in patients with difficult to treat Asherman syndrome.

Proliferative Phase

[4] By convention, the first day of vaginal bleeding is called day 1 of the menstrual cycle. After menses, the decidua basalis is composed of primordial glands and dense scant stroma in its location adjacent to the myometrium. The proliferative phase is characterized by progressive mitotic growth of the decidua functionalis in preparation for implantation of the embryo in response to rising circulating levels of estrogen (67). At the beginning of the proliferative phase, the endometrium is relatively thin (1 to 2 mm). The predominant change seen during this time is evolution of the initially straight, narrow, and short endometrial glands into longer, tortuous structures (68). Histologically, these proliferating glands have multiple mitotic cells, and their organization changes from a low columnar pattern in the early proliferative period to a pseudostratified pattern before ovulation. Throughout this time, the stroma is a dense compact layer, and vascular structures are infrequently seen.

Secretory Phase

In the typical 28-day cycle, ovulation occurs on cycle day 14. Within 48 to 72 hours following ovulation, the onset of progesterone secretion produces a shift in histologic appearance of the endometrium to the secretory phase, so named for the clear presence of eosinophilic protein-rich secretory products in the glandular lumen. In contrast to the proliferative phase, the secretory phase of the menstrual cycle is characterized by the cellular effects of progesterone in addition to estrogen. In general, progesterone's effects are antagonistic to those of estrogen,

and there is a progressive decrease in the endometrial cell's estrogen receptor concentration. As a result, during the latter half of the cycle, estrogen-induced DNA synthesis and cellular mitosis are antagonized (67).

During the secretory phase, the endometrial glands form characteristic periodic acid–Schiff positive–staining, glycogen-containing vacuoles. These vacuoles initially appear subnuclearly and progress toward the glandular lumen (Fig. 7-10) (60). The nuclei can be seen in the midportion of the cells and ultimately undergo apocrine secretion into the glandular lumen, often by cycle day 19 or 20. At postovulatory day 6 or 7, secretory activity of the glands is generally maximal, and the endometrium is optimally prepared for implantation of the blastocyst.

The stroma of the secretory phase remains unchanged histologically until approximately the 7th postovulatory day, when there is a progressive increase in edema. Coincident with maximal stromal edema in the late secretory phase, the spiral arteries become clearly visible and progressively lengthen and coil during the remainder of the secretory phase. By around day 24, an eosinophilic-staining pattern, known as *cuffing*, is visible in the perivascular stroma. Eosinophilia progresses to form islands in the stroma followed by areas of confluence. This staining pattern of the edematous stroma is termed *pseudodecidual* because of its similarity to the pattern that occurs in pregnancy. Approximately 2 days before menses, there is a dramatic increase in the number of polymorphonuclear lymphocytes that migrate from the vascular system. This leukocytic infiltration heralds the collapse of the endometrial stroma and the onset of the menstrual flow.

Menses

In the absence of implantation, glandular secretion ceases and an irregular breakdown of the *decidua functionalis* occurs. The resultant shedding of this layer of the endometrium is termed *menses*. The destruction of the corpus luteum and its production of estrogen and progesterone is the presumed cause of the shedding. With withdrawal of sex steroids, there is a profound spiral artery vascular spasm that ultimately leads to endometrial ischemia. Simultaneously, there is a breakdown of lysosomes and a release of proteolytic enzymes, which further promote local tissue destruction. This layer of endometrium is shed, leaving the decidua basalis as the source of subsequent endometrial growth. Prostaglandins are produced throughout the menstrual cycle and are at their highest concentration during menses (66). Prostaglandin $F_2\alpha$ ($PGF_2\alpha$) is a potent vasoconstrictor, causing further arteriolar vasospasm and endometrial ischemia. $PGF_2\alpha$ produces myometrial contractions that decrease local uterine wall blood flow and may serve to expel physically the sloughing endometrial tissue from the uterus.

Dating the Endometrium

The changes seen in secretory endometrium relative to the LH surge were thought to allow the assessment of the "normalcy" of endometrial development. Since 1950, it was felt that by knowing when a patient ovulated, it was possible to obtain a sample of endometrium by endometrial biopsy and determine whether the state of the endometrium corresponds to the appropriate time of the cycle. Traditional thinking held that any discrepancy of more than 2 days between chronologic and histologic date indicated a pathologic condition termed *luteal phase defect*; this abnormality was linked to infertility (via implantation failure) and early pregnancy loss (69).

Evidence suggests a lack of utility for the endometrial biopsy as a diagnostic test for either infertility or early pregnancy loss (59). In a randomized, observational study of regularly cycling, fertile women, it was found that endometrial dating by hematoxylin and eosin staining is far less accurate and precise than originally claimed and does not provide a valid method for the diagnosis of luteal phase defect (70). Furthermore, a large prospective, multicenter trial sponsored by the National Institutes of Health showed that histologic dating of the endometrium does not discriminate between fertile and infertile women (71). Thus, after half a century of using this test in the evaluation of the subfertile couple, it became clear that the traditional endometrial biopsy has no role in the routine evaluation of infertility or early pregnancy loss.

Given the lack of histologic efficacy in evaluating the receptivity of the endometrium, investigation turned to the use of molecular and genetic markers. Cyclin E and p27 were found to be credible markers to discern endometrial receptivity (72,73). Microarray technology has been utilized to link gene expression to functionally receptive endometrium, with promising results (74,75).

Ovarian Follicular Development

The number of oocytes peaks in the fetus at 6 to 7 million by 20 weeks of gestation **(Fig. 7-10)** (76). Simultaneously (and peaking at the 5th month of gestation), atresia of the oogonia occurs, rapidly followed by follicular atresia. At birth, only 1 to 2 million oocytes remain in the ovaries, and **at puberty, only 300,000 of the original 6 to 7 million oocytes are available for ovulation** (76,77). **Of these, only 400 to 500 will ultimately be released during ovulation.** By the time of menopause, the ovary will be composed primarily of dense stromal tissue with only rare interspersed oocytes remaining.

A central dogma of reproductive biology is that in postnatal mammalian females there is no capacity for oocyte production. Because oocytes enter the diplotene resting stage of meiosis in the fetus and persist in this stage until ovulation, much of the DNA, proteins, and messenger RNA (mRNA) necessary for development of the preimplantation embryo is synthesized by this stage. At the diplotene stage, a single

layer of 8 to 10 granulosa cells surrounds the oogonia to form the primordial follicle. The oogonia that fail to become properly surrounded by granulosa cells undergo atresia (78). The remainder proceeds with follicular development. Thus, most oocytes are lost during fetal development, and the remaining follicles are steadily "used up" throughout the intervening years until menopause.

Evidence has begun to challenge this theory. Studies in the mouse showed that production of oocytes and corresponding folliculogenesis can occur well into adult life (79). The reservoir of germline stem cells responsible for this oocyte development appears to reside in the bone marrow (80). While stem cells have been found in the human adult ovary (81,82), it is not clear if these cells are true ovarian germline stem cells and if they play a physiologic role within the ovary regarding follicular development (82,83).

Meiotic Arrest of Oocyte and Resumption

Meiosis **(the germ cell process of reduction division) is divided into four phases: prophase, metaphase, anaphase, and telophase. The prophase of meiosis I is further divided into five stages: *leptotene, zygotene, pachytene, diplotene,* and *diakinesis.***

Oogonia differ from spermatogonia in that only one final daughter cell (oocyte) forms from each precursor cell, with the excess genetic material discarded in two polar bodies. When the developing oogonia begin to enter meiotic prophase I, they are known as primary oocytes (84). This process begins at roughly 8 weeks of gestation. Only those oogonia that enter meiosis will survive the wave of atresia that sweeps the fetal ovary before birth. The oocytes arrested in prophase (in the late diplotene or "dictyate" stage) will remain thus until the time of ovulation, when the process of meiosis resumes. The mechanism for this mitotic stasis is believed to be an oocyte maturation inhibitor (OMI) produced by granulosa cells (85). Granulosa-derived cAMP seems to be implicated in inhibiting germinal vesicle breakdown and meiosis resumption (86). This inhibitor gains access to the oocyte via gap junctions connecting the oocyte and its surrounding cumulus of granulosa. These intercellular channels are formed by proteins known as connexins. With the midcycle LH surge, the gap junctions are disrupted, granulosa cells are no longer connected to the oocyte, and meiosis I is allowed to resume.

Follicular Development

Follicular development, also known as folliculogenesis, is a dynamic process that continues from menarche until menopause. The process is designed to allow the monthly recruitment of a cohort of primordial follicles and, ultimately, to release a single, mature, dominant follicle during ovulation each month. Therefore, it is highly coordinated with oocyte maturation.

Folliculogenesis has been divided into different steps according to follicular

characteristics regarding the number and appearance of granulosa cells, development of theca cells and formation of a fluid-filled structure known as antrum. **Preantral follicles** include primordial, primary, and secondary follicles. **Antral follicles** include tertiary and preovulatory follicles.

Primordial follicles are 0.03 to 0.05 mm in diameter structures formed by a primary oocyte (arrested in prophase of meiosis I), surrounded by one layer of flattened granulosa cells contained by the basal lamina.

Primary follicles are 0.1 mm follicles formed when granulosa cells are still a one cell layer but acquire a cuboidal form. This is the first sign of follicular recruitment. Protein synthesis and secretion form an extracellular matrix capsule known as the zona pellucida, traversed by intercellular channels (gap unions) that maintain active connections between granulosa cells and the oocyte. Granulosa cells in the primary follicle develop FSH receptors, without endocrine effect as a result of the absence of follicular vascularization and, therefore, nonexistent exposure to circulating FSH.

Secondary follicles are 0.2 mm in size and develop several layers of cuboidal granulosa cells with marked expression of FSH receptors. Stromal cell in contact with the granulosa and basal lamina are differentiated into theca cells with LH receptor expression. In the theca layer neoangiogenesis occurs, vascularizing the follicle and exposing it to circulating FSH and LH.

Tertiary follicles are characterized by the formation of the antral cavity or antrum, as a consequence of granulosa cell secretion intercellular accumulation. **Early tertiary follicles** are 0.2 to 5 mm in size and at this point the theca layer is divided into theca interna and theca externa, which forms a transition with the ovarian stroma. **Late tertiary follicles** are 10 to 20 mm in size. Their large antral cavity divides granulosa in several cell populations, the corona radiata in contact with the oocyte, mural (membranous) granulosa in contact with the follicular wall and the cumulus ophorus that appears as a stalk joining the corona radiata and the mural granulosa.

Preovulatory follicles are the final stage of follicular development and >20 mm in size, structures from which ovulation occurs. Late in this stage and before ovulation, the primary oocyte completes meiosis I, becoming a secondary oocyte arrested in metaphase of meiosis II. Late tertiary/preovulatory follicles are also known as Graafian follicles.

Gonadotropin dependence in folliculogenesis is conditioned by the expression of FSH and LH receptors in granulosa and theca cells, respectively, and by the presence of follicular vascularization. Considerable expression of granulosa FSH receptors and formation of vascularized theca layer occurs in the secondary follicle. Consequently, follicular development is gonadotropin independent up to the formation of secondary follicles or late preantral phase. Early antral follicle development and its maturation process up to a preovulatory follicle is a gonadotropin dependent phase.

Primordial Follicles

The initial recruitment and growth of the primordial follicles is gonadotropin independent and affects a cohort over several months (87). The stimuli responsible for the recruitment of a specific cohort of follicles in each cycle are yet to be understood, but it seems to be under autocrine and paracrine control. Interaction between oocyte and neighboring granulosa cells seems to be fundamental for oocyte growth development, granulosa cell proliferation and the resultant primordial follicle activation.

Maintenance of a population of dormant primordial follicles is the basis for guaranteeing an oocyte supply throughout reproductive life (88). Whether secretion of stimulating or inhibiting factors is involved in recruitment regulation is being studied, although accelerated recruitment in isolated primordial follicles cultured in vitro suggests inhibitory mechanisms can have a more important role (89). Several factors have been implicated with an inhibitory effect over primordial follicle activation, such as anti-mullerian hormone (AMH) (90), phosphate and tensin homolog (PTEN) (91), tuberin/tuberous sclerosis complex (TSC) (92), Forkhead boxL2 (Foxl2) (93), and Forkhead box O3 (FOXO3a) (94). Their expression is responsible for preservation of primordial follicular dormancy and depletion of these factors in knockout mice has been associated with premature activation and early depletion of primordial follicles. On the other hand, phosphotidylinositol-3-kinase signaling mediated by 3-phosphoinositide dependent kinase-1 (PDK1), and mammalian target of rapamycin complex-1 (mTORC1), and S6 kinase-ribosomal protein (S6K1-rpS6), have been related to primordial follicle activation and survival (95–98).

Preantral Follicle

At the secondary follicle stage, after initial recruitment, FSH assumes control of follicular differentiation and growth and allows a cohort of follicles to continue differentiation. This process signals the shift from gonadotropin-independent to gonadotropin-dependent growth. The decline in luteal phase estrogen, progesterone, and inhibin A production by the now fading corpus luteum from the previous cycle allows the increase in FSH that stimulates this follicular growth (99).

Simultaneously, theca cells in the stroma bordering the granulosa cells proliferate. Both cell types function synergistically to produce estrogens that are secreted into the systemic circulation. At this stage of development, each of the seemingly identical cohort members must be either selected for dominance or undergo atresia. It is likely that the follicle destined to ovulate was selected before this point, although the mechanism for selection remains obscure.

Two-Cell, Two-Gonadotropin Theory

The fundamental tenet of follicular development is the two-cell, two-gonadotropin

theory (Fig. 7-11) (87,100,101). **This theory states that there is a subdivision and compartmentalization of steroid hormone synthesis activity in the developing follicle.** Most aromatase activity (for estrogen production) is in the granulosa cells (102). Aromatase activity is enhanced by FSH stimulation of specific receptors on these cells (103,104). Granulosa cells lack several enzymes that occur earlier in the steroidogenic pathway and require androgens as a substrate for aromatization. Androgens, in turn, are synthesized primarily in response to stimulation by LH, and the theca cells possess most of the LH receptors at this stage (103,104). Therefore, a synergistic relationship must exist: LH stimulates the theca cells to produce androgens (primarily androstenedione), which are transferred to the granulosa cells for FSH-stimulated aromatization into estrogens. These locally produced estrogens create a microenvironment within the follicle that is favorable for continued growth and nutrition (105). FSH and local estrogens serve to further stimulate estrogen production, FSH receptor synthesis and expression, and granulosa cell proliferation and differentiation.

Androgens have two positive regulatory roles in follicular development. Within the ovary, androgens promote granulose cell proliferation, aromatase activity, and inhibit programmed death of these cells (106).

As the peripheral estrogen level rises, it negatively feeds back on the pituitary and hypothalamus to decrease circulating FSH levels (107). **Increased ovarian production of inhibin B further decreases FSH production at this point.**

The falling FSH level that occurs with the progression of the follicular phase represents a threat to continued follicular growth. The resulting adverse environment can be withstood only by follicles with a selective advantage for binding the diminishing FSH molecules; that is, those with the greatest number of FSH receptors. The dominant follicle, therefore, can be perceived as the one with a richly estrogenic microenvironment and the most FSH receptors (108). Increase in FSH receptors results from an increase in granulosa cell population, because FSH receptor number is similar and constant in each granulosa cell (109,110). As it grows and develops, the follicle continues to produce estrogen, which results in further lowering of the circulating FSH and creates a more adverse environment for competing follicles. This process continues until all members of the initial cohort, with the exception of the single dominant follicle, have suffered atresia. The stage is set for ovulation.

Chronic elevation of androgens suppresses hypothalamic–pituitary secretion of FSH, a detriment to the development and maturation of a dominant follicle (106). Clinically, androgen excess results in chronic anovulation, as is seen in polycystic ovarian syndrome.

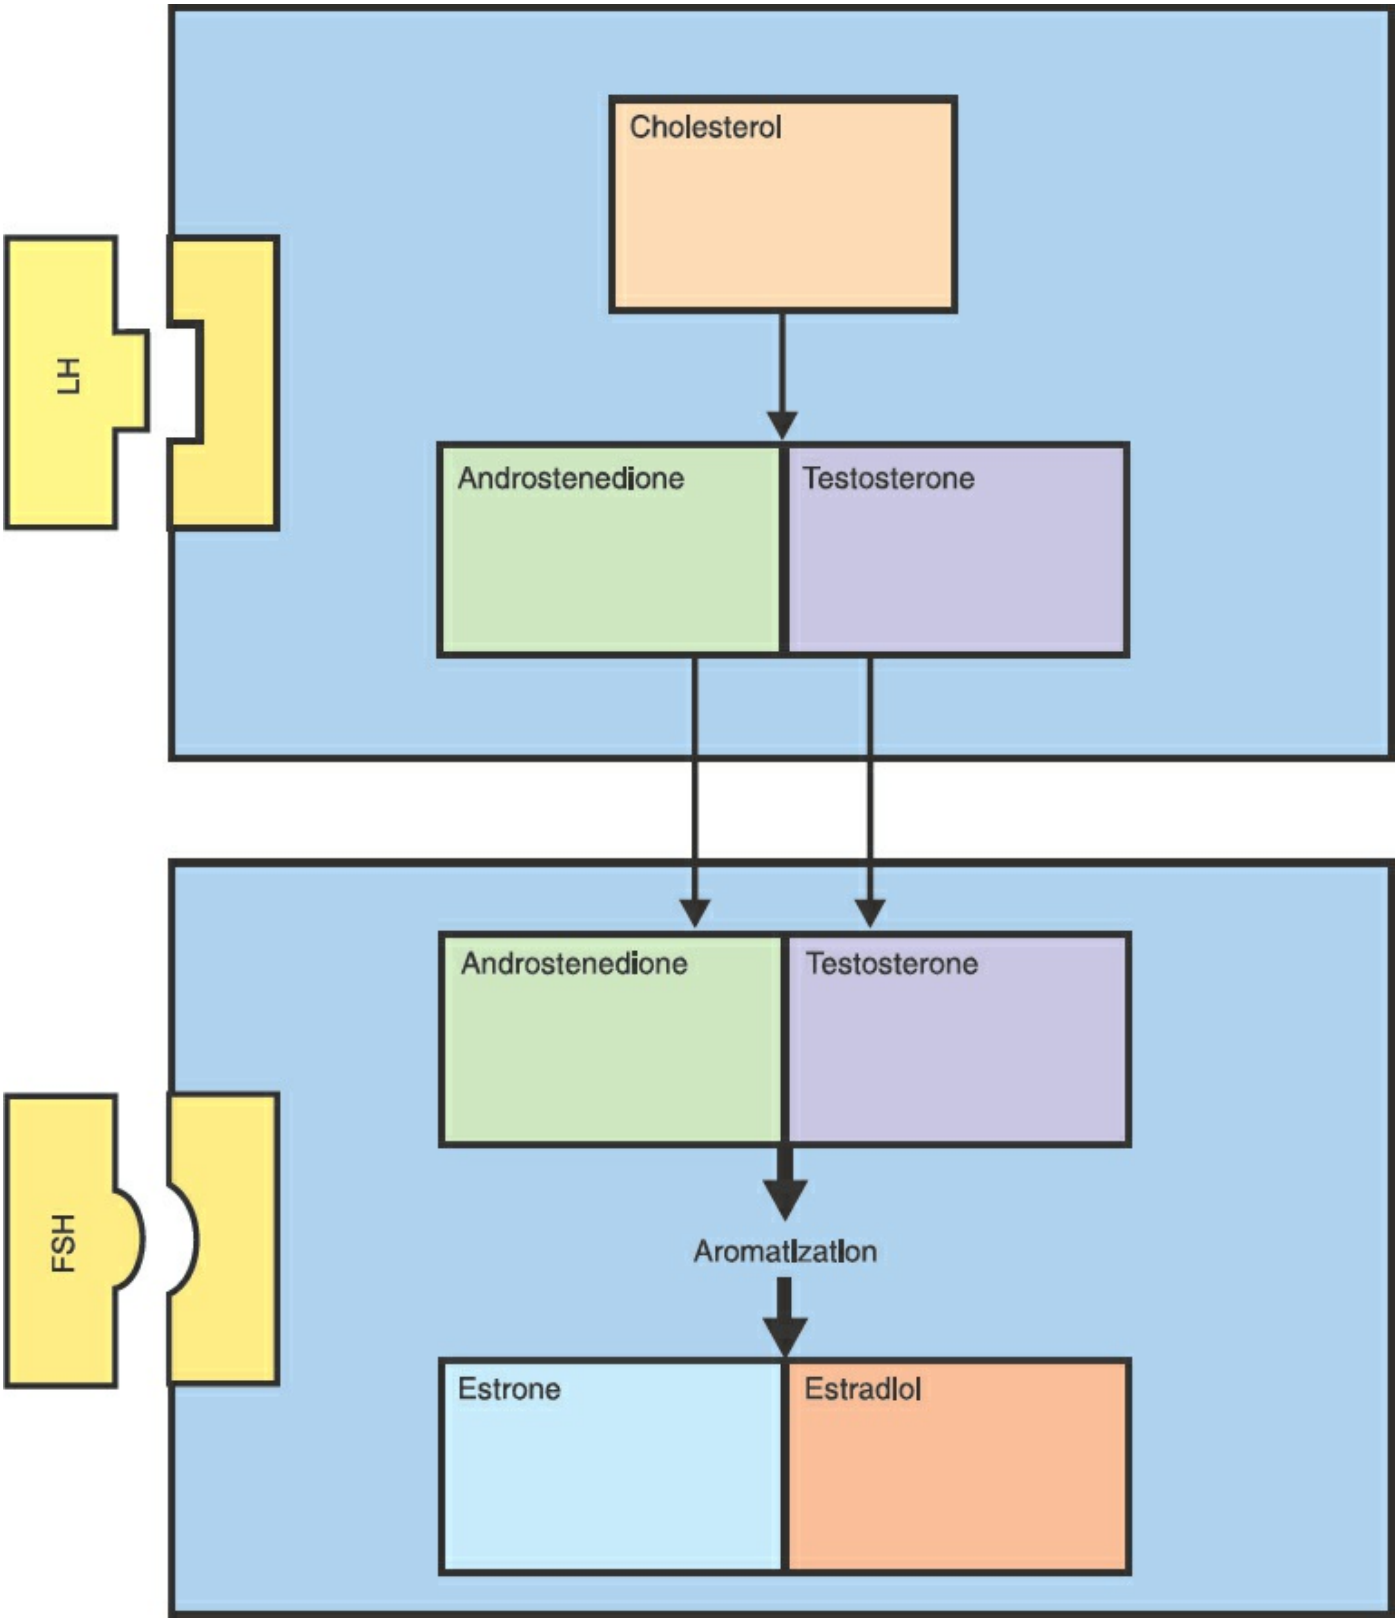

FIGURE 7-11 The two-cell, two-gonadotropin theory of follicular development in which there is compartmentalization of steroid hormone synthesis in the developing follicle. LH, luteinizing hormone; FSH, follicle-stimulating hormone.

Preovulatory Follicle

Preovulatory follicles are characterized by a fluid-filled antrum that is composed of plasma with granulosa cell secretions. The granulosa cells at this point have further differentiated into a heterogeneous population. The oocyte remains connected to the follicle by a stalk of specialized granulosa known as the *cumulus oophorus*.

Rising estrogen levels have a negative feedback effect on FSH secretion. Conversely, LH undergoes biphasic regulation by circulating estrogens. At lower concentrations, estrogens inhibit LH secretion. At higher levels, estrogen enhances LH release. This stimulation requires a sustained high level of estrogen (>200 pg/mL) for more than 48 hours (111). When the rising estrogen level produces positive feedback, a substantial surge in LH secretion occurs.

Concomitant to these events, the local estrogen–FSH interactions in the dominant follicle induce LH receptors on the granulosa cells. Exposure to high levels of LH results in a specific response by the dominant follicle—the result is luteinization of the granulosa cells, production of progesterone, and initiation of ovulation. Late follicular phase progesterone secretion is responsible for the FSH midcycle surge that stimulates plasminogen activator, LH granulosa cell receptor formation, and debilitates oocyte binding to the follicular wall (110). Ovulation will occur in the single mature, or Graafian, follicle 10 to 12 hours after the LH peak or 34 to 36 hours after the initial rise in midcycle LH (112–114).

The sex steroids are not the only gonadotropin regulators of follicular development. Two related granulosa cell–derived peptides were identified that play opposing roles in pituitary feedback (115). **The first of these peptides, inhibin, is secreted in two forms: inhibin A and inhibin B.** Inhibin B is secreted primarily in the follicular phase and is stimulated by FSH, whereas inhibin A is mainly active in the luteal phase (116). **Both forms of inhibin act to inhibit FSH synthesis and release** (117,118). The second peptide, activin, stimulates FSH release from the pituitary gland and potentiates its action in the ovary (119,120). It is likely that there are numerous other intraovarian regulators similar to inhibin and activin, each of which may play a key role in promoting the normal ovulatory process (121). Some of these include follistatin, insulin-like growth factor-1 (ILGF-1), (EGF)/transforming growth factor-α (TGF-α), TGF-β1, growth differentiation factor 9 (GDF-9) (122,123), fibroblast growth factor-β (FGF-β), interleukin-1, tissue necrosis factor-α, OMI, and renin–angiotensin. Anti-mullerian hormone, produced exclusively by granulosa cells of growing primary and preantral follicles, is the most accurate reflection of ovarian reserve and seems to influence the dominant follicle selection by decreasing FSH sensitivity at receptor level, thus inhibiting the initial selection of preantral and small antral follicles (124–126).

Ovulation

The midcycle LH surge is responsible for a dramatic increase in local

concentrations of prostaglandins and proteolytic enzymes in the follicular wall (127). These substances progressively weaken the follicular wall, allowing the formation of a bleb-like superficial follicular protrusion known as the stigma and ultimately the wall's perforation. Ovulation most likely represents a slow extrusion of the oocyte through this opening in the follicle rather than a rupture of the follicular structure (128). Direct measurements of intrafollicular pressures were recorded and failed to demonstrate an explosive event.

Luteal Phase

Structure of Corpus Luteum

After ovulation, the remaining follicular shell is transformed into the primary regulator of the luteal phase: the corpus luteum. Membranous granulosa cells remaining in the follicle begin to take up lipids and the characteristic yellow lutein pigment for which the structure is named. These cells are active secretory structures that produce progesterone, which supports the endometrium of the luteal phase. In addition, estrogen and inhibin A are produced in significant quantities. Unlike the process that occurs in the developing follicle, the basement membrane of the corpus luteum degenerates to allow proliferating blood vessels to invade the granulosa-luteal cells in response to secretion of angiogenic factors such as vascular endothelial growth factor (129). This angiogenic response allows large amounts of luteal hormones to enter the systemic circulation.

Hormonal Function and Regulation

The hormonal changes of the luteal phase are characterized by a series of negative feedback interactions designed to lead to regression of the corpus luteum if pregnancy does not occur. Corpus luteum steroids (estradiol and progesterone) provide negative central feedback and cause a decrease in FSH and LH secretion. Continued secretion of both steroids will decrease the stimuli for subsequent follicular recruitment. Similarly, luteal secretion of inhibin potentiates FSH withdrawal. In the ovary, local production of progesterone inhibits the further development and recruitment of additional follicles.

Continued corpus luteum function depends on continued LH production. In the absence of this stimulation, the corpus luteum will invariably regress after 12 to 16 days and form the scar-like *corpora albicans* (130). The exact mechanism of luteolysis is unclear and most likely involves local paracrine factors. In the absence of pregnancy, the corpus luteum regresses, and estrogen and progesterone levels wane. This removes central inhibition on gonadotropin secretion and allows FSH and LH levels to rise and recruit another cohort of follicles.

If pregnancy does occur, placental hCG will mimic LH action and continually stimulate the corpus luteum to secrete progesterone. Successful implantation results

in hormonal support to allow continued maintenance of the corpus luteum and the endometrium. Evidence from patients undergoing oocyte donation cycles demonstrated that continued luteal function is essential for continuation of the pregnancy until approximately 5 weeks of gestation, when sufficient progesterone is produced by the developing placenta (131). This switch in the source of regulatory progesterone production is referred to as the luteal–placental shift.

Summary of Menstrual Cycle Regulation

Following is a summary of the regulation of the menstrual cycle:

1. **GnRH is produced in the arcuate nucleus of the hypothalamus and secreted in a pulsatile fashion into the portal circulation, where it travels to the anterior pituitary.**
2. **Ovarian follicular development moves from a period of gonadotropin independence to a phase of FSH dependence.**
3. **As the corpus luteum of the previous cycle fades, luteal production of progesterone and inhibin A decreases, allowing FSH levels to rise.**
4. **In response to FSH stimulus, the follicles grow, differentiate, and secrete increasing amounts of estrogen and inhibin B.**
5. **Estrogen stimulates growth and differentiation of the functional layer of the endometrium, which prepares for implantation. Estrogens work with FSH in stimulating follicular development.**
6. **The two-cell, two-gonadotropin theory dictates that with LH stimulation, the ovarian theca cells will produce androgens that are converted by the granulosa cells into estrogens under the stimulus of FSH.**
7. **Rising estrogen and inhibin levels negatively feedback on the pituitary gland and hypothalamus and decrease the secretion of FSH.**
8. **The one follicle destined to ovulate each cycle is called the dominant follicle. It has relatively more FSH receptors and produces a larger concentration of estrogens than the follicles that will undergo atresia. It is able to continue to grow despite falling FSH levels.**
9. **Sustained high estrogen levels cause a surge in pituitary LH secretion that triggers ovulation, progesterone production, and the shift to the secretory, or luteal, phase.**
0. **Luteal function is dependent on the presence of LH. The corpus luteum secretes estrogen, progesterone, and inhibin A, which serve to maintain gonadotropin suppression. Without continued LH secretion, the corpus luteum will regress after 12 to 16 days. The resulting loss of progesterone secretion**

results in menstruation.

1. If pregnancy occurs, the embryo secretes hCG, which mimics the action of LH by sustaining the corpus luteum. The corpus luteum continues to secrete progesterone and supports the secretory endometrium, allowing the pregnancy to continue to develop.

Differential Diagnosis and Evaluation
Mixed Gonadal Dysgenesis
Genital Ambiguity at Birth

KEY POINTS

1 Normal pubertal development occurs in a predictable orderly sequence over a definite time frame.
2 The earliest pubertal changes are detectable in females, on average, at age 10, but the normal age range for the onset of puberty is wide.
3 Delayed puberty is often constitutional but underlying pathology should be investigated.
4 When pubertal development occurs asynchronously with development of breasts in the absence of significant pubic and axillary hair, the diagnosis is usually androgen insensitivity.
5 The most common cause of precocious puberty is constitutional (idiopathic), but more serious causes must be ruled out and therapy focused toward optimizing adult height.
6 The most common cause of heterosexual development at the expected age of puberty is polycystic ovary syndrome.

***Puberty* is the period during which secondary sexual characteristics develop and the capability for sexual reproduction is attained.** The physical changes accompanying pubertal development result directly or indirectly from maturation of the hypothalamus, stimulation of the sex organs, and secretion of sex steroids. Hormonally, puberty in humans is characterized by the resetting of the classic negative gonadal steroid feedback loop, alterations in circadian and ultradian (frequent) gonadotropin rhythms, and the acquisition in the woman of a positive estrogen feedback loop, which controls monthly cycles as an interdependent expression of gonadotropins and ovarian steroids.

The ability to evaluate and treat aberrations of pubertal development, such as amenorrhea and other menstrual abnormalities, requires thorough comprehension of the normal hormonal and physical changes that occur at puberty.

NORMAL PUBERTAL DEVELOPMENT

Factors Affecting Time of Onset

The major determinant of the timing of the onset of puberty is primarily genetic, but a number of other factors appear to influence both the age at onset and the progression of pubertal development. Among these influences are nutritional state, general health, geographic location, exposure to light, and psychological state (1). **The concordance of the age of menarche in mother–daughter pairs and between sisters and in ethnic populations illustrates the importance of genetic factors** (1). Typically, the age of menarche is earlier than average in children with moderate obesity (up to 30% above normal weight for age), whereas delayed menarche is common in those with severe malnutrition. Children who live in urban settings, closer to the equator, and at lower altitudes typically begin puberty earlier than those who live in rural areas, farther from the equator, and at higher elevations. The risk of earlier onset of puberty has been a topic of interest for developmental biologists, associating family discord, lack of a parent, inadequate financial resources, and other domestic stressors with increased risk of early puberty and sexual maturity (2,3). Other risk factors implicated for precocious puberty include

exposure to naturally occurring and synthetic estrogenic endocrine–disrupting chemicals (3). Blind girls apparently undergo menarche earlier than sighted girls, suggesting some influence of light (4).

In Western Europe, the age of menarche declined 4 months each decade between 1850 and 1960 (1). Data suggest that the trend toward earlier pubertal development may be continuing among girls (but not boys) who live in the United States as reported from studies comparing populations of girls from 1940 to 1994 (5). It is presumed that these changes represent improved nutritional status and healthier living conditions.

One of the more controversial hypotheses centers on the role of total body weight and body composition on the age of menarche. It has been suggested that a minimum of 17% body fat must be achieved before the initiation of menarche, and body fat should be at 22% in females older than 16 to maintain regular periods (6). This hypothesis is supported by observations that menarche occurs earliest in overweight girls, followed by normal-weight girls, then underweight girls, and lastly anorectic girls **(Fig. 8-1)**. The importance of other factors is indicated by observations that menarche is often delayed in morbidly obese girls, those with diabetes, and those who exercise intensely but are of normal body weight and body fat percentage. Girls with precocious puberty may undergo menarche even if they have a low body fat percentage, and other girls show no pubertal development with a body fat percentage of 27% (7). Although body fat and weight are factors in determining onset of puberty and maturation, other factors have been the subject of investigation, such as birth weight, accelerated weight gain in infancy, and in utero exposures to toxins or stress (3,8).

FIGURE 8-1 Normal twins at 12 years of age. The heavier twin (weighing 143 lb) is clearly more advanced in puberty than the lighter twin (weighing 87 lb). Anecdotal photographs and data such as these served to provide the basis for the theory that body fat, body mass, and menarche are linked. (From **Wilkins L.** *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. 3rd ed. Springfield, IL:

Charles C Thomas; 1965:218, with permission.)

Physical Changes During Puberty

[1] The changes associated with puberty occur in an orderly predictable sequence over a definite time frame. Any deviation from this sequence or time frame should be regarded as abnormal. The pubertal changes, their relationship to one another, and the ages at which they occur are distinctly different in girls than in boys. Although this chapter focuses on girls, changes in boys are briefly considered.

Tanner Stage

[2] In girls, pubertal development typically takes place over 4.5 years (Fig. 8-2). The first sign of puberty is accelerated growth, and breast budding is usually the first recognized pubertal change, followed by the appearance of pubic hair, peak growth velocity, and menarche. Pubertal changes begin, on average, in the 11th year of life, but the range of normal is wide. The stages initially described by Marshall and Tanner are often used to describe breast and pubic hair development (9).

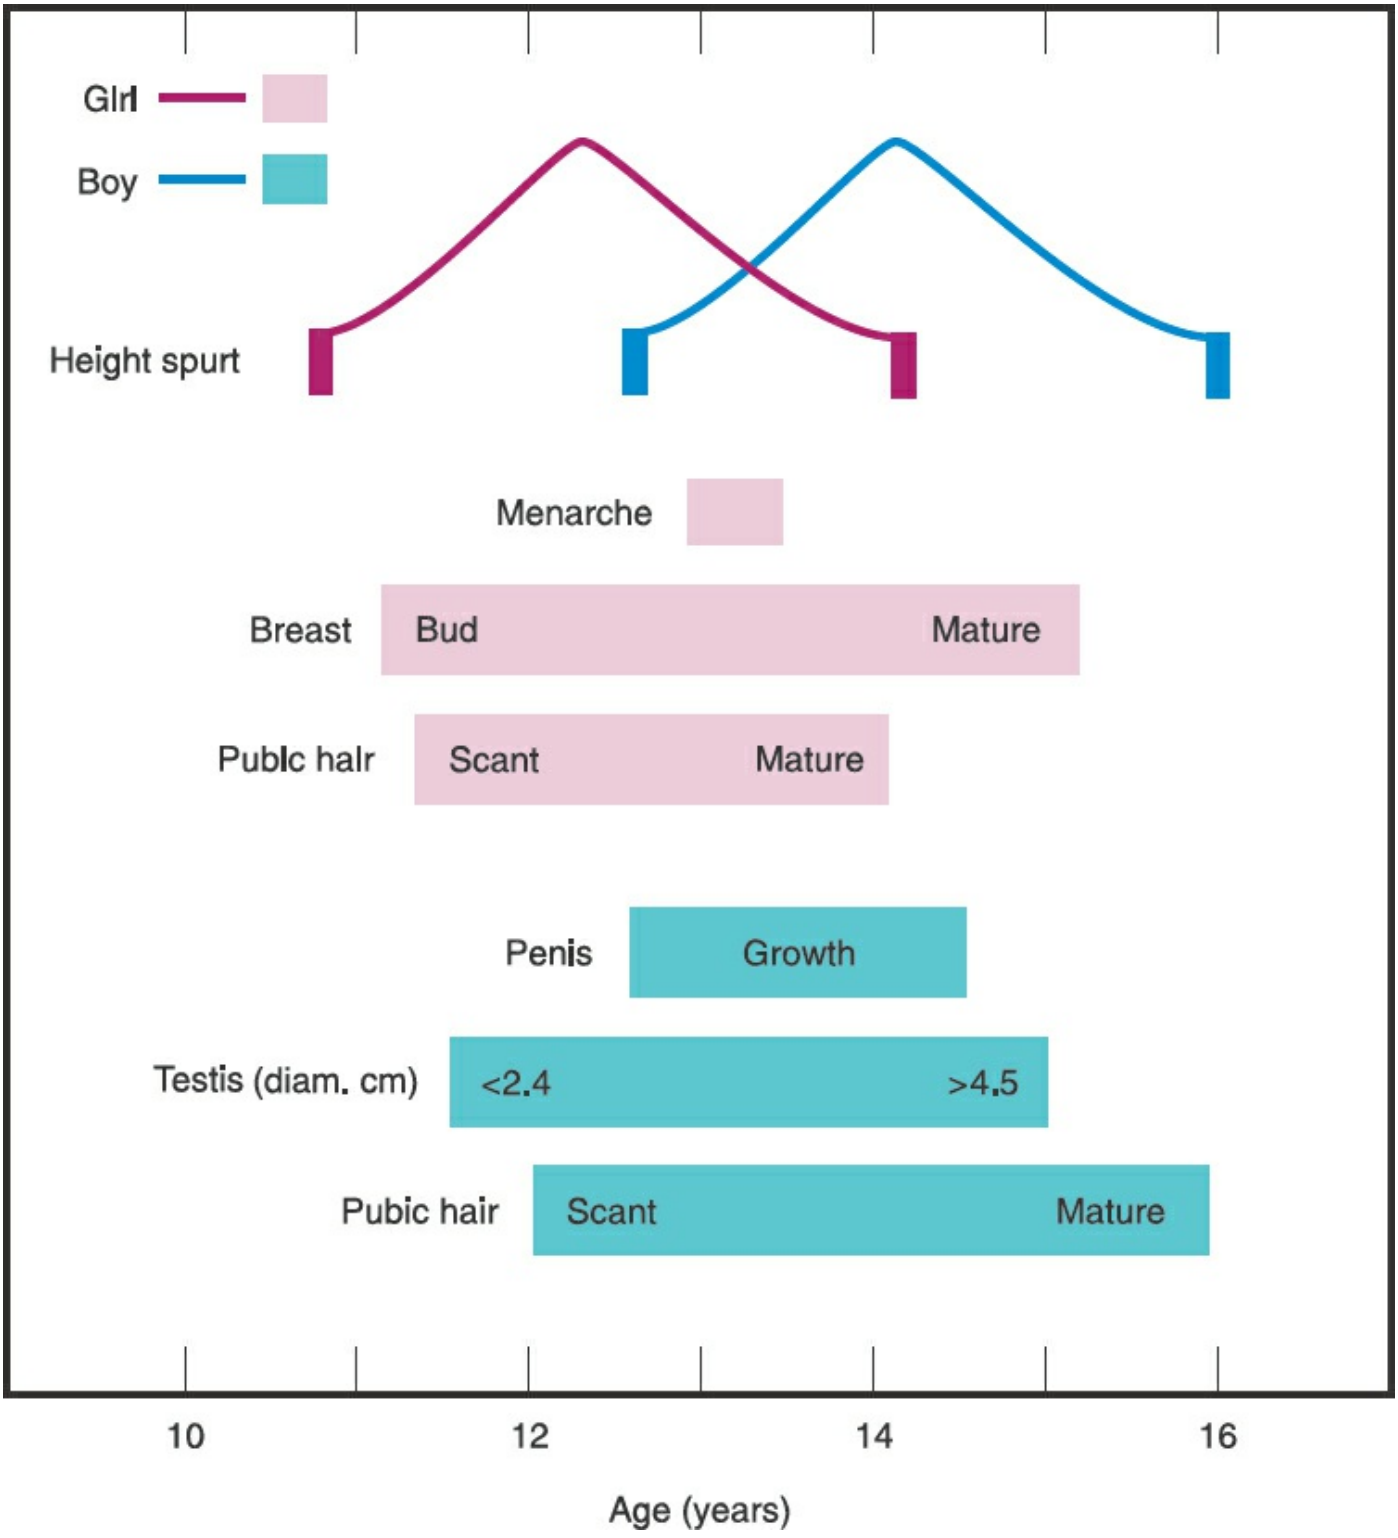

FIGURE 8-2 Schematic sequence of events at puberty. An idealized average girl and an idealized average boy are represented. (From **Rebar RW.** Practical evaluation of hormonal status. In: Yen SSC, Jaffe RB, eds. *Reproductive Endocrinology: Physiology, Pathophysiology and Clinical Management*. 3rd ed. Philadelphia, PA: WB Saunders; 1991:830, with permission; based on data from **Marshall WA, Tanner JM.** Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303; and **Marshall WA, Tanner JM.** Variation in the pattern of pubertal changes in boys. *Arch Dis Child* 1970;45:13–23, with permission.)

With regard to breast development, *Tanner stage 1* refers to the prepubertal

state and includes no palpable breast tissue, with the areolae generally less than 2 cm in diameter. The nipples may be inverted, flat, or raised. In *Tanner stage 2*, breast budding occurs, with a visible and palpable mound of breast tissue. The areolae begin to enlarge, the skin of the areolae thins, and the nipple develops to varying degrees. *Tanner stage 3* is reflected by further growth and elevation of the entire breast. When the individual is seated and viewed from the side, the nipple is generally at or above the midplane of breast tissue. In most girls, *Tanner stage 4* is defined by projection of the areola and papilla above the general breast contour in a secondary mound. Breast development is incomplete until *Tanner stage 5*, in which the breast is mature in contour and proportion. In most women, the nipple is more pigmented at this stage than earlier in development, and Montgomery glands are visible around the circumference of the areola. The nipple is generally below the midplane of breast tissue when the woman is seated and viewed from the side. Full breast development usually occurs over 3 to 3.5 years, but it may occur in as little as 2 years or not progress beyond stage 4 until the first pregnancy. Breast size is no indication of breast maturity.

Pubic hair staging is related to quantity and distribution (Fig. 8-3). In *Tanner stage 1*, there is no sexually stimulated pubic hair present, but some nonsexual hair may be present in the genital area. *Tanner stage 2* is characterized by the first appearance of coarse, long, crinkly pubic hair along the labia majora. In *Tanner stage 3*, coarse, curly hair extends onto the mons pubis. *Tanner stage 4* is characterized by adult hair in thickness and texture, but the hair is not as widely distributed as in adults and typically does not extend onto the inner aspects of the thighs. Except in certain ethnic groups, including Asians and American Indians, pubic hair extends onto the thighs in *Tanner stage 5*.

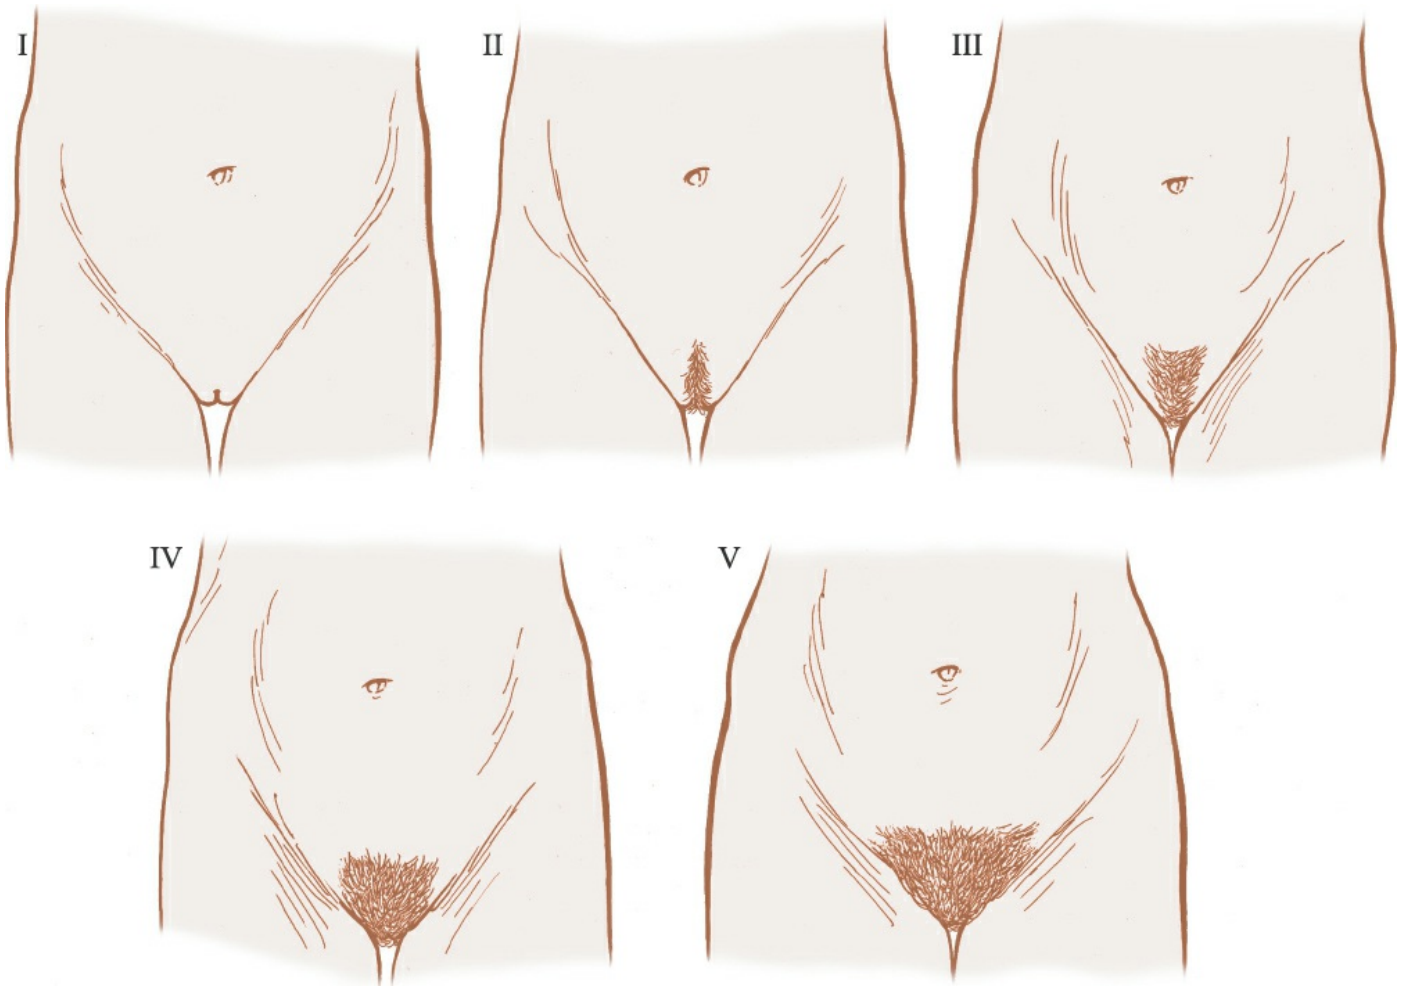

FIGURE 8-3 Diagrammatic depiction of Tanner pubic hair staging in adolescent women. (From **Ross GT, VandeWiele RL, Frantz AG.** The ovaries and the breasts. In: Williams RH, ed. *Textbook of Endocrinology*. 6th ed. Philadelphia, PA: WB Saunders; 1981:355, with permission; adapted from **Marshall WA, Tanner JM.** Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303.)

The staging of male pubertal sexual maturation is based on genital size and pubic hair development. *Tanner stage 1* is prepubertal. *Tanner stage 2* of genital growth begins when testicular enlargement is first evident. Testis length along the longitudinal axis ranges from 2.5 to 3.2 cm. The size of the penis increases. Pigmented, curly pubic hair is first visible around the base of the penis. In *Tanner stage 3*, there is further growth of the penis in length and diameter, the scrotum develops further, and testis length increases to 3.3 to 4 cm. Thicker, curly hair extends above the penis. *Tanner stage 4* involves further growth of the genitalia, with testis length ranging from 4 to 4.5 cm. Extension of pubic hair over the genital area continues, but the volume is less than in the adult. At this stage, the prostate gland is palpable by rectal examination. In *Tanner stage 5*, the genitalia are within the adult range in size. Average flaccid penile length in adult men ranges between 8.6 and 10.5 cm from tip to base. Pubic hair spreads laterally onto the medial

thighs. Hair may extend from the pubic area toward the umbilicus and anus.

Pigmented pubic hair is often the first recognized sign of male puberty even though it typically occurs 6 months after genital growth begins. Tanner stage 3 puberty is often accompanied by symmetric or asymmetric gynecomastia, and mature sperm first can be identified with microscopic urinalysis.

Height and Growth Rate

Plotting height increments (i.e., growth velocity) against the phases of puberty allows one to see relationships during puberty (Fig. 8-2). Girls reach peak height velocity early in puberty before menarche. As a consequence, they have limited growth potential after menarche. In contrast, boys reach peak height velocity about 2 years later than girls. Boys grow an average of 28 cm during the growth spurt, in comparison to a mean of 25 cm for girls. Adult men eventually are an average of 13 cm taller than adult women because they are taller at the onset of the growth spurt. Hormonal control of the pubertal growth spurt is complex. Growth hormone (GH), insulinlike growth factor 1 (IGF-1), and gonadal steroids play major roles. Adrenal androgens appear to be less important. Mutations limiting conversion of androgens to estrogens in males confirmed that estrogen is a major stimulus to the pubertal growth spurt in boys and girls (10). The transient elevation of gonadotropins and sex steroids observed in the first few months of life has been implicated as an important contributor to subsequent skeletal bone growth and general pubertal development (11).

During the growth spurt associated with puberty, the long bones in the body lengthen and the epiphyses ultimately close. The bone or skeletal age of any individual can be estimated closely by comparing x-rays documenting the development of bones in the nondominant hand (most commonly), knee, or elbow to standards of maturation for the normal population. The Greulich and Pyle atlas is used most often for this purpose (12). Skeletal age is more closely correlated with pubertal stage than with chronologic age during puberty. **With height and chronologic age, an individual's bone age can be used to predict final adult height using the Bayley–Pinneau tables** (13). Bone age determinations can be used to assess the degree of delay, monitor subsequent development, and estimate final adult height.

Another practical clinical approach to predicting adult height uses midparental height. **The adjusted midparental height is calculated by adding 13 cm to the mother's height (for boys) or subtracting 13 cm from the father's height (for girls) and then determining the mean of the heights of the parents, including the adjusted height of the opposite-sex parent. Adding and subtracting 8.5 cm to the calculated predicted height approximates the target range of the 3rd to the 97th percentile for the anticipated adult height of the child.** This quick calculation can be of assistance in evaluating individuals with delayed or precocious pubertal development and those with short stature.

Several changes in body composition occur during pubertal development. **Although lean body mass, skeletal mass, and body fat are equal in prepubertal boys and girls, by maturity, men have 1.5 times the lean body mass and almost 1.5 times the skeletal mass of women, whereas women have twice as much body fat as men** (1). **The changes in body contour in girls, with accumulation of fat at the thighs, hips, and buttocks, occur during the pubertal growth spurt. In this regard, testosterone is a potent anabolic steroid and is responsible for the major changes in boys, whereas estrogen increases total body fat in a characteristic distribution at the thighs, buttocks, and abdomen in girls.**

Other physical changes show sexual dimorphism at puberty. In boys the membranous and cartilaginous portions of the vocal cords lengthen much more than they do in girls, accounting for deepening of the voice. Comedones, acne, and seborrhea of the scalp begin because of increased secretion of adrenal and gonadal steroids at puberty. In general, early-onset acne correlates with the development of severe acne later in puberty. **The appearance of comedones in the nasal creases and behind the pinna may be the first indications of impending pubertal development.**

Hormonal Changes

By 10 weeks of gestation, gonadotropin-releasing hormone (GnRH) is present in the hypothalamus, and luteinizing hormone (LH) and follicle-stimulating hormone (FSH) are present in the pituitary gland (14). Gonadotropin levels are elevated in female and male fetuses midgestation; the levels of FSH are higher in females. The levels of gonadotropins and sex steroids are suppressed before birth, but increase in the first few weeks of life, a process named "mini-puberty." This period lasts until approximately 6 months of age in boys and up to age 3 years in girls and is suspected to be the foundation of development of reproductive competency later in life (5). After this early surge, the gonadotropins are suppressed in childhood, and remain low during the prepubertal years. The hypothalamic–pituitary unit appears to be suppressed by the extremely low levels of gonadal steroids present in childhood. Gonadal suppression of gonadotropin secretion is demonstrated by higher gonadotropin levels in children with gonadal dysgenesis and those who undergo gonadectomy before puberty (15).

Several of the hormonal changes associated with pubertal development begin before any of the physical changes are obvious. Early in puberty, there is increased sensitivity of LH to GnRH. Sleep-entrained increases in both LH and FSH can be documented early in puberty (16). In boys, the nocturnal increases in gonadotropin levels are accompanied by simultaneous increases in circulating testosterone levels (17). In contrast, in girls, the nighttime increases in circulating gonadotropin levels are followed by increased secretion of estradiol the next day **(Fig. 8-4)** (18). This delay in estradiol secretion is believed to result from the additional synthetic steps required in

the aromatization of estrogens from androgens. Basal levels of FSH and LH increase through puberty. The patterns differ in boys and girls, with LH levels (measured in mIU/mL) eventually becoming greater than FSH levels **(Fig. 8-5)** (19). Although it appears that gonadotropins are always secreted in an episodic or pulsatile fashion, even before puberty, the pulsatile secretion of gonadotropins is more easily documented as puberty progresses and basal levels increase (20).

Increased adrenal androgen secretion is important in stimulating adrenarche, the appearance of pubic and axillary hair, in boys and girls. Pubarche specifically refers to the appearance of pubic hair. Progressive increases in circulating levels of the major adrenal androgens, dehydroepiandrosterone (DHEA) and its sulfate (DHEAS), begin as early as 2 years of age, accelerate at 7 to 8 years of age, and continue until 13 to 15 years of age (5). The accelerated increases in adrenal androgens begin about 2 years before the increases in gonadotropin and gonadal sex steroid secretion when the hypothalamic–pituitary–gonadal unit is still functioning at a low prepubertal level. **Pubarche and adrenarche, although often temporally related to gonadarche, should not be used as markers for the onset of puberty** (5).

In girls, mean levels of estradiol, secreted predominantly by the ovaries, increase steadily during puberty (19). Although increases in estradiol first appear during the daytime hours, basal levels eventually increase during the day and night. Estrone, which is secreted in part by the ovaries and arises in part from extraglandular conversion of estradiol and androstenedione, increases early in puberty but plateaus by midpuberty. Thus, **the ratio of estrone to estradiol decreases throughout puberty, indicating that ovarian production of estradiol becomes increasingly important and peripheral conversion of androgens to estrone becomes less important during maturation.**

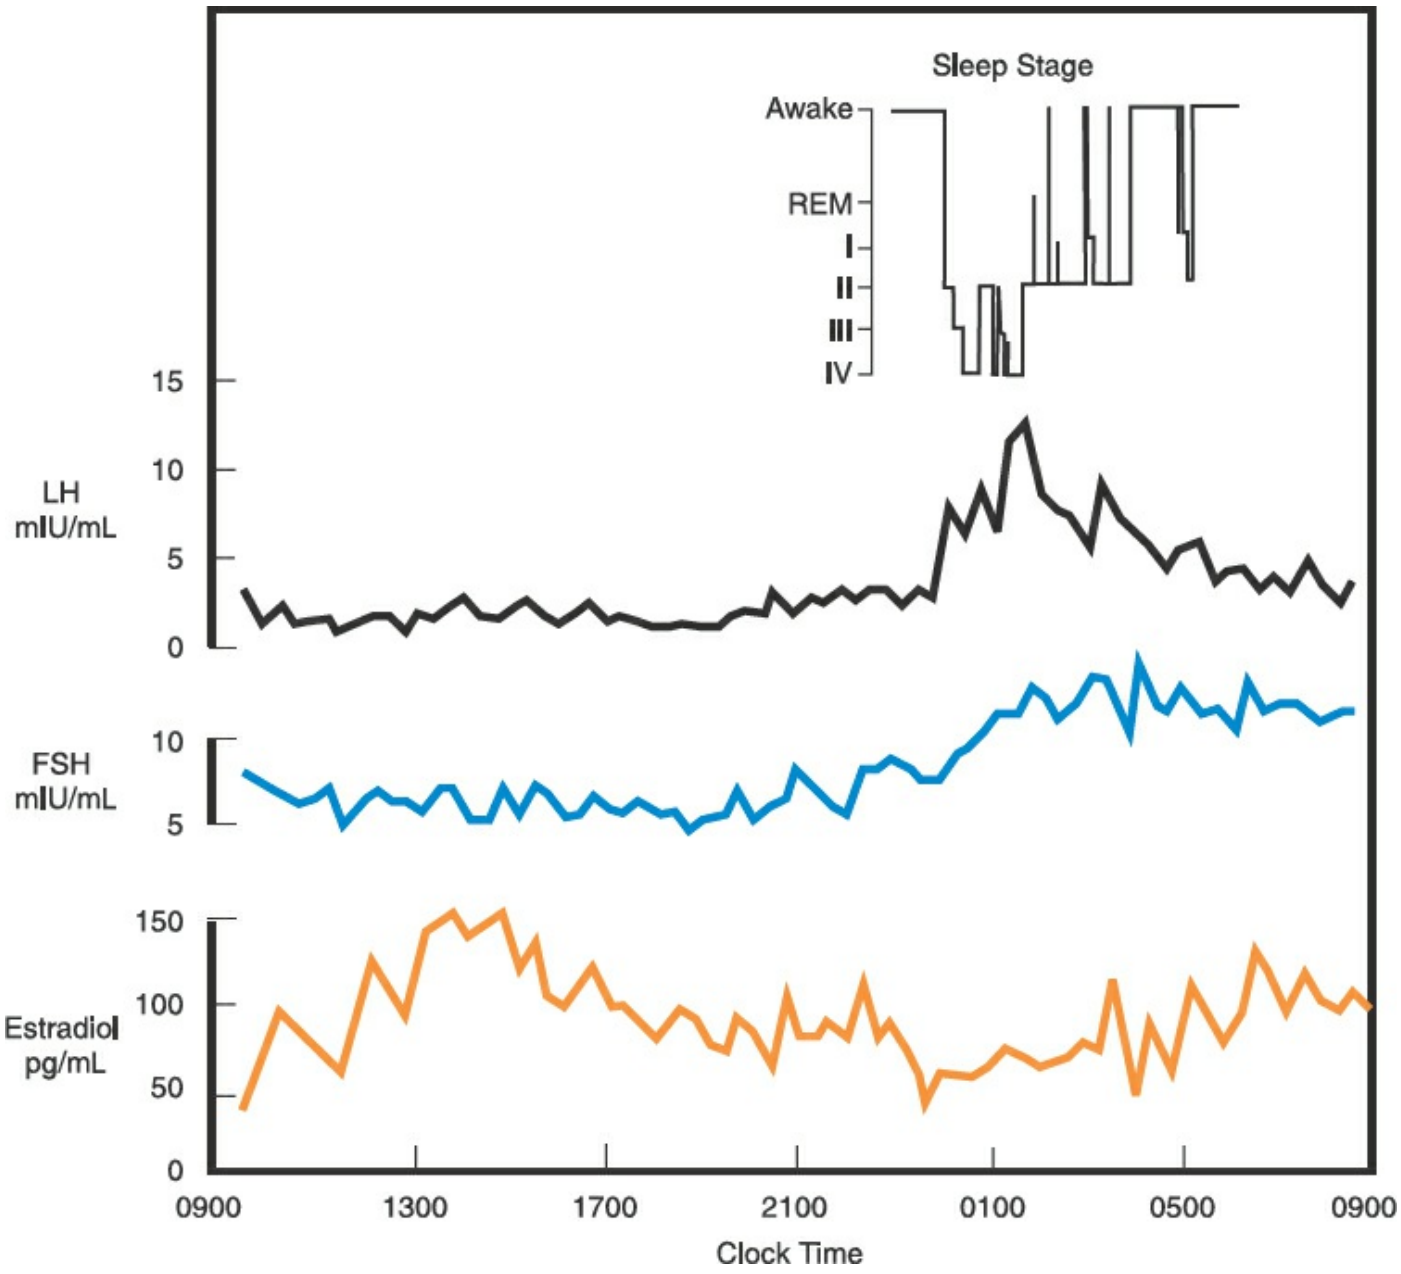

FIGURE 8-4 Patterns of circulating luteinizing hormone (LH), follicle-stimulating hormone (FSH), and estradiol in a stage 3 pubertal girl over a 24-hour period, with the encephalographic stage of sleep indicated. (From **Boyar RM, Wu RHK, Roffwarg H, et al.** Human puberty: 24-hour estradiol patterns in pubertal girls. *J Clin Endocrinol Metab* 1976;43:1418–1421, with permission.)

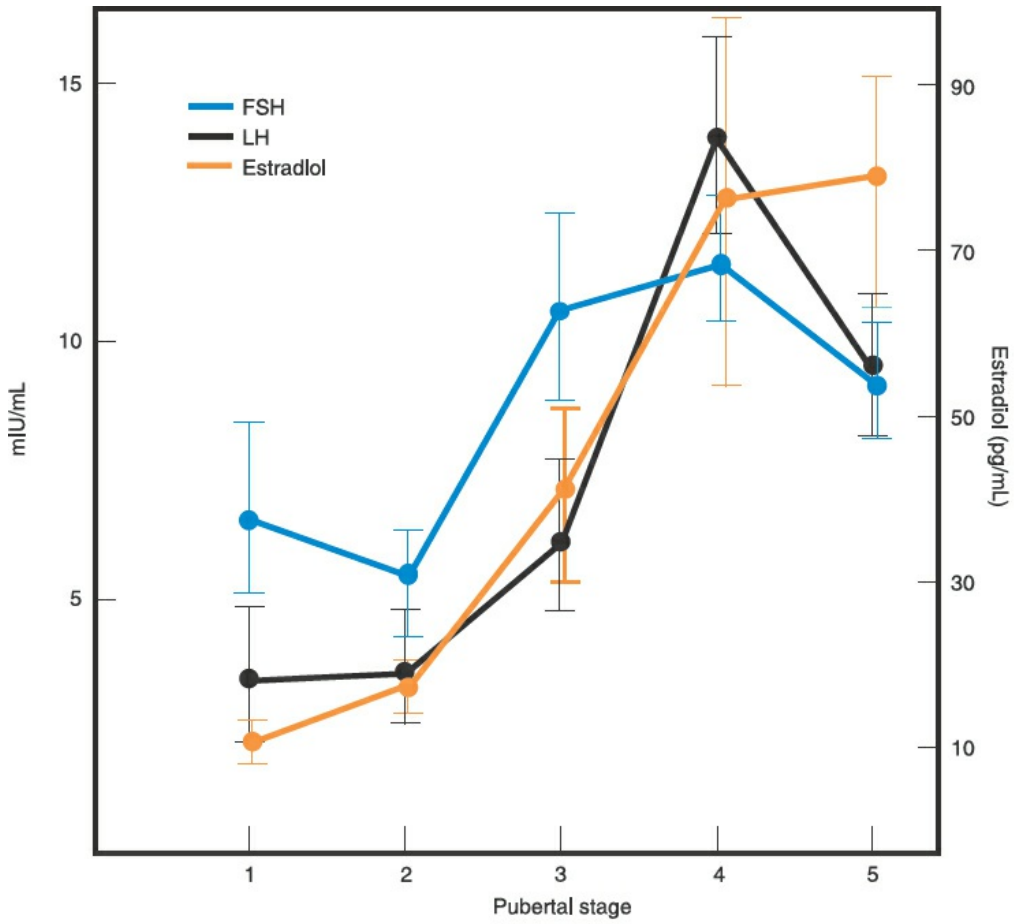
In boys, most of the testosterone in the circulation arises from direct secretion by the Leydig cells of the testis. Testosterone induces development of a male body habitus and voice change, whereas dihydrotestosterone (DHT), produced following 5α-reduction within target cells, induces enlargement of the penis and prostate gland, beard growth, and temporal hair recession during puberty. Mean plasma testosterone levels rise progressively during puberty, with the greatest increase occurring during Tanner stage 2 (21).

GH secretion increases along with increased gonadotropin secretion at the onset



of puberty. It is believed that the increase in GH is mediated by estrogen, which in boys is dependent on aromatization of testosterone to estradiol and reflects increasing sex steroid production at puberty. Nonetheless, there are profound sex differences in GH secretion during puberty. Girls have higher basal levels of GH throughout puberty, reaching maximal levels around the time of menarche and decreasing thereafter. In contrast, basal concentrations of GH remain constant throughout puberty in boys. GH secretion is highly pulsatile, with most pulses occurring during sleep and with sex steroids increasing pulse amplitude rather than altering pulse frequency.

GH stimulates production of IGF-1 in all tissues, with concentrations found in the circulation spilling over from the liver. During puberty the negative feedback effect of IGF-1 on GH secretion must be reduced because IGF-1 and GH levels are high. GH and IGF-1 play significant roles in the changes in body composition that occur at puberty because both hormones are potent anabolic agents.

In the final stages of puberty in both boys and girls, GH secretion begins to diminish, returning to prepubertal levels in adult life, despite continued exposure to high levels of gonadal steroids.

Mechanisms Underlying Puberty

The mechanisms responsible for the numerous hormonal changes that occur during puberty are poorly understood, although it is recognized that a "central nervous system program" must be responsible for initiating puberty. It appears that the hypothalamic–pituitary–gonadal axis in girls develops in two distinct stages during puberty. First, sensitivity to the negative or inhibitory effects of the low levels of circulating sex steroids present in childhood decreases early in puberty. Second, late in puberty, there is maturation of the positive or stimulatory feedback response to estrogen, which is responsible for the ovulatory midcycle surge of LH.

Boston, MA: Little, Brown; 1990:95, with permission.)

Evidence suggests that the central nervous system inhibits the onset of puberty until the appropriate time (22). Based on this theory, the neuroendocrine control of puberty is mediated by GnRH-secreting neurons in the medial basal hypothalamus, which act as an endogenous pulse generator. At puberty, the GnRH pulse generator is reactivated (i.e., disinhibited), leading to increased amplitude and frequency of GnRH pulses. The increased GnRH secretion results in increased gonadotropin and then gonadal steroid secretion.

Increasing evidence indicates that there are several influences on the initiation and progression of the GnRH pulse generator, and these include both neuroendocrine signalers and metabolic modifiers. Although the exact details of the pathways are still in the discovery phase, regulators such as *kisspeptin* and *neurokinin B* have been implicated as gatekeepers for the onset of puberty. Metabolic modifiers, such as *leptin* and *nesfatin-1,* can alter the actions of the gatekeepers (23).

Table 8-1 Aberrations of Pubertal Development

I. ***Delayed or interrupted puberty***
A. ***Anatomic abnormalities of the genital outflow tract***
1. Müllerian dysgenesis (Mayer–Rokitansky–Küster–Hauser syndrome)
2. Distal genital tract obstruction
a. Imperforate hymen
b. Transverse vaginal septum
A. ***Hypergonadotropic (follicle-stimulating hormone >30 mIU/mL) hypogonadism (gonadal "failure")***
1. Gonadal dysgenesis with stigmata of Turner syndrome
2. Pure gonadal dysgenesis
a. 46,XX
b. 46,XY
c. Early gonadal "failure" with apparent normal ovarian development
A. ***Hypogonadotropic (luteinizing hormone and follicle-stimulating hormone <10 mIU/mL) hypogonadism***

1. Constitutional delay
2. Isolated gonadotropin deficiency
    a. Associated with midline defects (Kallmann syndrome)
    b. Independent of associated disorders
    c. Prader–Labhart–Willi syndrome
    d. Laurence–Moon–Bardet–Biedl syndrome
    e. Many other rare syndromes
3. Associated with multiple hormone deficiencies
4. Neoplasms of the hypothalamic–pituitary area
    a. Craniopharyngiomas
    b. Pituitary adenomas
    c. Other
5. Infiltrative processes (Langerhans cell–type histiocytosis)
6. After irradiation of the central nervous system
7. Severe chronic illnesses with malnutrition
8. Anorexia nervosa and related disorders
9. Severe hypothalamic amenorrhea (rare)
10. Antidopaminergic and gonadotropin-releasing hormone–inhibiting drugs (especially psychotropic agents, opiates)
11. Primary hypothyroidism
12. Cushing syndrome
13. Use of chemotherapeutic (especially alkylating) agents

II. ***Asynchronous pubertal development***

A. ***Complete androgen insensitivity syndrome (testicular feminization)***

B. ***Incomplete androgen insensitivity syndrome***

III. ***Precocious puberty***

A. ***Central (true) precocious puberty***

1. Constitutional (idiopathic) precocious puberty
2. Hypothalamic neoplasms (most commonly hamartomas)

3. Congenital malformations
4. Infiltrative processes (Langerhans cell–type histiocytosis)
5. After irradiation
6. Trauma
7. Infection

B. ***Precocious puberty of peripheral origin (precocious pseudopuberty)***

1. Autonomous gonadal hypersecretion
    a. Cysts
    b. McCune–Albright syndrome
2. Congenital adrenal hyperplasia
    a. 21-Hydroxylase (P450c21) deficiency
    b. 11β-Hydroxylase (P450c11) deficiency
    c. 3β-Hydroxysteroid dehydrogenase deficiency
3. Iatrogenic ingestion/absorption of estrogens or androgens
4. Hypothyroidism
5. Gonadotropin-secreting neoplasms
    a. Human chorionic gonadotropin secreting
        i. Ectopic germinomas (pinealomas)
        ii. Choriocarcinomas
        iii. Teratomas
        iv. Hepatoblastomas
    b. Luteinizing hormone–secreting (pituitary adenomas)
6. Gonadal neoplasms
    a. Estrogen-secreting
        i. Granulosa–theca cell tumors
        ii. Sex-cord tumors
    b. Androgen-secreting
        i. Sertoli–Leydig cell tumors (arrhenoblastomas)
        ii. Teratomas

7. Adrenal neoplasms
a. Adenomas
b. Carcinomas
D. ***Heterosexual puberty***
A. ***Polycystic ovarian syndrome***
B. ***Nonclassic forms of congenital adrenal hyperplasia***
C. ***Idiopathic hirsutism***
D. ***Mixed gonadal dysgenesis***
E. ***Rare forms of male pseudohermaphroditism (Reifenstein syndrome, 5a-reductase deficiency)***
F. ***Cushing syndrome (rare)***
G. ***Androgen-secreting neoplasms (rare)***

ABERRATIONS OF PUBERTAL DEVELOPMENT

Classification

Several aberrations of pubertal development, as detailed in Table 8-1, can occur in girls. Pubertal aberrations can be classified into four broad categories:

1. ***Delayed or interrupted puberty*** **exists in girls who fail to develop any secondary sex characteristics by age 13, have not had menarche by age 15 (95th percentile is 14.5 years), or have not attained menarche 5 or more years since the onset of pubertal development.**
2. ***Asynchronous pubertal development*** **is characterized by pubertal development that deviates from the normal pattern of puberty.**
3. ***Precocious puberty*** is **defined as pubertal development beginning before the age of 7 years in white girls and before the age of 6 years in African American girls.** This definition has its origin from data collected in the 1960s, using the 95th percentile as the normal designation. However, many pediatric endocrinologists continue to use 8 years as the threshold for initiation of diagnostic testing (24). It is clear that, in most cases, development nearer the mean age of puberty is less likely to have a pathologic basis. Precocious pubertal development is characterized in several ways. In *isosexual* precocious puberty, the early changes are common to the phenotypic sex of the individual. In *heterosexual* precocious puberty, the development is characteristic of the opposite sex. Precocious puberty is sometimes

termed "true" when it is of central origin with activation of the hypothalamic–pituitary unit. In precocious pseudopuberty, also known as *precocious puberty of peripheral origin,* secretion of hormones in the periphery (commonly by neoplasms) stimulates pubertal development.

4. ***Heterosexual puberty*** **is characterized by a pattern of development that is typical of the opposite sex occurring at the expected age of normal puberty.**

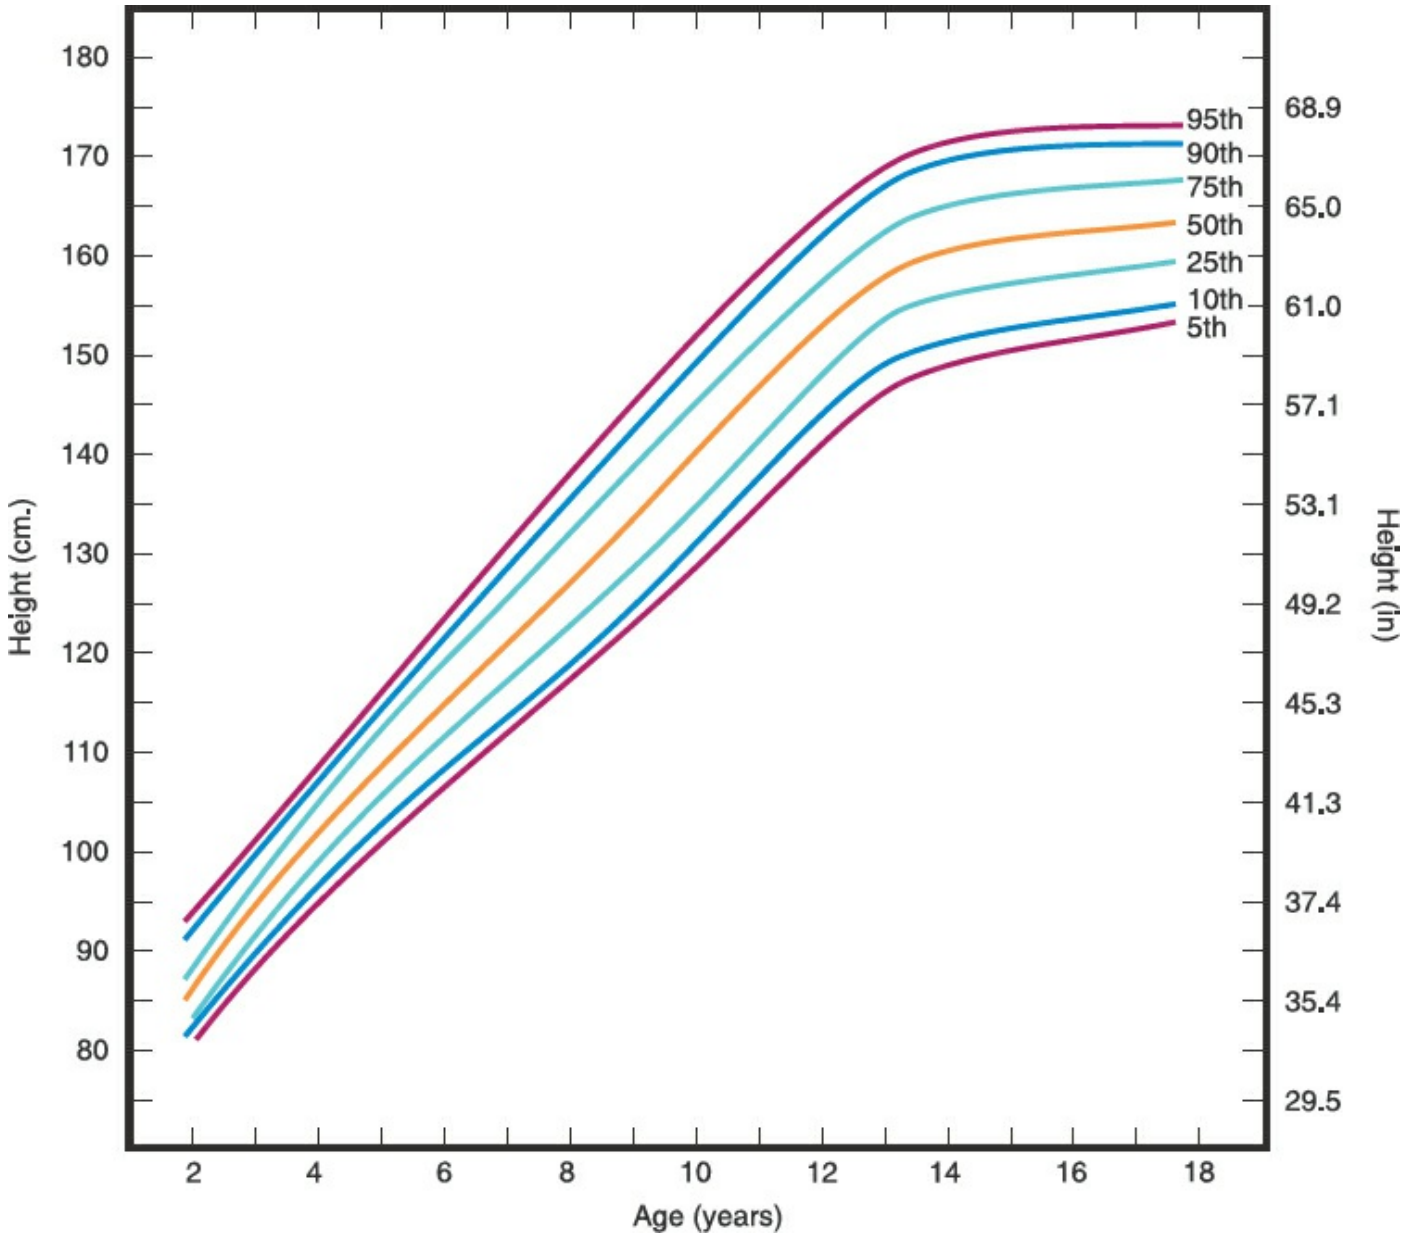

FIGURE 8-6 Growth chart showing stature by age percentiles for girls aged 2 to 18 years. Weight can be plotted in a similar fashion. Several excellent growth charts are available to clinicians, including those from Ross Laboratories (Columbus, OH), Serono Laboratories (Randolph, MA), and Genentech, Inc. (South San Francisco, CA). (From **Hamill PVV, Drizd TA, Johnson CL, et al.** Physical growth: National Center for Health Statistics percentiles. *Am J Clin Nutr* 1979;32:607–629, with permission; based on data from the National Center for Health Statistics.)

Disorders of sexual development and amenorrhea may be considered in relation to this classification of the aberrations of puberty. It is very helpful to document the growth of the individual and to plot the individual's height and weight on one of several commonly available growth charts **(Fig. 8-6)**.

Delayed or Interrupted Puberty

The history and physical examination, with particular attention to growth, are most important in the evaluation of individuals with delayed puberty. **Pubertal delay is much more common in boys than in girls. [3] The single most common cause of delayed puberty in both sexes is constitutional delay of growth and development (CDGD), which can be assigned when any underlying pathology has not been identified. CDGD has a strong genetic component and it represents an extreme of the normal spectrum of age distribution** (25). **It is important to remember that puberty may be delayed in any child suffering from any severe chronic disease,** including celiac disease, Crohn disease, sickle cell anemia, and cystic fibrosis. Chronic illness should be reviewed during the history and physical examination. One possible approach to evaluation is depicted in **Figure 8-7.**

Anatomic Abnormalities of the Genital Outflow Tract

Those girls who have mature secondary sex characteristics and any of a number of disorders of the outflow tract and uterus, often termed müllerian agenesis and dysgenesis, are most often identified on examination (Fig. 8-8). One of the earlier and more logical proposed classification schemes is shown in Table 8-2 (26). However, this older classification system does not lend itself to describing all possible anomalies and is not entirely based on objective embryologic data. There have been systematic attempts to modify this scheme that are quite complex but may be more effective (27), and other efforts are now underway. The incidence of these anomalies was estimated to be 0.02% of the female population, but the incidence may have increased as a result of the maternal ingestion of diethylstilbestrol (DES) and the resultant increase in anomalies of the lumen of the uterus (class VI) (28). Of the disorders unrelated to drug use, the septate uterus (class V) is most common.

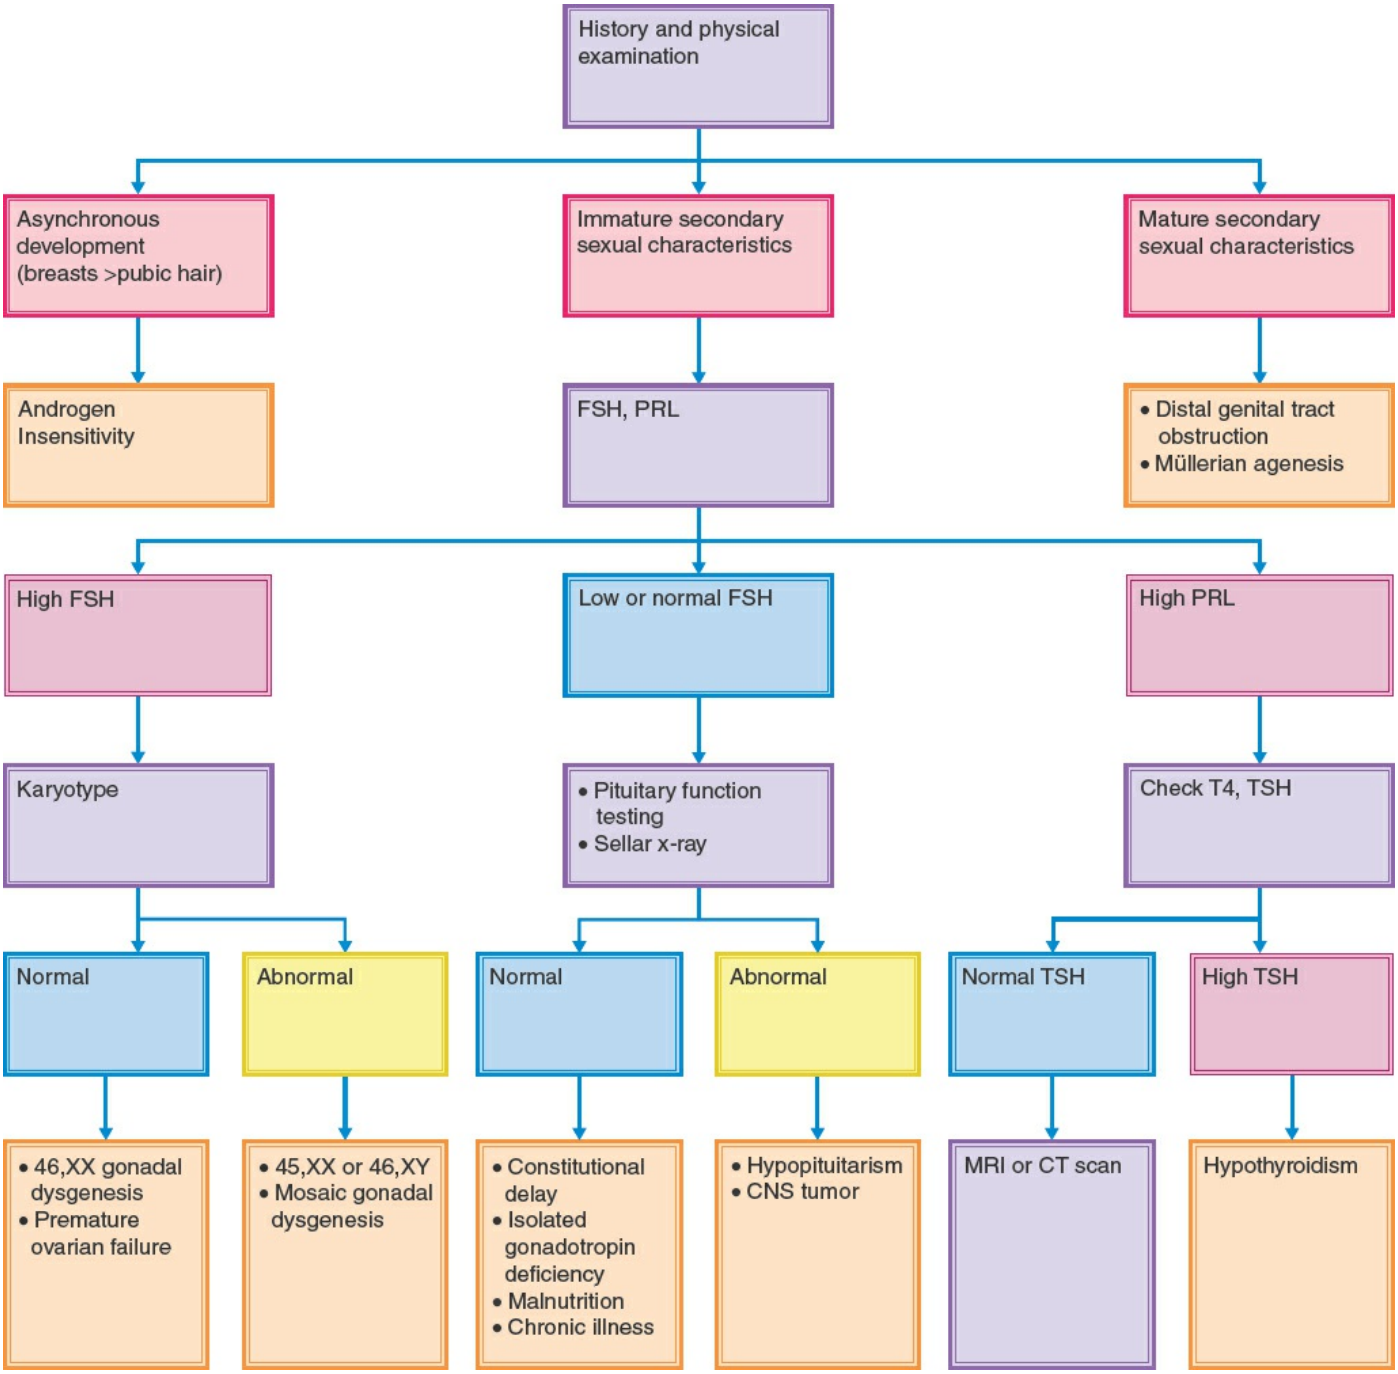

FIGURE 8-7 Flow diagram for the evaluation of delayed or interrupted pubertal development, including primary amenorrhea, in phenotypic girls. Girls with asynchronous development often present because of failure to menstruate. FSH, follicle-stimulating hormone; PRL, prolactin; T4, thyroxine; TSH, thyroid-stimulating hormone; CNS, central nervous system; MRI, magnetic resonance imaging; CT, computed tomography. In: Hollingsworth D, Resnik R, eds. *Medical Counselling Before Pregnancy*. New York: Churchill Livingstone; 1988:213–248, with permission.)

Disorders of the outflow tract and uterus often occur as a part of a syndrome of malformations that include abnormalities of the skeletal and renal systems (***Mayer–Rokitansky–Küster–Hauser syndrome***). Familial aggregates of the most common disorders of müllerian differentiation in girls—müllerian aplasia and incomplete müllerian fusion—are best explained on the basis of polygenic and multifactorial inheritance (29). It is clear that the *HOX* genes, a family of regulatory genes that encode for transcription factors, are essential for proper development of the müllerian tract in the embryonic period, and *HOXA13* is altered in hand–foot–genital syndrome (30). *WNT4* may be involved in uterine development, as a *WNT4* mutation was described in cases involving a Mayer–Rokitansky–Küster–Hauser-like syndrome with

hyperandrogenism (31).

Table 8-2 Classification of Müllerian Anomalies

Class I. Segmented müllerian agenesis or hypoplasia
A. Vaginal
B. Cervical
C. Fundal
D. Tubal
E. Combined
Class II. Unicornuate uterus
A. With a rudimentary horn
1. With a communicating endometrial cavity
2. With a noncommunicating cavity
3. With no cavity
B. Without any rudimentary horn
Class III. Uterus didelphys
Class IV. Bicornuate uterus
A. Complete to the internal os
B. Partial
C. Arcuate
Class V. Septate uterus
A. With a complete septum
B. With an incomplete septum
Class VI. Uterus with internal luminal changes

Adapted from **Buttram VC Jr, Gibbons WE.** Müllerian anomalies: a proposed classification (an analysis of 144 cases). *Fertil Steril* 1979;32:40, with permission.

The most common single anatomic disorder of puberty is the imperforate hymen, which prevents the passage of endometrial tissue and blood. These products can accumulate in the vagina (*hydrocolpos*) or uterus (*hydrometrocolpos*) and result in a bulging hymen that is often bluish in color. The affected individual often has a history of vague abdominal pain with approximately monthly exacerbations. It is sometimes

difficult to distinguish an imperforate hymen from a transverse vaginal septum, and in most situations, examination under anesthesia is required.

Regardless of the cause, uterine anomalies not involving segmental müllerian agenesis or hypoplasia (class I) can be compatible with spontaneous pregnancy. However, increased fetal loss is reported in the presence of these anomalies (32). Uterine malformations are associated with spontaneous abortion, preterm labor, abnormal presentations, and complications of labor (i.e., retained placenta). Many of these uterine anomalies can be identified with hysterosalpingography **(Fig. 8-8)**. Hysterosalpingography, laparoscopy, and hysteroscopy are used to differentiate a septate uterus (class V) from a bicornuate uterus (class IV). Three-dimensional ultrasound has been emerging as the modality of choice in imaging these anomalies and has had a high concordance with results from magnetic resonance imaging (MRI) (33).

Obstruction or malformation of the distal genital tract must be distinguished from androgen insensitivity. Individuals with androgen insensitivity have breast development in the absence of significant pubic and axillary hair development; the vagina may be absent or foreshortened in these women.

Hypergonadotropic and Hypogonadotropic Hypogonadism

Basal levels of FSH and prolactin should be determined in individuals in whom secondary sex characteristics have not developed to maturity (Fig. 8-7). Bone age should be estimated from x-rays of the nondominant hand. If prolactin levels are elevated, thyroid function should be assessed to determine whether the individual has primary hypothyroidism. Paradoxically, primary hypothyroidism can result in precocious puberty. If thyroid function is normal, a hypothalamic or pituitary neoplasm is possible, and careful evaluation of the hypothalamic and pituitary area by MRI or computed tomography (CT) is indicated.

The karyotype should be determined in any individual with delayed puberty and increased basal FSH concentrations. Regardless of the karyotype, the individual with hypergonadotropic hypogonadism has some form of ovarian "failure" (i.e., primary hypogonadism, now known as premature ovarian insufficiency [POI]).

Forms of Gonadal Failure

Turner Syndrome

The diagnosis of Turner syndrome requires the presence of characteristic features in phenotypic females coupled with complete or partial absence of the second sex chromosome, with or without cell line mosaicism. **Most affected individuals have a 45,X karyotype, while others have mosaic karyotypes (i.e., 45,X/46,XX; 45,X/46,XY).** Intrauterine growth restriction is common in infants with a 45,X karyotype. After birth, these patients generally grow slowly, beginning in the 2nd or 3rd

year of life. They typically have many of the associated stigmata, including lymphedema and sometimes large cystic hygromas of the neck at birth; a webbed neck; multiple pigmented nevi; and disorders of the heart, kidneys (most commonly horseshoe), and great vessels (commonly coarctation of the aorta) **(Fig. 8-9)**. Many of the anatomic findings can be detected in prenatal screening. Diabetes mellitus, thyroid disorders, essential hypertension, and other autoimmune disorders are often present in individuals with 45,X karyotypes (32).

Most 45,X patients have normal intelligence, but many affected individuals have an unusual cognitive defect characterized by an inability to appreciate the shapes and relations of objects with respect to one another (i.e., space-form blindness). As they grow older, affected children typically are shorter than normal. Although they do not develop breasts at puberty, some pubic or axillary hair may develop because appropriate adrenarche can occur with failure of thelarche (i.e., breast development).

Although less severe short stature and some adolescent development may occur with chromosomal mosaicism, it is reasonable to assume that any short, slowly growing, sexually infantile girl has Turner syndrome until proved otherwise because this disorder is so prevalent (about 1 in 2,500 newborn phenotypic females). In fact, the 45,X karyotype is the single most frequent chromosomal disorder in humans, but most affected fetuses are aborted spontaneously early in pregnancy.

The short stature commonly associated with the Turner phenotype appears to result from the loss of a homeobox-containing gene, which encodes an osteogenic gene. This gene, which is called *SHOX* (short stature homeobox-containing gene), escapes X inactivation because of its pseudoautosomal location on the short arm of the X (at Xp22). The gene appears to account for the height deficit and other skeletal aberrations commonly associated with Turner syndrome (34).

Even in the presence of typical Turner stigmata, a karyotype is indicated to eliminate the possibility of the presence of any portion of a Y chromosome. Analysis of pooled data suggests that the **presence of Y chromosome material is associated with an increased risk of a gonadoblastoma** (35). **If a Y chromosome is identified, laparoscopic prophylactic gonadectomy is recommended at the time of diagnosis to eliminate the risk of malignancy. Although gonadoblastomas are benign tumors with no metastatic potential that can arise spontaneously in gonads containing a portion of a Y chromosome, they can be precursors to germ cell malignancies, such as dysgerminomas (most commonly), teratomas, embryonal carcinomas, or endodermal sinus tumors** (36). In individuals in whom there is no evidence of neoplastic dissemination, the uterus may be left in situ for donor in vitro fertilization and embryo transfer.

Turner syndrome carries a significantly increased risk of structural and

functional cardiac abnormalities. All individuals with Turner syndrome should have an initial comprehensive cardiac evaluation followed by regular follow-up. **Individuals with Turner syndrome are at increased risk of sudden death from aortic rupture or dissection resulting from cystic medial necrosis during pregnancy, and the risk may be as great as 2% or more** (37). The Practice Committee of the American Society for Reproductive Medicine, in 2012, published guidelines stating that Turner syndrome is a relative contraindication for pregnancy because of this increased risk (38).

FIGURE 8-9 Typical appearance of two individuals with 45,X gonadal dysgenesis. **A:** This 16-year-old individual has obvious short stature, a webbed neck, shortened fourth metatarsals, and a thoracotomy scar from the repair of the coarctation of the aorta that was performed at 13 years of age. **B:** This 11-year-old individual also has obvious short stature and stigmata of Turner syndrome. Note that these two individuals look more like each other than they might look like any genetic siblings.

The evaluation of other commonly involved organ systems should include a careful physical examination, with special attention to the cardiovascular system, and thyroid function tests (including antibody assessment), fasting blood glucose, renal function tests, and intravenous pyelography or a renal ultrasonography.

Treatment of Turner Syndrome

Short stature is the most common finding in females with Turner syndrome. To increase final adult height, commonly accepted treatment strategies include use of exogenous GH. Therapy with GH accelerates growth velocity and improves final adult height. Initiation of therapy as early as 4 years of age maximizes height outcome. GH has had a favorable profile in patients with TS, but unwanted side effects such as scoliosis, benign intracranial hypertension, and others should be screened for on a regular basis (39).

It is not clear if a nonaromatizable anabolic steroid such as *oxandrolone* will provide additional growth. In girls older than 8 years at initiation of therapy or those with extremely short stature, consideration can be given to using high doses of GH and adding *oxandrolone* (39).

Gonadal steroids should be administered to compensate for gonadal failure, typically beginning at ages 12 to 14 years in an emotionally prepared individual, and are required for bone health, breast development, and uterine growth. The dosing of the hormone replacement should be aligned to the physiologic process as much as possible. Transdermal estradiol patches can be used effectively, easily allowing for increasing doses slowly over time. After several months of low-dose estrogen only, or if there is uterine bleeding, a progestogen can be added in phase to mimic natural cycles. The medication regimen should be individualized for each patient based on tolerance of the medication, side effects, and compliance (39).

Long-term use of estrogens and progestogens in women with Turner syndrome necessitates awareness of the increased risk of venous thromboembolism (VTE). In addition to the risk imposed by the medications, there are case reports suggesting a higher rate of VTE in individuals with Turner syndrome (39).

Mosaic Forms of Gonadal Dysgenesis

Individuals with rare mosaic forms of gonadal dysgenesis may develop normally at puberty. The decision to initiate therapy with exogenous estrogen should be based mainly on circulating FSH levels. Levels in the normal range for the patient's age imply

the presence of functional gonads.

Pure Gonadal Dysgenesis

The term *pure gonadal dysgenesis* refers to 46,XX or 46,XY phenotypic females who have streak gonads. This condition may occur sporadically or may be inherited as an autosomal recessive trait or as an X-linked trait in XY gonadal dysgenesis **(Fig. 8-10)**. Affected girls typically are of average height and have none of the stigmata of Turner syndrome, but they have elevated levels of FSH because the streak gonads produce neither steroid hormones nor inhibin. **When gonadal dysgenesis occurs in 46,XY individuals, it is sometimes termed *Swyer syndrome*. Surgical extirpation is warranted in individuals with a 46,XY karyotype to prevent development of germ cell neoplasms.** Both 46,XX and 46,XY forms of gonadal dysgenesis benefit from exogenous estrogen and are potential candidates for donor oocytes.

FIGURE 8-10 A: A 16-year-old individual with 46,XX gonadal dysgenesis and primary amenorrhea. Circulating follicle-stimulating hormone (FSH) levels were markedly elevated. The small amount of breast development (Tanner stage 2) is unusual, but some pubertal development may occur in such patients. **B: A 16-year-old individual with 46,XY gonadal dysgenesis who presented with primary amenorrhea and markedly elevated FSH levels.** Most affected individuals do not present with as much pubic and axillary hair development. The right gonad contained a dysgerminoma, but there was no evidence of metastases. **C:** Clitoromegaly noted in the girl with 46,XY gonadal dysgenesis depicted in Figure 8-10B. **D:** The same individual as depicted in Figure 8-10B with 46,XY gonadal dysgenesis 1 year after gonadectomy and replacement with exogenous estrogen. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. *Gynecology and Obstetrics: A Longitudinal Approach*. New York: Churchill Livingstone; 1993:97–133, with permission.)

In early gonadal failure, the ovaries apparently develop normally but contain no oocytes by the expected age of puberty. These disorders are considered further in the discussion delineating the evaluation of amenorrhea (see Chapter 34).

Hypogonadotropic Hypogonadism

Hypothalamic–pituitary disturbances are usually associated with low levels of circulating gonadotropins (with both LH and FSH levels less than or equal to 10 mIU/mL) (40). There are sporadic and familial causes of hypogonadotropic hypogonadism, and the differential diagnosis is extensive. **Mutations in several genes cause hypogonadotropic hypogonadism in humans** (41). This condition can arise from abnormalities in hypothalamic GnRH secretion, impaired release of gonadotropins from the pituitary gland, or both.

At least 17 different single-gene mutations are identified as being associated with delayed or absent puberty in humans (42). They are estimated to account for about 30% of individuals with disorders of puberty. These genes include *KAL1* (X-linked Kallmann syndrome), *FGFR1* (autosomal Kallmann syndrome), *DAX1* (the gene for X-linked congenital adrenal hypoplasia), *GNRHR* (the gene for the GnRH receptor), *PC1* (the gene for prohormone convertase 1), and *GPR54* (encoding a G-protein coupled receptor). Delayed puberty may result from mutations in genes affecting gonadotrophs specifically (*GNRHR, LH*b, *FSH*b) or in genes involved more generally in the development and functioning of the pituitary gland (*LHX3, PROP1, HESX1*).

Constitutional Delay

It is important to remember that low levels of LH and FSH are normally present in the prepubertal years; thus, girls with constitutionally delayed puberty may mistakenly be presumed to have hypogonadotropic hypogonadism. **Constitutional delay is the most common cause of delayed puberty.** In a normal population, 2% to 3% of normal children will be classified as having pubertal delay, and this finding may be considered a normal variant.

Kallmann Syndrome

Kallmann syndrome **consists of the triad of anosmia, hypogonadism, and color blindness in men** (43)**. Women may be affected, and other associated defects may include cleft lip and palate, cerebellar ataxia, nerve deafness, and abnormalities of thirst and vasopressin release.** The frequency approximates 1 in 10,000 men and 1 in 50,000 women. Sporadic cases are more common than inherited forms. Inheritance is described as being X-linked recessive, autosomal dominant, and autosomal recessive. Because autopsy studies show partial or complete agenesis of the olfactory bulb, the term *olfactogenital dysplasia* is used to describe the disorder. These anatomic findings coincide with embryologic studies documenting that GnRH neurons originally develop in the epithelium of the olfactory placode and normally migrate into the hypothalamus (44).

Clinically, affected individuals typically present with sexual infantilism and a eunuchoid habitus, but some degree of breast development may occur (Fig. 8-11). Primary amenorrhea is the rule. The ovaries are usually small, with follicles seldom developing beyond the primordial stage. Circulating gonadotropin levels are usually very low but almost invariably measurable. For women not seeking pregnancy, therapy with exogenous estrogen and progestin is indicated.

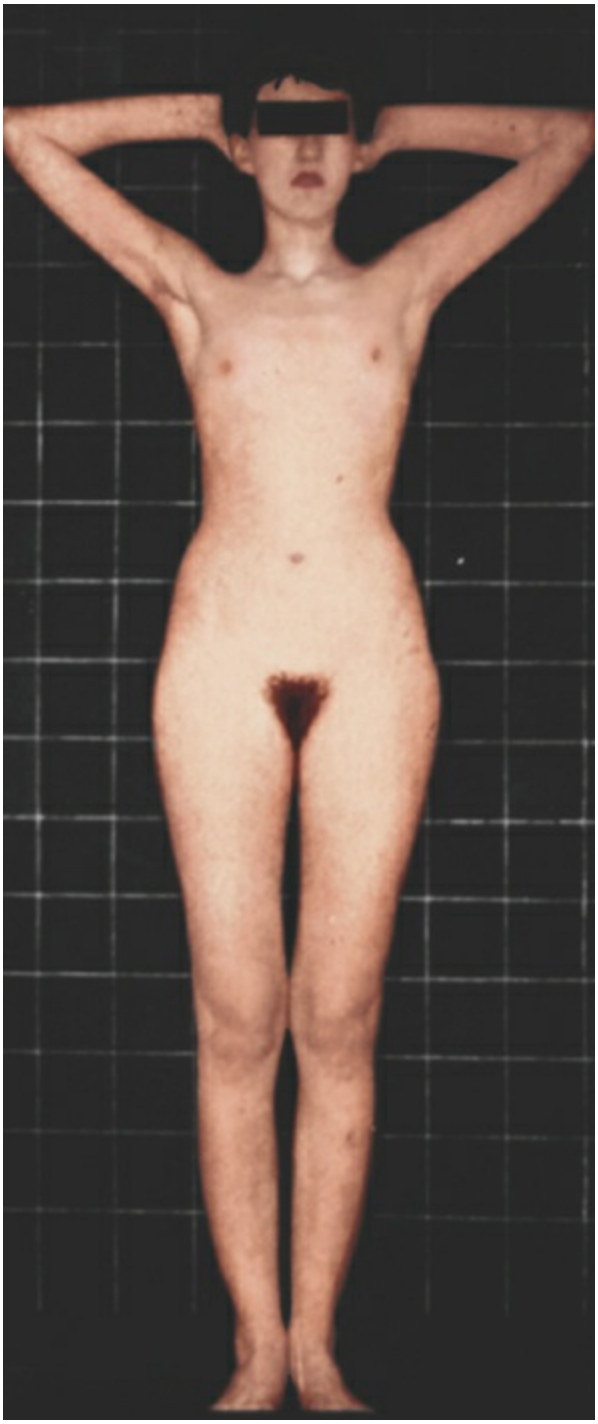

FIGURE 8-11 A 21½-year-old woman with Kallmann syndrome. Note that the patient has some pubic and axillary hair. Bone age was 16 years. It is rare to see affected individuals today who were not given oral contraceptive agents to induce menses (with some consequent breast development). (From **Wilkins L.** *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. 3rd ed. Springfield, IL: Charles C Thomas; 1965:284, with permission.)

Isolated gonadotropin deficiency can occur in association with the *Prader–Labhart–Willi syndrome,* which is characterized by obesity, short stature, hypogonadism, small hands and feet (acromicria), mental retardation, and infantile hypotonia. When the syndrome occurs in association with the Laurence–Moon–Bardet–

Biedl syndrome, retinitis pigmentosa, postaxial polydactyly, obesity, and hypogonadism may be present. Prader–Labhart–Willi syndrome apparently results from rearrangements of chromosome 15q11 to q13, an imprinted region of the human genome (45). Laurence–Moon–Bardet–Biedl syndrome, inherited in an autosomal recessive manner, is apparently heterogeneous, with at least four involved gene loci having been mapped (46).

Multiple pituitary hormone deficiencies, which are usually hypothalamic in origin, may be congenital and either part of an inherited constellation of findings or sporadic. If GH or thyroid-stimulating hormone (TSH) concentrations are subnormal, growth and pubertal development will be affected. Thus, the condition should be diagnosed before the age of puberty. Because individuals with hypopituitarism have a high mortality rate, predominantly caused by vascular and respiratory disease, it is important to identify affected individuals. Later age at diagnosis, female sex, and above all craniopharyngioma are identified as significant independent risk factors (47). Untreated gonadotropin deficiency is an important risk factor for early mortality.

Tumors of the Hypothalamus and Pituitary

Several different tumors of the hypothalamic and pituitary regions may lead to hypogonadotropic hypogonadism (Fig. 8-12A) (48). **Except for craniopharyngiomas, these tumors are relatively uncommon in children. A craniopharyngioma is a tumor of the Rathke pouch. It is the most common neoplasm associated with delayed puberty, and it accounts for 10% of all childhood central nervous system tumors. Craniopharyngiomas are usually suprasellar in location and may be asymptomatic well into the second decade of life.** Such tumors may present as headache, visual disturbances, short stature or growth failure, delayed puberty, or diabetes insipidus. Visual field defects (including bilateral temporal hemianopsia), optic atrophy, or papilledema may be seen on physical examination. Laboratory evaluation should document hypogonadotropism and may reveal hyperprolactinemia as a result of interruption of hypothalamic dopamine inhibition of prolactin release. Radiographically, the tumor may be either cystic or solid and may show areas of calcification. Appropriate therapy for hypothalamic–pituitary tumors may involve surgical excision or radiotherapy (with adequate pituitary hormone replacement therapy) and are best managed by a team of physicians that includes an endocrinologist, a neurosurgeon, and a radiotherapist.

FIGURE 8-12 A: A 16-year-old girl with delayed puberty. Breast budding began at 11 years of age, but there was no further development. During the year before presentation, her scholastic performance in school deteriorated, she gained 25 lb, she became increasingly lethargic, and nocturia and polydipsia were noted. Initial evaluation documented low follicle-stimulating hormone, elevated prolactin, and a bone age of 10.5 years. Computed tomography scanning documented a large hypothalamic neoplasm that proved to be an ectopic germinoma. The patient was also documented to be hypothyroid and hypoadrenal and to have diabetes insipidus. Despite the elevated prolactin, she had no galactorrhea because of the minimal breast development. **B: A16-year-old girl (frontal view) with primary amenorrhea who progressed in puberty until about 12 years of age.** Breast budding occurred at about 10 years of age. The patient's short stature is obvious. She proved to have hypopituitarism. Classic radiographic findings established the diagnosis of Langerhans cell–type histiocytosis (Hand–Schüller–Christian disease). **C: Side view of the girl shown in** Figure 8-12B. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. *Gynecology and Obstetrics: A Longitudinal Approach*. New York: Churchill Livingstone; 1993:97–133, with permission.)

Other Central Nervous System Disorders

Other central nervous system disorders that may lead to delayed puberty include infiltrative diseases, such as Langerhans cell–type histiocytosis, particularly the form known previously as ***Hand–Schüller–Christian disease*** **(Fig. 8-12B,C)**. Diabetes insipidus is the most common endocrinopathy (because of infiltration of the supraoptic nucleus in the hypothalamus), but short stature resulting from GH deficiency and delayed puberty caused by gonadotropin deficiency are not uncommon in this disorder (49).

Irradiation of the central nervous system for treatment of any neoplasm or leukemia may result in hypothalamic dysfunction. Although GH deficiency is the most frequent finding, partial or complete gonadotropin deficiency may develop in some patients.

Severe chronic illnesses, often accompanied by malnutrition, may lead to slowed growth in childhood and delayed adolescence. Regardless of the cause, weight loss to less than 80% to 85% of ideal body weight often results in hypothalamic GnRH deficiency. If adequate body weight and nutrition are maintained in chronic illnesses such as Crohn disease or chronic pulmonary or renal disease, sufficient gonadotropin secretion usually is present to initiate and maintain pubertal development.

Human Immunodeficiency Virus Infection

Most of the information gathered regarding pubertal development and the presence of HIV are from females who have congenital HIV. Delays in development coincide with treatment status and CD4 count (50).

Anorexia Nervosa and Bulimia

Significant weight loss and endocrine and psychological dysfunction occur simultaneously in anorexia nervosa (51). Although many anorectic girls experience amenorrhea after pubertal development begins, if the disorder begins sufficiently early, pubertal development may be delayed or interrupted **(Fig. 8-13)**. **The following constellation of associated findings confirms anorexia nervosa in most individuals:**

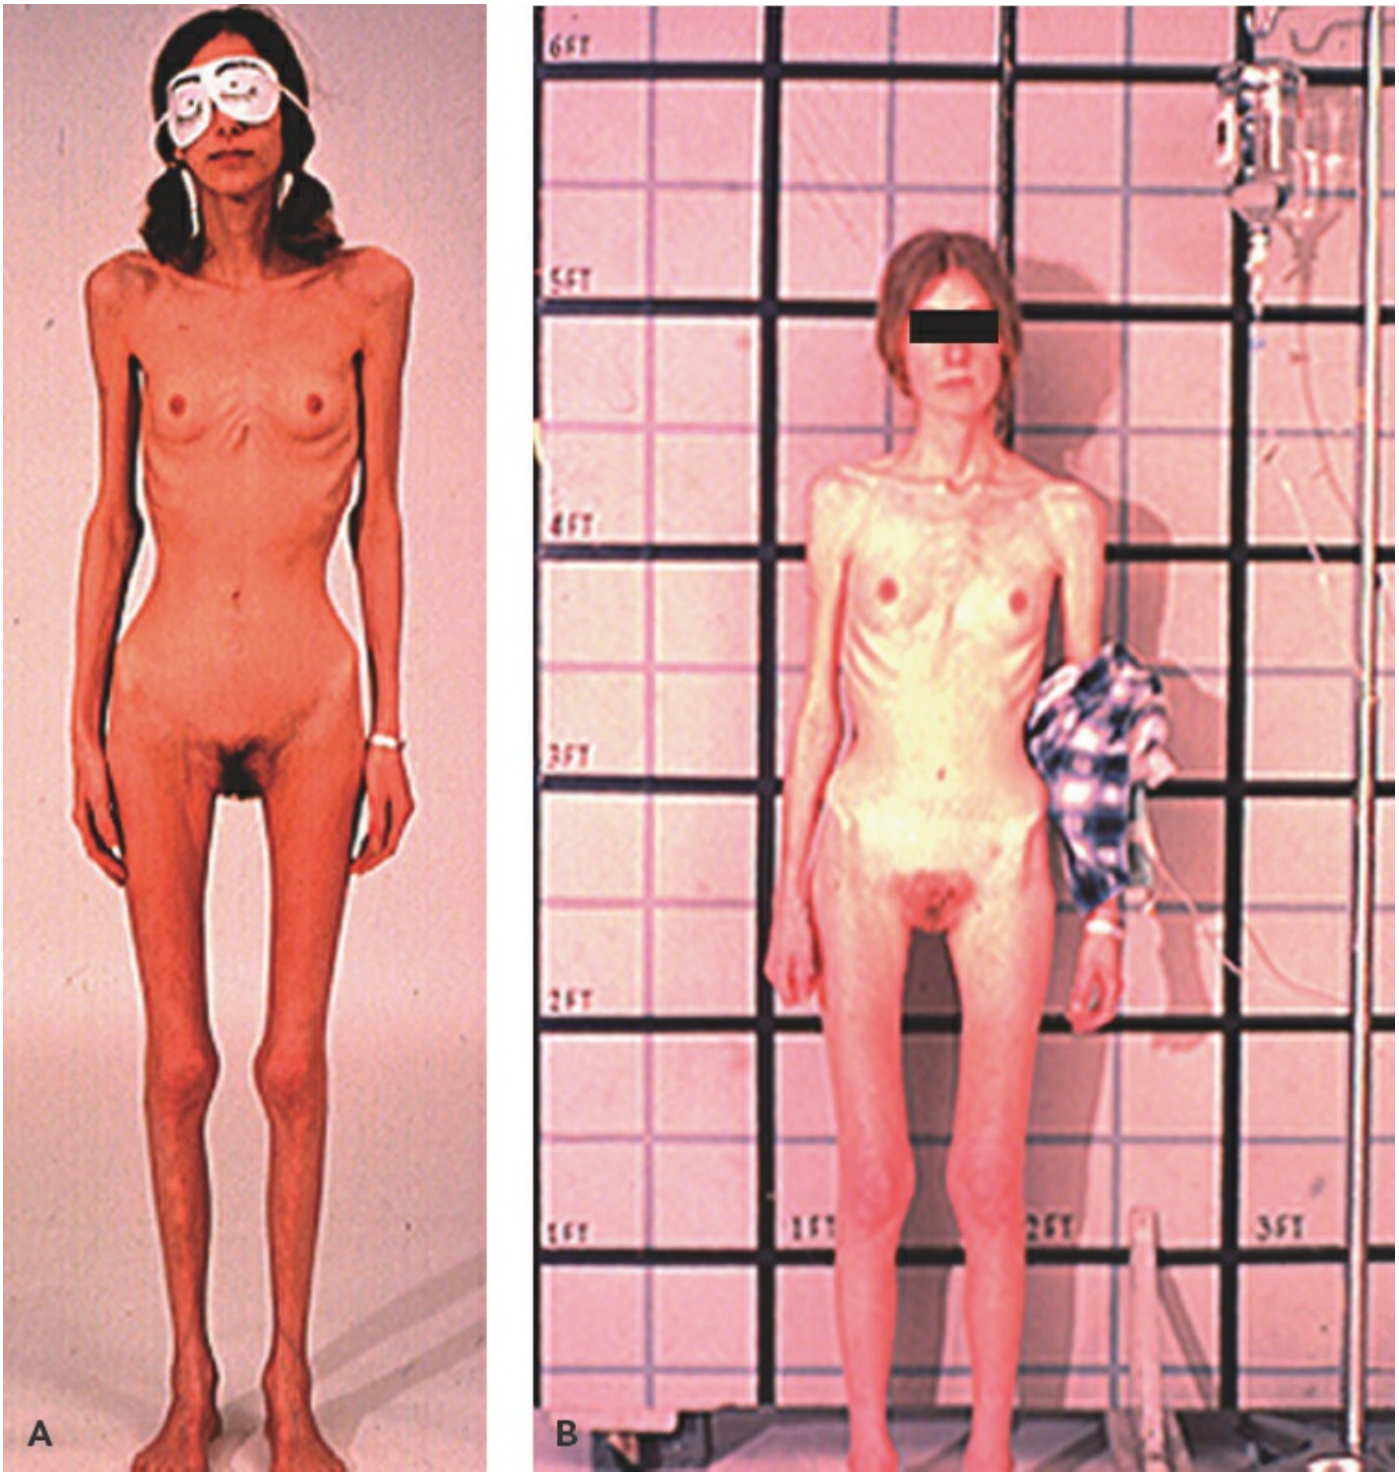

FIGURE 8-13 **A:** A 20-year-old college woman with anorexia nervosa. **B:** A 16-year-old student with anorexia nervosa. In both cases, as is true of most such patients, pubertal development had been completed and menses initiated before anorexia led to marked weight loss.

1. **Relentless pursuit of thinness**
2. **Amenorrhea, sometimes preceding the weight loss**
3. **Extreme inanition**
4. **Obsessive–compulsive personality often characterized by overachievement**

5. **Distorted and bizarre attitude toward eating, food, or weight**
6. **Distorted body image**

Because normal body weight is commonly maintained in bulimia, it is unusual for bulimic patients to experience either delayed development or amenorrhea. Girls with anorexia nervosa may have, in addition to hypogonadotropic hypogonadism, partial diabetes insipidus, abnormal temperature regulation, hypotension, chemical hypothyroidism with low serum triiodothyronine (T_3) and high reverse T_3 levels, and elevated circulating cortisol levels in the absence of evidence of hypercortisolism (51,52). Other common features include hypokalemia, anemia, hypoalbuminemia, high β-carotene levels, and high cholesterol levels. All features of anorexia nervosa are reversible with weight gain, except for amenorrhea (which persists in 30% to 47%) and osteopenia (i.e., it now seems that any bone lost cannot be fully recovered). **Management of patients with anorexia nervosa is notoriously difficult. A team approach involving the primary clinician, psychiatrist, and nutritionist is most effective. In fact, anorexia nervosa has the highest mortality of any psychiatric disorder. Deaths are often sudden and unexpected. Cause of death (often unknown) can include hypoglycemia and electrolyte imbalance.**

Fear of obesity, a syndrome of self-induced malnutrition common among teenage gymnasts and ballet dancers, may slow growth and delay pubertal development (53). These children voluntarily reduce their caloric intake as much as 40%, leading to nutritional growth retardation. An additive role of the energy drain associated with endurance training in the delayed development is possible, but the mechanisms are unclear at this point. These conditions are essentially severe forms of hypothalamic amenorrhea. Inevitably delayed puberty will occur unless adequate caloric intake is provided.

Hyperprolactinemia

Low levels of LH and FSH may be associated with hyperprolactinemia. Galactorrhea cannot occur in the absence of complete breast development. Pituitary prolactinomas are rare during adolescence but must be considered when certain signs and symptoms are present. **Many individuals with prolactinomas have a history of delayed menarche.** The association between the ingestion of certain drugs (most often psychotropic agents and opiates in this age group) is well established. Primary hypothyroidism is associated with hyperprolactinemia because increased levels of thyrotropin-releasing hormone (TRH) stimulate secretion of prolactin. The ***empty sella syndrome***, in which the sella turcica is enlarged but is replaced by cerebrospinal fluid, may be associated with hyperprolactinemia.

Use of Chemotherapeutic Agents

As survival rates following treatment for childhood malignancy improve, the effects of cancer therapy become more important. Radiation therapy to the abdomen and systemic chemotherapeutic agents, particularly alkylating agents, have toxic effects on germ cells. Although prepubertal gonads appear less vulnerable than those of adults, ovarian failure is common. An argument can be made for endocrine assessment as early as 1 year following completion of therapy to identify children who will suffer from hypogonadism. Spontaneous ovarian activity can resume even years after therapy. Counseling regarding preservation of oocytes or ovarian tissue for young women with malignancies prior to treatment is now warranted because of the possibility of future pregnancies with in vitro fertilization using frozen samples.

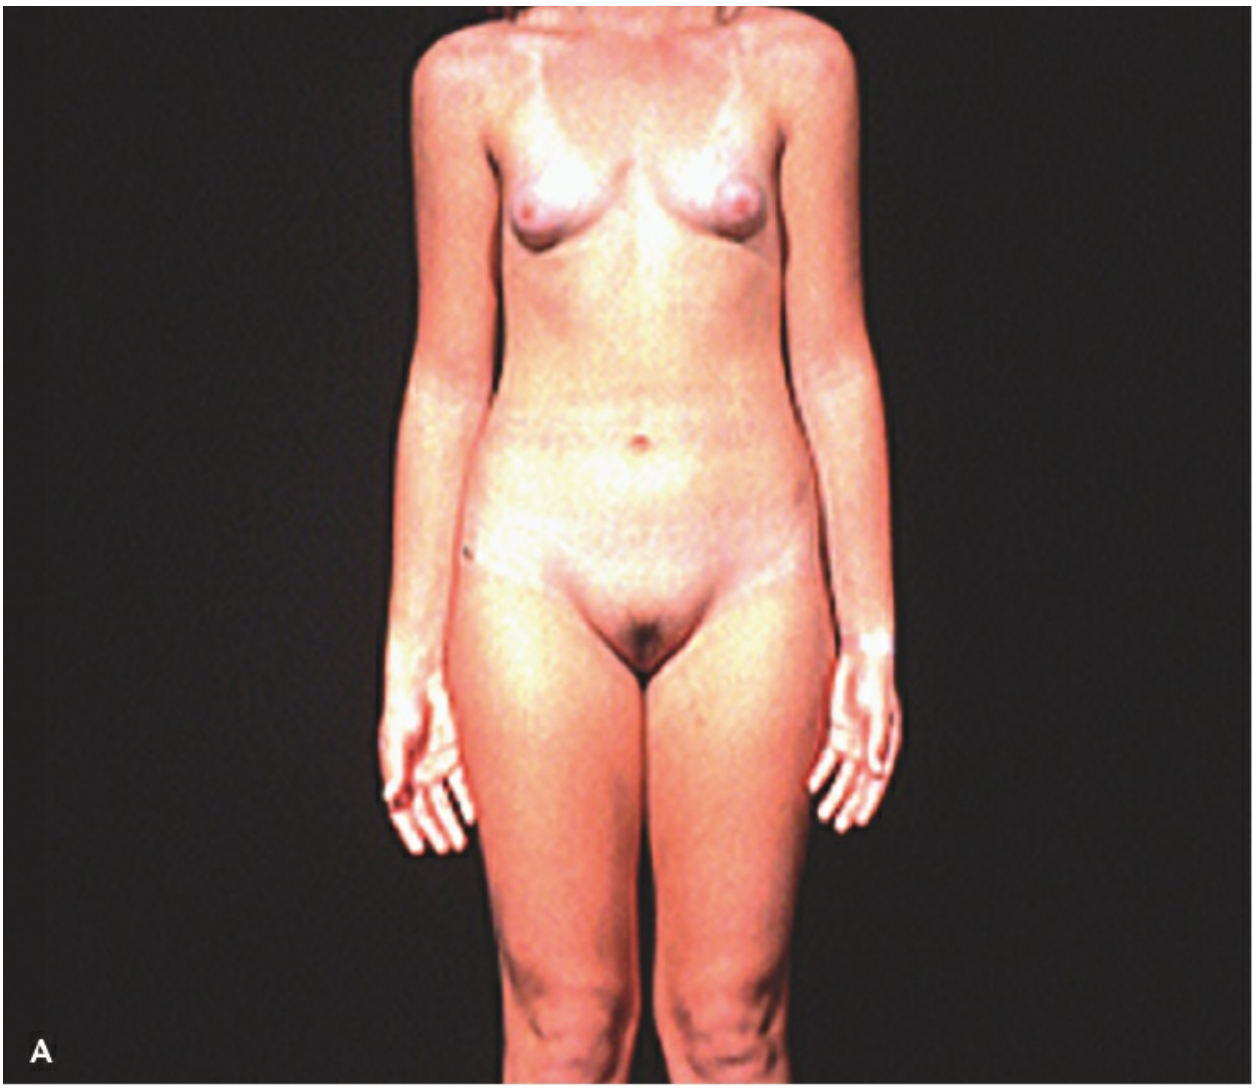
Asynchronous Puberty

[4] Asynchronous pubertal development is characteristic of androgen insensitivity (i.e., testicular feminization). Affected individuals typically present with breast development (usually only to Tanner stage 3) out of proportion with the amount of pubic and axillary hair present **(Fig. 8-14)**. In this disorder, 46,XY individuals have bilateral testes, female external genitalia, a blind-ending vagina (often foreshortened and sometimes absent), and no müllerian derivatives (i.e., uterus and fallopian tubes) (54). Infrequently, patients may have clitoral enlargement and labioscrotal fusion at puberty, which is referred to as *incomplete androgen insensitivity*.

Asynchronous puberty is heterogeneous but is always related to some abnormality of the androgen receptor or of androgen action (54). In perhaps 60% to 70% of cases, androgen receptors cannot be detected (i.e., the patient is receptor negative). In the remaining cases, androgen receptors are present (i.e., receptor positive), but mutations in the androgen receptor are detected or there is a defect at a more distal step in androgen action (i.e., a postreceptor defect). Receptor-positive individuals are indistinguishable clinically from receptor-negative individuals. Several different mutations in the androgen-receptor gene, most of which occur within the androgen-binding domain of the receptor, are identified in affected individuals who are receptor positive. Severe X-linked androgen-receptor gene mutations cause complete androgen insensitivity, whereas mild mutations impair virilization with or without infertility, and moderate mutations result in a wide phenotypic spectrum of expression among siblings (54).

Because the Sertoli cells of the testes make antimüllerian hormone (AMH), müllerian derivatives are absent in this disorder; thus, müllerian regression occurs normally. The testes are often normal in size and may be located anywhere along the path of embryonic testicular descent—in the abdomen, inguinal canal, or labia. Half of all individuals with androgen insensitivity develop inguinal hernias. It is important to determine the karyotype in prepubertal girls with inguinal hernias, especially if a uterus

cannot be detected with certainty by ultrasound, because a small percentage will have androgen insensitivity.



The risk of germ cell malignancy is 2% in complete androgen insensitivity syndrome (54). Most clinicians believe the risk for gonadal neoplasia is low before 25 years of age; thus, the **testes should be left in place until after pubertal feminization, especially because the risk of neoplasia appears to increase with age.** Exogenous estrogen should be provided after gonadectomy.

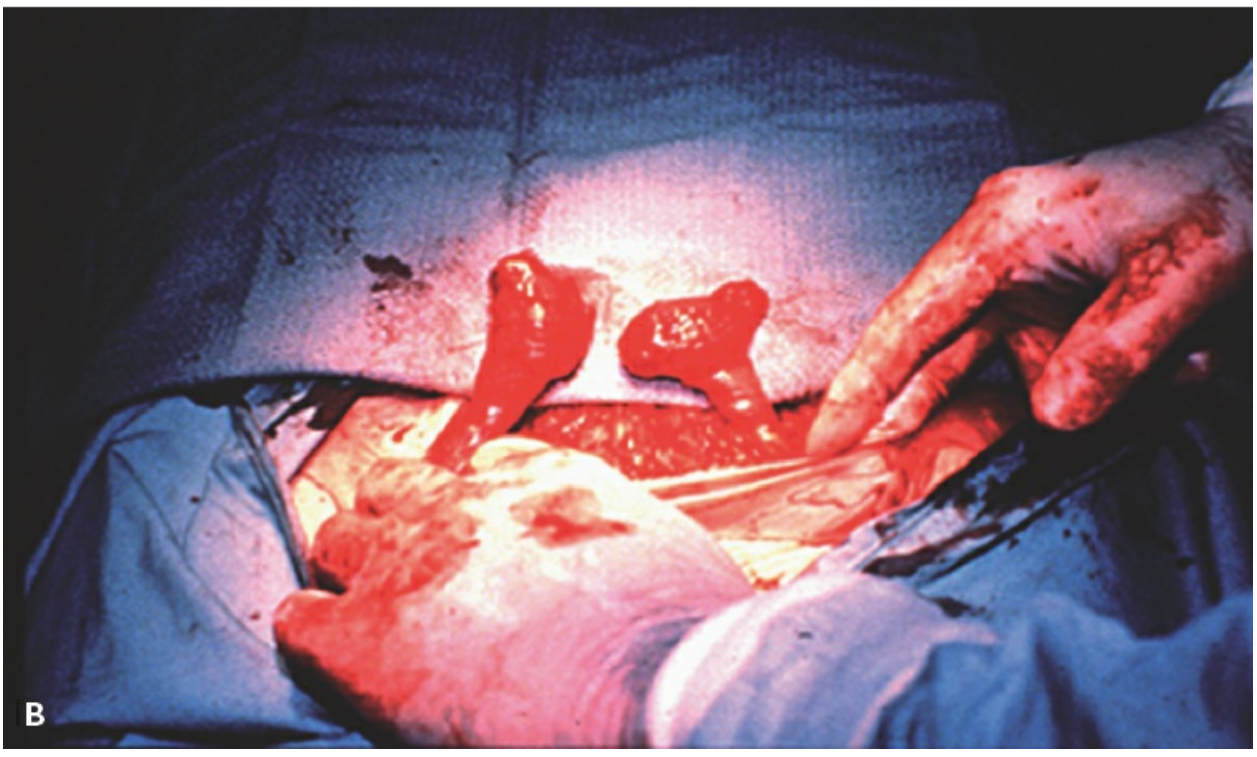
The diagnosis is often suspected by the typical physical findings and strongly suggested by normal (or even somewhat elevated) male levels of testosterone, normal or somewhat elevated levels of LH, and normal levels of FSH. The diagnosis is confirmed by a 46,XY karyotype.

Interacting with the patient and family requires sensitivity and care. It may be inadvisable to begin by informing the patient of the karyotype; the psychological implications may be devastating because the patient was reared as a girl. Family members should be informed initially that müllerian aplasia occurred and that the risk for neoplasia mandates gonadectomy after puberty. Because the disorder can be inherited in an X-linked recessive fashion, families should undergo appropriate genetic counseling and screening to identify the possible existence of other affected family members.

Precocious Puberty

[5] Although precocious pubertal development may be classified in several ways, it is perhaps simplest to think of the development as gonadotropin dependent (in which case it is almost invariably of central origin) or gonadotropin independent (of peripheral origin). Precocious puberty is 20 times more common in girls than in boys. In 90% of girls, the precocious development is idiopathic, whereas this appears to be true for only 10% of boys. Family history, the rapidity with which secondary sexual characteristics are developing, the rate of growth, and the presence or absence of central nervous system disease should all be considered in deciding whether to pursue evaluation of a girl for precocious puberty. The evaluation of precocious puberty is as follows **(Fig. 8-15)**:

A



B

FIGURE 8-14 **A:** This 17-year-old individual presented with primary amenorrhea and was found to have a blind-ending vagina and bilateral inguinal masses. Circulating levels of testosterone were at the upper limits of the normal range for men and the karyotype was 46,XY, confirming androgen insensitivity. **B:** Two inguinal testes were found at surgery. (From **Simpson JL, Rebar RW.** Normal and abnormal sexual differentiation and development. In: Becker KL, ed. *Principles and Practice of Endocrinology and Metabolism*. 2nd ed. Philadelphia, PA: JB Lippincott; 1995:788–822, with permission.)

1. Obtain a complete medical, birth, and family history, including details of timing and events of the pubertal development.
2. Specifically determine if there are any signs or symptoms of neurologic disease.
3. Determine the extent of development by examination and assignment of Tanner stage.
4. Carefully determine if signs of other conditions that may be associated with precocious puberty (abdominal mass, skin lesions, etc.) are present.
5. **Determine bone age.**
6. **Initial hormonal evaluation should include measurement of basal gonadotropin levels and assessment of thyroid function.**
7. **Pelvic imaging and imaging of the central nervous system are warranted depending on other findings.**

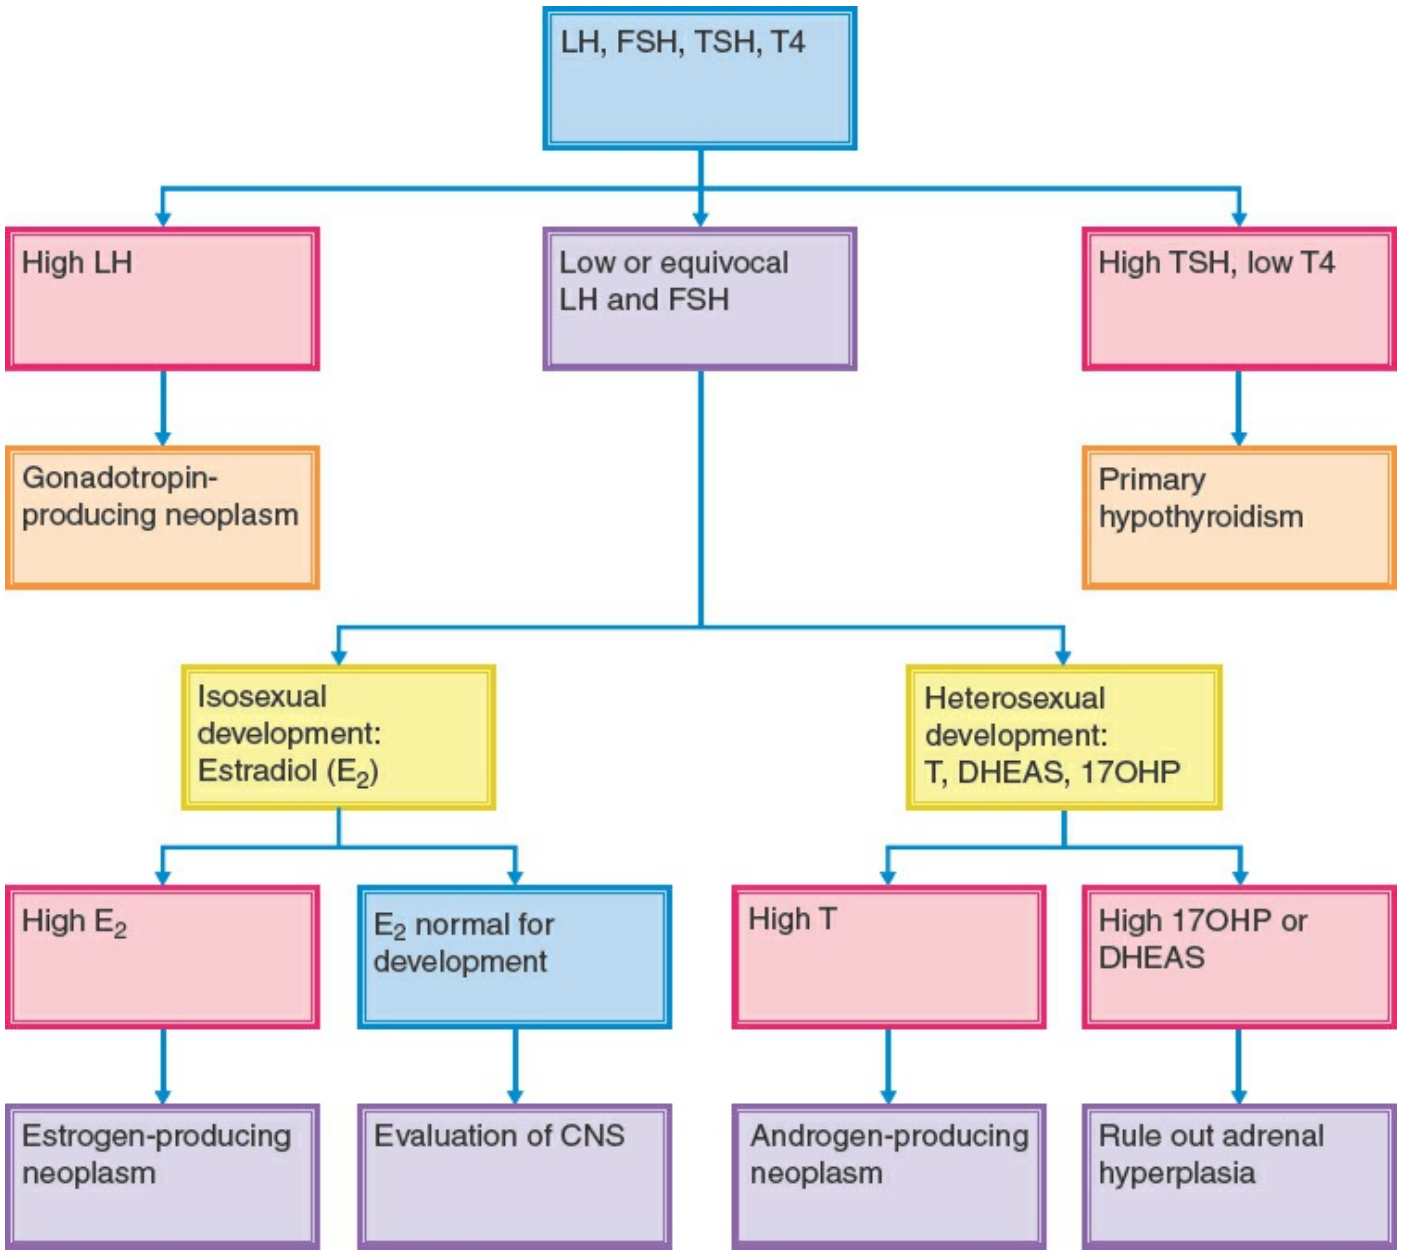


FIGURE 8-15 Flow diagram for the evaluation of precocious puberty in phenotypic females. LH, luteinizing hormone; FSH, follicle-stimulating hormone; TSH, thyroid-stimulating hormone; T4, thyroxine; T, testosterone; DHEAS, dehydroepiandrosterone sulfate; 17OHP, 17-hydroxyprogesterone; CNS, central nervous system. (From **Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. *Gynecology and Obstetrics: A Longitudinal Approach*. New York: Churchill Livingstone; 1993:97–133, with permission.)

The goal of testing is to determine if the diagnosis of precocious puberty is correct, if the etiology is central or peripheral, and to direct treatment if needed (23).

Perhaps the most difficult decision for the gynecologist is determining how much evaluation is warranted for the young girl brought in by her mother for precocious breast budding only (*precocious thelarche*) or the appearance of pubic or axillary hair alone (*precocious pubarche* or *adrenarche*) (Fig. 8-16). In such cases, it is acceptable to many clinicians to follow the patient at frequent intervals and proceed

with evaluation if there is evidence of pubertal progression. The feasibility of this approach may depend on the concerns of the parents.

Premature Thelarche

Premature thelarche is uni- or bilateral breast enlargement without other signs of sexual maturation. There is no significant nipple or areolar development. It usually occurs by 2 years of age and rarely after age 4. It may be caused by increased sensitivity of the breasts to low levels of estrogen or to increased estradiol secretion by follicular cysts. It is a benign self-limited disorder and thus only reassurance and follow-up are required. In many cases, onset of puberty, adult height, and adult reproductive function are normal. Rarely, premature thelarche can be a harbinger of progressive gonadarche. It has been suggested that measurement of uterine volume (anteroposterior diameter × longitudinal diameter × transverse diameter × 0.523) may be the most sensitive and specific discriminator between premature thelarche and early true precocious puberty (55). If needed, breast ultrasound can help distinguish unilateral premature thelarche from fibroadenomas, cysts, neurofibromas, or other lesions.

Premature Adrenarche

Premature adrenarche or pubarche may be caused by increased sensitivity to low levels of androgens and must be distinguished from late-onset (nonclassic) CAH. If there is no evidence of breast development or of progression, these conditions are virtually always benign.

Girls with premature adrenarche are at increased risk of developing polycystic ovary syndrome (PCOS), hyperinsulinemia, acanthosis nigricans, and dyslipidemia in adolescence and adult life, especially if fetal growth was reduced and birth weight was low (56). Although mean androgen levels are within the normal range, a significant minority have an exaggerated response to corticotropin stimulation. The magnitude of this response is inversely related to insulin sensitivity. Thus, premature adrenarche may be the first sign of insulin resistance or PCOS in some individuals. Treatment of coexisting obesity and long-term follow-up are indicated to address potential complications of PCOS and insulin resistance.

A

B

FIGURE 8-16 A 5-year-old girl with development of pubic hair (**A**) as shown more closely in **B** (precocious adrenarche). Gonadotropin levels were prepubertal, and bone age was appropriate for age. No further development occurred until breast budding at approximately age 9.

Isolated Premature Menarche

Isolated premature menarche is vaginal bleeding at age 1 to 9 years in the absence of other signs of puberty. The bleeding is usually limited to a few days. It can recur for 1 to 6 years and then cease. The etiology is uncertain. Most cases are associated with subsequent normal pubertal development and fertility. The differential diagnosis includes vaginal foreign bodies, trauma, sexual abuse, vaginal infection, or neoplasms such as rhabdomyosarcoma, McCune–Albright syndrome (in which menarche may occur before other manifestations of sexual precocity), and primary hypothyroidism. Ingestion of a large dose of estrogens (such as may be found in several oral contraceptive agents) may also lead to vaginal bleeding.

Central (True) Precocious Puberty

In central precocious puberty, GnRH prematurely stimulates increased gonadotropin secretion. Central precocious puberty may occur in children in whom there is no structural abnormality, in which case it is termed *constitutional* or *idiopathic*. **Constitutional (idiopathic) sexual precocity is the most common cause of precocious puberty.** It is often familial and represents the so-called tail of the Gaussian curve (i.e., the early 2.5% for the age distribution for the onset of puberty). In many of these girls, puberty is slowly progressive, but in a few, development progresses rapidly. The major complication of sexual precocity is limitation of height. Thus, therapy may be warranted to prevent this consequence.

Alternatively, central precocious puberty may result from a tumor, infection, congenital abnormality, or traumatic injury affecting the hypothalamus. A number of congenital malformations, including hydrocephalus, craniostenosis, arachnoid cysts, and septo-optic dysplasia, can be associated with precocious puberty (and with sexual infantilism).

A common etiology (2% to 28%) of central precocious puberty is a hypothalamic hamartoma. It is a congenital malformation composed of a heterotopic mass of nerve tissue containing GnRH neurosecretory neurons, fiber bundles, and glial cells. It is not a true neoplasm and it generally does not change over time based on long-term follow-up studies with periodic CT or MRI scans. Hamartomas appear as isodense, abnormal fullnesses that do not enhance with contrast material. Extreme precocity (usually before 3 years of age) and the absence of tumor markers, such as β-human chorionic gonadotropin and α-fetoprotein, suggest a hamartoma (24). Hamartomas can be associated with laughing (gelastic) seizures, behavioral disturbances, mental retardation, and dysmorphic syndromes. It appears that hamartomas produce GnRH in a

pulsatile manner and thus stimulate gonadotropin secretion **(Fig. 8-17)**. Central precocious pubertal development can be controlled with GnRH-agonist therapy (24).

The efficacy of gonadotropin-releasing hormone analogs (GnRHa) in increasing adult height is undisputed only in early-onset (girls less than 6 years old) central precocious puberty (57). Concerns of weight gain and long-term decrease in bone mineral density with the use of GnRHa do not seem to be warranted. The most important clinical criterion for initiating GnRHa treatment is documented progression of pubertal development over a 3- to 6-month period. This observational period may not be necessary if the child is at or past Tanner stage 3, particularly with advanced skeletal maturation. It appears that discontinuation of GnRHa at a chronologic age of about 11 years and a bone age of about 12 years is associated with maximum adult height (57–60). There are a variety of GnRHa formulations, and the choice of a particular agent depends on patient and physician preference.

FIGURE 8-17 A $7^{1}/_{2}$-year-old girl with Tanner stage 4 pubertal development who began menstruating 1 month earlier. She was 57 in tall (above the 95th percentile). Luteinizing hormone and follicle-stimulating hormone levels were consistent with her development. A large neoplasm that proved to be a hypothalamic hamartoma was present on computed tomography scan. Pubertal development began at about 5 years of age.

Precocious Puberty of Peripheral Origin

In gonadotropin-independent precocious puberty, production of estrogens or

androgens from the ovaries, adrenals, or rare steroid-secreting neoplasms leads to early pubertal development. Small functional ovarian cysts, typically asymptomatic, are common in children and may cause transient sexual precocity (61). **Simple cysts (with a benign ultrasonographic appearance) can be observed and usually resolve over time.** Of the various ovarian neoplasms that can secrete estrogens, granulosa–theca cell tumors occur most frequently but are still rare (24). Although such tumors may grow rapidly, more than two-thirds are benign.

Exposure to exogenous estrogens can mimic gonadotropin-independent precocious puberty. Ingestion of oral contraceptives, other estrogen-containing pharmaceutical agents, and estrogen-contaminated foods and the topical use of estrogens have been implicated in cases of precocious development in infants and children. Ingestion of exogenous steroids over a considerable length of time is required to induce changes typical of complete precocious development.

McCune–Albright Syndrome

The *McCune–Albright syndrome* is characterized by the classic triad of polyostotic fibrous dysplasia of bone, irregular café au lait spots on the skin, and GnRH-independent sexual precocity. The café au lait spots are usually large, do not cross the midline, and have irregular "coast of Maine" margins. They are often located on the same side as the bony lesions. Sexual precocity often begins in the first 2 years and usually presents with menstrual bleeding. Girls develop sexual precocity as a result of functioning ovarian cysts. Serum estradiol is elevated. Other endocrinopathies may be present and include hyperthyroidism, hypercortisolism, hyperprolactinemia, acromegaly, and hyperparathyroidism. Osteomalacia, hepatic abnormalities, and cardiac arrhythmias may occur. Mutations of the G_sa subunit of the G protein, which couple extracellular hormonal signals to the activation of adenylate cyclase, are responsible for the autonomous hyperfunction of the endocrine glands and presumably for other defects present in this disorder (62). Treatment with a GnRH agonist is not effective because the precocious pubertal development is GnRH independent (63). A multicenter trial showed that *tamoxifen* decreases vaginal bleeding, growth rate, and the rate of bone age advancement (64).

Primary Hypothyroidism

Longstanding primary hypothyroidism is associated with sexual precocity. It can present with premature breast development or isolated vaginal bleeding. If serum prolactin is elevated, galactorrhea may be present. On pelvic ultrasound, solitary or multiple ovarian cysts may be found. Primary hypothyroidism is the only cause of precocious puberty that is associated with a delayed bone age. These features return to normal within a few months of initiation of *levothyroxine* therapy.

Congenital Adrenal Hyperplasia

***Heterosexual precocious puberty* is always of peripheral origin and is most often caused by CAH.** In most untreated or poorly treated adolescent girls and in some adolescent boys, spontaneous true isosexual pubertal development does not occur until proper treatment is instituted. In most patients treated satisfactorily from early life, the onset of puberty occurs at the expected chronologic age. Three adrenal enzyme defects —21-hydroxylase deficiency, 11β-hydroxylase deficiency, and 3β-hydroxysteroid dehydrogenase (3β-HSD) deficiency—can lead to heterosexual precocity and to virilization of the external genitalia because of increased androgen production beginning in utero (65). The clinical presentation of the various forms of CAH depends on the following factors: (i) the affected enzyme, (ii) the extent of residual enzymatic activity, and (iii) the physiologic consequences of deficiencies in the end products and excesses of precursor steroids.

21-Hydroxylase Deficiency

Most patients with classic CAH have 21-hydroxylase deficiency (Fig. 8-18). All forms of 21-hydroxylase deficiency are caused by homozygous or compound heterozygous mutations in the human *CYP21A2* gene, which encodes the 21-hydroxylase enzyme; in the carrier, heterozygote state, only one allele is mutated. Two *CYP21A2* genes, a *CYP21A2B* gene encoding the functional enzyme and a pseudogene termed *CYP21A2A,* are situated very close to each other within the major histocompatibility locus on the short arm of chromosome 6. At least one-fourth of cases of 21-hydroxylase deficiency result from unequal crossover and genetic recombination between the two genes during meiosis. Severe mutations do not correlate with severe phenotype, and phenotypic variability likely depends on the activity of other interacting genes (66).

FIGURE 8-18 **A:** A $10^{1}/_{2}$-year-old girl with 21-hydroxylase deficiency before treatment. 17-Ketosteroid (KS) excretion was 34 mg per day. **B:** The same patient after 9 months of therapy with cortisone (17-KS excretion: 4.6 mg per day). (From **Wilkins L.** *The Diagnosis and Treatment of Endocrine Disorders in Childhood and Adolescence*. 3rd ed. Springfield, IL: Charles C Thomas; 1965:439, with permission.)

Neonatal screening suggests an incidence of about 1 in 15,000 births. Because of the location of the gene within the major histocompatibility locus, siblings with 21-hydroxylase deficiency usually have identical human leukocyte antigen (HLA) types.

There are various forms of 21-hydroxylase deficiency, including simple virilizing (typically identified at birth because of genital ambiguity), salt-wasting (in which there is impairment of mineralocorticoid and glucocorticoid secretion), and late-onset or nonclassic (in which heterosexual development occurs at the expected age of puberty). The so-called classic form includes the simple virilizing and salt-wasting forms. The nonclassic form is discussed in the following section on heterosexual pubertal development.

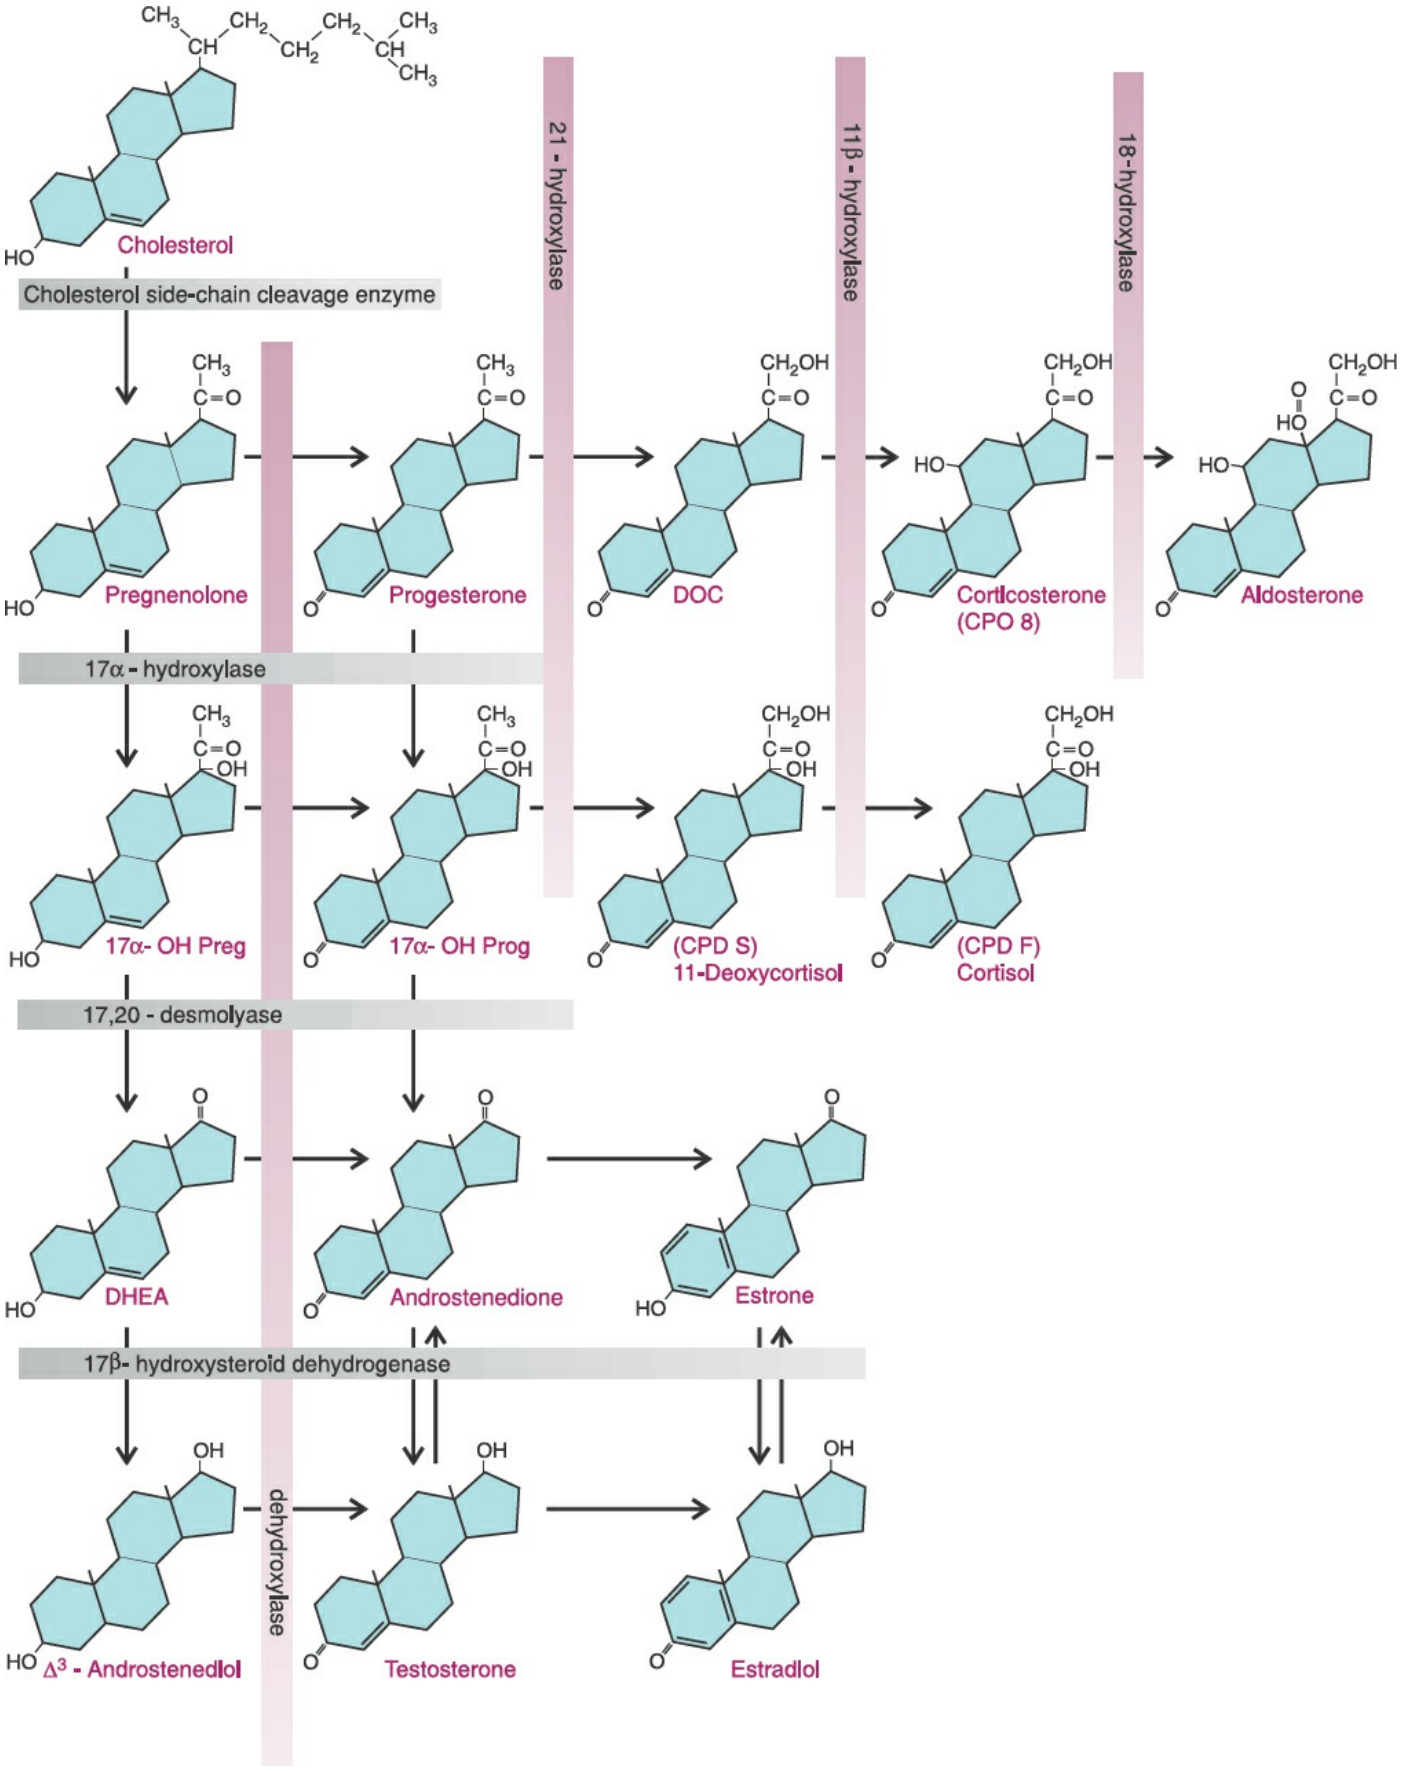

FIGURE 8-19 Gonadal and adrenal steroid pathways and the enzymes required for steroid conversion.

DOC, deoxycorticosterone; 17α-OH Preg, 17α-hydroxypregnenolone; 17α-OH Prog, 17α-hydroxyprogesterone; DHEA, dehydroepiandrosterone sulfate. (From **Rebar RW, Kenigsberg D, Hodgen GD.** The normal menstrual cycle and the control of ovulation. In: Becker KL, ed. *Principles and Practice of Endocrinology and Metabolism*. 2nd ed. Philadelphia, PA: JB Lippincott; 1995:868–880, with permission.)

Deficiency of 21-hydroxylase results in the impairment of the conversion of 17α-hydroxyprogesterone to 11-deoxycortisol and of progesterone to deoxycorticosterone (Fig. 8-19). As a consequence, precursors accumulate, and there is increased conversion to adrenal androgens. Because the development of the external genitalia is controlled by androgens, in the classic form of this disorder, girls are born with ambiguous genitalia, including an enlarged clitoris and fusion of the labioscrotal folds and the urogenital sinus (Fig. 8-20). The internal female organs (including the uterus, fallopian tubes, and ovaries) develop normally because they are not affected by the increased androgen levels. In three-quarters of cases with classic 21-hydroxylase deficiency, salt-wasting occurs, as defined by hyponatremia, hyperkalemia, and hypotension. It is important to recognize that the extent of virilization may be the same in simple virilizing and salt-wasting CAH. Thus, **even a mildly virilized newborn with 21-hydroxylase deficiency should be observed closely for signs of a potentially life-threatening crisis within the first hours, days, and weeks of life.** During childhood, untreated girls with the classic form grow rapidly but have advanced bone ages, enter puberty early, experience early closure of their epiphyses, and ultimately are short in stature as adults. CAH, with appropriate therapy, is the only inherited disorder of sexual differentiation in which normal pregnancy and childbearing are possible. **The classic forms of 21-hydroxylase deficiency are easily diagnosed based on the presence of genital ambiguity and markedly elevated levels of 17α-hydroxyprogesterone.** Some states in the United States have neonatal screening programs to detect 21-hydroxylase deficiency at birth.

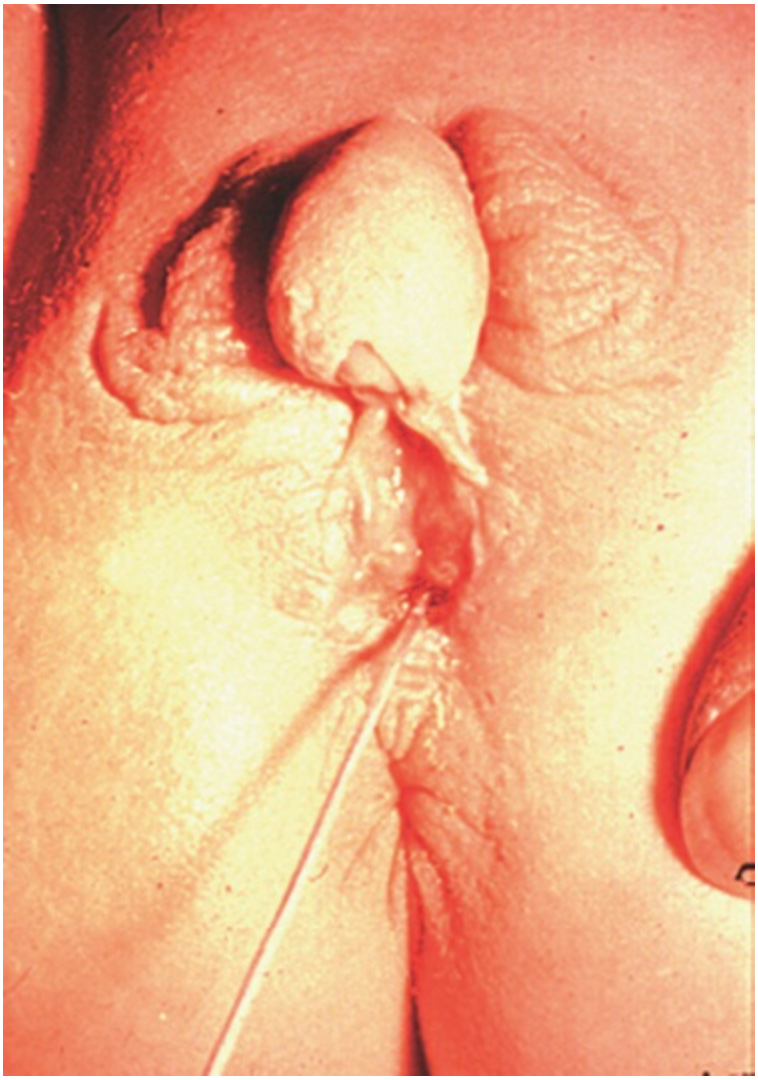

FIGURE 8-20 Newborn girl with 46,XX karyotype and genital ambiguity. There is obvious clitoral hypertrophy, paired frenula, so-called scrotalization of the labia, and a common urogenital sinus (shown by the probe). She had 21-hydroxylase deficiency. (**Rebar RW.** Normal and abnormal sexual differentiation and pubertal development. In: Moore TR, Reiter RC, Rebar RW, et al., eds. *Gynecology and Obstetrics: A Longitudinal Approach.* New York: Churchill Livingstone; 1993:97–133, with permission.)

3b-Hydroxysteroid Dehydrogenase

Deficiency of 3β-HSD, caused by mutations in the *HSD3B2* gene that encodes the 3β-HSDII enzyme, affects the synthesis of glucocorticoids, mineralocorticoids, and sex steroids. Typically, levels of 17-hydroxypregnenolone and DHEA are elevated (Fig. 8-19). The classic form of the disorder, detectable at birth, is quite rare, and affected girls may be only slightly masculinized. In severe cases, salt wasting may be present.

A nonclassic form of this disorder may be associated with heterosexual precocious pubertal development (as is the classic form if untreated), but postpubertal hyperandrogenism occurs more often. The androgen excess in individuals with nonclassic 3β-HSD deficiency appears to result from androgens derived from the peripheral conversion of increased serum concentrations of DHEA.

This disorder is inherited in autosomal recessive fashion, with allelism at the *3*b-*HSD* gene on chromosome 1 believed to be responsible for the varying degrees of enzyme deficiency.

11-Hydroxylase Deficiency

The classic form of 11-hydroxylase deficiency is believed to constitute 5% to 8% of all cases of CAH. Deficiency in 11-hydroxylase, caused by mutations in the *CYP11B1* gene, results in the inability to convert 11-deoxycortisol to cortisol and the consequent accumulation of androgen precursors **(Fig. 8-19)**. Markedly elevated levels of 11-deoxycortisol and deoxycorticosterone are present in the disorder. Because deoxycorticosterone acts as a mineralocorticoid, many individuals with this disorder become hypertensive. A mild nonclassic form of 11-hydroxylase deficiency was reported but apparently is very uncommon (65).

Treatment of Congenital Adrenal Hyperplasia

The treatment of CAH involves providing replacement doses of the deficient steroid hormones. *Hydrocortisone* (10 to 20 mg/m^2 body surface area) or its equivalent is given daily in divided doses to suppress the elevated levels of pituitary corticotropin present and thus suppress the elevated androgen levels. With such treatment, signs of androgen excess should regress. In children, growth velocity, bone age, and hormone levels should be monitored carefully because both overreplacement and underreplacement can result in premature closure of the epiphyses and short stature. Data now indicate that early diagnosis and compliance with therapy lead to adult height within 1 standard deviation of the anticipated target height in girls with 21-hydroxylase deficiency (67).

Mineralocorticoid replacement is generally required in individuals with 21-hydroxylase deficiency whether or not they are salt losing. The intent of glucocorticoid therapy should be to suppress morning 17α-hydroxyprogesterone levels to between 300 and 900 ng/dL. Sufficient *fludrocortisone* should be given daily to suppress plasma renin activity to less than 5 mg/mL per hour.

It is possible to diagnose 21-hydroxylase deficiency prenatally in women known to be at risk of delivering an affected infant (65). The diagnosis is established by documenting elevated levels of 17α-hydroxyprogesterone or 21-deoxycortisol in amniotic fluid. Genetic diagnosis using specific probes and cells obtained by chorionic villus sampling or amniocentesis is also possible. *Dexamethasone*, administered to the pregnant mother, will cross the placenta and can reduce or prevent virilization, but there are maternal risks of induced hypercortisolism and possible neurodevelopmental and physical effects on the infant. Although the risks remain uncertain and not all affected female fetuses appear to benefit, many parents may choose prenatal treatment because of the psychological impact of ambiguous genitalia (68).

Girls with ambiguous genitalia may require reconstructive surgery, including clitoral recession and vaginoplasty. Timing of such surgery is debated, but the girl must be of appropriate size to ensure the surgery is as simple as possible.

Heterosexual Pubertal Development

[6] The most common cause of heterosexual development at the expected age of puberty is PCOS **(Fig. 8-21)**. Because the syndrome is heterogeneous and poorly defined, clinical difficulties affect diagnosis and management (69). For the sake of simplicity, **PCOS may be defined as LH-dependent hyperandrogenism** (70). The Rotterdam criteria are commonly used to identify individuals with PCOS and require the presence of at least two of the following: oligo- or anovulation, clinical and/or biochemical signs of hyperandrogenism, and polycystic ovaries, with exclusion of other etiologies (CAH, androgen-secreting tumors, Cushing syndrome) (71). Polycystic ovaries ultrasonically are defined as the presence of 12 or more follicles in each ovary measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL). Most clinical manifestations arise as a consequence of the hyperandrogenism and often include hirsutism beginning at or near puberty and irregular menses from the age of menarche because of oligo- or anovulation. **Clinical manifestations are as follows:**

A

B

C

FIGURE 8-21 Typical facial hirsutism in three women with polycystic ovarian syndrome. **A:** 25-year-old. **B:** 21-year-old. **C:** 17-year-old.

1. **Affected girls may be but are not necessarily somewhat overweight.**
2. **In rare instances, menarche may be delayed, and primary amenorrhea may occur.**
3. **Basal levels of LH tend to be elevated in most affected individuals, and androgen production is invariably increased, even though circulating levels of androgens may be near the upper limits of the normal range in many affected women.**
4. **In anovulatory women, estrone levels are typically greater than estradiol levels.**
5. **Because circulating levels of estrogens are not diminished in PCOS and androgen levels are only mildly elevated, affected girls become both feminized and masculinized at puberty. This is an important feature because girls with classic forms of CAH who do not experience precocious puberty (and even those who do) only become masculinized at puberty (i.e., they do not develop breasts).**
6. **Some degree of insulin resistance may be present, even in the absence of overt glucose intolerance** (72).
7. **Polycystic ovaries are frequently, but not always, present in ultrasound examination.**

Differential Diagnosis and Evaluation

Distinguishing PCOS from the nonclassic forms of CAH can be challenging (70). The evaluation is as follows:

1. **Some clinicians advocate measurement of 17α-hydroxyprogesterone in all women who develop hirsutism.** Although values of 17α-hydroxyprogesterone are commonly elevated more than 100-fold in individuals with classic 21-hydroxylase deficiency, they may or may not be elevated in nonclassic late-onset forms of the disorder.
2. **Measurement of 17α-hydroxyprogesterone can identify women with various forms of 11-hydroxylase deficiency.**
3. **Basal levels of DHEAS and 17α-hydroxyprogesterone may be moderately elevated in patients with PCOS, making the diagnosis even more difficult.**
4. **To screen for CAH, 17α-hydroxyprogesterone should be measured in early morning.**
5. **In women with regular cyclic menses, it is important to measure 17α-hydroxyprogesterone only in the follicular phase because basal levels increase**

at midcycle and in the luteal phase.

Measurements of 17α-hydroxyprogesterone appear to be of value in populations at high risk for nonclassic late-onset 21-hydroxylase deficiency. In the white population, the gene occurs in only about 1 in 1,000 individuals, but it occurs in 1 in 27 Ashkenazi Jews, 1 in 40 Hispanics, 1 in 50 Yugoslavs, and 1 in 300 Italians (66). The incidence is increased among Eskimos and French Canadians. Alternatively, screening might be restricted to hirsute teenagers presenting with the more "typical" features of nonclassic 21-hydroxylase deficiency, including severe hirsutism beginning at puberty, "flattening" of the breasts (i.e., defeminization), shorter stature than other family members, and increased DHEAS levels (between 5,000 and 7,000 ng/mL). Women with a strong family history of hirsutism or hypertension might be screened **(Fig. 8-22)** (40).

FIGURE 8-22 A 19-year-old girl with secondary amenorrhea and severe acne and hirsutism beginning at the normal age of puberty. Stimulatory testing with corticotropin documented nonclassic 21-hydroxylase deficiency. Flattening of the breasts is apparent. She was shorter than her one sister and her mother.

Basal Levels of 17α-Hydroxyprogesterone

Basal levels of 17α-hydroxyprogesterone higher than 800 ng/dL are virtually diagnostic of CAH. Levels between 300 and 800 ng/dL require stimulatory testing with corticotropin to distinguish between PCOS and CAH. To complicate the situation even further, nonclassic 21-hydroxylase deficiency may occur even when basal levels of 17α-hydroxyprogesterone are below 300 ng/dL, thus requiring stimulatory testing in those cases.

Cosyntropin Stimulation Test

The most commonly used stimulatory test involves measurement of 17α-hydroxyprogesterone 30 minutes after administration of a bolus of 0.25 mg of synthetic cosyntropin (*Cortrosyn*) (73). In normal women, this value seldom exceeds 400 ng/dL. Patients with classic 21-hydroxylase deficiency achieve peak levels of 3,000 ng/dL or higher. Patients with nonclassic 21-hydroxylase deficiency commonly achieve levels of 1,500 ng/dL or more. Heterozygous carriers achieve peak levels up to about 1,000 ng/dL. In hirsute women with hypertension, 11-deoxycortisol levels can be determined during the test. If both 11-deoxycortisol and 17α-hydroxyprogesterone levels are increased, the rare 11-hydroxylase deficiency is present. Only measurements of several steroid precursors after corticotropin stimulation can identify individuals with nonclassic forms of 3β-HSD deficiency.

The elevated levels of 17α-hydroxyprogesterone present in all forms of 21-hydroxylase deficiency are rapidly suppressed by administration of exogenous corticoids. Even a single dose of a glucocorticoid such as *dexamethasone* will suppress 17α-hydroxyprogesterone in CAH but not in virilizing ovarian and adrenal neoplasms.

Hirsutism

It has been suggested that androgen-receptor blockade may be preferable to glucocorticoids as primary treatment of nonclassic 21-hydroxylase deficiency (74). Although menses usually (but not always) become regular shortly after beginning therapy with glucocorticoids, the hirsutism in this disorder is remarkably refractory to glucocorticoids. Ovulatory cycles may not occur even with appropriate therapy, and ovulation induction may be required.

Distinguishing nonclassic forms of CAH from idiopathic hirsutism may be problematic. Individuals with idiopathic hirsutism have regular ovulatory menses, thus effectively eliminating PCOS from consideration. Confusion can be created by the fact that some women with nonclassic CAH may continue to ovulate. Basal levels of 17α-hydroxyprogesterone are normal in idiopathic hirsutism, as is the response to adrenocorticotropic hormone stimulation. Idiopathic hirsutism represents enhanced androgen action at the hair follicle (75).

Mixed Gonadal Dysgenesis

The term *mixed gonadal dysgenesis* is used to designate those individuals with asymmetric gonadal development, with a germ cell tumor or a testis on one side and an undifferentiated streak, rudimentary gonad, or no gonad on the other side. Most individuals with this rare disorder have a mosaic karyotype of 45,X/46,XY and are raised as girls who experience virilization at puberty. Gonadectomy is indicated to remove the source of androgens and eliminate any risk for neoplasia.

Rare Forms of Male Pseudohermaphroditism

Individuals who have rare forms of male pseudohermaphroditism, especially 5α-reductase deficiency (the so-called *penis at twelve syndrome*) and the *Reifenstein syndrome,* generally have ambiguous female genitalia with variable virilization at puberty. *Cushing syndrome* may occur rarely during the pubertal years, as may adrenal or ovarian androgen-secreting neoplasms.

GENITAL AMBIGUITY AT BIRTH

Ambiguous external genitalia in a newborn constitutes a major diagnostic challenge. Prompt evaluation is of critical importance to identify a possible life-threatening disorder and to assign the appropriate gender. The prime diagnosis until ruled out is CAH because it is the only condition that is life threatening. Extreme sensitivity is required in interacting with the family, and no attempt should be made to guess the sex of the baby. The incidence of genital ambiguity is 1 in 4,500, although some degree of male undervirilization or female virilization may be present in as many as 2% of live births (76).

Physical Signs

During the 3 to 4 days required for evaluation, it is important to be supportive of the parents. Many clinicians believe that it is important not to attach unusual significance to the genital ambiguity and to treat the abnormality as just another "birth defect." Physicians should emphasize that the child should undergo normal psychosexual development regardless of the sex-of-rearing selected. A name compatible with either sex should be chosen or the naming of the infant should be delayed until the studies are completed.

Although the diagnosis is not usually obvious on examination, there are some helpful distinguishing features **(Fig. 8-20)**. **In normal boys, there is only a single midline frenulum on the ventral side of the phallus; in normal girls, there are two frenula lateral to the midline. A girl with clitoral enlargement still has two frenula, and a boy with hypospadias has a single midline frenulum or several irregular fibrous bands (chordee).** It is important to determine whether any müllerian derivatives are

present. Studies suggest that MRI may be the most effective way of evaluating the infant for the presence of müllerian tissue (77).

The location or consistency of the gonad may be helpful in deducing its composition. A gonad located in the labial or inguinal regions almost always contains testicular tissue. A testis is generally softer than an ovary or a streak gonad and is more apt to be surrounded by blood vessels, imparting a reddish cast. An ovary is more often white, fibrous, and convoluted. A gonad that varies in consistency may be an ovotestis or a testis or a streak gonad that underwent neoplastic transformation. If a well-differentiated fallopian tube is absent on only one side, the side without the tube probably contains a testis or ovotestis.

Diagnosis and Management

Optimal clinical management includes the following (78):

1. **Gender assignment must be avoided before expert evaluation of newborns.**
2. **Evaluation and long-term management should be performed at a center with an experienced multidisciplinary team (pediatric endocrinologist, pediatric urologist, geneticist, clinical psychologist, and reproductive endocrinologist).**
3. **All individuals should receive a gender assignment after appropriate assessment.**
4. **Open communication with patients and families is essential, and participation in decision making should be encouraged.**
5. **Patient and family concerns should be respected and addressed in strict confidence.**

First-line testing in newborns includes:

1. **Karyotyping with X- and Y-specific probe detection (even when prenatal karyotype is available).**
2. **Measurement of serum 17-hydroxyprogesterone, testosterone, gonadotropins, antimüllerian hormone, and electrolytes.**
3. **Abdominopelvic ultrasound (to assess anatomy of the vagina, uterus, or urogenital sinus, exclude renal anomalies, and locate any inguinal gonads).**
4. **Urinalysis (to check for protein as a screen for any associated renal anomaly).**

The results of these investigations are generally available within 48 hours and sufficient to develop a working diagnosis. If needed, additional testing may include (79)**:**

1. **Human chorionic gonadotropin- and adrenocorticotropin-stimulation tests to**

assess testicular and adrenal steroid biosynthesis.

2. **Urinary steroid analysis by gas chromatography mass spectroscopy.**
3. **Further imaging studies.**
4. **Biopsies of gonadal material.**
5. **More detailed genetic testing.**

Although genetic ambiguity is almost always identified at birth, it may not be recognized for several years. Questions about changing the sex-of-rearing may arise. The earlier any necessary sex-of-rearing change may be made, the better. In any case, **surgery for genital ambiguity to make the external genitalia (and development) compatible with the sex-of-rearing of the individual is warranted but is not always completely successful.** Clitoral recession and clitorectomy are the most frequently performed surgical procedures.

Teratogens

It is important to recognize that ambiguous genitalia can result from the maternal ingestion of various teratogens, most of which are synthetic steroids. Exposure to the teratogen must occur early in the pregnancy, during genital organogenesis. Not all exposed fetuses manifest the same anomalies or even the presence of any anomalies. In principle, most synthetic steroids with androgenic properties, including weakly androgenic progestins, can affect female genital differentiation. However, the doses required to produce genital ambiguity are generally so great that the concern is only theoretical. **The one agent that can lead to genital ambiguity when ingested in clinically used quantities is *danazol*. There is no evidence that inadvertent ingestion of oral contraceptives, which contain relatively low doses of steroids, results in virilization** (80).

KEY POINTS

1 The causes of abnormal bleeding vary by age, with anovulatory bleeding most likely in adolescents and perimenopausal women.
2 Pelvic masses in adolescents are most commonly functional or benign neoplastic ovarian masses, whereas the risks of malignant ovarian tumors increase with age.
3 Although pelvic ultrasonography is an excellent technique for imaging pelvic masses and ultrasonographic characteristics may suggest reassuring characteristics of an ovarian mass, the possibility of malignancy must be kept in mind.
4 Vulvovaginal symptoms of any sort in a young child should prompt the consideration of possible sexual abuse.
5 Preventive services for adolescents should be based on knowledge of the behavioral and medical health risks that can affect their future health, including substance use and abuse, sexual behaviors that invite unintended pregnancy and sexually transmitted diseases (STDs), and the symptoms of impaired mental health.

The gynecologic problems of prepubertal girls and adolescents differ from those of adult women. In the case of prepubertal girls, there are significant differences from adolescents and adult women in the anatomy, bacteriology, physiology, pathophysiology, and epidemiology of gynecologic conditions that are likely to occur. While gynecologists tend to think of menarche as the dividing line between young girls and adolescents, the real differences in the types of gynecologic conditions that occur during adolescence typically begin with the onset of puberty, when steroid hormone production causes changes in breast development **(Fig. 9-1)**, the vaginal epithelium, growth of the uterus, and vulvar changes of hair growth.

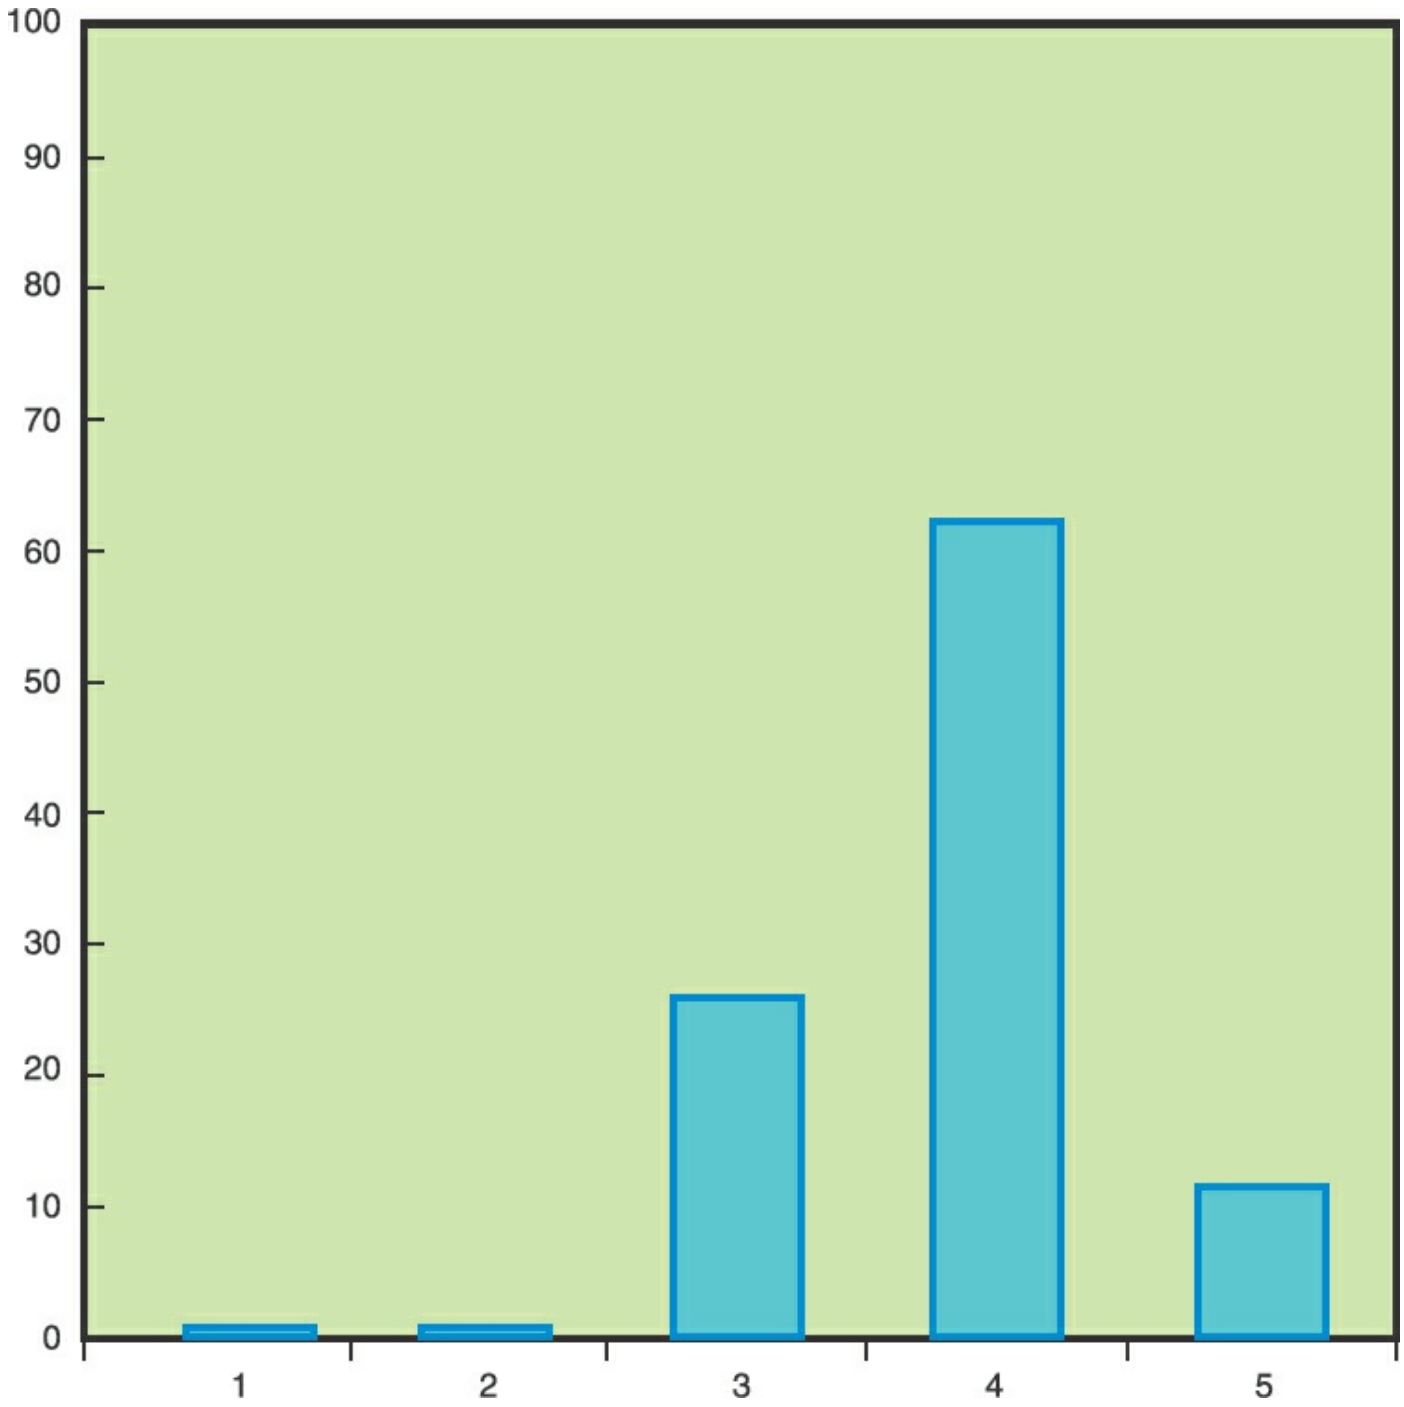

FIGURE 9-1 Tanner breast stage at menarche.

Menarche signals the onset of cyclic ovarian hormone production leading to menstrual bleeding, although many early menstrual cycles are anovulatory. Some conditions, potential developmental genital anomalies, are more likely to be diagnosed during adolescence than in adults. The incidence of ovarian tumors varies by age, with young girls and adolescents more likely to develop germ cell tumors than adults. Some of the gynecologic conditions that occur during adolescence are related to sexual behaviors, including greater risks of sexually transmitted infections and pelvic

inflammatory disease (PID). **The gynecologist's interactions with an adolescent are sometimes more challenging, given that adolescents are developing in a number of spheres: physical maturity, cognitive development, psychosocial development, relationships with family and peers, and sexuality.**

All those spheres do not develop synchronously, and a young adolescent may appear physically more mature than her psychosocial or cognitive development allows her to behave. These are some of the aspects of relating to adolescents with regard to their gynecologic problems that make it challenging. On the other hand, adolescents will often be refreshingly candid if a trusting relationship has been established with their physician. Observing adolescents' growth and development into young adulthood can be immensely rewarding, as they have the capacity to make behavioral changes that adults often find difficult.

The gynecologic examination of prepubertal girls and adolescents is discussed in Chapter 1, as are elements of communication that apply equally to adolescents and to adults. However, **there are some aspects of communication with prepubertal girls and adolescents that are unique to these age groups. It is important to keep in mind that most medical problems in children lead to maternal anxiety, and maternal or parental anxiety may manifest in different ways.** The clinician may occasionally interact with a parent who is not accepting of their parental roles and responsibilities and who is neglectful of the child's health, or who because of their own medical or mental health issues including substance use disorders, is unable to appropriately provide care for their child. These situations are rare, but typically require multidisciplinary interventions, including the services of a social worker or mandatory reporting to local child protective services. Gynecologic conditions for a daughter may be particularly fraught, as they may revive the mother's history of interpersonal violence, sexual abuse, exploitation, reproductive coercion, or adverse interactions with the health care system. **Parents may be concerned that a gynecologic condition will impact their daughter's future fertility or ability to lead a sexually satisfying adult life.** The clinician must recognize that these concerns are quite common, and should address them directly with accurate information.

Communication with toddlers and infants will be primarily with the child's mother. The gynecologic history in a young child will include issues described in Table 9-1.

Adolescents who present for gynecologic consultation are often accompanied by a parent, typically their mother. **ACOG recommends that an adolescent's initial visit to a gynecologist for reproductive health guidance, screening, and provision of preventive services should take place between the ages of 13 and 15 years** (1). **This visit provides an opportunity to directly observe mother–daughter communication during the visit, and to assess whether the relationship appears to be an open and trusting one or whether the mother appears excessively anxious,**

controlling, domineering, authoritarian, or permissive. Adolescents must be afforded confidentiality during a visit in which it is essential to obtain a history of risk-taking behaviors including sexual behaviors, substance use/abuse, and mental health concerns (1,2). Concerns about confidentiality can be a major obstacle to adolescents' willingness to seek health care services.

Safety discussion with child: “No, Go, Tell”

One structure of an adolescent’s gynecologic consultation visit has been described in which the adolescent and her parent (typically her mother) meet together initially, followed by time in which the physician addresses the mom’s concerns and ascertains her concerns about such issues as risk-taking behaviors **(Table 9-2)** (3). Concepts of confidentiality are explained to the mother at this time, and preventive guidance about adolescent development is provided. The order in which the mother and daughter are seen is intentional, in that the clinician has not yet spoken privately with the adolescent, allowing the clinician to speak in generalities about adolescent behaviors. Subsequently, the adolescent is seen alone, concepts of confidentiality are explained, and psychosocial issues are addressed. Among adolescent medicine clinicians, this assessment is often referred to as the HEEADSSS assessment **(Table 9-3)** (4).

[5] Preventive services for adolescents should be based on knowledge of the behavioral and medical health risks that can affect their future health, including substance use and abuse, sexual behaviors that invite unintended pregnancy and sexually transmitted diseases (STDs), and the symptoms of impaired mental health.

This chapter will address the gynecologic problems of prepubertal girls and adolescents. The gynecologic problems that will be addressed by age group include bleeding, pelvic masses, and vulvovaginal conditions.

PREPUBERTAL AGE GROUP

Prepubertal Bleeding

Prior to menarche, which frequently does not occur before 9 years of age, *any* vaginal bleeding requires evaluation. To appropriately evaluate a young girl with vaginal bleeding, a practitioner should understand the events of puberty (5–7). The hormonal changes that control the cyclic functioning of the hypothalamic–pituitary–ovarian axis are described in Chapter 7. An understanding of the normal sequence and timing of these events is critical to an appropriate assessment of a girl at the onset of bleeding (see Chapter 8). Menarche typically occurs when an adolescent has reached Tanner stage 3 or 4 of breast development **(Fig. 9-1)**. Bleeding in the absence of breast development must be evaluated.

Differential Diagnosis of Prepubertal Vaginal Bleeding

Slight vaginal bleeding can occur within the first few days of life because of withdrawal from exposure to high levels of maternal estrogen. New mothers of female infants should be informed of this possibility to preclude unnecessary anxiety. After the neonatal period, causes of bleeding that should be considered in the prepubertal age group include sexual abuse, precocious puberty, benign and malignant ovarian tumors, as well as vulvar, vaginal, and cervical lesions or tumors **(Table 9-4)**. Menses do not normally occur before breast budding (8,9).

[4] **The causes of bleeding in this age group range from the medically mundane to malignancies that may be life-threatening. The source of bleeding is sometimes difficult to identify, and parents who observe blood in a child's diapers or panties may be unsure of the source—whether from the urinary tract, the vagina, or the rectum. Pediatricians usually look for urinary causes of bleeding, and gastrointestinal factors such as constipation and/or anal fissure, or inflammatory bowel disease should be considered. The possibility of abuse should always be assessed in girls with any vulvovaginal symptoms, particularly if bleeding is present (10). Failure to diagnose sexual abuse may leave a child in significant danger.**

Table 9-2 **Visit Structure for Adolescent Consultation Visit**

Step	Topics Covered	The Clinician in Consultation With
1	Review structure of visit Obtain history of present illness/chief concerns Obtain past medical history and family history	Adolescent and parent(s)
2	Address parental concerns Provide preventive guidance about adolescent development Address confidentiality	Parent(s)
3	Address confidentiality Obtain history, including sexuality and risk-taking behaviors	Adolescent
4	Perform physical examination, as indicated	Adolescent (+/- parent, per adolescent's preference)
5	Summarize findings and recommendations Determine parameters of parental involvement Determine method of notification of laboratory results Provide preventive guidance	Adolescent
6	Summarize findings and recommendations, as appropriate	Adolescent and parent(s)

Vulvar Lesions

Vulvar irritation can lead to pruritus with excoriation, maceration of the vulvar skin, or fissures that can bleed. Other visible external causes of bleeding in this age group include urethral prolapse, condylomas, lichen sclerosus, or molluscum contagiosum. **Urethral prolapse can present acutely with a tender mass that may be friable or bleed slightly; it is most common in African American girls and may be confused with a vaginal mass (Fig. 9-2)**. The classic presentation is a donut-shaped mass symmetrically surrounding the urethra. This condition can typically be managed medically with the topical application of estrogens, although some authors have advocated primary surgical excision (11). The presence of condyloma should prompt questioning about abuse, although it has been suggested that **condyloma that appear during the first several years of life may be acquired perinatally from maternal infection with human papillomavirus (HPV) (Fig. 9-3)** (12). Excoriation and subepithelial hemorrhage ("blood blisters") into the skin can cause external bleeding in the presence of prepubertal lichen sclerosus; this finding may mistakenly be identified as abuse, and the conditions are not mutually exclusive (Fig. 9-4) (13). **Although most gynecologists recognize the appearance of lichen sclerosus in postmenopausal women, the condition can occur in prepubertal girls and may not be recognized by clinicians who are unfamiliar with this condition.** As with adults, the cause of lichen sclerosus remains uncertain; a familial incidence has been identified (14).

FIGURE 9-4 Prepubertal lichen sclerosus.

Foreign Body

A foreign body in the vagina is a common cause of vaginal discharge, which may appear purulent or bloody. Young children explore all orifices and may place all varieties of small objects inside their vaginas **(Fig. 9-5)**. An object, such as a small plastic toy, can sometimes be palpated on rectal examination, and occasionally "milked" toward the vaginal introitus to allow removal. The most common foreign bodies found in the vagina are small pieces of toilet paper (15). Although it has been suggested that the presence of vaginal foreign bodies might be a marker for sexual abuse, this is not always the case; but the possibility of abuse should always be considered.

Precocious Puberty

Vaginal bleeding in the absence of other secondary sexual characteristics may result from precocious puberty (see Chapter 8), although as with normal puberty, the onset of breast budding or pubic hair growth is more likely to occur before vaginal bleeding. A large observational study suggested that the onset of pubertal changes—breast budding and pubic hair—might occur earlier than previously thought (6). Evaluation for precocious puberty was recommended for girls with pubertal development younger than age 8 years. Guidelines proposed evaluation of white girls younger than age 7 years and African American girls younger than age 6 years who have either breast development or pubic hair, rather than the traditional age of 8 (16). An expert panel concluded that **there is reasonable evidence that pubertal milestones are occurring at a younger age in girls** (17).

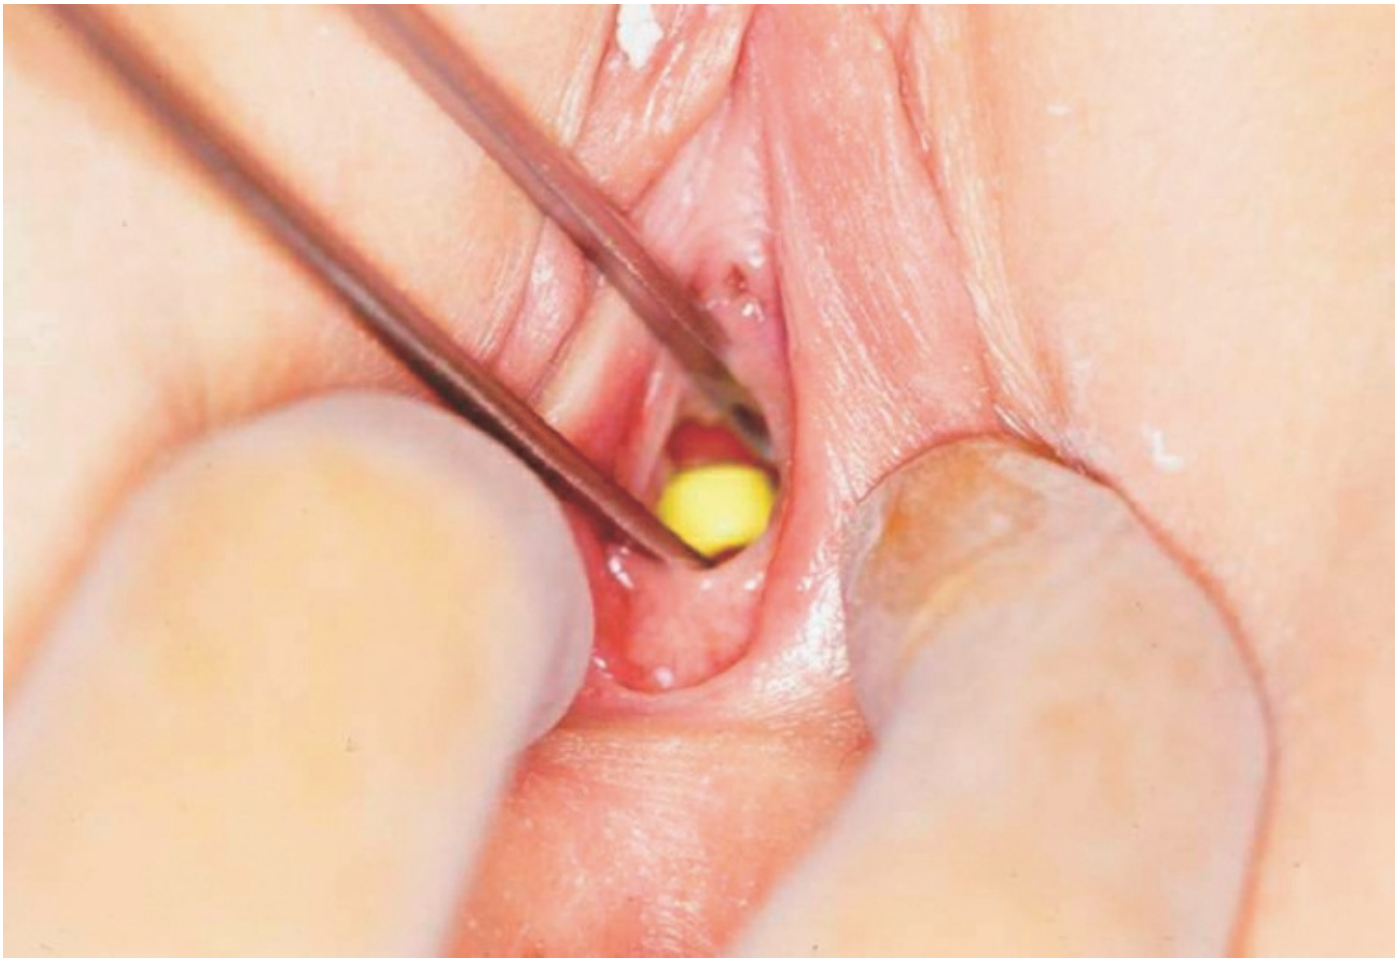

FIGURE 9-5 Foreign body (plastic toy) in the vagina of an 8-year-old girl.

Trauma

Trauma can be a cause of genital bleeding. **A careful history should be obtained from one or both parents or caretakers and the child herself, because trauma caused by sexual abuse often is not recognized. Trauma can be characterized as accidental or nonaccidental, which is described as child abuse.** Physical findings that are inconsistent with the description of the alleged accident should prompt consideration of abuse and appropriate consultation or referral to an experienced social worker or sexual abuse team. **All states impose a mandatory legal obligation to report suspected child physical abuse;** most states specifically require reporting child sexual abuse, but even in those that do not, the laws are broad enough to encompass sexual abuse implicitly (10). Notification is required even with the suspicion of sexual abuse. In general, a straddle injury occurring with accidental trauma affects the anterior and lateral vulvar area, whereas penetrating injuries with lesions of the fourchette or lesions that extend through the hymenal ring are less likely to occur as a result of accidental trauma **(Fig. 9-6)** (18).

Abuse

The medical evaluation of suspected child sexual abuse is best managed by individuals who have experience in assessing the physical findings, laboratory results, and the children's statements and behaviors. Genital findings have been categorized as follows (10):

1. Findings documented in newborns or commonly seen in nonabused children
2. Findings with no expert consensus on interpretation with respect to sexual contact or trauma
3. Findings caused by trauma and/or sexual contact

Most cases of child sexual abuse do not come to light with an acute injury and instead are associated with normal or nonspecific genital findings (10). Forms of abuse such as fondling or digital penetration may not result in visible genital lesions.

Other Causes

Other serious but rare causes of vaginal bleeding include vaginal tumors. The most common tumor in the prepubertal age group is a rhabdomyosarcoma (sarcoma botryoides), which is associated with bleeding and a grapelike clustered mass (see Chapter 38). Other forms of vaginal tumor are rare but should be ruled out with a thorough examination under anesthesia with vaginoscopy if no other obvious external source of bleeding is found.

Hormonally active ovarian tumors can cause endometrial proliferation and bleeding. Likewise, exogenously administered estrogens can result in bleeding. Rarely, bleeding can result from the prolonged use of topical estrogens prescribed as therapy for vulvovaginitis or labial adhesions or from accidental ingestion of prescription estrogens.

Diagnosis of Prepubertal Bleeding

Examination

A careful examination is indicated when a child has genital symptoms. The technique of examining the prepubertal child is described in Chapter 1. **If no obvious cause of bleeding is visible externally or within the distal vagina, an examination can be performed using anesthesia with vaginoscopy to completely visualize the vagina and cervix. This examination should be performed by a clinician who has experience in pediatric and adolescent gynecology.**

FIGURE 9-6 Straddle injury—vulvar hematoma in a 13-year-old girl.

Imaging

If an ovarian or vaginal mass is suspected, a transabdominal pelvic ultrasonographic examination can provide useful information. The appearance of the ovaries (normal prepubertal size and volume, follicular development, cystic, or solid) can be noted, as well as the size and configuration of the uterus. **The prepubertal uterus has a distinctive appearance, with equal proportions of cervix and fundus and a size of approximately 2 to 3.5 cm in length and 0.5 to 1 cm in width (Fig. 9-7)**. The uterine fundus enlarges with estrogen stimulation, resulting in the postmenarchal appearance in which the uterine fundus is larger than the cervix (19). An ultrasonographic examination should be the first imaging study performed; more sophisticated imaging techniques, such as magnetic resonance imaging (MRI) or computed tomography (CT) scanning, are

rarely indicated as initial diagnostic modalities, and they add unnecessary expense and radiation exposure with CT.

Management of Prepubertal Vaginal Bleeding

The management of bleeding in prepubertal-age girls is directed toward the cause of bleeding. If bloody discharge believed to result from nonspecific vulvovaginitis persists despite therapy, further evaluation may be necessary to rule out the presence of a foreign body. Skin lesions (chronic irritation) and lichen sclerosus may be difficult to manage but can be treated with a course of topical steroids; lichen sclerosus often requires the use of ultrahigh-potency topical steroids and ongoing maintenance therapy. **Vaginal and ovarian tumors should be managed in consultation with a gynecologic oncologist.**

Prepubertal Pelvic Masses

Presentation of Prepubertal Pelvic Masses

The probable causes of a pelvic mass found on physical examination or through radiologic studies are vastly different in prepubertal children than they are in adolescents or postmenopausal women (Table 9-5). A pelvic mass may be gynecologic in origin, or it may arise from the urinary tract or bowel. The gynecologic causes of a pelvic mass may be uterine, adnexal, or more specifically ovarian. Because of the small pelvic capacity of a prepubertal child, a pelvic mass very quickly becomes abdominal in location as it enlarges and may be palpable on abdominal examination. Ovarian masses in this age group may be asymptomatic, associated with chronic pressure-related bowel or bladder symptoms, or may present with acute pain caused by rupture or torsion. Abdominal or pelvic pain is one of the most frequent initial symptoms. The diagnosis of ovarian masses in prepubertal girls is difficult because the condition is rare in this age group and, consequently, there is a low index of suspicion. Many symptoms are nonspecific, and acute symptoms are more likely to be attributed to more common entities such as appendicitis. **Abdominal palpation and bimanual rectoabdominal examination are important in any child who has nonspecific abdominal or pelvic symptoms.** An ovarian mass that is abdominal in location can be confused with other abdominal masses occurring in children, such as Wilms tumor or neuroblastoma. Acute pain is often associated with torsion. The ovarian ligament becomes elongated as a result of the abdominal location of ovarian tumors, thus creating a predisposition to torsion. Adnexal torsion is more likely to occur with an ovarian mass than with a normal-size ovary. While torsion of a normal ovary is rare in adolescents and adults, it is more likely to occur in prepubertal girls. **Symptoms of torsion include the acute onset of severe abdominal pain, accompanied by nausea and vomiting.** Recurrent torsion is also a possibility, noted by intermittent episodes of severe pain.

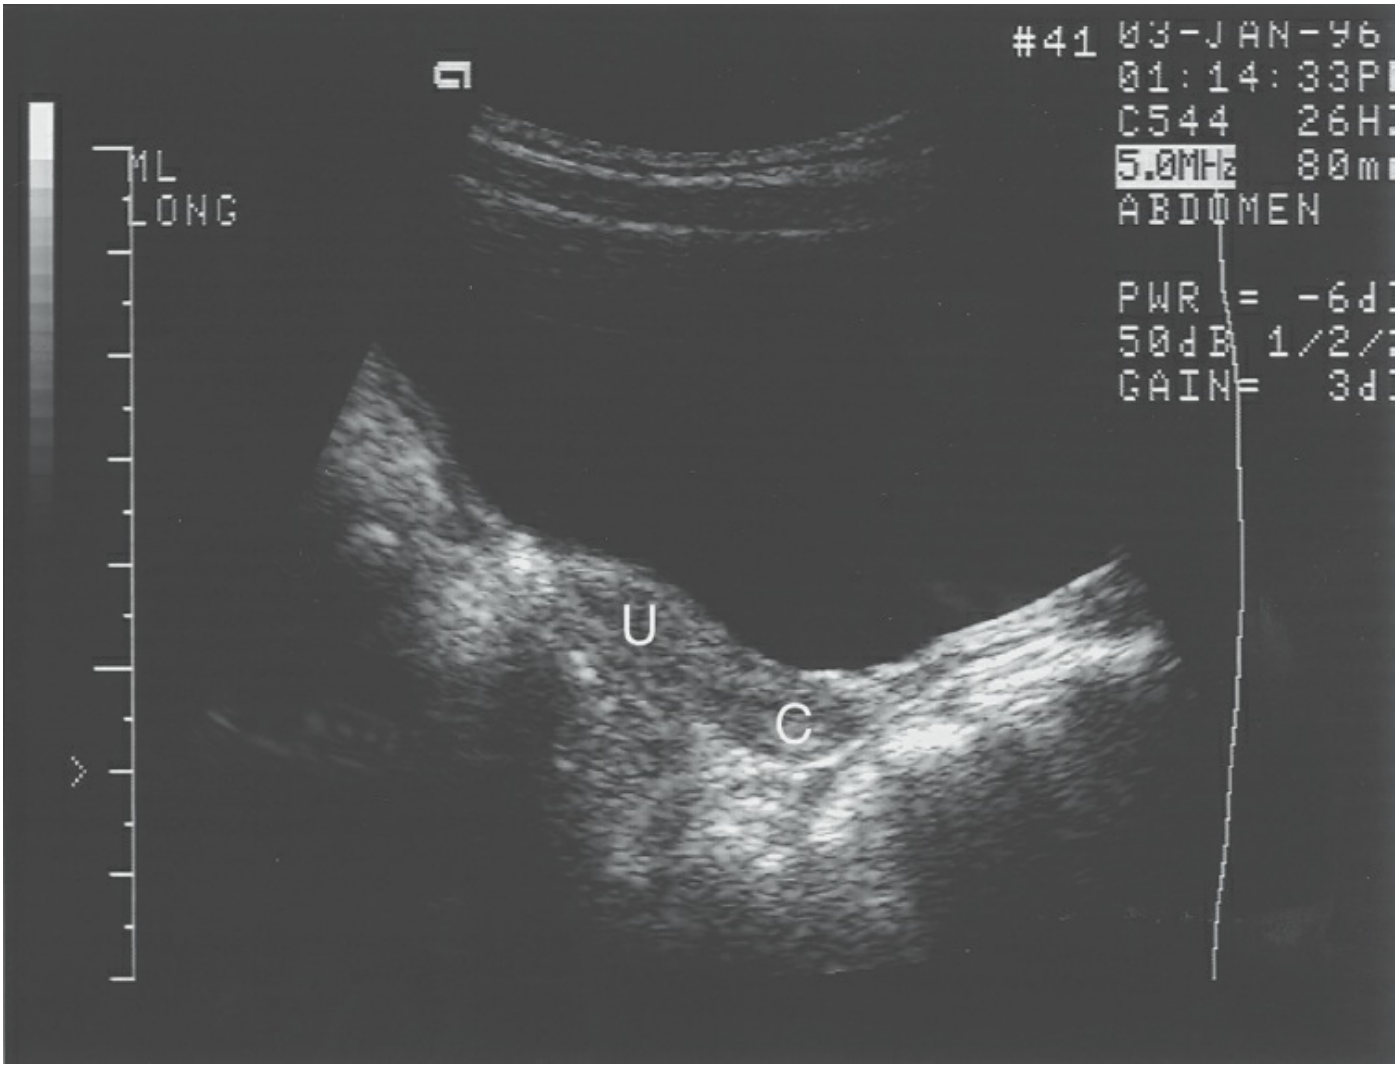

FIGURE 9-7 Pelvic ultrasound (transabdominal) of a premenarchal 10-year-old girl. U, uterine fundus; C, cervix. In prepubertal child, uterine fundus and cervix are similar in size.

Diagnosis of Prepubertal Pelvic Masses

[3] Ultrasonography is the most valuable tool for diagnosing ovarian masses. The characteristics of a pelvic mass can be determined. Whereas both uni- and multilocular cysts frequently resolve with observation, the finding of a solid component mandates surgical assessment because of the high risk of a germ cell tumor (20). Additional imaging studies, such as CT scanning, MRI, or Doppler flow studies, may be helpful in establishing the diagnosis (21).

Table 9-5 Causes of Pelvic Mass by Approximate Frequency and Age

Infancy	Prepubertal	Adolescent	Reproductive	Perimenopausal	Postmenopausal
Functional cyst	Functional cyst	Functional cyst	Functional cyst	Fibroids	Ovarian tumor (malignant or benign)
Germ cell tumor	Germ cell tumor	Pregnancy	Pregnancy	Epithelial ovarian tumor	Functional cyst
		Benign cystic teratoma/other germ cell tumors	Uterine fibroids	Functional cyst	Bowel, malignant tumor or inflammatory
		Obstructing vaginal or uterine anomalies	Epithelial ovarian tumor		Metastases
		Epithelial ovarian tumor			

Differential Diagnosis

Fewer than 2% of ovarian malignancies occur in children and adolescents (22,23). **Ovarian tumors account for approximately 1% of all malignant tumors in these age groups. Germ cell tumors make up one-half to two-thirds of ovarian neoplasms in individuals younger than 20 years of age.** A review of studies conducted from 1940 until 1975 concluded that 35% of all ovarian neoplasms occurring during childhood and adolescence were malignant (24). **In girls younger than 9 years of age, approximately 80% of the ovarian neoplasms were malignant.** Germ cell tumors account for approximately 60% of ovarian neoplasms in children and adolescents compared with 20% of these tumors in adults (24). Epithelial neoplasms are rare in the prepubertal age group; thus, data usually are reported from referral centers. Some reports include only neoplastic masses, whereas others include nonneoplastic masses; some series combine data from prepubertal and adolescent girls. One community survey of ovarian masses revealed that the frequency of malignancy was much lower than previously reported; **of all ovarian masses confirmed surgically in childhood and adolescence, [2]** only 6% of patients with ovarian enlargement had malignant neoplasms, and only 10% of neoplasms were malignant (25). Surgical decision making influences the statistics on incidence; the surgical excision of functional masses that would resolve in time inflates the percentage of benign masses. In one series, nonneoplastic masses in young women and girls younger than 20 years of age constituted two-thirds of the total (26). Even in girls younger than 10 years of age, 60% of the masses were nonneoplastic, and two-thirds of the neoplastic masses were benign. Authors of older case series were less aware of the benign and functional masses that are now found incidentally with routine sonographic images. Functional, follicular cysts can occur in fetuses, newborns, and prepubertal children (27). Rarely, they may be associated with sexual precocity.

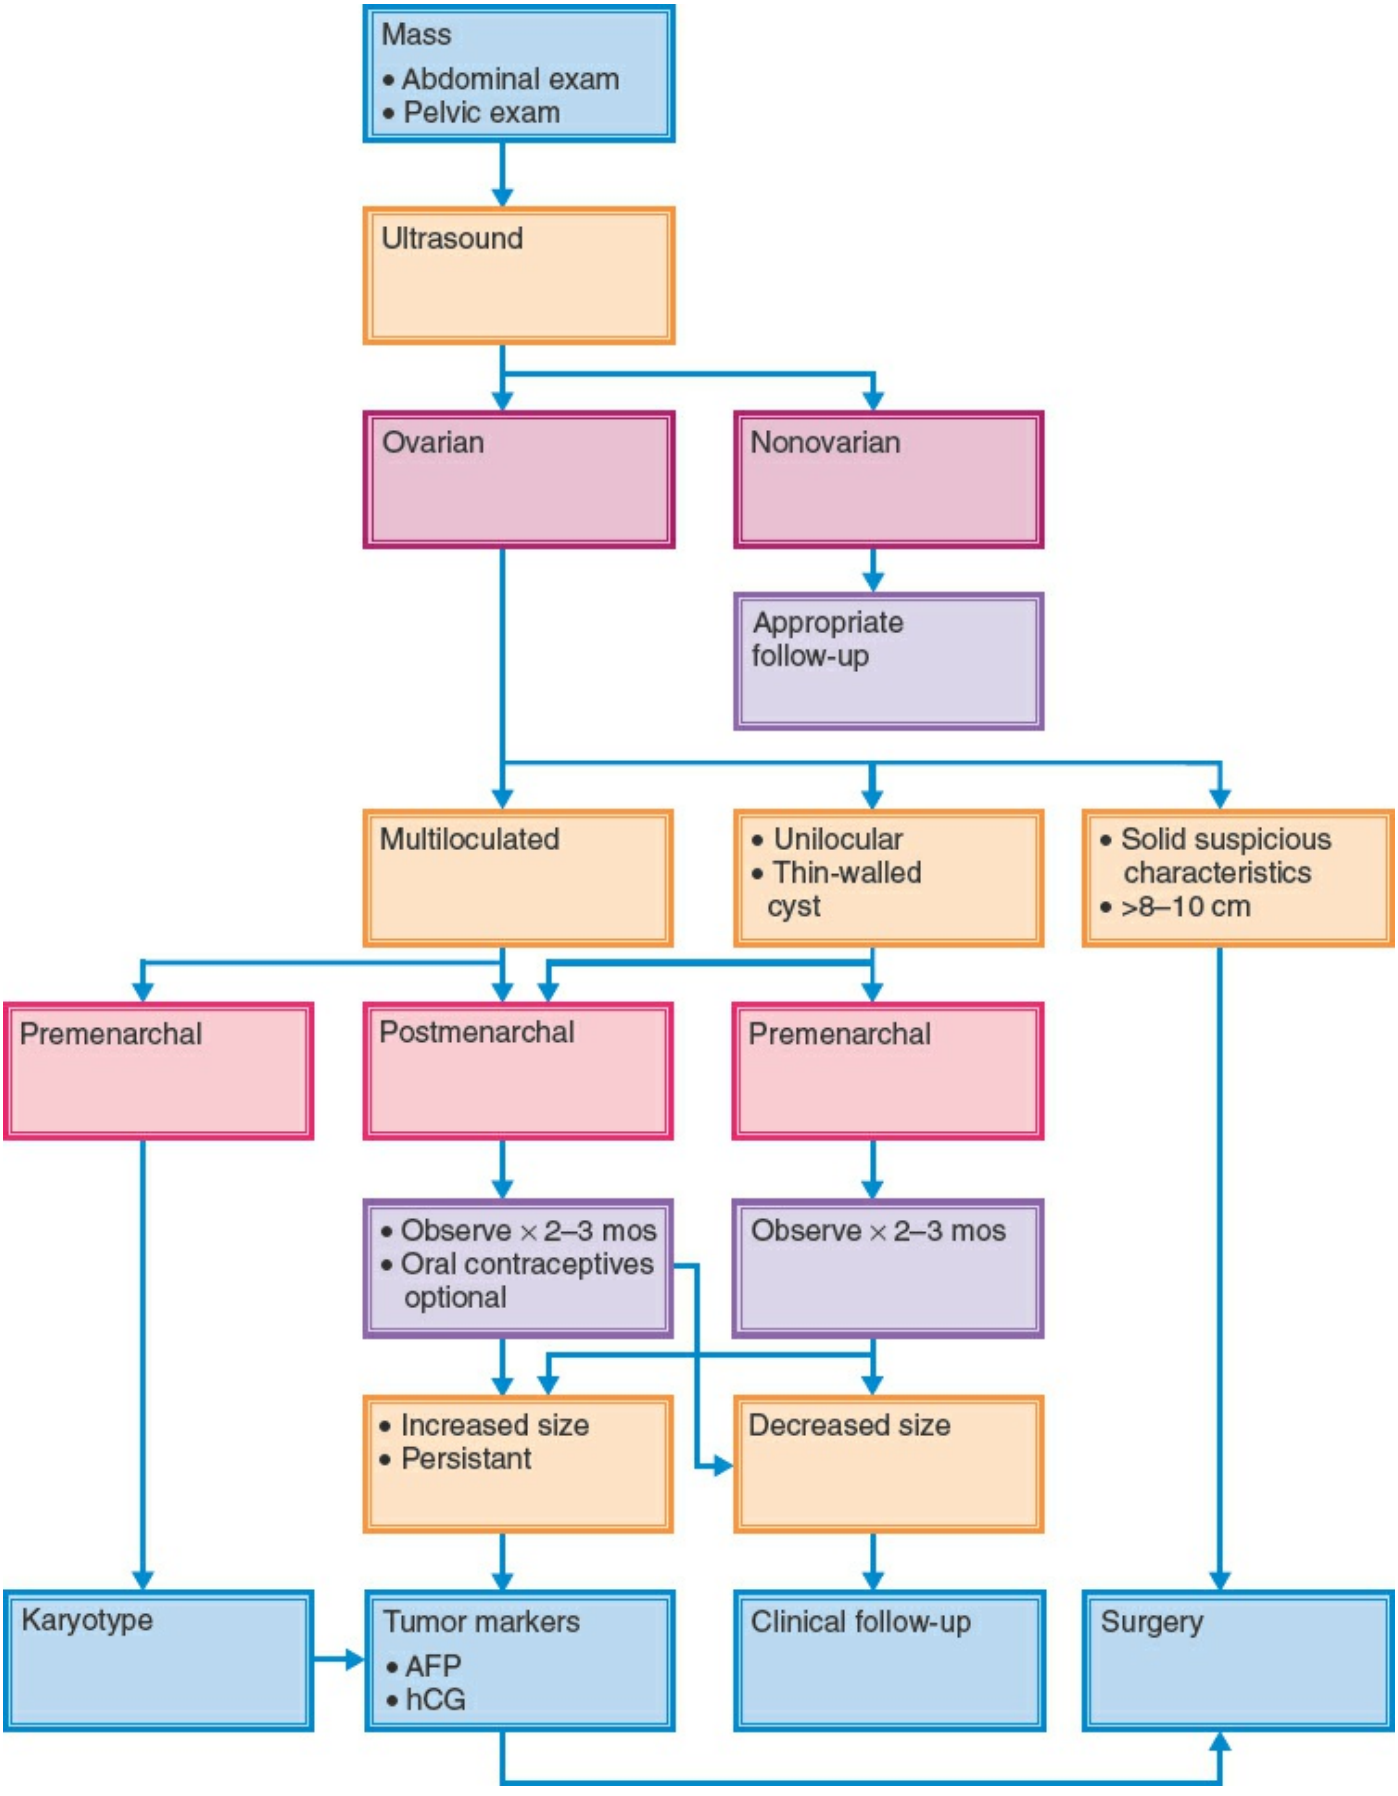

FIGURE 9-8 Management of pelvic masses in premenarchal and adolescent girls.

Management of Prepubertal Pelvic Masses

A plan for the management of pelvic masses in prepubertal-age girls is shown in **Figure 9-8**. **Unilocular cysts are virtually always benign, even in this age group, and will regress in 3 to 6 months; thus, they do not require surgical management with oophorectomy or oophorocystectomy.** Close observation is recommended, and there is a risk of ovarian torsion that must be discussed with the child's parents (28). Recurrence rates after cyst aspiration (either ultrasonographically guided or with laparoscopy) may be as high as 50%. Attention should be directed to long-term effects on endocrine function and future fertility; preservation of ovarian tissue is a priority for patients with benign tumors. Oophorectomy should be avoided if at all possible for benign masses (29–31). **Premature surgical therapy for a functional ovarian mass can result in ovarian and tubal adhesions that can adversely affect future fertility.** Solid masses, those larger than approximately 8 cm, and enlarging masses require surgical intervention, as the likelihood of neoplasm is high.

Prepubertal Vulvar Conditions

Neonatal Vulvar Conditions

Various developmental and congenital vulvovaginal abnormalities are detected in the neonatal age group. Obstetrician-gynecologists will recognize that they must be prepared to deal with the parents and family when an infant is born with ambiguous genitalia. The etiology of these problems and intersex disorders (now termed disorder of sex development [DSD]) that may be discovered in an older child can be complex (32). Chromosomal abnormalities, enzyme deficiencies (including 17- or 21-hydroxylase deficiency as causes of congenital adrenal hyperplasia), or prenatal masculinization of a female fetus resulting from maternal androgen-secreting ovarian tumors or, rarely, drug exposure can all result in genital abnormalities that are noted at birth. These abnormalities are described in Chapter 34.

Ambiguous genitalia represent a social and potential medical urgency that is best handled by a team of specialists, which may include urologists, neonatologists, endocrinologists, and pediatric gynecologists (32). The first question parents ask after a baby is born "is it a boy or a girl?" In the case of ambiguous genitalia, the parents should be informed that the baby's genitals are not fully developed and, therefore, a simple examination of the external genitalia cannot determine the actual sex. The parents should be told that data will be collected but that it may take several days or longer to determine the baby's intended sex. In some situations, it may be best to state simply that the baby has some serious medical complications. The issues of sex assignment and appropriateness or timing of surgical therapy are controversial and should be managed by clinicians with extensive experience in this area (32).

Other genital abnormalities may be noted at birth, although few obstetricians or pediatricians carefully examine the external genitalia of female neonates. It is argued that **careful inspection of the external genitalia of all female infants should be performed, with gentle probing of the introitus and anus to determine the patency of the hymen or a possible imperforate anus.** If patency is in doubt, a rectal thermometer may be used to gently test the patency. It is suggested that this examination should be performed on all female infants in the delivery room (33). Various types of hymenal configurations in the newborn are described, ranging from imperforate to microperforate, to cribriform, to hymenal bands, and to hymens with central anterior, posterior, or eccentric orifices (34). An examination during the neonatal period would prevent the discovery of an imperforate hymen or vaginal septum after a young woman experiences periodic pelvic and abdominal pain with the development of a large hematometra or hematocolpos.

Congenital vulvar tumors may include strawberry hemangiomas, which are relatively superficial vascular lesions, and large cavernous hemangiomas. Treatment is controversial, and many lesions will spontaneously regress.

Childhood Vulvar Conditions

Vulvar and vaginal symptoms, such as burning, dysuria, itching, or a rash, are common initial symptoms among children that are reported to gynecologists. It may be difficult for a young child to describe vulvar sensations. Parents may notice the child crying during urination, scratching herself repeatedly, or complaining of vague symptoms. Often, the child's pediatrician will have evaluated the child for urinary tract infection (UTI). Evaluation for pinworms is warranted, because pinworms can cause severe itching in the vulvar and perianal area. **Vulvovaginitis is the most common gynecologic problem of childhood.** Prepubertally, the vulva, vestibule, and vagina are anatomically and histologically vulnerable to bacterial infection, with the bacteria typically present in the perianal area. The physical proximity of the vagina and vestibule to the anus can result in overgrowth of bacteria that can cause primary vulvitis and secondary vaginitis. Yeast infections are rare in prepubertal children who are toilet trained and out of diapers (35).

The clinician should be familiar with normal prepubertal genital anatomy and hymenal configuration. **The unestrogenized vulvar vestibule is mildly erythematous and can be confused with infection. In addition, smegma in the interlabial sulci and beneath the clitoral prepuce may resemble patches of candida vulvitis. In prepubertal girls, the vulvar area is quite susceptible to chemical irritants.**

Chronic skin conditions such as lichen sclerosus, psoriasis, seborrheic dermatitis, and atopic vulvitis may occur in children (11). Lichen sclerosus, the cause of which is not well-established, has a characteristic "cigarette paper" appearance in a keyhole distribution (around the vulva and anus) **(Fig. 9-4)**. Lichen sclerosus should be treated

in pediatric patients as it is in adults; there is some evidence that the condition may regress as the child progresses through adrenarche and menarche, although this appears to be infrequent. The use of ultrapotent steroids topically has been successful in children and adolescents (36).

Labial agglutination or adhesions may occur as a result of chronic vulvar inflammation from any cause **(Fig. 9-9A)**. The treatment of labial adhesions consists of observation, if they are asymptomatic. With urinary or vulvovaginal symptoms, a brief course (2 to 6 weeks) of externally applied estrogen cream or topical steroid is appropriate (37). The area of agglutination (adhesion) will become thin as a result, and separation can usually be performed in the office with the use of a topical anesthetic (e.g., lidocaine jelly) **(Fig. 9-9B)**. Manual separation in the office without pretreatment and without anesthesia is discouraged, as this practice may be so traumatic to the child that she will not allow subsequent examination. In the absence of a previously traumatic examination, failure of medical therapy, or acute symptoms such as urinary retention, surgical separation is infrequently required (37). Treatment with a topical emollient (such as petrolatum) is indicated after lysis to prevent recurrent adhesions. Urethral prolapse may cause acute pain or bleeding, or the presence of a mass may be noted **(Fig. 9-2)**.

Vulvovaginal symptoms of any sort in a young child should prompt the consideration of possible sexual abuse. Sexually transmitted infections may occur in prepubertal children (38). Although vulvar condyloma presenting before age 2 to 3 years can be transmitted during vaginal delivery from the mother or from warts on caretakers' hands, the possibility of abuse should be considered in all children with genital warts. Condyloma in older girls may be spread in a nonsexual manner, but was classified as "indeterminant" in classification findings that may be associated with sexual abuse (39). Sensitive, but direct, questioning of the parent or caretaker and the child should be a part of the evaluation; if sexual abuse is suspected, the incident must be reported to the appropriate social services agency.

Nonsexually transmitted vulvar ulcers can occur in peripubertal and adolescent girls, often in association with systemic symptoms suggestive of a viral illness (40). Herpes simplex virus, syphilis, and Behçet disease can cause vulvar ulcers, and they may occur as a form of genital aphthosis **(Fig. 9-10)**.

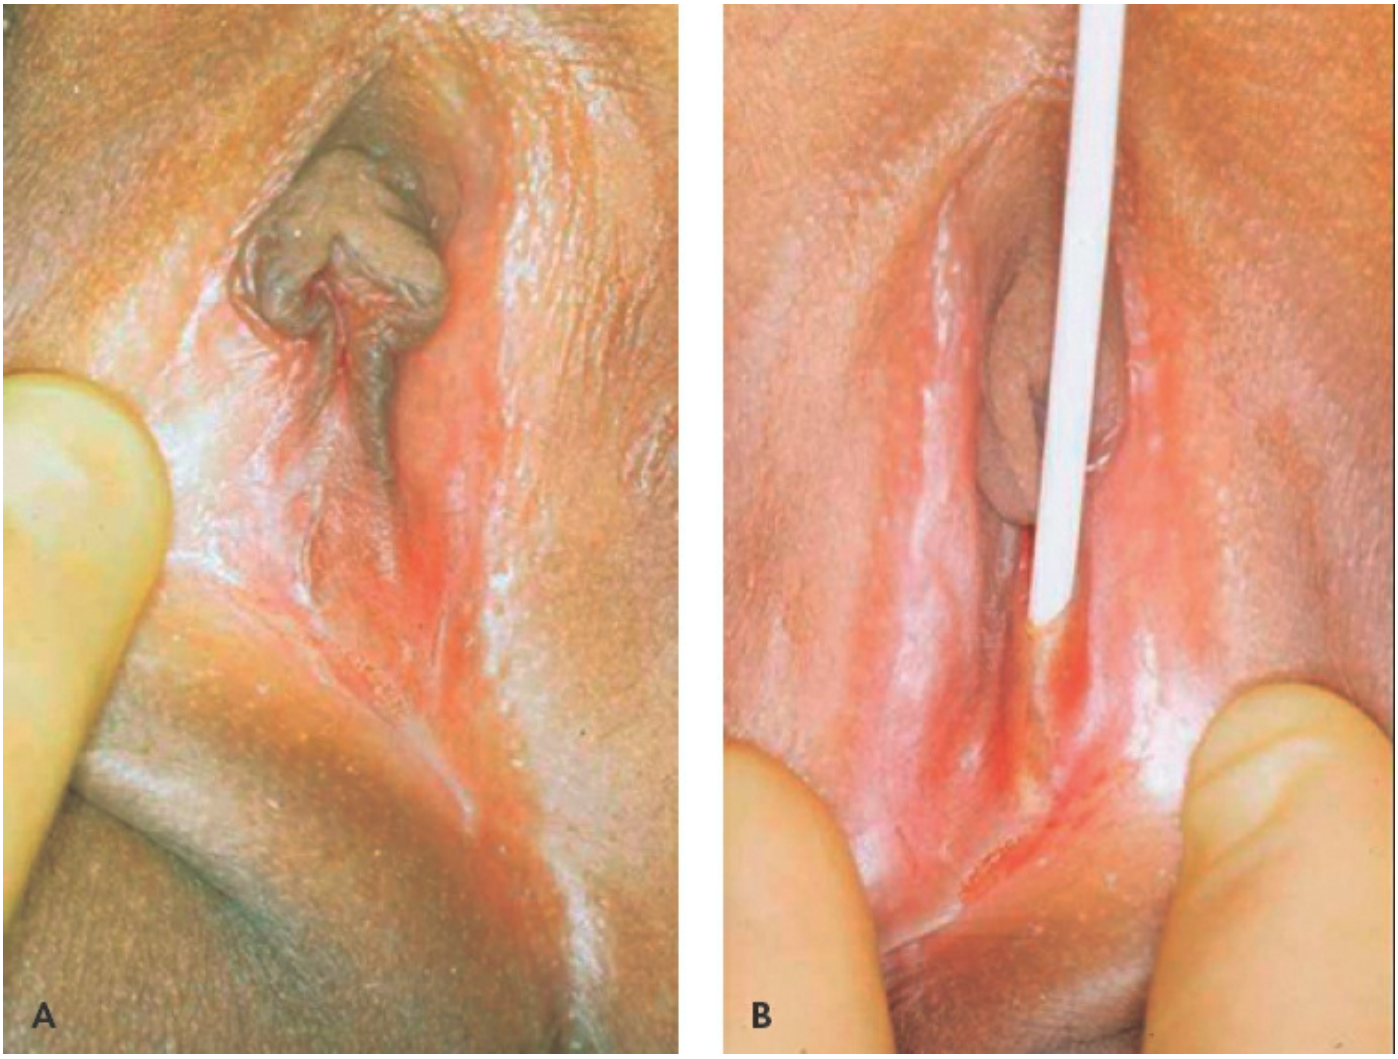

FIGURE 9-9 **A:** Labial adhesions. **B:** Cotton-tipped applicator placed inside the labial adhesions shown in **A**.

Prepubertal Vaginal Conditions

Vaginal Discharge in Prepubertal Girls

The symptom of vaginal discharge in the prepubertal age group is almost always caused by inflammation and irritation. In prepubertal girls, the primary site typically is the vulva with vaginitis following secondarily, whereas in adolescents and adults, vaginitis typically is the primary finding with vulvitis occurring secondarily. **Sexual abuse should always be considered in prepubertal children with vaginal discharge or a foreign body** (41). Although the routine use of cultures to detect STDs in girls with a history of sexual abuse was questioned, vaginal testing for gonorrhea and chlamydia should be performed in girls who have symptoms that include vaginal discharge (10). In prepubertal girls, vulvovaginitis is usually caused by multiple organisms that are present in the perineal area, although a single organism such as *Streptococcus,* or even rarely *Shigella,* may be causative (42). When the cause is related to poor perineal

hygiene, cultures often reveal a mixture of bacterial organisms. In this situation, the typical history is intermittent symptoms of irritation, itching, discharge, and odor over many months to years. Treatment should be initiated with a focus on hygiene and cleansing measures (11). A short-term (less than 4 weeks) course of treatment with topical estrogens and broad-spectrum antibiotics may be necessary. The problem is frequently recurrent. In girls who have a relatively acute onset of vaginal discharge and vulvovaginal symptoms, a single bacterial organism is more likely to be the cause of their symptoms.

Pokorny and Stormer described a technique for obtaining vaginal cultures and for performing vaginal irrigation (43). A catheter within a catheter can be fashioned using the tubing from an intravenous butterfly setup within a sterile urethral catheter. Nonbacteriostatic saline (1 to 3 mL) can be injected, aspirated, and sent for culture **(Fig. 9-11)**. Cultures taken in this manner are almost always better tolerated than cultures obtained using a cotton-tipped applicator. A larger quantity of saline can be used to irrigate the vagina while the catheter is still within the vagina. Small foreign bodies can often be flushed from the vagina in this manner. The most common foreign body is a small piece of toilet paper, although children will place other objects (toys, beans, coins) within their vaginas **(Fig. 9-5)**. **A persistent vaginal discharge after treatment or a discharge that is bloody or brown in color without other obvious external lesions should prompt vaginal irrigation or vaginoscopy to rule out a foreign body** (15).

ADOLESCENT AGE GROUP

The adolescent's experience and expression of illness and pain should be viewed within the context of her life experiences. Most adolescents have limited life experiences with problems such as pain, discomfort, or bleeding. An adolescent may state that she is experiencing the "worst pain of her life" and yet may appear to be reasonably comfortable. She may well be stating the truth about this experience, which the clinician must interpret differently from the symptoms of an adult woman who, for instance, may be in active labor. It should be remembered that an individual's response to illness and pain is to some extent a learned behavior.

FIGURE 9-10 Vulvar aphthosis in a prepubertal girl.

Adolescent Abnormal Bleeding

Normal Menses in Adolescents

[1] To assess vaginal bleeding during adolescence, it is necessary to understand the range of normal menstrual cycles (see Chapter 7). During the first 2 to 5 years after menarche, most cycles are anovulatory. Despite this, they are somewhat regular, within a range of approximately 21 to 45 days, in contrast to adult women, whose cycles typically range between 21 and 38 days (44–46). A pattern of plus or minus 10 days and a cycle length of 21 to approximately 45 days are established within 2 years of menarche **(Table 9-6)**.

The mean duration of menses is 4.7 days; 89% of cycles last 7 days. The average blood loss per cycle is 35 mL, and the major component of menstrual discharge is endometrial tissue (47). An 80 mL/cycle is used as a definition of heavy menstrual bleeding and recurrent bleeding in excess of 80 mL/cycle results in anemia, although the clinical utility of the 80 mL/cycle is question able as neither women nor clinicians can easily estimate this volume (48,49).

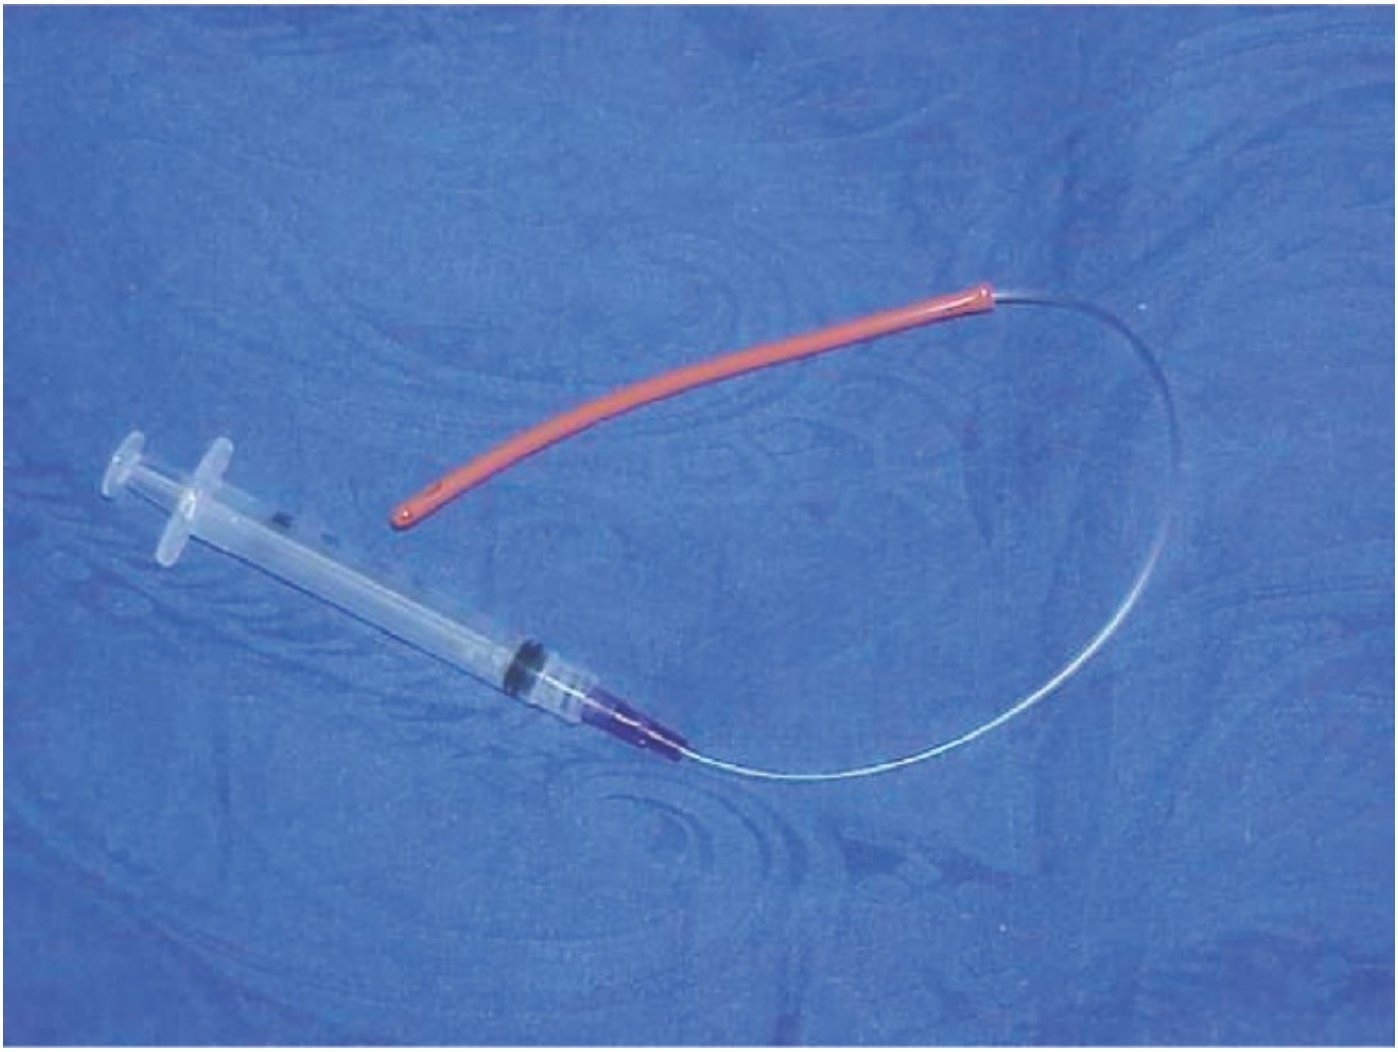

FIGURE 9-11 Catheter technique for obtaining vaginal culture and irrigation.

The common clinical practice of asking how many pads or tampons are soaked on a heavy day or per cycle can give a rough approximation of blood loss (three to five pads per day is typical). Individual variations in fastidiousness, lack of familiarity with the volume of blood loss other than one's own, and errors in estimation or recollection result in inaccuracies in estimations of menstrual volume. One study found that one-third of individuals who estimated their cycles to be moderate or light had bleeding in excess of 80 mL/cycle, whereas nearly one-half of those who described the bleeding as heavy had flow less than 80 mL/cycle (50). In addition, the amount of menstrual blood contained in each tampon or pad may vary both within brands as well as from one brand to another. However, changing a pad hourly, clots larger than "50-pence size," and requiring a change overnight are associated with a measured volume of greater than 80 mL (49).

The transition from anovulatory to ovulatory cycles during adolescence takes place during the first several years after menarche. It results from the so-called *maturation of the hypothalamic–pituitary–ovarian axis,* characterized by positive

feedback mechanisms in which a rising estrogen level triggers a surge of luteinizing hormone and ovulation. **Most adolescents have ovulatory cycles by the end of their second year of menstruation, although most cycles (even anovulatory ones) remain within a rather narrow range of approximately 21 to 42 days.**

Table 9-6 Parameters for Normal Menstrual Cycles in Adolescents

	Normal
Menstrual cycle frequency	21–45 days
Cycle variation from cycle to cycle	Less than in adults
Duration of flow	4–8 days
Volume of flow	4–80 mL

From **Hillard PJ.** Menstruation in young girls: a clinical perspective. *Obstet Gynecol* 2002;99:655–662.

Differential Diagnosis of Adolescent Abnormal Bleeding

Cycles that are longer than 42 days, bleeding that occurs more frequently than 21 days, and bleeding that lasts more than 7 days should be considered abnormal, particularly after the first 2 years from the onset of menarche. Bleeding occurring less frequently than in an interval of 90 days is abnormal, even in the first gynecologic year after menarche (44). The variability in cycle length is greater during adolescence than adulthood; thus, greater irregularity is acceptable if neither significant anemia nor hemorrhage is present. However, consideration should be given to an evaluation of possible causes of abnormal menses (particularly underlying causes of anovulation such as androgen excess syndromes or causes of oligomenorrhea such as eating disorders) for girls whose cycles are consistently outside normal ranges or whose cycles were previously regular and become irregular (45). Conditions that are associated with abnormal bleeding are listed in Table 9-7 and more fully discussed in Chapter 10.

Anovulation

Anovulatory bleeding can be too frequent, prolonged, or heavy, particularly after a long interval of amenorrhea. The physiology of this phenomenon relates to a failure of the feedback mechanism in which rising estrogen levels result in a decline in follicle-stimulating hormone (FSH) with subsequent decline of estrogen levels. In anovulatory cycles, estrogen secretion continues, without opposing progesterone, resulting in endometrial proliferation with subsequent unstable growth and incomplete shedding. The clinical result is irregular, prolonged, and heavy bleeding.

Table 9-7 Conditions Associated With Anovulation and Abnormal Bleeding

Eating disorders
Anorexia nervosa
Bulimia nervosa
Excessive physical exercise
Chronic illness
Primary ovarian insufficiency (POI) (previously termed premature ovarian failure [POF])
Alcohol and other drug abuse
Stress
Thyroid disease
Hypothyroidism
Hyperthyroidism
Diabetes mellitus
Androgen excess syndromes (e.g., polycystic ovary syndrome [PCOS])

Studies of adolescent menses show differences in rates of ovulation based on the number of months or years postmenarche. **The younger the age at menarche, the sooner regular ovulation is established.** In one study, the time from menarche until 50% of the cycles were ovulatory was 1 year for girls whose menarche occurred when they were younger than 12 years of age, 3 years for girls whose menarche occurred between 12 and 12.9 years of age, and 4.5 years for girls whose menarche occurred at 13 years of age or older (51).

Pregnancy-Related Bleeding

The possibility of pregnancy must be considered when an adolescent seeks treatment for abnormal bleeding (Table 9-8). Bleeding in pregnancy can be associated with a spontaneous abortion, ectopic pregnancy, or other pregnancy-related complications, such as a molar pregnancy. In the United States, 11% of 15-year-old adolescent girls have had sexual intercourse, as have 55% of those 18 years old (52). Issues of confidentiality for adolescent health care are critical to an adolescent's willingness to seek appropriate reproductive health care (see Chapter 1).

Table 9-8 Causes of Bleeding by Approximate Frequency and Age Group

Infancy	Prepubertal	Adolescent	Reproductive	Perimenopausal	Postmenopausal
Maternal estrogen withdrawal	Vulvovaginitis	Anovulation	Exogenous	Anovulation	Atrophy
	Vaginal foreign body	Exogenous hormone use	Pregnancy	Fibroids	Endometrial polyps
	Precocious puberty	Pregnancy	Anovulation	Cervical and endometrial polyps	Endometrial cancer
	Tumor	Coagulopathy	Fibroids	Thyroid dysfunction	Hormonal therapy
			Cervical and endometrial polyps		Other tumor—vulvar, vaginal, cervical
			Thyroid dysfunction		

Exogenous Hormones

The cause of abnormal bleeding that is experienced while an individual is taking exogenous hormones usually is very different from bleeding that occurs without hormonal manipulation (53). **Oral contraceptive use is associated with breakthrough bleeding, which occurs in as many as 30% to 40% of individuals during the first cycle of combination pill use. In addition, irregular bleeding can result from missed pills** (54,55). Strict adherence to correct and consistent pill taking is difficult for many individuals who take oral contraceptives; one study reported that only 40% of women took a pill every day (56). Other studies suggest that adolescents have an even more difficult time taking oral contraceptives than do adults. A study of urban teens reported approximately two episodes of three or more consecutive missed pills occurring during each 3-month interval (57). With this many missed pills, it is not surprising that some individuals experience irregular bleeding. The solution is to emphasize consistent pill taking; if the individual is unable to comply with daily pill use, an alternative contraceptive method may be preferable.

All forms of hormonal contraception, from combination and progestin-only minipills, to contraceptive patches, rings, intrauterine devices (IUDs), and injectable and implantable contraception, can be associated with abnormal bleeding, although studies assessing bleeding have not used uniform methodologies and thus comparisons are difficult (58). Irregular bleeding occurs frequently in users of *depomedroxyprogesterone acetate* (*DMPA*), although at the end of 1 year, more than 50% of users will be amenorrheic (59). The mechanism of bleeding associated with these hormonal methods is not well-established; an atrophic endometrium or factors related to angiogenesis may be involved, suggesting options for therapy (60,61). It should not be assumed that any bleeding occurring while an individual is using a hormonal method of contraception is caused by that method. Other local causes of bleeding, such as cervicitis or endometritis, can occur during the use of hormone therapy and may be particularly important to consider in adolescents who are at risk for STDs.

FIGURE 9-12 Uterus didelphys.

Hematologic Abnormalities

In the adolescent age group, the possibility of a hematologic cause of abnormal bleeding must be considered. One classic study reviewed all visits by adolescent patients to an emergency room with the symptom of excessive or abnormal bleeding (62). The most common coagulation abnormality diagnosed was idiopathic thrombocytopenic purpura, followed by von Willebrand disease. Subsequent studies confirmed this association, particularly with excessive bleeding at the time of menarche. Von Willebrand disease occurs in approximately 1% of women in the United States and, in its mildest form, menorrhagia may be the only symptom (63). **Adolescents who have severe menorrhagia, especially at menarche, should be screened for coagulation abnormalities, including von Willebrand disease.**

Infections

Irregular or postcoital bleeding can be associated with chlamydial cervicitis. **Adolescents have the highest rates of chlamydial infections of any age group, and sexually active teens should be screened routinely for chlamydia** (64). **Menorrhagia can be the initial sign in patients infected with sexually transmissible organisms.** Adolescents have the highest rates of PID of any age group of sexually experienced individuals (see Chapter 15).

Other Endocrine or Systemic Problems

Abnormal bleeding can be associated with thyroid dysfunction. Signs and symptoms of thyroid disease can be somewhat subtle in teens (see Chapter 35). Hepatic dysfunction should be considered because it can lead to abnormalities in clotting factor production. Hyperprolactinemia can cause amenorrhea or irregular bleeding.

Polycystic ovary syndrome (PCOS) can occur during adolescence, and manifestations of excess androgen (hirsutism, acne) should prompt evaluation, although the diagnostic criteria for PCOS during adolescence are not well-established (65). **Androgen disorders occur in about 5% to 10% of adult women, making them the most common endocrine disorders in women** (see Chapter 35). **Classic PCOS, functional ovarian hyperandrogenism, or partial late-onset congenital adrenal hyperplasia can occur in adolescence. These disorders often are overlooked, unrecognized, or untreated.** Women with even mild disorders are candidates for intervention, including lifestyle interventions to normalize weight and pharmacologic interventions to manage abnormal bleeding or hirsutism. These disorders may be a harbinger of type 2 diabetes, endometrial cancer, and cerebrovascular disease. **Acne, hirsutism, and menstrual irregularities are often dismissed as normal during adolescence but may be manifestations of hyperandrogenism** (65,66). Androgen abnormality can persist beyond adolescence. Obesity, hirsutism, and acne should be evaluated to minimize the significant psychosocial costs. Androgenic changes are partially reversible if detected early and managed appropriately. Behavioral changes in lifestyle (diet and exercise) should be strongly encouraged but are often difficult to achieve. Signs of insulin resistance (acanthosis nigricans) should be evaluated and managed appropriately (67,68).

Anatomic Causes

Obstructive or partially obstructive genital anomalies typically present during adolescence. Complex müllerian abnormalities, such as an obstructing longitudinal vaginal septum with uterus didelphys, can cause hematocolpos or hematometra **(Fig. 9-12)**. If these obstructing anomalies have or develop a small outlet, persistent dark-brownish discharge (old blood) may appear instead of or in addition to a pelvic mass. Many varieties of uterine and vaginal anomalies exist, and clinicians who have expertise with these anomalies should be involved in their management. **Figure 9-13** illustrates situations in which abnormal bleeding can result from partially obstructing septa.

Diagnosis of Adolescent Abnormal Bleeding

Examination

A careful general physical examination can reveal signs of androgen excess such as acanthosis nigricans or facial, chest or periareolar, or abdominal terminal hair growth. Because body hair is felt by many to be culturally unacceptable in women and girls,

sensitive questioning about specific hair removal techniques (bleaching, waxing, use of depilatories, shaving, plucking, threading) is warranted during an examination. A complete pelvic examination is appropriate in patients who are sexually active, are having severe pain, or may have an anatomic anomaly. Testing for gonorrhea and *Chlamydia trachomatis* infection is appropriate during a speculum examination if the patient is sexually active. Some young teens who have a history that is classic for anovulation, who deny sexual activity, and who agree to return for follow-up evaluation may be managed with a limited gynecologic examination supplemented with pelvic ultrasonography.

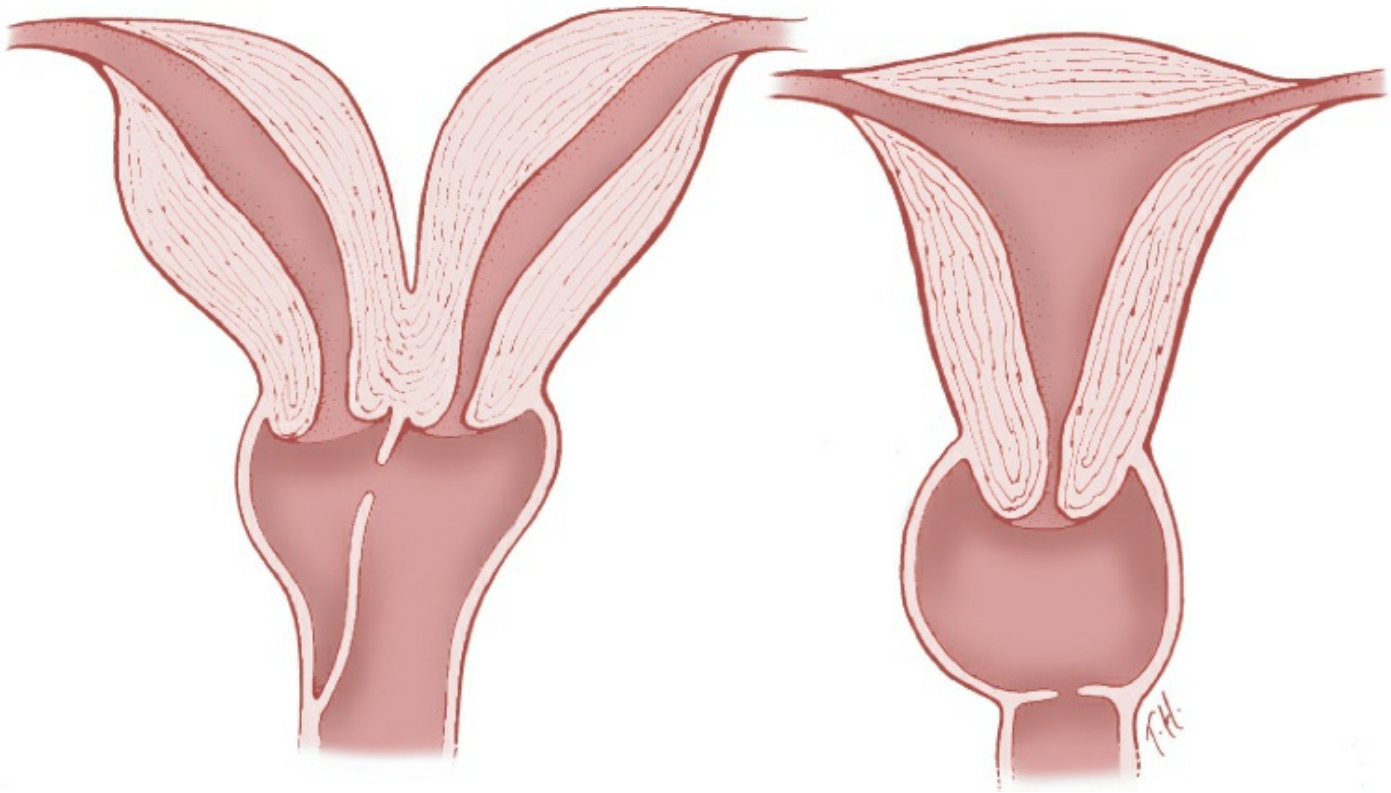

FIGURE 9-13 The types of obstructive or partially obstructive genital anomalies that can occur during adolescence.

Laboratory Testing

Any adolescent with abnormal bleeding should undergo sensitive pregnancy testing, regardless of whether she states that she has had intercourse. The medical consequences of failing to diagnose a pregnancy are too severe to risk missing the diagnosis. Complications of pregnancy should be managed accordingly. In addition to a pregnancy test, laboratory testing should include a complete blood count with platelet count and screening tests for coagulopathies and platelet dysfunction. An international expert panel made recommendations about when a gynecologist should suspect a bleeding disorder and pursue a diagnosis (Table 9-9). The consensus report recommends measurement of complete blood cell count (CBC), platelet count and

function, prothrombin time (PT), activated partial thromboplastin time (aPTT), von Willebrand factor (VWF) (measured with ristocetin cofactor activity and antigen, factor VIII), and fibrinogen to be assessed in collaboration with a hematologist (69).

Thyroid studies may be relevant. Testing for STDs may be performed as warranted on either a cervical or a urine specimen using DNA amplification techniques. Cervical cytology testing is generally not appropriate for adolescents, particularly at an emergency or urgent visit for excessive bleeding (70).

Imaging Studies

If the pregnancy test results are positive, pelvic imaging using ultrasonography may be necessary to confirm a viable intrauterine pregnancy and rule out a spontaneous abortion or ectopic pregnancy. If a pelvic mass is suspected on examination, or if the examination is inadequate (more likely to be the case in an adolescent than an older woman) and additional information is required, pelvic ultrasonography may be helpful. Although transvaginal ultrasonographic examination can be more helpful than transabdominal ultrasonography in ascertaining details of pelvic anatomy, the use of the vaginal probe may not be possible in a young girl or one who has not used tampons or had intercourse. Direct communication between the clinician and the radiologist can be helpful in identifying patients who are appropriate candidates for transvaginal ultrasonographic examination, such as those who are sexually active, rather than a blanket prohibition against transvaginal ultrasound examination in adolescents.

Table 9-9 When Should a Gynecologist Suspect a Bleeding Disorder

Heavy menstrual bleeding since menarche
Family history of bleeding disorder
Personal history of any of the following:
Epistaxis in the last year
Bruising without injury >2 cm diameter
Minor wound bleeding
Oral or gastrointestinal bleeding without anatomic lesion
Prolonged or heavy bleeding after dental extraction
Unexpected postoperative bleeding
Hemorrhage from ovarian cyst
Hemorrhage requiring blood transfusion
Postpartum hemorrhage, especially delayed >24 hrs

Failure to respond to conventional management of menorrhagia

From **James AH, Kouides PA, Abdul-Kadir R, et al.** Von Willebrand disease and other bleeding disorders in women: consensus on diagnosis and management from an international expert panel. *Am J Obstet Gynecol* 2009;201(1):12e11–12e18.

Other imaging studies are not indicated as initial testing but may be helpful in selected instances. **If a pelvic ultrasonographic examination does not lead to clarification of the anatomy when vaginal septa, uterine septa, uterine duplication, or vaginal agenesis is suspected, MRI can be helpful in delineating anatomic abnormalities** (71). This imaging technique is useful in the evaluation of uterine and vaginal developmental anomalies, although laparoscopy can still play a role in the clarification of abnormal anatomy (72). CT scanning may be helpful in detecting nongenital intra-abdominal abnormalities.

Management of Abnormal Bleeding

Management of bleeding abnormalities related to pregnancy, thyroid dysfunction, hepatic abnormalities, hematologic abnormalities, or androgen excess syndromes should be directed to treating the underlying condition. Oral contraceptives can be extremely helpful in managing androgen excess syndromes, inherited bleeding disorders, and anovulation, although an appropriate evaluation should be performed prior to initiation of hormonal contraception (67,73,74).

Treatment with *mefenamic acid* and other nonsteroidal anti-inflammatory agents (NSAIDs) results in decreased menstrual bleeding when compared with placebo (75). *Tranexamic acid,* an antifibrinolytic agent, is more effective in decreasing heavy menstrual bleeding, and was approved by the U.S. Food and Drug Administration (FDA) for this indication in late 2009. After specific diagnoses are ruled out by appropriate laboratory testing, this condition can be managed either expectantly or with hormone therapy, depending on the clinical presentation and other factors, such as the need for contraception.

Anovulation: Mild Bleeding

Adolescents who have mildly abnormal bleeding, as defined by adequate hemoglobin levels and minimal disruption of daily activities, are best managed with prospective menstrual charting, frequent reassurance, close follow-up, and supplemental iron. If the patient is bleeding heavily or for a prolonged interval, an apparent decrease in the bleeding does not necessarily mean that therapy is not required. Intermittent bleeding characterizes anovulatory bleeding and is likely to continue in the absence of therapy.

A patient who is mildly anemic will benefit from hormone therapy. If the patient is not bleeding at the time of evaluation and has no contraindications to the use of estrogen, **a**

combination low-dose oral contraceptive can be prescribed for use in the manner in which it is used for contraception. If the patient is not sexually active, she should be reevaluated after three to six cycles to determine whether she desires to continue this regimen. Parents may sometimes object to the use of oral contraceptives if their daughter is not sexually active (or if they believe her not to be or even if they would like her not to be). These objections are frequently based on misconceptions about the potential risks of the pill and can be overcome by careful explanation of the pill's role as medical therapy. Objections may be based on concerns that hormonal therapy for medical indications is likely to hasten the onset of coitarche or sexual debut, although no data support this fear. If the medication is discontinued when the young woman is not sexually active and she subsequently becomes sexually active and requires contraception, it may be difficult to explain the reinstitution of oral contraceptives to the parents. Oral contraceptives are especially appropriate for the management of abnormal bleeding in adolescents for a number of reasons:

1. **Over 40% of adolescents in the United States are sexually experienced** (52).
2. **Adolescents typically wait many months after initiating sexual activity to seek medical contraception.**
3. **At least 80% of adolescent pregnancies are unintended** (76).
4. **Approximately one-quarter of adolescent pregnancies in the United States end in abortion** (77).
5. **Approximately 11% of adolescent females in the United States give birth before age 20, although these rates vary by race/ethnicity: 8% of white teens, 16% of black teens, and 17% of Hispanic teens** (78).

Consideration should certainly be given to continuing the oral contraception use, and parents should be reassured that the medical risks are small in otherwise healthy adolescents and that there are no significant risks associated with prolonged use. Individuals may choose to continue oral contraceptives for contraception or their noncontraceptive benefits (improvement of acne, decreased dysmenorrhea, and lighter, more regular menstrual flow, protective effect for endometrial and ovarian cancer).

Sometimes, providing parents with accurate information about the safety of oral contraceptives, emphasizing that currently available oral contraceptive preparations contain lower doses of estrogens and progestins than those used in the 1960s and 1970s, and emphasizing the hormonal rather than contraceptive function may not be persuasive. In such cases, cyclic progestins are an alternative. A systematic review of the use of combination hormonal therapy versus progestins alone for the treatment of anovulatory bleeding found a paucity of evidence supporting the efficacy of one management regimen over another (79). ***Medroxyprogesterone acetate,* 5 to 10 mg/day for 10 to 13 days every 1 to 2 months, prevents excessive endometrial buildup and irregular**

shedding caused by unopposed estrogen stimulation. This therapy should be reevaluated regularly and accompanied by oral administration of iron. Eventual maturation of the hypothalamic–pituitary–ovarian axis usually will result in the establishment of regular menses unless there are underlying conditions such as hyperandrogenism.

Acute Bleeding

Moderate

The initial assessment of an adolescent with acute heavy menstrual bleeding requires assessment for hemodynamic instability and signs of hypovolemia.

Consideration should be given to the causes of acute heavy menstrual bleeding, which are the same as the causes of chronic abnormal bleeding, and which have been described by a classification system approved by the International Federation of Gynecology and Obstetrics and ACOG (80). This system describes the causes of abnormal bleeding as related or unrelated to structural abnormalities and categorized by the acronym PALM-COEIN (see Chapter 10) (81). In adolescents, structural abnormalities are much rarer than in women of older reproductive age, and thus the COEIN etiologies: **C**oagulopathy, **O**vulatory dysfunction, **E**ndometrial, **I**atrogenic, and **N**ot otherwise classified are more likely to be causative.

Patients who are bleeding acutely but in a stable condition and do not require hospital admission will typically require hormonal treatment to effectively stop anovulatory bleeding. Limited evidence and expert opinion suggest options for therapy, which in adolescents focus on medical rather than surgical therapies. Options include IV estrogen, combined oral contraceptives, and oral progestins (80). With hormonal therapy, bleeding usually stopped within a few days, and the dosing is typically tapered or stopped to allow shedding of the dyssynchronous endometrium and withdrawal bleeding. With this therapy, the patient and her parents should be given specific written and oral instructions warning them about the potential side effects of high-dose hormone therapy—nausea, breast tenderness, and breakthrough bleeding. The patient should be instructed to call with any concerns rather than discontinue the hormonal treatment, and she must understand that stopping the prescribed regimen may result in a recurrence of heavy bleeding. Both the patient and her mother should be warned to expect heavy withdrawal flow for the first period. Subsequently, the institution of combination low-dose oral contraceptive therapy, given once daily and continued for three to six cycles, allows regular withdrawal flow. If the patient is not sexually active, hormonal therapy may be discontinued after the recommended course of therapy and the menstrual cycles may be reassessed.

Emergency Management

The decision to hospitalize a patient depends on the rate of current bleeding and

the severity of any existing anemia. The actual acute blood loss may not be reflected adequately in the initial blood count but will be revealed with serial hemoglobin assessments. The cause of acute menorrhagia may be a primary coagulation disorder; thus, measurements of coagulation and hemostasis, including screening for coagulopathy, should be performed for any adolescent patient with acute menorrhagia, as noted above in the recommendations of an international panel (63). Von Willebrand disease, platelet disorders, or hematologic malignancies can cause menorrhagia. Depending on the patient's level of hemodynamic stability or compromise, a blood sample can be analyzed for type and screen. The decision to transfuse must be considered carefully, and the benefits and risks should be discussed with the adolescent and her parents. The need for transfusion is determined by hemodynamic stability.

In patients who, by exclusion, are diagnosed as having anovulatory bleeding, hormone therapy usually makes it possible to avoid surgical intervention (dilation and curettage [D&C], operative hysteroscopy, or laparoscopy). A patient who is hospitalized for severe bleeding requires aggressive management as follows:

1. **After stabilization, when appropriate laboratory assessment and an examination establish a working diagnosis of anovulation, hormonal management will usually control bleeding** (80).
2. As noted for moderate bleeding, hormonal therapy is typically effective within 12 to 24 hours.
3. **If this hormonal therapy is not effective, the patient should be reevaluated and the diagnosis should be reassessed.** The failure of hormonal management suggests that a local cause of bleeding is more likely. In this event, consideration should be given to a pelvic ultrasonographic examination to determine any anatomic causes of bleeding (such as uterine leiomyomas, endometrial polyps, or endometrial hyperplasia) and to assess the presence of intrauterine clots that may impair uterine contractility and prolong the bleeding episode. Although anatomic causes of heavy menstrual bleeding are rare in adolescents, they become increasingly common in women of reproductive age (see Chapter 10).
4. **If intrauterine clots are detected, consideration may be given to evacuation of the clots (suction curettage or D&C); alternatively, uterotonics such as misoprostol may be helpful. An intrauterine tamponade with a 26F Foley catheter and 30 mL balloon may be required.** Although a D&C will provide effective immediate control of the bleeding, it is unusual to use this approach in adolescents.

More drastic forms of treatment other than D&C (such as ablation of the

endometrium by laser or cryotherapy) are considered inappropriate for adolescents because of concerns about future fertility.

If intravenous or oral administration of hormonal therapy controls the bleeding, a tapering regimen of hormonal therapy may be given (80). **Subsequent hormonal therapy with combined oral contraceptives, the levonorgestrel intrauterine system (IUS), progestin therapy, and nonhormonal therapies are useful. Nonhormonal antifibrinolytic drugs, such as tranexamic acid, have been shown to reduce chronic abnormal bleeding by 30% to 55%** (80). **Tranexamic acid has been used for the treatment of acute heavy bleeding.**

In general, the prognosis for regular ovulatory cycles and subsequent normal fertility in young women who experience an episode of abnormal bleeding is good, particularly for patients who develop abnormal bleeding as a result of anovulation within the first years after menarche and in whom there are no signs of other specific conditions. Some girls, including those in whom there is an underlying medical cause, such as PCOS, will continue to have abnormal bleeding into middle and late adolescence and adulthood and will benefit from the ongoing use of hormonal therapy including combined oral contraceptives to manage hirsutism, acne, and irregular periods, or menstrual suppression using the levonorgestrel IUS, or IM or oral progestins. Individuals with coagulopathies may benefit from ongoing oral contraceptive use, use of *tranexamic acid,* or intranasal *desmopressin*.

A levonorgestrel-releasing IUD can be effective in managing heavy bleeding, with reductions of heavy bleeding by up to 90%, and can be appropriate for adolescent use (82–84). **Because IUD insertion is viewed as invasive by adolescents, particularly young teens, adjuncts to insertion, such as the use of local anesthesia may be appropriate** (85). The *levonorgestrel* IUD is approved by the FDA for treatment of heavy menstrual bleeding in women requiring contraception and is recommended as first-line medical therapy for this group of women (86).

Long-Term Menstrual Suppression

For patients with underlying medical conditions, such as coagulopathies, a malignancy requiring chemotherapy, or developmental disabilities, long-term therapeutic amenorrhea with menstrual suppression using the following regimens may be necessary or helpful (87,88):

1. Progestins such as oral *norethindrone, norethindrone acetate,* or *medroxyprogesterone acetate* on a continuous daily basis.
2. Continuous (noncyclic) combination regimens of oral estrogen and progestins (birth control pills) or other forms of combination estrogen/progestins (transdermal patch, vaginal ring) that do not include a withdrawal bleeding–placebo week.
3. Depot formulations of progestins (*DMPA*), with or without concurrent estrogens.

4. Gonadotropin-releasing hormone (GnRH) analogs with or without hormonal add-back therapy.
5. *Levonorgestrel* IUS.

The choice of regimen depends on the presence of any contraindications (such as active liver disease precluding the use of estrogens) and the clinician's experience. **Although the goal of these long-term suppressive therapies is amenorrhea, all of these regimens may be accompanied by breakthrough bleeding, especially in the initial months of use** (87). At 1 year, rates of amenorrhea approach 60% with extended cycle combination oral contraceptives, 50% with *DMPA,* and 50% with the *levonorgestrel* IUS (59,88–90). Because *DMPA* and GnRH analogs are associated with disadvantageous effects on bone mineral density, the potential risks must be weighed against their medical benefits. Regular follow-up visits and continued patient encouragement are required with all of these options. Episodes of spotting and breakthrough bleeding that do not result in a lowered hemoglobin level may be managed expectantly. When breakthrough bleeding affects the hemoglobin level, it should be evaluated with respect to the underlying disease. For example, in a patient with underlying platelet dysfunction, breakthrough bleeding may reflect a lowered platelet count. Bleeding in a patient with hepatic disease may reflect worsening hepatic function. The U.S. Selected Practice Recommendations from the Centers for Disease Control summarize the evidence for management of breakthrough bleeding during hormonal contraceptive use (61).

Adolescent Pelvic Masses

Presentation

Adolescents with pelvic masses may be asymptomatic or may have chronic or acute symptoms. An ovarian mass may be discovered incidentally when an ultrasonographic examination is performed to evaluate the urinary system or when imaging is performed to evaluate pelvic pain. The mere presence of a mass on imaging studies does not always indicate that the mass is the cause of pelvic pain. **A "ruptured ovarian cyst" is a classic diagnosis when an adolescent presents with pelvic pain, even if ultrasonography findings suggest only a simple cystic follicle and a physiologic amount of pelvic fluid that are unlikely to cause pain.** An adnexal mass is not always of ovarian origin. The algorithm in **Figure 9-14** illustrates a framework for thinking about adnexal masses in adolescents. Alternatively, ovarian masses can cause severe, acute, or intermittent symptoms caused by torsion, intraperitoneal rupture, or bleeding into the ovarian tissue **(Fig. 9-15)**. These conditions can represent a true surgical emergency or urgency, and their diagnoses can be challenging. The pressure of an enlarging ovarian mass can cause bowel-related symptoms such as constipation, vague

discomfort, and early satiety; urinary frequency; or even ureteral or bladder neck obstruction.

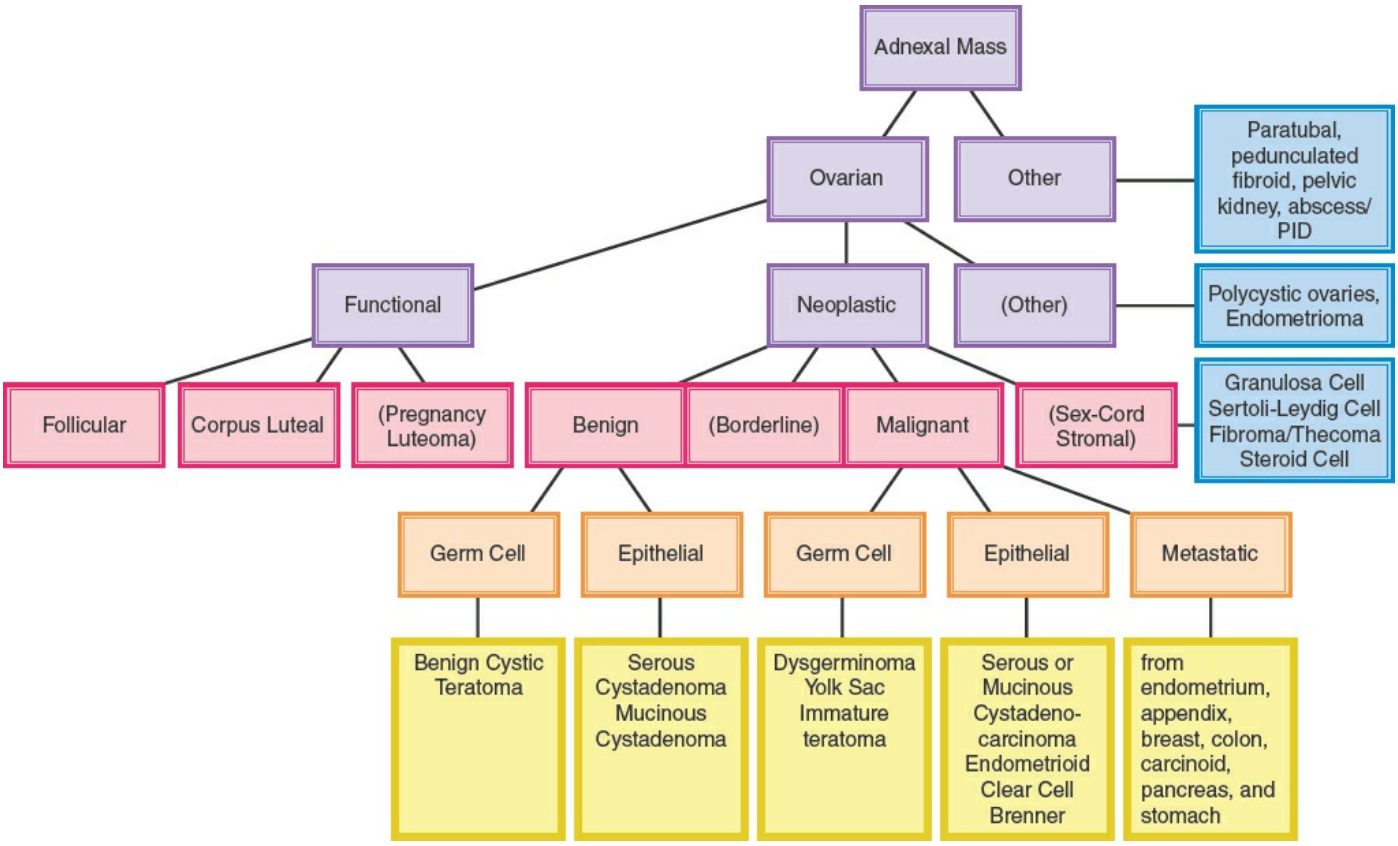

FIGURE 9-14 Algorithm for adnexal masses in adolescents—"dichotomies" of ovarian and other/functional (follicular and corpus luteum cysts) and neoplastic ovarian masses (benign and malignant [germ cell and epithelial]).

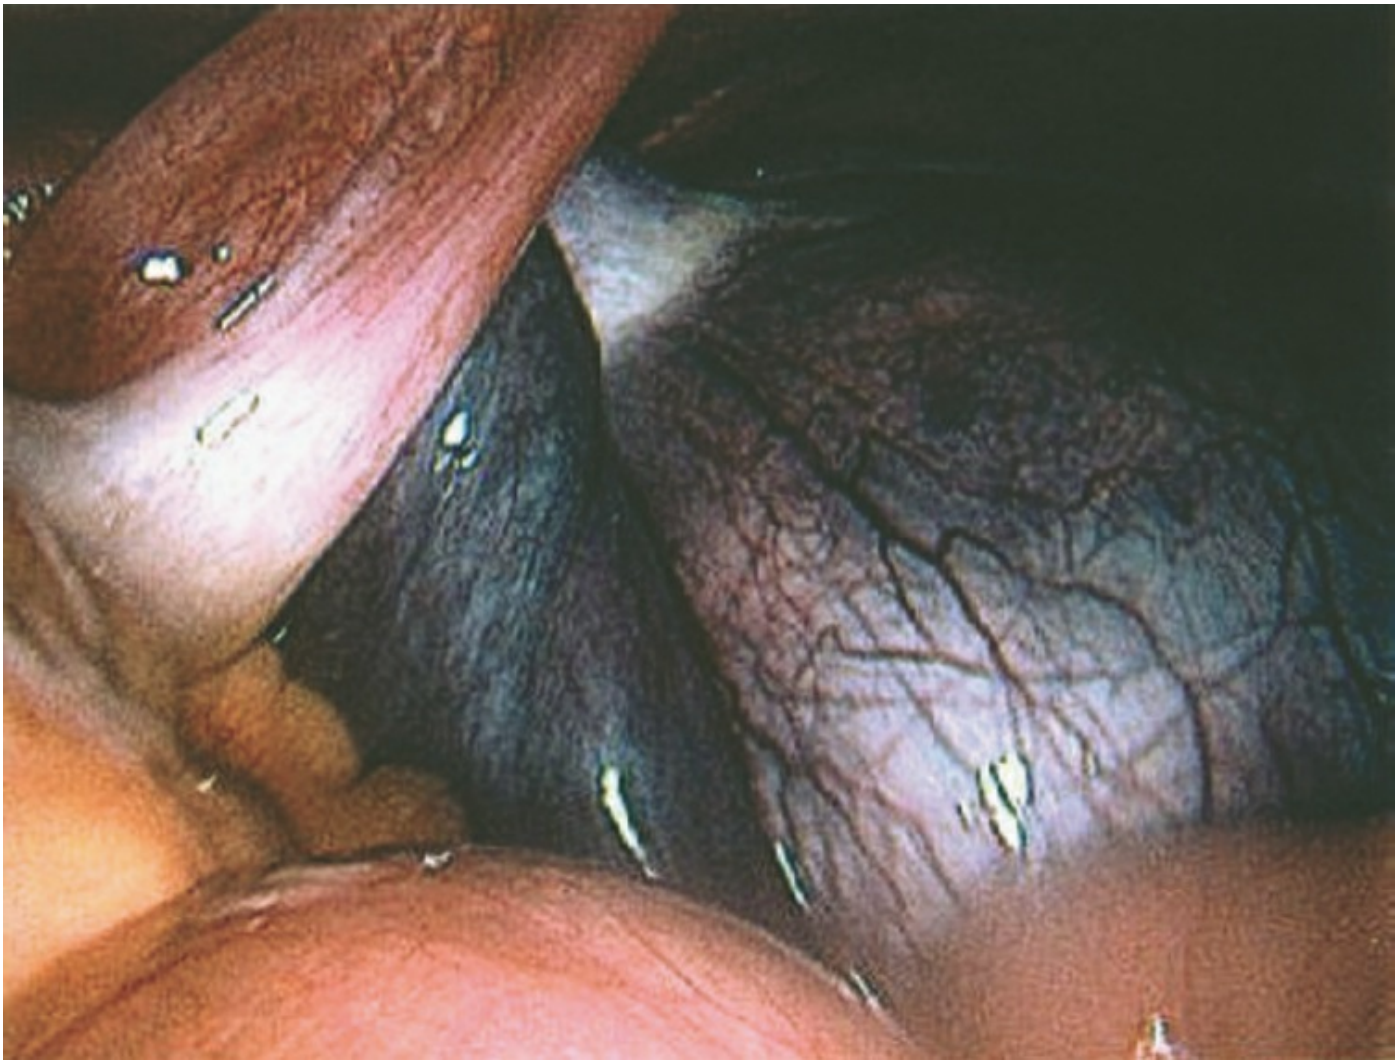

FIGURE 9-15 Adnexal mass with torsion.

Diagnosis

The history and pelvic examination are critical in the diagnosis of a pelvic mass. Considerations in adolescents include the anxiety associated with a first pelvic examination, and issues of confidentiality related to questions about sexual activity. Techniques for history taking and the performance of the first examination are discussed in Chapter 1.

Laboratory studies should always include a pregnancy test (regardless of stated sexual activity), and a complete blood count may be helpful in diagnosing inflammatory masses. Tumor markers, including α-fetoprotein and human chorionic gonadotropin (hCG), may be elaborated by germ cell tumors and can be useful in preoperative diagnosis and follow-up (see Chapter 39).

As in all other age groups, the primary diagnostic technique for evaluating pelvic masses in adolescents is ultrasonography. Although transvaginal ultrasonographic examinations may provide more detail than transabdominal ultrasonography,

particularly with inflammatory masses, a transvaginal examination may not be well-tolerated by adolescents (91,110). Ultrasonography usually is the most helpful imaging technique for assessing ovarian masses. **For cases in which the suspected diagnosis is appendicitis or another nongynecologic condition, or if the results of the ultrasonographic examination are inconclusive, CT or MRI may be helpful.** An accurate preoperative assessment of anatomy is critical, particularly in cases of uterovaginal malformations. MRI can be useful for evaluating this group of rare anomalies (88). Adolescents who present with abdominal pain should be evaluated with some type of imaging procedure because an unexpected finding of a complex uterine or vaginal anomaly requires careful surgical planning and management.

Differential Diagnosis of Adolescent Pelvic Masses

Ovarian Masses in Adolescents

Many studies of ovarian tumors in the pediatric and adolescent age group do not distinguish between prepubertal or premenarchal girls and menarchal adolescents. The findings of some reports are based on the age group, although this is less helpful than a distinction by pubertal development. In evaluating a pelvic or abdominal mass, the clinician must take into consideration the patient's pubertal status because the likelihood of functional masses increases after menarche (Table 9-4). The risk of malignant neoplasms is lower among adolescents than among younger children. Germ cell tumors are the most common tumors of the first decade of life but occur less frequently during adolescence (see Chapter 39). Mature cystic teratoma is the most frequent neoplastic tumor of children and adolescents, accounting for more than one-half of ovarian neoplasms in women younger than 20 years of age (92). Epithelial neoplasms occur with increasing frequency beyond adolescence.

It is well-established that neoplasia can arise in dysgenetic gonads. The risk of malignant tumors in dysgenetic gonads of patients with a Y chromosome depends on the nature of the DSD, the presence of the gonadoblastoma region of the Y chromosome, and other factors—both established and as yet unknown (93). A number of genes involved in gonadal differentiation were described. Recent perspectives suggest that the estimation of individual risk of malignancy should be assessed, and that this may permit a more conservative approach to gonadectomy or its timing (94,95). A multidisciplinary approach to diagnosis of disorders of sex development with attention to biologic, genetic, and psychological factors is advocated (96). **Functional ovarian cysts occur frequently in adolescence.** They may be an incidental finding on examination or may be associated with pain caused by torsion, leakage, or rupture. Paratubal cysts represent embryologic remnants that may be confused with an ovarian mass; they are typically asymptomatic, but can be associated with adnexal torsion **(Fig. 9-15)**. Adnexal or ovarian torsion is a challenging diagnosis to make in prepubertal girls or adolescents; torsion of a mass is more likely to occur than torsion of normal adnexa, although this can

occur. Doppler ultrasound examination may not predict the presence of torsion, although discrepancy in ovarian volume and large volume of the torsed adnexa may be helpful in making the diagnosis (91,97). Management should consist of detorsion rather than oophorectomy, even if the mass appears to have no blood flow, as recovery of ovarian function is likely (98).

Endometriosis is less common during adolescence than in adulthood, although it can occur during adolescence. Of adolescents not responding to conventional medical management of pelvic pain and dysmenorrhea, up to 70% may be found to have endometriosis at the time of laparoscopy (99). Although endometriosis can occur in young women with obstructive genital anomalies (presumably as a result of retrograde menstruation), most adolescents with endometriosis do not have associated obstructive anomalies. In young women, endometriosis may have an atypical appearance characterized by nonpigmented or vesicular lesions, peritoneal windows, and puckering (99).

Uterine Masses in Adolescents

Other causes of pelvic masses, such as uterine abnormalities, are rare in adolescence. Uterine leiomyomas are not often seen in this age group. Obstructive uterovaginal anomalies occur during adolescence, at the time of menarche, or shortly thereafter. Frequently, the correct diagnosis either is not suspected or is delayed (100). A wide range of anomalies can occur, from imperforate hymen to transverse vaginal septa, from vaginal agenesis with a normal uterus and functional endometrium to vaginal duplications with obstructing longitudinal septa, and obstructed uterine horns **(Fig. 9-13)**. Patients may seek treatment for cyclic pain, amenorrhea, vaginal discharge, or an abdominal, pelvic, or vaginal mass. A hematocolpos, hematometra, or both, frequently will be present, and the resulting mass can be quite large (101).

Inflammatory Masses in Adolescents

Adolescents comprise 20% of all diagnoses of PID in the United States (102). An adolescent who has pelvic pain may have an inflammatory mass. Such masses may consist of a tubo-ovarian complex (a mass of matted bowel, tube, and ovary), tubo-ovarian abscess (a mass consisting primarily of an abscess cavity within an anatomically defined structure such as the ovary), pyosalpinx, or, chronically, hydrosalpinx.

The diagnosis of PID is primarily a clinical one based on the presence of lower abdominal, pelvic, and adnexal tenderness; cervical motion tenderness; a mucopurulent discharge; and elevated temperature, white blood cell count, or sedimentation rate (see Chapter 15). The US Centers for Disease Control recommends that clinicians should maintain a low threshold for making this diagnosis, given the potential risks of missing the diagnosis (64). The risk of PID is clearly associated with that of acquiring STDs,

and methods of contraception may either decrease the risk (male latex condoms) or increase it (the IUD in the 3-week interval immediately after insertion) (103,104).

Pregnancy

In adolescents, pregnancy should always be considered as a cause of a pelvic mass. In the United States, more than 40% of adolescent women have experienced sexual intercourse (52). Most pregnancies in adolescents are unintended, and the younger the adolescent, the greater the likelihood that a pregnancy is unintended. Adolescents may be more likely than adults to deny the possibility of pregnancy because of wishful thinking, anxiety about discovery by parents or peers, or unfamiliarity with menstrual cycles and information about fertility. Ectopic pregnancies may cause pelvic pain and an adnexal mass. With the availability of quantitative measurements of β-hCG, more ectopic pregnancies are being discovered before rupture, allowing conservative management with laparoscopic surgery or medical therapy (see Chapter 32). The risk of ectopic pregnancy varies by the method of contraception; users of no contraception have the highest risk, whereas oral contraceptive users have the lowest risk; while levonorgestrel IUSs have a very low risk of failure and pregnancy; if a pregnancy occurs, there is a higher risk of ectopic than if no contraception were used (105). As with older patients, paraovarian cysts and nongynecologic masses can appear as a pelvic or abdominal mass in adolescents **(Fig. 9-16)**.

Management of Pelvic Masses in Adolescents

The management of masses in adolescents depends on the suspected diagnosis and the initial symptom. **Figure 9-8** outlines a plan of management for pelvic masses in adolescents. **Asymptomatic unilocular cystic masses are best managed conservatively because the likelihood of malignancy is low. If surgical management is required based on symptoms or uncertainty of diagnosis, attention should be directed to minimizing the risks of subsequent infertility resulting from pelvic adhesions. Every effort should be made to conserve the ovarian tissue. In the presence of a malignant unilateral ovarian mass, management may include unilateral oophorectomy rather than more radical surgery, even if the ovarian tumor metastasized** (see Chapter 39). **Analysis of frozen sections may not be reliable. In general, conservative surgery is appropriate; further surgery can be performed, if necessary, after an adequate histologic evaluation of the ovarian tumor.**

When symptoms persist in a patient with the clinical diagnosis of PID or tubo-ovarian abscess, laparoscopy should be considered to confirm the diagnosis. A clinical diagnosis may be incorrect in as many as one-third of patients. The surgical management of inflammatory masses is rarely necessary in adolescents, except to treat the rupture of tubo-ovarian abscess or failure of medical management with

broad-spectrum antibiotics (see Chapter 15). Some surgeons advocated laparoscopy to perform irrigation, lysis of adhesions, drainage of unilateral or bilateral pyosalpinx or tubo-ovarian abscess, or extirpation of significant disease. If surgical management is required because of failed medical therapy, conservative, unilateral adnexectomy usually can be performed in these situations, rather than a pelvic clean-out, thereby maintaining reproductive potential. Percutaneous drainage, transvaginal ultrasonographic drainage, and laparoscopic management of tubo-ovarian abscesses are being done more often, although evidence supporting this approach is sparse (106). As with the laparoscopic management of ovarian masses, the clinician's skill and experience with this procedure are critical, and prospective studies on its effectiveness are lacking. Laparoscopic management is associated with a risk of major complications, including bowel obstruction and bowel or vessel injury.

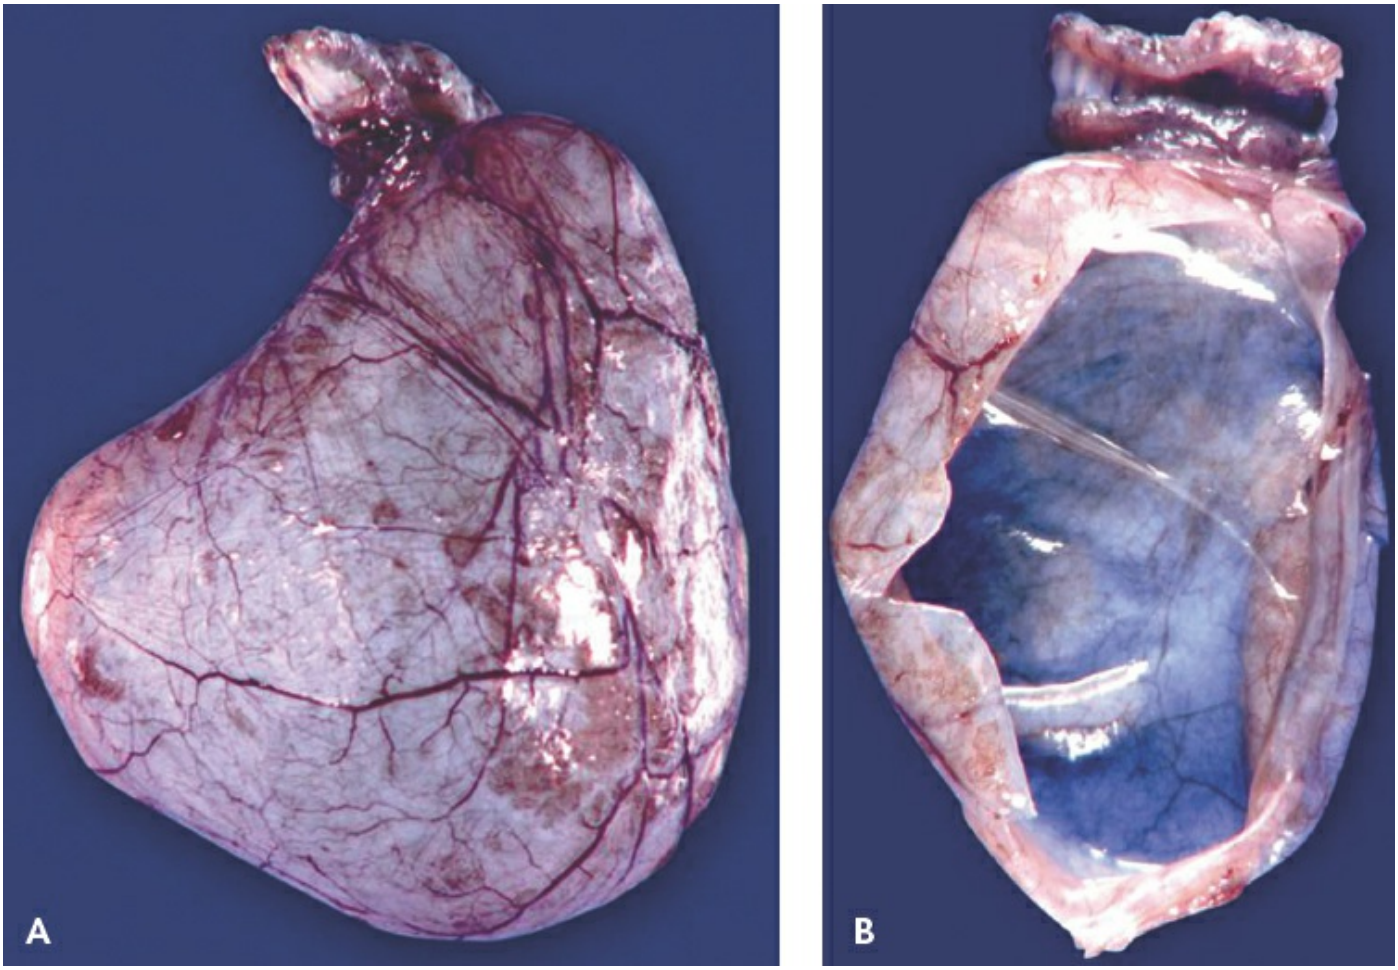

FIGURE 9-16 **A:** Paratubal cyst. **B:** Paratubal cyst, incised.

Adolescent Vulvar Conditions

Disorders of sex development may cause genital ambiguity, typically noted at birth, although virilization may occur at puberty (32). **Adolescents with gonadal**

dysgenesis or androgen insensitivity may have abnormal pubertal development and primary amenorrhea (see Chapters 8, 34, and 35). Various developmental anomalies—vaginal agenesis, imperforate hymen, transverse and longitudinal vaginal septa, vaginal and uterine duplications, hymenal bands, and septa—most frequently are diagnosed in early adolescents with amenorrhea (for the obstructing abnormalities) or with concerns such as inability to use tampons (for hymenal and vaginal bands and septa). These developmental abnormalities must be evaluated carefully to determine both external and internal anatomy.

A tight hymenal ring may be discovered when the patient seeks care because of concerns about the inability to use tampons or have intercourse. Both manual dilation and small relaxing incisions at 6 and 8 o'clock in the hymenal ring can be effective. This procedure can sometimes be done in the office using local anesthesia but may require conduction or general anesthesia in the operating room. Hymenal bands are not rare and lead to difficulty in using tampons; they often can be incised in the office using local anesthetic **(Fig. 9-17)**. "Hypertrophy" of the labia minora may be considered a variant of normal, and reassurance rather than a cosmetic surgical reduction is usually appropriate as the primary therapy (107). Surgical management has been described, although the procedure could be considered to be esthetic rather than medically mandated, and rarely indicated in adolescents (108). Genital ulcerations may occur in girls with leukemia or other cancers requiring chemotherapy. Vulvar ulcerations in the absence of sexual activity or infectious etiology are described as vulvar aphthosis **(Fig. 9-10)** (40). The possibility of sexual abuse, incest, or involuntary intercourse should be considered for young adolescents with vulvovaginal symptoms, STDs, or pregnancy.

The presence of vulvar symptoms such as itching or burning may prompt a patient to seek care; however, this anatomic site is not one that is easily inspected by the patient. Thus, vulvar lesions that were not noticed by the patient may be found on examination. **Vulvar self-examination should be encouraged and could potentially result in the earlier diagnosis of vulvar lesions such as melanoma.** Adolescents presenting with vulvar itching may have lichen sclerosus; this condition can be relatively asymptomatic, even when an examination reveals loss of anatomic structures and scarring **(Fig. 9-4)** (36).

Adolescents and adults often incorrectly self-diagnose vulvovaginal candidiasis; in one study, only one-third of women with self-diagnosed yeast vaginitis were found to have this infection (see Chapter 15) (109). A clinical examination and appropriate testing can be performed even on young adolescents using a clinician or self-obtained cotton swab to obtain vaginal secretions for pH testing and microscopic examination **(Fig. 9-18)**.

Vulvar condyloma is an extremely common cause of vulvar lesions in adolescents (see Chapter 15). Genital warts can affect the vulva, perineum, and perianal skin, and

the vagina, urethra, and anus (Fig. 9-19). Condyloma in adolescents typically is sexually transmitted. They may be asymptomatic or cause symptoms of itching, irritation, or bleeding. Symptomatic, enlarging, or extensive vulvar condyloma can be managed with topical medication applied by the patient or clinician. The choice of treatment should be guided by patient preference, available resources, and the clinician's experience; no one treatment is superior to the others (64). The recent availability of an HPV vaccine that includes HPV types 6 and 11 has had a beneficial impact on the incidence of vulvar condyloma and potentially on HPV-related vulvar intraepithelial neoplasia (VIN).

FIGURE 9-17 Hymenal band.

FIGURE 9-18 Candidal vulvitis.

FIGURE 9-19 Extensive vulvar condyloma.

Adolescent Vaginal Conditions

Vulvovaginal symptoms in adolescents may be caused by a variety of conditions, ranging from vulvar lichen sclerosus to UTI to *C. trachomatis* to non–STD-related vaginitis. Urinary or vaginal symptoms do not differentiate well between UTIs and vaginitis. Adolescent girls who are screened for both *C. trachomatis* and UTI have high rates of concurrent disease (110). Because clinical diagnosis based on symptoms is imprecise, female adolescents with vaginal or urinary symptoms should be tested for *C. trachomatis* and UTI. Testing with DNA-based procedures may be performed on samples obtained from the cervix, from swabs of vaginal secretions (either clinician or patient obtained), and from urine specimens. Testing that does not involve a speculum examination may be particularly helpful for adolescents; a rigorous review concluded that noninvasive chlamydia testing was comparable to cervical or urethral screening, although this was not the case with testing for gonorrhea (111).

Discharge is one of the most common vaginal symptoms. Conditions ranging from

vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis may cause vaginal discharge in adolescents. Infectious vaginal conditions are described in more detail in Chapter 15. The risks of self-diagnosis of vaginal discharge in adolescents may be greater than in adult women, as infection with STDs—including *Neisseria gonorrhoeae, Trichomonas vaginalis, C. trachomatis,* herpes simplex, and *Condyloma accuminata*—are common in adolescents and may be less likely recognized.

Use of tampons is associated with microscopic and macroscopic ulcerations. Healing of the macroscopic ulcerations occurs within several weeks without specific therapy if tampon use is suspended. A follow-up examination to demonstrate healing is appropriate, with biopsy of any persistent ulceration to rule out other lesions.

Toxic shock syndrome (TSS) is associated with tampon use and vaginal exotoxins produced by *Staphylococcus aureus*. This syndrome consists of fever, hypotension, a diffuse erythroderma with desquamation of the palms and soles, plus involvement of at least three major organ systems (112). Vaginal involvement includes mucous membrane inflammation. The frequency of TSS appears to be declining, and an increasing percentage of cases are not associated with menses. Approximately one-half of all cases of TSS are menstrual related (113). Epidemiologic studies suggest that adolescents are at greater risk of menstrual TSS than older women; however, this finding does not appear to be explained by differences in the detection of antibodies to the TSST-1 toxin-producing strain of *S. aureus* or in *S. aureus* vaginal colonization rates (114).

Abscesses of Bartholin and Skene glands are related to both aerobic and anaerobic organisms, with mixed infections accounting for approximately 60% of these and other vulvar and labial abscesses, although the possibility of methicillin-resistant *S. aureus* (MRSA) infections must be considered (115). Therapy consists of surgical drainage, with use of antibiotics as a secondary measure. In younger adolescents, incision and drainage may require general anesthesia.

KEY POINTS

1 The causes of abnormal bleeding vary by age, with anovulatory bleeding most likely in adolescents and perimenopausal women.

2 Anatomic causes of abnormal bleeding including endometrial polyps and leiomyoma occur more frequently in women of reproductive age than in women in other age groups

3 Pelvic masses in adolescents and women of reproductive age are most commonly functional or benign neoplastic ovarian masses, whereas the risks of malignant ovarian tumors increase with age.

4 Although pelvic ultrasonography is an excellent technique for imaging pelvic masses and ultrasonographic characteristics may suggest reassuring characteristics of an ovarian mass, the possibility of malignancy must be kept in mind.

5 Most uterine leiomyomas are asymptomatic, although bleeding, pressure symptoms, or pain may necessitate medical or surgical management.

Benign gynecologic conditions can present with signs and symptoms that vary by age. In this chapter, the most likely causes of specific signs and symptoms, diagnosis, and management are described for reproductive age and postmenopausal women. **Common**

gynecologic problems include those that cause pain and bleeding, such as pelvic masses (which may be symptomatic or asymptomatic), and vulvar and vaginal symptoms. Benign conditions of the female genital tract include anatomic lesions of the uterine corpus and cervix, ovaries, fallopian tubes, vagina, and vulva. A classification of benign lesions of the vulva, vagina, and cervix appears in Table 10-1. Leiomyoma, polyps, and hyperplasia are the most common benign conditions of the uterus in adult women. Benign uterine leiomyoma (uterine fibroids) are presented in Chapter 11. Benign tumors of the ovaries are listed in Table 10-2. Malignant diseases are presented in Chapters 37 to 42. Pediatric and adolescent conditions are discussed in Chapter 9.

REPRODUCTIVE AGE GROUP

Abnormal Bleeding

Normal Menses

After adolescence, menstrual cycles generally conform to a cycle length of 21 to 35 days, with the duration of menstrual flow fewer than 7 days (1). **[1] As a woman approaches menopause, the cycle length becomes more irregular because fewer cycles are ovulatory (1,2). The most frequent cause of irregular bleeding in the reproductive age group is hormonal, although other causes such as pregnancy-related bleeding (spontaneous abortion, ectopic pregnancy) should always be considered (Table 10-3).** A variety of imprecise terms such as menorrhagia or menometrorrhagia have been used to describe abnormal uterine bleeding (AUB); it is strongly recommended that these confusing terms be abandoned in favor of simple designations of menstrual cycles, describing cycle regularity, frequency, duration, and heaviness of flow (Table 10-4) (3,4). The International Federation of Gynecology and Obstetrics (FIGO) and the American College of Obstetricians and Gynecologists (ACOG) have recommended that systematized nomenclature, the PALM-COEIN acronym, be used to describe abnormal menses (Table 10-5). **The term dysfunctional uterine bleeding (DUB) should no longer be used** (3–6).

Prospective charting of bleeding can be helpful in characterizing abnormal bleeding. **The mean duration of menses is 4.7 days; 89% of cycles last 7 days or longer. The average blood loss per cycle is 35 mL** (6). **Menses comprises a suspension of blood- and tissue-derived solids within a mixture of serum and cervicovaginal fluid; the blood content of menses varies over the days of bleeding, but on average is close to 50%** (7). Heavy menstrual bleeding is defined as greater than 80 mL per day, which will result in anemia if recurrent (8).

Pregnancy-Related Bleeding

Pregnancy should always be excluded in women of reproductive age presenting with AUB.

Table 10-3 Causes of Bleeding by Approximate Frequency and Age Group

Infancy	Prepubertal	Adolescent	Reproductive	Perimenopausal	Postmenopausal
Maternal estrogen withdrawal	Vulvovaginitis	Anovulation	Exogenous	Anovulation	Atrophy
	Vaginal foreign body	Exogenous hormone use	Pregnancy	Fibroids	Endometrial polyps
	Precocious puberty	Pregnancy	Anovulation	Cervical and endometrial polyps	Endometrial cancer
	Tumor	Coagulopathy	Fibroids	Thyroid dysfunction	Hormonal therapy
			Cervical and endometrial polyps		Other tumor—vulvar, vaginal, cervical
			Thyroid dysfunction		

Spontaneous abortion can be associated with excessive or prolonged bleeding. A woman may be unaware that she conceived and may seek care because of abnormal bleeding. In the United States, nearly half of pregnancies are unintended. These women may be at particular risk for bleeding related to an unsuspected pregnancy. About one-half of unintended pregnancies result from nonuse of contraception; the other one-half result from contraceptive failures (9). [1] **Unintended pregnancies are most likely to occur among adolescents and women older than 40 years of age** (see Chapter 14). If an ectopic pregnancy is ruled out, the management of spontaneous abortion may include either observation, if the bleeding is not excessive; medical or pharmacologic uterine evacuation (with *misoprostol*); or surgical management with suction curettage or dilation and curettage (D&C), depending on the clinician's judgment and the patient's preference (10).

Differential Diagnosis of Abnormal Bleeding

Structural causes of AUB include the PALM in PALM-COEIN (Polyps, Adenomyosis, Leiomyoma, Malignancy/Hyperplasia). [2] **Anatomic causes of abnormal bleeding occur more frequently in women of reproductive age than in women in other age groups.** [5] **Uterine leiomyomas and endometrial polyps are common conditions that most often are asymptomatic; however, they remain important causes of abnormal bleeding** (11).

Polyps, AUB-P

[2] **Endometrial polyps are a cause of intermenstrual bleeding, heavy menstrual bleeding, irregular bleeding, and postmenopausal bleeding. They are associated with the use of *tamoxifen* and infertility, and can cause dysmenorrhea. As with leiomyomas, most endometrial polyps are asymptomatic.** [2] The incidence of

endometrial polyps increases with age throughout the reproductive years (12). The diagnosis may be suspected on the basis of endometrial thickening on transvaginal pelvic ultrasound, and vascular patterns of feeder blood vessels may aid in distinguishing endometrial polyps from intracavity fibroids and from endometrial malignancy (13–15). Confirmation of a polyp requires visualization with hysteroscopy, sonohysterography, or the microscopic assessment of tissue obtained by a biopsy done in the office or with a D&C. Whether and when to recommend removal is not well established, particularly if a polyp is asymptomatic and is found incidentally. The effect of polyps on fertility is not clear, though there is evidence that removal may improve rates of pregnancy in infertile patients (16). One study of randomly selected Danish women using transvaginal ultrasound and sonohysterography found polyps in 5.8% of asymptomatic premenopausal women and 11.8% of asymptomatic postmenopausal women. In this study, abnormal bleeding was present in 38% of those without polyps versus 13% with polyps (15). Endometrial polyps can regress spontaneously, although it is not clear how frequently this occurs. In one study of asymptomatic women, the 1-year regression rate was 27% (17). Smaller polyps are more likely to resolve, and larger polyps may be more likely to result in abnormal bleeding (18). Whereas polyps may resolve spontaneously over time, a clinically important question is whether they are likely to undergo malignant transformation. Because even asymptomatic polyps are usually removed at the time of identification, this question is difficult to answer. **[2]** The chance of malignancy or premalignant changes in endometrial polyps appears to be quite low in premenopausal women and higher among postmenopausal women, with bleeding reports that range from 0.2% to 24% in premalignant change and 0% to 13% in malignancy (16).

Table 10-4 Menstrual Terminology

Cycle		Normal	
Regularity	Absent	Regular	Irregular
Frequency of menstruation	Infrequent	Normal	Frequent
Duration of menstrual flow	Shortened	Normal	Prolonged
Volume of menstrual flow	Light	Normal	Heavy

Table 10-5 Abnormal Uterine Bleeding Terminology

Structural Causes	PALM
AUB-P	Polyp
AUB-A	Adenomyosis
AUB-L	Leiomyoma
AUB-M	Malignancy + Hyperplasia

Nonstructural	COEIN
AUB-C	Coagulopathy
AUB-O	Ovulatory dysfunction
AUB-E	Endometrial
AUB-I	Iatrogenic
AUB-N	Not yet classified

Adenomyosis, AUB-A

Traditionally adenomyosis has been diagnosed by histology at the time of hysterectomy, making estimates of prevalence and contribution to AUB and pelvic pain unclear. **With improving imaging technology and evolving diagnostic criteria for adenomyosis on ultrasound and MRI, adenomyosis can be diagnosed prior to hysterectomy and is included as a structural cause of abnormal bleeding.** The incidence of incidentally identified adenomyosis on pelvic imaging is not yet known (5).

Leiomyoma, AUB-L

[5] Uterine leiomyomas occur in as many as one-half of all women older than age 35 years and are the most common tumors of the genital tract (12). The incidence varies from 30% to 70%, depending on the criteria for study, whether clinical symptoms, ultrasound, or histologic assessment (11). One study of a randomly selected population estimated a cumulative prevalence of greater than 80% in black women and nearly 70% in white women based on ultrasound (19). Abnormal bleeding is the most common symptom for women with leiomyomas who are symptomatic. **Although the number and size of uterine leiomyomas do not appear to influence the occurrence of abnormal bleeding, submucosal myomas are the most likely to cause bleeding.** The mechanism of abnormal bleeding related to leiomyomas is not well established (see Chapter 11 for further discussion of uterine fibroids).

Malignancy and Hyperplasia, AUB-M

Unopposed estrogen is associated with a variety of abnormalities of the endometrium, from cystic hyperplasia to adenomatous hyperplasia, hyperplasia with cytologic atypia, and invasive carcinoma. **Abnormal bleeding is the most frequent symptom of women with invasive cervical cancer.** A visible cervical lesion should be evaluated by biopsy rather than awaiting the results of cervical cytology testing, because those results may be falsely negative with invasive lesions as caused by tumor necrosis. Although vaginal neoplasia is uncommon, the vagina should be evaluated carefully when abnormal bleeding is present. Attention should be directed to all surfaces of the vagina, including anterior and posterior areas that may be obscured by the vaginal speculum on

examination.

Nonstructural causes of AUB include the COEIN in PALM-COEIN (Coagulopathy, Ovulatory dysfunction, Endometrial, Iatrogenic, NOS)

Coagulopathy, AUB-C

As with adolescents, hematologic causes of abnormal bleeding should be considered in women with heavy menstrual bleeding, particularly in those who have had heavy bleeding since menarche. **Of all women with menorrhagia, 5% to 20% have a previously undiagnosed bleeding disorder, primarily the von Willebrand disease** (20). Table 10-6 presents guidelines for a gynecologist's suspicion of a bleeding disorder and pursuit of a diagnosis (21). Abnormal liver function, which can be seen with alcoholism or other chronic liver diseases, results in inadequate production of clotting factors and can lead to excessive menstrual bleeding.

Ovulatory Dysfunction, AUB-O

[1] Most anovulatory bleeding results from what is termed *estrogen breakthrough*. In the absence of ovulation and the production of progesterone, the endometrium responds to estrogen stimulation with proliferation. This endometrial growth without periodic shedding results in eventual breakdown of the fragile endometrial tissue. Healing within the endometrium is irregular and dyssynchronous. Relatively low levels of estrogen stimulation will result in irregular and prolonged bleeding, whereas higher sustained levels result in episodes of amenorrhea followed by acute, heavy bleeding.

Many ovulatory disorders relate to endocrine disturbances. **Both hypothyroidism and hyperthyroidism can be associated with abnormal bleeding. With hypothyroidism, menstrual abnormalities, including menorrhagia, are common (see Chapter 35). The most common cause of thyroid hyperfunctioning in premenopausal women is Graves' disease, which occurs four to five times more often in women than men. Hyperthyroidism can result in oligomenorrhea or amenorrhea, and it can lead to elevated levels of plasma estrogen (22). Other causes of anovulation include hypothalamic dysfunction, hyperprolactinemia, premature ovarian failure (POF), and primary pituitary disease (Table 10-7). These conditions often are considered causes of amenorrhea, but they may be the cause of irregular bleeding (see Chapter 34). The rare and unusual causes of abnormal bleeding should not be overlooked. Women with primary ovarian insufficiency (POI; previously termed POF) frequently see several clinicians with symptoms of oligomenorrhea or amenorrhea prior to receiving a diagnosis; the diagnosis of POI is often delayed during waning ovarian function and insufficiency (23,24).** POI is thought to occur in approximately 1 of 100 women by age 40, 1 of 1,000 women by age 30, and 1 of 10,000 women by age 20. Women should be encouraged to track their menstrual cyclicity and to consider that the menstrual cycle can be a "vital sign" that

reflects the overall health (25).

Table 10-6 When Should a Gynecologist Suspect a Bleeding Disorder

Heavy menstrual bleeding since menarche
Family history of bleeding disorder
Personal history of any of the following:
Epistaxis in the last year
Bruising without injury >2-cm diameter
Minor wound bleeding
Oral or gastrointestinal bleeding without anatomic lesion
Prolonged or heavy bleeding after dental extraction
Unexpected postoperative bleeding
Hemorrhage from ovarian cyst
Hemorrhage requiring blood transfusion
Postpartum hemorrhage, especially delayed >24 h
Failure to respond to conventional management of menorrhagia

From **James AH, Kouides PA, Abdul-Kadir R, et al.** von Willebrand disease and other bleeding disorders in women: Consensus on diagnosis and management from an international expert panel. *Am J Obstet Gynecol* 2009;201:12e1–e8.

Table 10-7 Conditions Associated with Anovulation and Abnormal Bleeding

Eating disorders
Anorexia nervosa
Bulimia nervosa
Excessive physical exercise
Chronic illness
Primary ovarian insufficiency—POI (previously termed premature ovarian failure [POF])
Alcohol and other drug abuse
Stress
Thyroid disease
Hypothyroidism

Hyperthyroidism
Diabetes mellitus
Androgen excess syndromes (e.g., polycystic ovary syndrome [PCOS])

Diabetes mellitus can be associated with anovulation, obesity, insulin resistance, and androgen excess. Androgen disorders are very common among women of reproductive age and should be evaluated and managed accordingly. Polycystic ovary syndrome (PCOS) is present in 5% to 8% of adult women and undiagnosed in many of them (26). Because androgen disorders are associated with significant cardiovascular disease, the condition should be diagnosed promptly and treated. This condition becomes of more immediate concern in women of reproductive age because of concerns related to fertility. Management of bleeding disorders associated with androgen excess consists of an appropriate diagnostic evaluation followed by the use of oral contraceptives (in the absence of significant contraindications or the desire for conception) or the use of insulin-sensitizing agents, coupled with dietary and exercise modification (27,28).

Endometrial, AUB-E

In ovulatory cycles, the endometrium itself may contribute to abnormal or heavy menstrual bleeding (AUB/HMB). There is evidence that deficiencies of vasoconstrictors or excess of vasodilators may lead to heavy bleeding. Local vasoconstrictors include endothelin-1 and prostaglandin F2alpha. Local vasodilators include prostacyclin I2 and prostaglandin E2 (29). Inflammation and infection can affect the endometrium. **Menorrhagia can be the first sign of endometritis in women infected with sexually transmissible organisms. Women with cervicitis, particularly chlamydial cervicitis, can experience irregular bleeding and postcoital spotting** (see Chapter 15). Cervical testing for *Chlamydia trachomatis* should be considered, especially for adolescents, women in their 20s, and women who are not in a monogamous relationship. Endometritis can cause excessive menstrual flow. A woman who seeks treatment for menorrhagia and increased menstrual pain and has a history of light-to-moderate previous menstrual flow may have an upper genital tract infection or pelvic inflammatory disease (PID) (endometritis, salpingitis, oophoritis). Occasionally, chronic endometritis will be diagnosed when an endometrial biopsy is obtained for evaluation of abnormal bleeding in a patient without specific risk factors for PID.

Iatrogenic, AUB-I

Iatrogenic-Exogenous Hormones

Irregular bleeding that occurs while a woman is using contraceptive hormones should be considered in a different context than bleeding that occurs in the absence of exogenous hormone use. Breakthrough bleeding during the first 1 to 3 months of

oral contraceptive use occurs in as many as 30% to 40% of users; it should almost always be managed expectantly with reassurance because the frequency of breakthrough bleeding decreases with each subsequent month of use (30). Irregular bleeding can result from inconsistent use (31,32). Other estrogen–progestin delivery systems, including the contraceptive patch, vaginal ring, and intramuscular regimens, are associated with irregular breakthrough bleeding. These nondaily contraceptive regimens may promote successful use, making irregular bleeding a less important factor for some women in assessing the balance of risks versus benefits (see Chapter 14).

The use of progestin-only methods—including depot medroxyprogesterone acetate (*DMPA),* progestin-only pills, the contraceptive implant, and the *levonorgestrel* intrauterine system (IUS)—is associated with relatively high rates of initial irregular and unpredictable bleeding; rates of amenorrhea vary over time and by method (33). Counseling about the frequent side effects of irregular bleeding is imperative before initially prescribing these methods of contraception. Women who do not believe that they can cope with irregular, unpredictable bleeding may not be good candidates for these methods. Hormonal implants and IUDs releasing progestins do offer significant benefits of high efficacy and ease of use (34,35). **The management of irregular bleeding with hormonal contraceptive use can range from reassurance and initial expectant management to recommendations for a change in the hormonal delivery system or regimen.** The use of additional oral estrogen or combined oral contraceptives for 10 to 20 days improves bleeding with both *DMPA* and the subdermal *levonorgestrel in some studies* (36). The use of a 5- to 7-day course of NSAIDs may result in decreased breakthrough bleeding (36). The development of a better understanding of the mechanisms causing irregular bleeding will likely result in more effective and acceptable management strategies (33).

Not all bleeding that occurs while an individual is using hormonal contraception is a consequence of hormonal factors. In one study, women who experienced irregular bleeding while taking oral contraceptives had a higher frequency of *C. trachomatis* infection (37). Screening for sexually transmitted infections (STIs) should be considered in women presenting with irregular bleeding while using hormonal contraception.

Not Yet Classified, AUB-N

This includes causes of AUB not yet discovered and those rarer and less-understood causes, including myometrial hypertrophy and AV malformations (8).

Diagnosis of Abnormal Bleeding

For all women, the evaluation of excessive and abnormal menses includes a thorough medical and gynecologic history, the exclusion of pregnancy, the consideration of

possible malignancy, and a careful gynecologic examination. **Abnormal bleeding, either intermenstrual or postcoital, can be caused by cervical lesions. Bleeding can result from endocervical polyps and infectious cervical lesions, such as condylomata,** herpes simplex virus ulcerations, chlamydial cervicitis, or cervicitis caused by other organisms. Other benign cervical lesions, such as wide eversion of endocervical columnar epithelium or nabothian cysts, may be detected on examination, but rarely cause bleeding.

For women of normal weight between the ages of approximately 20 and 35 years who do not have clear risk factors for STDs, have no signs of androgen excess, are not using exogenous hormones, and have no other findings on examination, management may be based on a clinical diagnosis. Additional laboratory or imaging studies may be indicated if the diagnosis is not apparent on the basis of examination and history.

Laboratory Studies

In any patient with heavy menstrual bleeding, an objective measurement of hematologic status should be performed with a complete blood count to detect anemia or thrombocytopenia. A pregnancy test should be performed to rule out pregnancy-related problems. A TSH level and chlamydia testing should be considered. Because of the possibility of a primary coagulation problem, screening coagulation studies should be ordered where appropriate (Table 10-6). The consensus report of an international expert panel recommends measurement of CBC, platelet count and function, PT, activated PTT, VWF (measured with ristocetin cofactor activity and antigen, factor VIII), and fibrinogen to be assessed in collaboration with a hematologist (38).

Imaging Studies

Women with abnormal bleeding who have a history consistent with chronic anovulation, are obese, or older than 35 to 40 years of age, require further evaluation. A pelvic ultrasonographic examination may be helpful in delineating anatomic abnormalities if the examination results are suboptimal or if an ovarian mass is suspected. A pelvic ultrasonographic examination is the best initial technique for evaluating the uterine contour, endometrial thickness, and ovarian structure (39,40). The use of a vaginal probe transducer allows assessment of endometrial and ovarian disorders, particularly in women who are obese. **Because of variation in endometrial thickness with the menstrual cycle, measurements of endometrial stripe thickness are significantly less useful in premenopausal than postmenopausal women** (41). Sonohysterography is especially helpful in visualizing intrauterine problems such as polyps or submucosal leiomyoma. Although these sonographic techniques are helpful in visualizing intrauterine pathology, histologic evaluation is required to rule out malignancy. Other techniques, such as CT scanning and MRI, are not as helpful in the

initial evaluation of causes of abnormal bleeding and should be reserved for specific indications, such as exploring the possibility of other intra-abdominal pathology or adenopathy. MRI can be a secondary step in evaluating the location of uterine fibroids with relationship to the endometrial cavity, staging and preoperative evaluation of endometrial cancer, detecting adenomyosis, and delineating adnexal and ovarian pathology (42).

Endometrial Sampling

[1] Endometrial sampling should be performed to evaluate abnormal bleeding in women who are at risk for endometrial pathology, including polyps, hyperplasia, or carcinoma. Such sampling is mandatory in the evaluation of anovulatory bleeding in women older than 45 or in younger women who are obese, in those who do not respond to medical therapy or those with a history of prolonged anovulation (10).

The technique of a D&C, which was previously used extensively for the evaluation of abnormal bleeding, has now been largely replaced by endometrial biopsy in the office. The classic study in which a D&C was performed before hysterectomy with the conclusion that less than one-half of the endometrium was sampled in more than one-half of the patients led to questioning the use of D&C for endometrial diagnosis (43,44). Hysteroscopy, either diagnostic or operative, with endometrial sampling, can be performed either in the office or operating room (45).

A number of devices are designed for endometrial sampling, including a commonly used, inexpensive, disposable, flexible plastic sheath with an internal plunger that allows tissue aspiration; disposable plastic cannulae of varying diameters that attach to a manually locking syringe that allows the establishment of a vacuum; and cannulae (both rigid metal and plastic) with tissue traps that attach to an electric vacuum pump **(Fig. 10-1)**. Several studies comparing the adequacy of sampling using these devices with D&C showed a comparable ability to detect abnormalities. It should be noted that these devices are designed to obtain a tissue sample rather than a cytologic washing. The diagnostic accuracy of endometrial biopsy for endometrial malignancy and hyperplasia is good, although persistent bleeding should prompt further testing (46). Hysteroscopy with targeted biopsies is more sensitive than a D&C in evaluating uterine pathology (29).

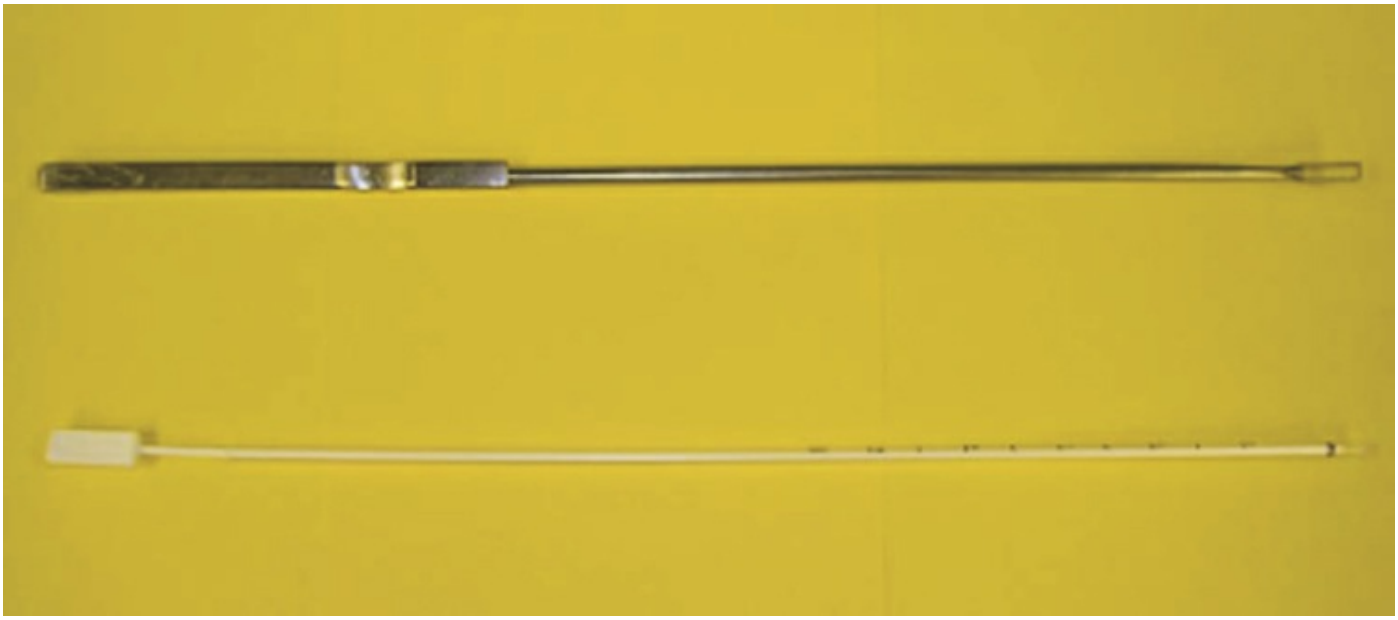

FIGURE 10-1 Devices used for sampling endometrium. **Top:** Kevorkian curette. **Bottom:** Pipelle.

Management of Abnormal Bleeding

Attention should be directed to establishing a cause of abnormal bleeding. In most cases, medical therapy is effective in managing abnormal bleeding and should be attempted before surgical management. [1] Medical management with either combined hormonal contraceptives or progestins is the preferred therapy of anovulatory bleeding in women of reproductive age (8). Progestin-releasing IUDs are effective in treating heavy menstrual bleeding and demonstrate comparable benefits for the quality of life (47). **It is argued that the IUD should be offered prior to consideration of hysterectomy, as there are comparable benefits on heavy menstrual bleeding and clear cost benefits** (48). When medical therapy fails in women with anovulatory uterine bleeding and without the desire for future childbearing, the surgical options of endometrial ablation or hysterectomy can be considered. Endometrial ablation is an efficient and cost-effective alternative to hysterectomy, although this therapy may not be definitive, with increasing rates of repeat ablation and hysterectomy over time (8). In women with leiomyomas, hysterectomy provides a definitive cure. A variety of surgical alternatives to hysterectomy are available to women with symptomatic uterine leiomyomas (see Chapter 11).

Nonsurgical Management

Most bleeding problems, including anovulatory bleeding, can be managed nonsurgically. Treatment with NSAIDs, such as *ibuprofen* and *mefenamic acid,* decreases menstrual flow by 30% to 50%, but is less effective than *tranexamic acid, danazol,* or *levonorgestrel* IUD (49). Antifibrinolytics, such as *tranexamic acid,* are

effective in reducing menstrual blood loss, and this indication was approved by the FDA in late 2008 (50).

Hormonal management of abnormal bleeding can frequently control excessive or irregular bleeding. The treatment of choice for anovulatory bleeding is medical therapy with combined oral contraceptives or progestins including the levonorgestrel IUD (5). Oral contraceptives are used clinically to decrease menstrual flow, although supporting data from prospective clinical trials are sparse (51). Low-dose oral contraceptives may be used by reproductive age women without medical contraindications and during the perimenopausal years in healthy nonsmoking women who have no major cardiovascular risk factors. The benefits of menstrual regulation in such women often override the potential risks. The medical treatment of acute abnormal bleeding in reproductive age women is the same as that described for adolescents (see Chapter 9).

For patients in whom estrogen use is contraindicated, progestins, both oral and parenteral, can be used to control excessive bleeding. Cyclic oral *medroxyprogesterone acetate,* administered from day 15 or 19 to day 26 of the cycle, reduces menstrual flow but offers no advantages over other medical therapies, such as NSAIDs, *tranexamic acid, danazol,* or the *levonorgestrel* IUD; progestin therapy for 21 days of the cycle reduces menstrual flow, although women found the treatment less acceptable than the *levonorgestrel* IUD (52). The benefits of progestins to the patient with oligomenorrhea and anovulation include a regular flow and the prevention of long intervals of amenorrhea, which may end in unpredictable, profuse bleeding. This therapy reduces the risk of hyperplasia resulting from persistent, unopposed estrogen stimulation of the endometrium. Depot formulations of *medroxyprogesterone acetate,* oral progestins, levonorgestrel IUDs, and combined oral contraceptives are used to establish amenorrhea in women at risk of excessive bleeding (53). Oral, parenteral, or intrauterine delivery of progestins is used in selected women with endometrial hyperplasia or early endometrial cancer who wish to maintain their fertility or in whom surgical risks are judged to be prohibitive (29). Continued monitoring with repeated sampling is indicated. *Danazol* is effective in decreasing bleeding and inducing amenorrhea; it is rarely used for ongoing management of abnormal bleeding because of its androgenic side effects, including weight gain, hirsutism, alopecia, and irreversible voice changes. GnRH analogs are used for short-term treatment of abnormal bleeding, either alone or with add-back therapy consisting of combined estrogen/progestogen or progestogen alone (54).

Surgical Therapy

The surgical management of abnormal bleeding should be reserved for situations in which medical therapy is unsuccessful or is contraindicated. Although sometimes appropriate as a diagnostic technique, D&C is questionable as a therapeutic modality. One study reported a measured reduction in menstrual blood loss for the first

menstrual period only (55). Other studies suggest a longer-lasting benefit (56).

The surgical options range from a variety of techniques for endometrial ablation or resection, to hysterectomy or a variety of conservative surgical techniques for the management of uterine leiomyoma, including hysteroscopy with resection of submucous leiomyomas, laparoscopic and robotic techniques of myomectomy, uterine artery embolization, and magnetic resonance–guided focused ultrasonography ablation (see Chapters 26 and 27). The choice of procedure depends on the cause of bleeding, the patient's preferences, the physician's experience and skills, the availability of newer technologies, and a careful assessment of risks versus benefits based on the patient's medical condition, concomitant gynecologic symptoms or conditions, and desire for future fertility. The assessment of the relative advantages, risks, benefits, complications, and indications of these procedures is a subject of ongoing clinical research. Various techniques of endometrial ablation were compared with the gold standard of endometrial resection, and the evidence suggests comparable success rates and complication profiles (57). The advantages of techniques other than hysterectomy include a shorter recovery time and reduced early morbidity. Symptoms can recur or persist and repeat procedures or subsequent hysterectomy may be required if conservative options are chosen. Additional studies that include quality-of-life outcomes will be helpful. Collaborative decision making, taking into account individual patient preferences, should follow a thorough discussion of options, risks, and benefits (58,59). Much is written about the psychological sequelae of hysterectomy, and some of the aforementioned surgical techniques were developed in an effort to provide less drastic management options. **Most well-controlled studies suggest that, in the absence of pre-existing psychopathology, indicated but elective surgical procedures for hysterectomy have few, if any, significant psychological sequelae (including depression)** (see Chapters 23 and 27) (60,61).

Pelvic Masses

[3] Conditions diagnosed as a pelvic mass in women of reproductive age are presented in Table 10-8.

Differential Diagnosis

It is difficult to determine the frequency of diagnoses of pelvic mass in women of reproductive age because many pelvic masses are not treated with surgery. **Nonovarian or nongynecologic conditions may be confused with an ovarian or uterine mass (Table 10-8). The frequency of masses found at laparotomy has been studied, although the percentages are affected by varying indications for surgery, indications for referral, type of practice (gynecologic oncology vs. general gynecology), and patient populations (e.g., a higher percentage of African**

Americans with uterine leiomyomas). Benign masses, such as functional ovarian cysts or asymptomatic uterine leiomyoma, typically do not require or warrant surgery (Table 10-9).

Table 10-8 Conditions Diagnosed as a Pelvic Mass in Women of Reproductive Age

Urinary
Full urinary bladder
Urachal cyst
Uterus
Sharply anteflexed or retroflexed uterus
Intraligamentous leiomyomas
Pregnancy (with or without concomitant leiomyomas)
Intrauterine
Tubal
Abdominal
Ovarian or adnexal masses
Functional cysts Neoplastic tumors Benign Malignant
Inflammatory masses Tubo-ovarian complex Diverticular abscess Appendiceal abscess
Other
Matted bowel and omentum
Peritoneal cyst
Stool in sigmoid
Paraovarian or paratubal cysts
Less common conditions that must be excluded:
Pelvic kidney
Carcinoma of the colon, rectum, appendix
Carcinoma of the fallopian tube

Retroperitoneal tumors (anterior sacral meningocele)
Uterine sarcoma or other malignant tumors

Table 10-9 Causes of Pelvic Mass by Approximate Frequency and Age

Infancy	Prepubertal	Adolescent	Reproductive	Perimenopausal	Postmenopausal
Functional cyst	Functional cyst	Functional cyst	Functional cyst	Fibroids	Ovarian tumor (malignant or benign)
Germ cell tumor	Germ cell tumor	Pregnancy	Pregnancy	Epithelial ovarian tumor	Functional cyst
		Benign cystic teratoma/ other germ cell tumors	Uterine fibroids	Functional cyst	Bowel, malignant tumor, or inflammatory
		Obstructing vaginal or uterine anomalies	Epithelial ovarian tumor		Metastases
		Epithelial ovarian tumor			

Age is an important determinant of the likelihood of malignancy. In one study of women who underwent laparotomy for pelvic mass, malignancy was seen in only 10% of those younger than 30 years of age, and most of these tumors had low malignancy potential (62). **The most common tumors found during laparotomy for pelvic mass are mature cystic teratomas or dermoids (seen in one-third of women younger than 30 years of age) and endometriomas (approximately one-fourth of women 31 to 49 years of age)** (62).

Uterine Masses

Uterine leiomyomas, commonly termed uterine fibroids, are by far the most common benign uterine tumors and are usually asymptomatic. Other benign uterine growths, such as uterine vascular tumors, are rare. See Chapter 11 for discussion of diagnosis, types and locations of fibroids, incidence, symptoms, causes, natural history, pathology, and management.

Ovarian Masses

[3] During the reproductive years, the most common ovarian masses are benign. Ovarian masses can be functional or neoplastic, and neoplastic tumors can be benign or malignant. Functional ovarian masses include follicular and corpus luteal cysts. About two-thirds of ovarian tumors are encountered during the reproductive years. Most ovarian tumors (80% to 85%) are benign, and two-thirds of these occur in women between 20 and 44 years of age. **The chance that a primary ovarian tumor is malignant in a patient younger than 45 years of age is less than 1 in 15.** Most tumors produce few or only mild, nonspecific symptoms. The most common symptoms include abdominal distention, abdominal pain or discomfort, lower abdominal pressure sensation, and urinary or gastrointestinal symptoms. If the tumor is hormonally active,

symptoms of hormonal imbalance, such as vaginal bleeding related to estrogen production, may be present. Acute pain may occur with adnexal torsion, cyst rupture, or bleeding into a cyst. Pelvic findings in patients with benign and malignant tumors may differ. Masses that are unilateral, cystic, mobile, and smooth are most likely to be benign, whereas those that are bilateral, solid, fixed, irregular, and associated with ascites, *cul-de-sac* nodules, and a rapid rate of growth are more likely to be malignant (63).

In assessing ovarian masses, the distribution of primary ovarian neoplasms by a decade of life can be helpful. Ovarian masses in women of reproductive age are most likely benign, but the possibility of malignancy must be considered **(Fig. 10-2)**.

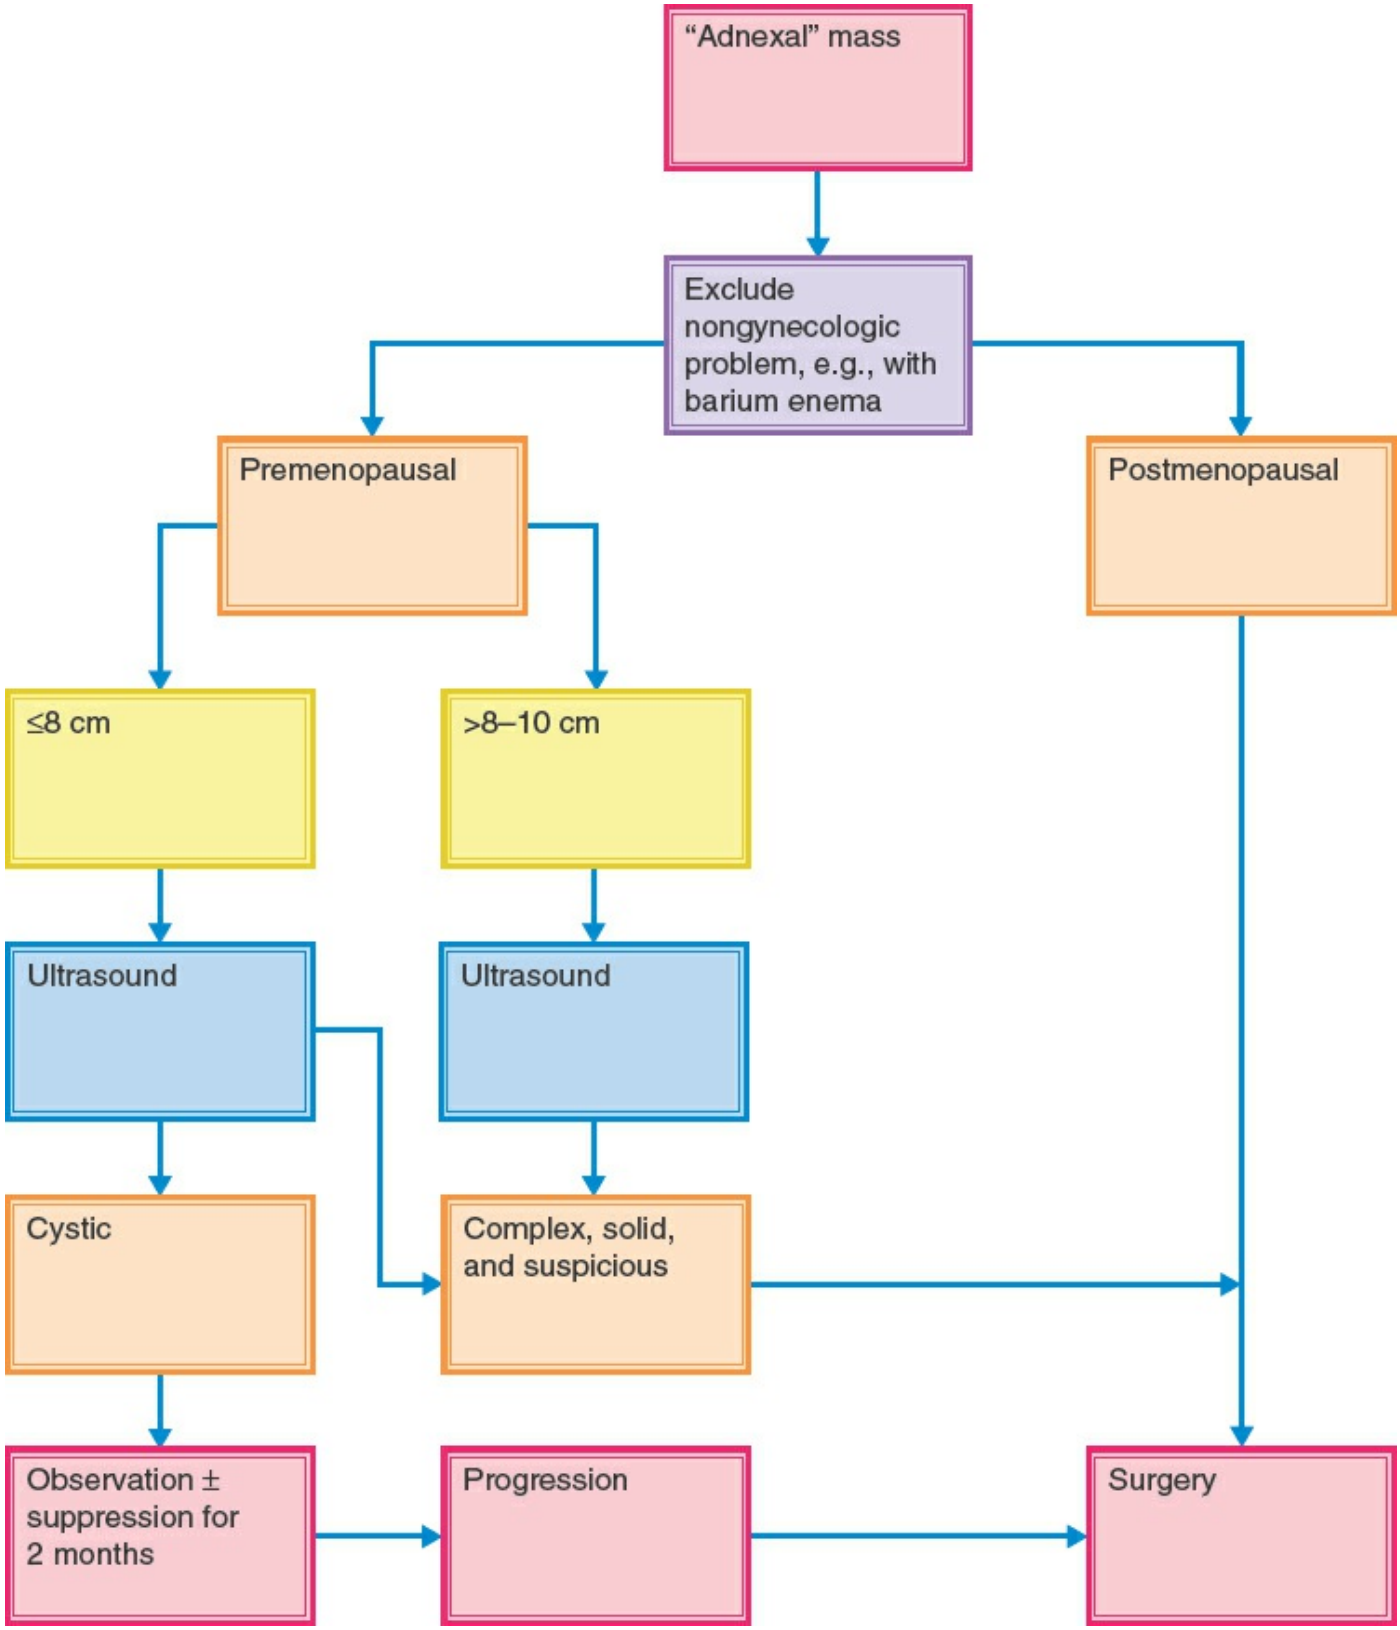

FIGURE 10-2 Preoperative evaluation of the patient with an adnexal mass.

Nonneoplastic Ovarian Masses

[3] Functional ovarian cysts include follicular cysts, corpus luteum cysts, and theca

lutein cysts. All are benign and usually do not cause symptoms or require surgical management. Cigarette and marijuana smoking are associated with an increased risk of functional cysts, although the increased risk may be attenuated in overweight or obese women (64). **Oral contraceptive use is associated with a decreased risk of developing functional ovarian cysts, although low-dose pills may have a smaller benefit. Oral contraceptives do not hasten the resolution of ovarian cysts** (65,66). The annual rate of hospitalization for functional ovarian cysts is estimated to be as high as 500 per 100,000 woman-years in the United States, although little is known about the epidemiology of the condition. **[3] The most common functional cyst is the follicular cyst, which is rarely larger than 8 cm.** A cystic follicle can be defined as a follicular cyst when its diameter is greater than 3 cm. These cysts usually are found incidental to pelvic examination or pelvic imaging, although they may rupture or torse, causing pain and peritoneal signs. They typically resolve in 4 to 8 weeks with expectant management (66).

Corpus luteum cysts are less common than follicular cysts. Corpus luteum cysts may rupture, leading to a hemoperitoneum and requiring surgical management. Patients taking anticoagulant therapy or with bleeding diatheses are at particular risk for hemorrhage and rupture. Rupture of these cysts occurs more often on the right side and may occur during intercourse. **Most ruptures occur on cycle days 20 to 26** (67). Unruptured corpus luteum cysts can cause pain, presumably because of bleeding into the enclosed ovarian cyst cavity. They can produce symptoms and be difficult to discern from adnexal torsion.

Theca lutein cysts are the least common of functional ovarian cysts. They are usually bilateral and occur with pregnancy, including molar pregnancies. They may be associated with multiple gestations, molar pregnancies, choriocarcinoma, diabetes, Rh sensitization, clomiphene citrate use, human menopausal gonadotropin–human chorionic gonadotropin ovulation induction, and the use of GnRH analogs. Up to one-quarter of complete molar pregnancies will have theca lutein cysts which will regress spontaneously (68).

Combination monophasic oral contraceptive therapy is reported to reduce the risk of developing functional ovarian cysts by suppression of both follicular development and ovulation (69). It appears that, in comparison with previously available higher-dose pills, the effect of cyst suppression with low-dose oral contraceptives is attenuated. The use of triphasic oral contraceptives is not associated with an appreciable increased risk of functional ovarian cysts.

Other Benign Masses

Women with endometriosis may develop ovarian endometriomas (“chocolate” cysts), which can enlarge from 6 to 8 cm in size. A mass that does not resolve with observation may be an endometrioma (see Chapter 13). Excision of endometriosis is preferable to

ablative techniques with regard to achievement of spontaneous pregnancy (70). New data suggests that women with or without endometriomas have similar success with conceiving when using ART and do not need removal prior to fertility treatment if asymptomatic and the diagnosis is not in question (71,72).

Although enlarged, polycystic ovaries were originally considered the *sine qua non* of PCOS, and are included among the Rotterdam diagnostic criteria; they are not always present with other features of the syndrome (73,74). An enlarged ovarian volume is suggested as an alternative diagnostic criterion, although what the threshold should be has been debated (75). The 2003 Rotterdam consensus uses a volume greater than 10 mL in either ovary or 12 or more subcentimeter antral follicles in either ovary (74).

The prevalence of PCOS among the general population depends on the diagnostic criteria used. In one study, 257 volunteers were examined with ultrasonography; 22% were found to have polycystic ovaries (76). The finding of generously sized ovaries on examination or polycystic ovaries on ultrasonographic examination should prompt evaluation for the full-blown syndrome, which includes hyperandrogenism, chronic anovulation, and polycystic ovaries (26). Therapy for PCOS is generally medical rather than surgical, with lifestyle modification and weight loss playing a potentially important role (77).

Neoplastic Masses

[3] Most benign cystic teratomas (dermoid cysts) occur during the reproductive years in adolescents and young women, although dermoid cysts have a wider age distribution than other ovarian germ cell tumors; in some case series, up to 25% of dermoids occur in postmenopausal women, and they can occur in newborns (78). **[3]** Histologically, benign cystic teratomas have an admixture of elements **(Fig. 10-3)**. Malignant transformation occurs in less than 2% of dermoid cysts in women of all ages; most cases occur in women older than 40 years of age. The risk of torsion with dermoid cysts is approximately 15%, and occurs more frequently than with other ovarian tumors, perhaps because of the high fat content of most dermoid cysts, allowing them to float within the abdominal and pelvic cavity. As a result of this fat content, on pelvic examination a dermoid cyst frequently is described as anterior in location. They are bilateral in approximately 10% of cases, although many have advanced the argument against bivalving a normal-appearing contralateral ovary because of the risk of adhesions, which may result in infertility. **An ovarian cystectomy is almost always possible, even if it appears that only a small amount of ovarian tissue remains.** Preserving a small amount of ovarian cortex in a young patient with a benign lesion is preferable to the loss of the entire ovary (79). Laparoscopic cystectomy often is possible, and intraoperative spill of tumor contents is rarely a cause of complications, although granulomatous peritonitis has been reported (80). A minimally invasive, fertility-sparing approach is preferred for benign masses (81).

[3] The risk of epithelial tumors increases with age. Although serous cystadenomas are often considered the more common benign neoplasm, in one study, benign cystic teratomas represented 66% of benign tumors in women younger than 50 years of age; serous tumors accounted for only 20% (82). **Serous tumors are generally benign; 5% to 10% have borderline malignant potential, and 20% to 25% are malignant. The major risk factor for ovarian cancer is a family history of ovarian cancer or a familial syndrome, particularly BRCA1 mutation (approx. 40% risk), BRCA2 mutation (15% risk) or the Lynch syndrome (5% risk)** (81).

Serous cystadenomas are often multilocular, sometimes with papillary components **(Fig. 10-4)**. The surface epithelial cells secrete serous fluid, resulting in a watery cyst content. Psammoma bodies, which are areas of fine calcific granulation, may be scattered within the tumor and are visible on the radiograph. A frozen section is necessary to distinguish between benign, borderline, and malignant serous tumors because this distinction cannot be made on gross examination alone. Mucinous ovarian tumors may grow to large dimensions. Benign mucinous tumors typically have a lobulated, smooth surface, are multilocular, and may be bilateral in up to 10% of cases. Mucoid material is present within the cystic loculations. **Five to 10% of mucinous ovarian tumors are malignant (see Chapter 39).** They may be difficult to distinguish histologically from metastatic gastrointestinal malignancies. Other benign ovarian tumors include fibromas (a focus of stromal cells), Brenner tumors (which appear grossly similar to fibromas and are frequently found incidentally), and mixed forms of tumors, such as the cystadenofibroma.

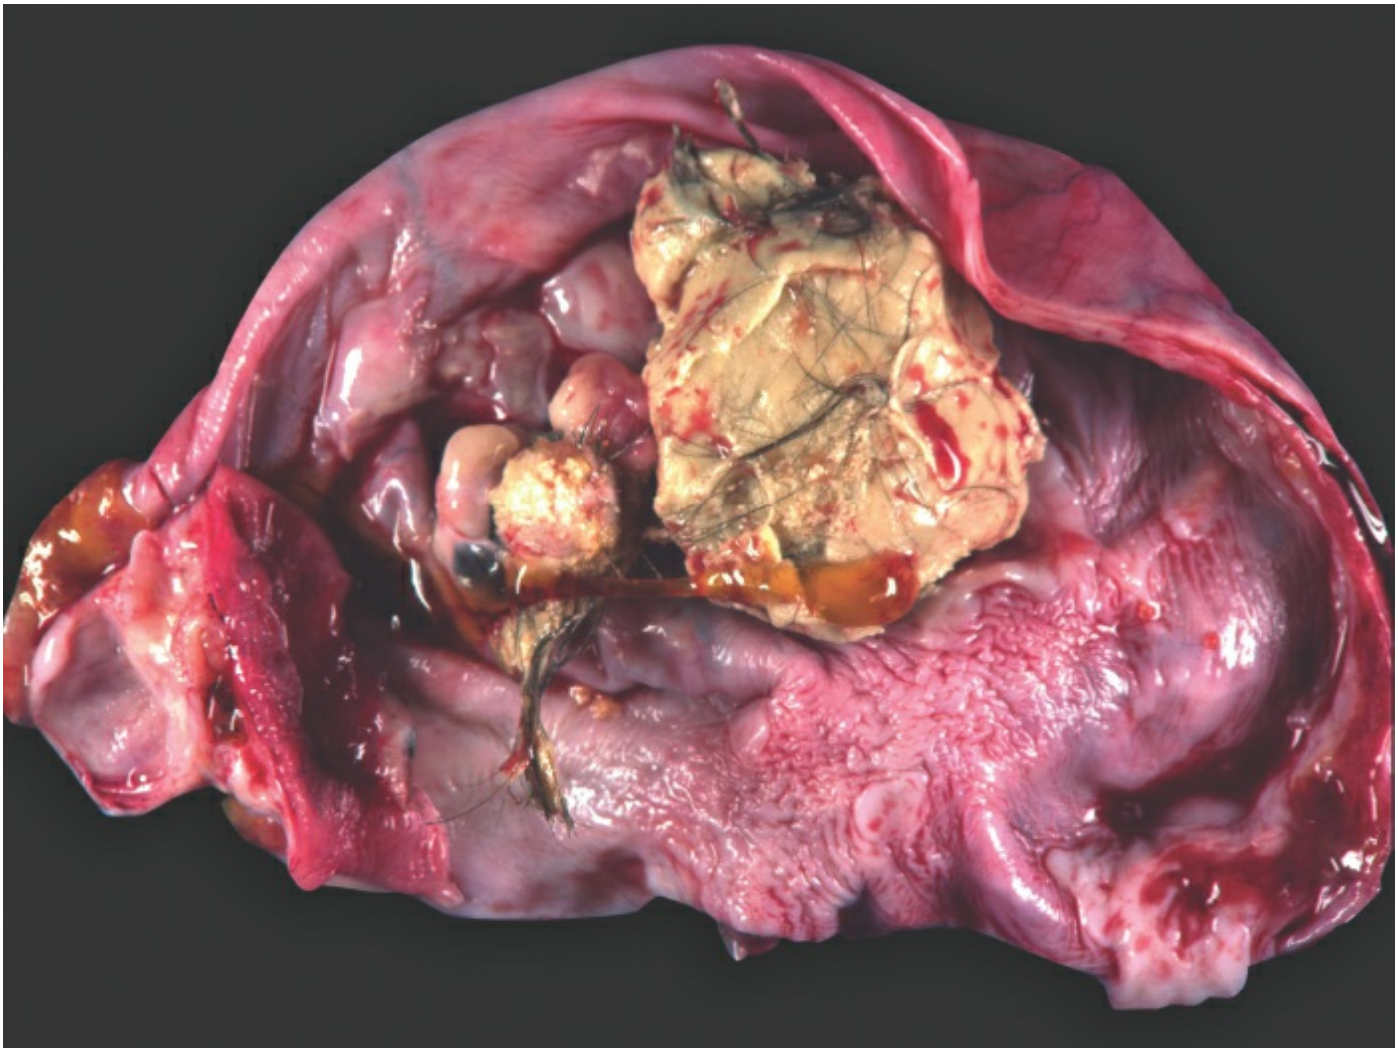

FIGURE 10-3 Mature cystic teratoma (dermoid cyst) of the ovary.

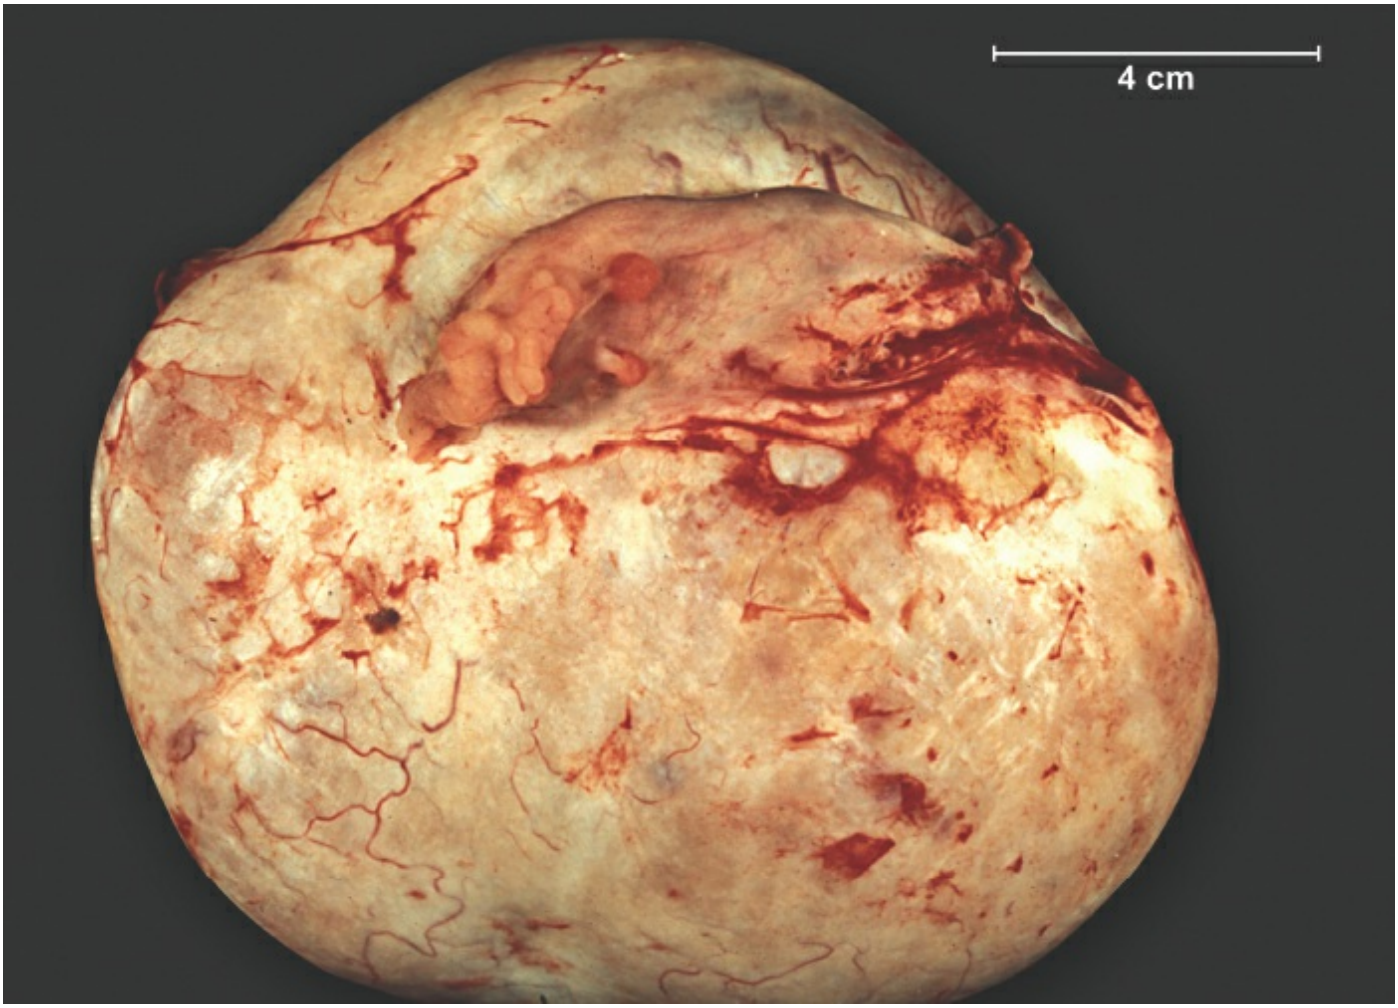

FIGURE 10-4 Serous cystadenoma.

Uterine, gastric, breast, and colorectal malignancies can metastasize to the ovaries and should be considered, although as with many malignancies, these tumors are more common in postmenopausal-aged women.

Other Adnexal Masses

[3] Masses that include the fallopian tube are related primarily to inflammatory causes in the reproductive age group. A tubo-ovarian abscess can be present in association with PID (see Chapter 15). A complex inflammatory mass consisting of the bowel, tube, and ovary may be present without a large abscess cavity. Ectopic pregnancies can occur in the reproductive age group and must be excluded when a patient presents with pain, a positive pregnancy test, and an adnexal mass (see Chapter 32). Paraovarian cysts may be noted on examination or in imaging studies. In many instances, a normal ipsilateral ovary can be visualized using ultrasonography. The frequency of malignancy in paraovarian tumors is quite low and may be more common in paraovarian masses larger than 5 cm (83).

Diagnosis of Pelvic Masses

A complete pelvic examination, including rectovaginal examination and Papanicolaou (Pap) test, should be performed. **Estimations of the size of a mass should be presented in centimeters** rather than in comparison to common objects or fruit (e.g., orange, grapefruit, tennis ball, golf ball). After pregnancy is excluded, one simple office technique that can help determine whether a mass is uterine or adnexal includes sounding and measuring the depth of the uterine cavity. Pelvic imaging can confirm the characteristics of the adnexal mass—whether solid or cystic or mixed echogenicity. Diagnosis of uterine leiomyomas usually is based on the characteristic finding of an irregularly enlarged uterus. The size and location of the usually multiple leiomyomas can be confirmed and documented with pelvic ultrasonography **(Fig. 10-5)**. If the examination is adequate to confirm uterine leiomyoma and symptoms are absent, ultrasonography is not always necessary unless an ovarian mass cannot be excluded. A fixed or nodular pelvic mass should always raise concern for malignancy.

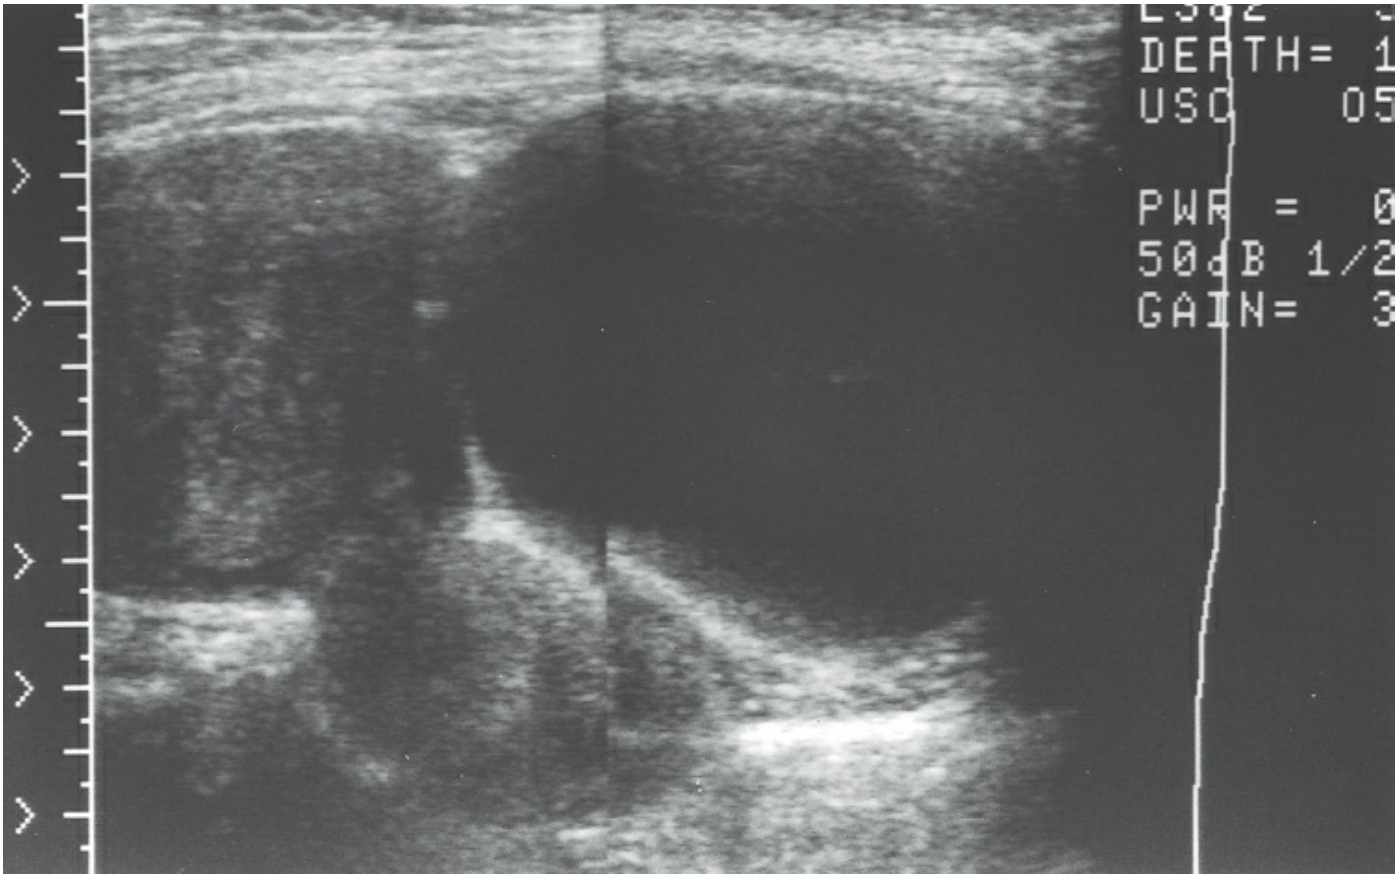

FIGURE 10-5 Transvaginal pelvic ultrasound demonstrating multiple uterine leiomyomas.

Other Studies

Endometrial sampling with an endometrial biopsy or hysteroscopy is mandatory when both pelvic mass and abnormal bleeding are present. An endometrial lesion—

carcinoma or hyperplasia—may coexist with a benign mass such as a leiomyoma. In a woman with leiomyomas, abnormal bleeding cannot be assumed to be caused solely by the fibroids. Clinicians differ in recommendations about the need for endometrial biopsy when the diagnosis is leiomyomas with regular menses.

If urinary symptoms are prominent, studies of the urinary tract may be necessary, including urodynamic testing, if incontinence or symptoms of pelvic pressure are present. Cystoscopy may be necessary or appropriate to rule out intrinsic bladder lesions.

Laboratory Studies

Laboratory studies that are indicated for women of reproductive age with a pelvic mass include pregnancy test, cervical cytology, and complete blood count. The value of tumor markers, such as CA125 in distinguishing malignant from benign adnexal masses in *premenopausal* women with a pelvic mass, is questioned. **A number of benign conditions, including uterine leiomyomas, PID, pregnancy, and endometriosis can cause elevated CA125 levels in premenopausal women; thus, measurement of CA125 levels is not as useful in premenopausal women with adnexal masses. Values greater than 200 in a premenopausal female may warrant gynecologic-oncology comanagement or referral** (81). **Ultrasonographic characteristics are more helpful than CA125 in suggesting risks of malignancy in premenopausal women** (84).

Imaging Studies

Other studies may be necessary or appropriate. **[4]** The most commonly indicated study is pelvic ultrasonography, which will help document the origin of the mass to determine whether it is uterine, adnexal, bowel, or gastrointestinal. The ultrasonographic examination provides information about the size of the mass and its consistency—unilocular cyst, mixed echogenicity, multiloculated cyst, or solid mass—which can help determine management (**Figs. 10-6** and **10-7**). Size greater than 10 cm, solid components, irregularity, papillary excrescences, and ascites increase the suspicion of malignancy (81). A number of different ultrasound scoring systems were developed in an effort to quantify the risks of malignancy.

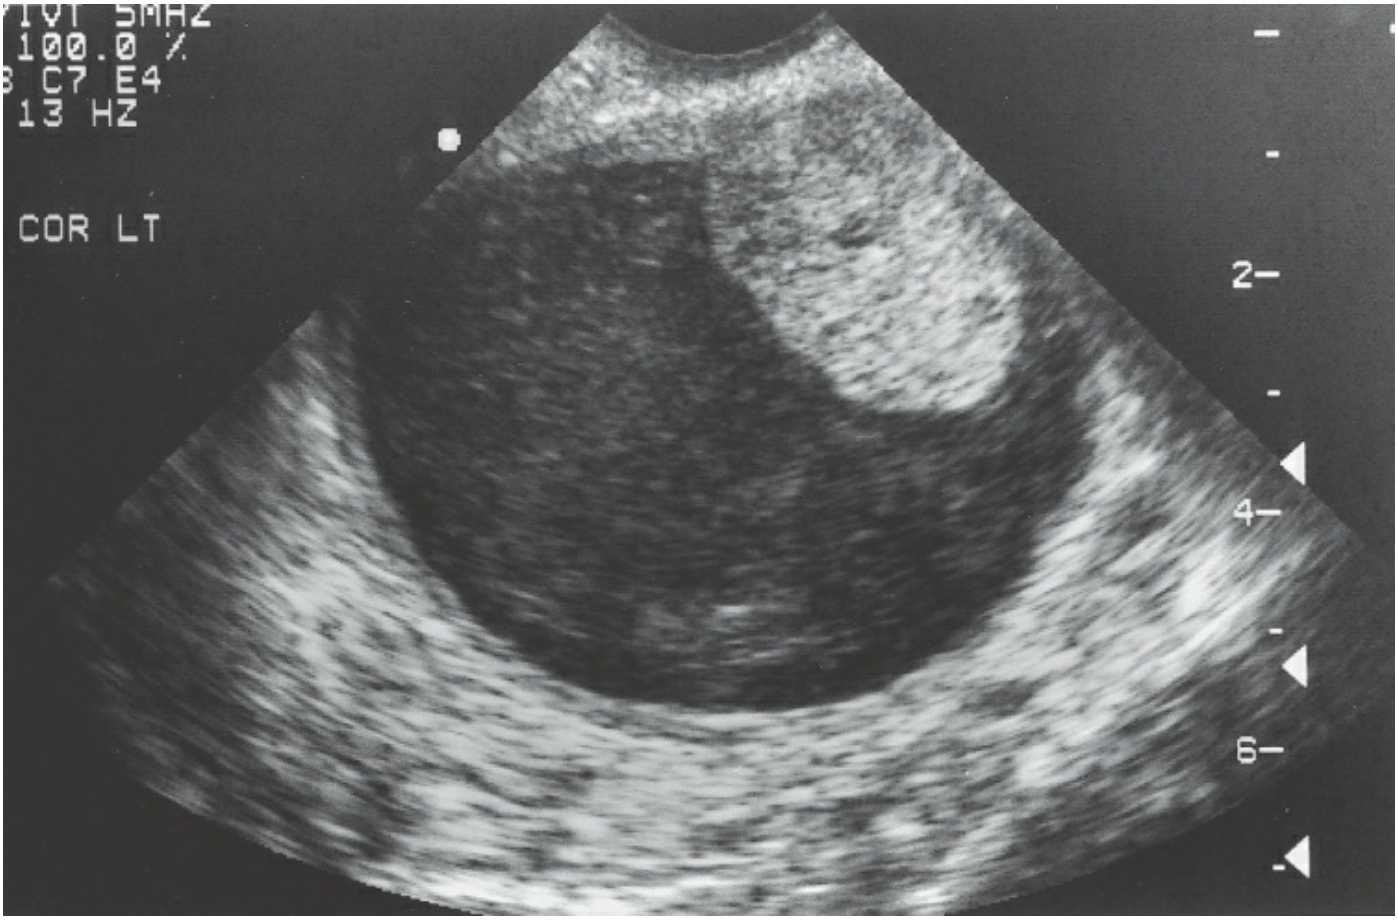

FIGURE 10-6 Transvaginal ultrasound of a unilocular ovarian cyst.

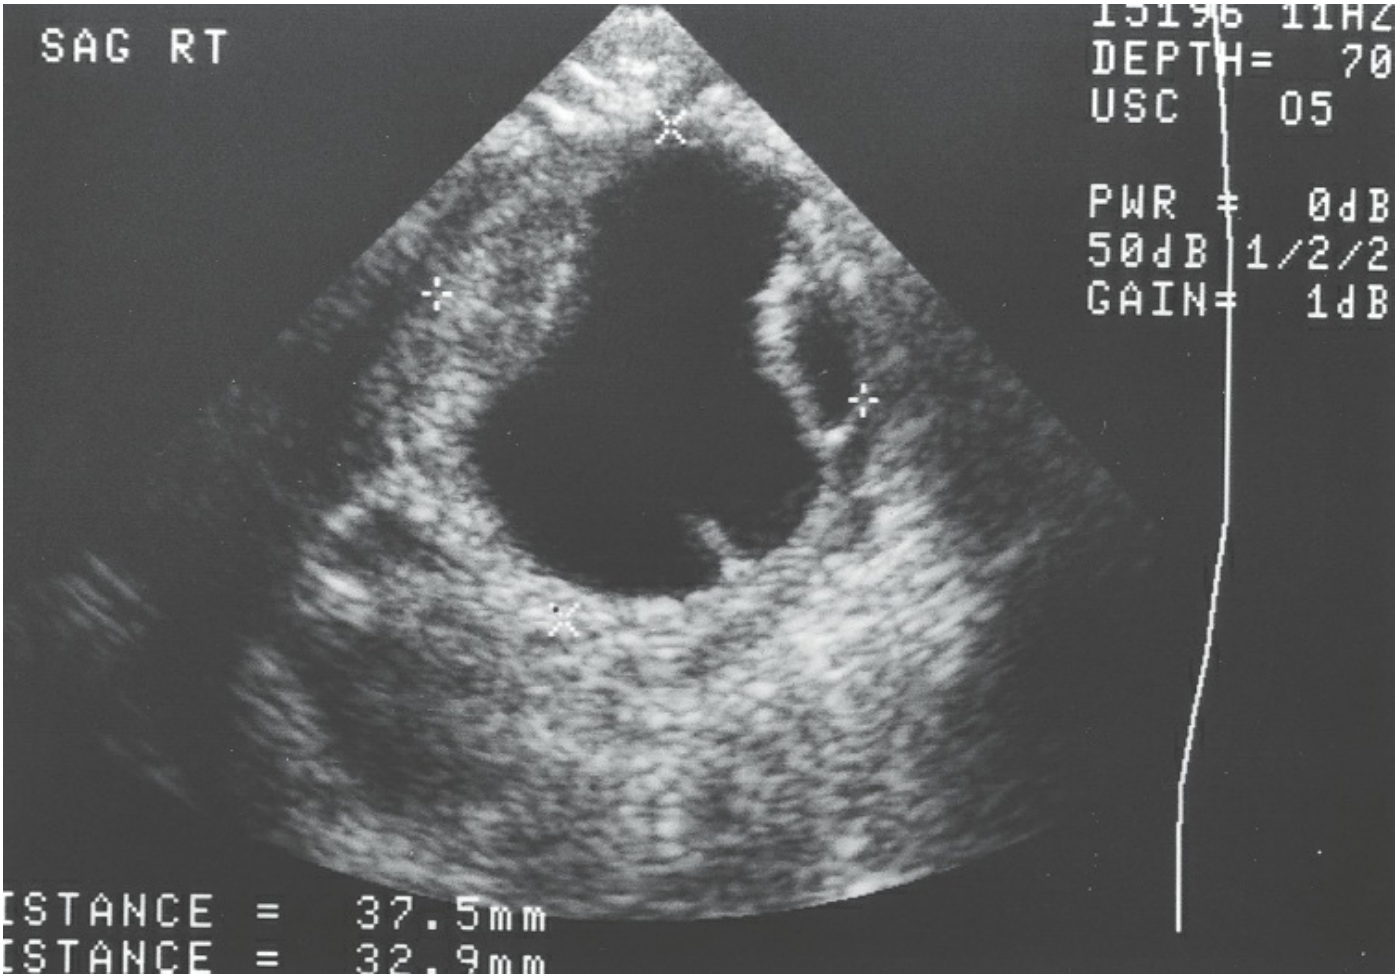

FIGURE 10-7 Transvaginal ultrasonogram of a complex, predominantly solid mass.

[4] Transvaginal and transabdominal ultrasonography are complementary in the diagnosis of pelvic masses, particularly those that have an abdominal component. Transvaginal ultrasonography has the advantage of providing additional information about the internal architecture or anatomy of the mass. Heterogeneous pelvic masses, described as tubo-ovarian abscesses on transabdominal ultrasonography, can be differentiated as pyosalpinx, hydrosalpinx, tubo-ovarian complex, and tubo-ovarian abscess with transvaginal ultrasonography **(Fig. 10-8)**.

The diagnostic accuracy of transvaginal ultrasonography in diagnosing endometrioma can be quite high (Fig. 10-9). Endometriomas can have a variety of ultrasonographic appearances, from purely cystic to varying degrees of complexity with septation or debris to a solid appearance. A variety of scoring systems were developed with the intent of predicting benign versus malignant adnexal masses using ultrasound; the ultrasonographic morphologic characteristics used in many types of scoring systems are listed in Table 10-10 (81). Color flow Doppler was added to other sonographic characteristics to predict the risk of malignancy; ultrasound techniques are comparable to CT and MRI in differentiating benign from malignant masses (81,85). Although an

analysis of such features may be helpful, histologic confirmation of surgically removed persistent masses remains the standard of care.

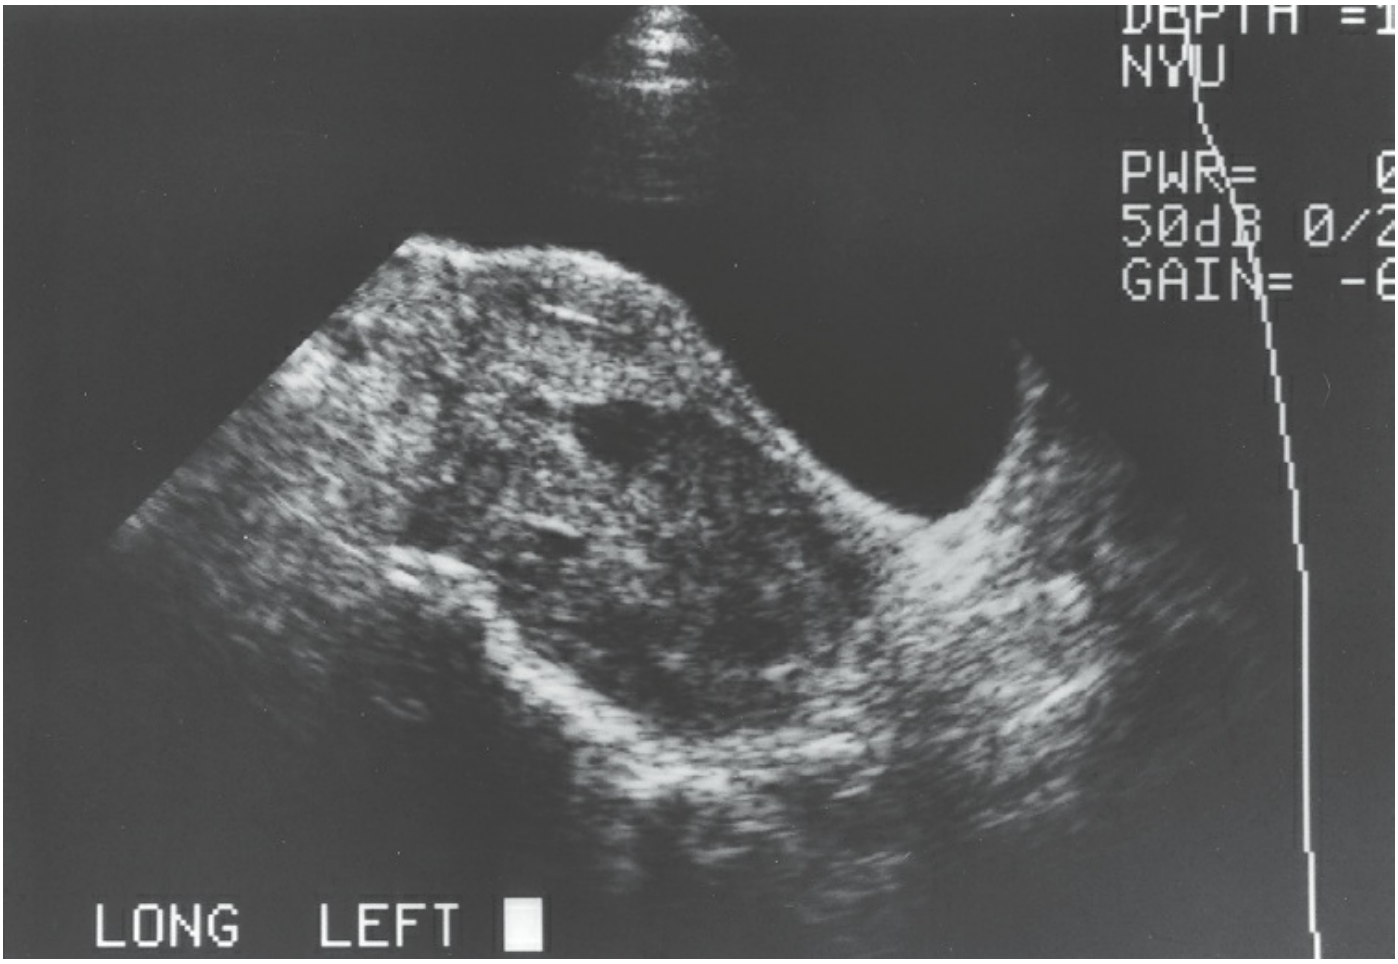

FIGURE 10-8 Transvaginal ultrasonogram of bilateral tubo-ovarian abscesses.

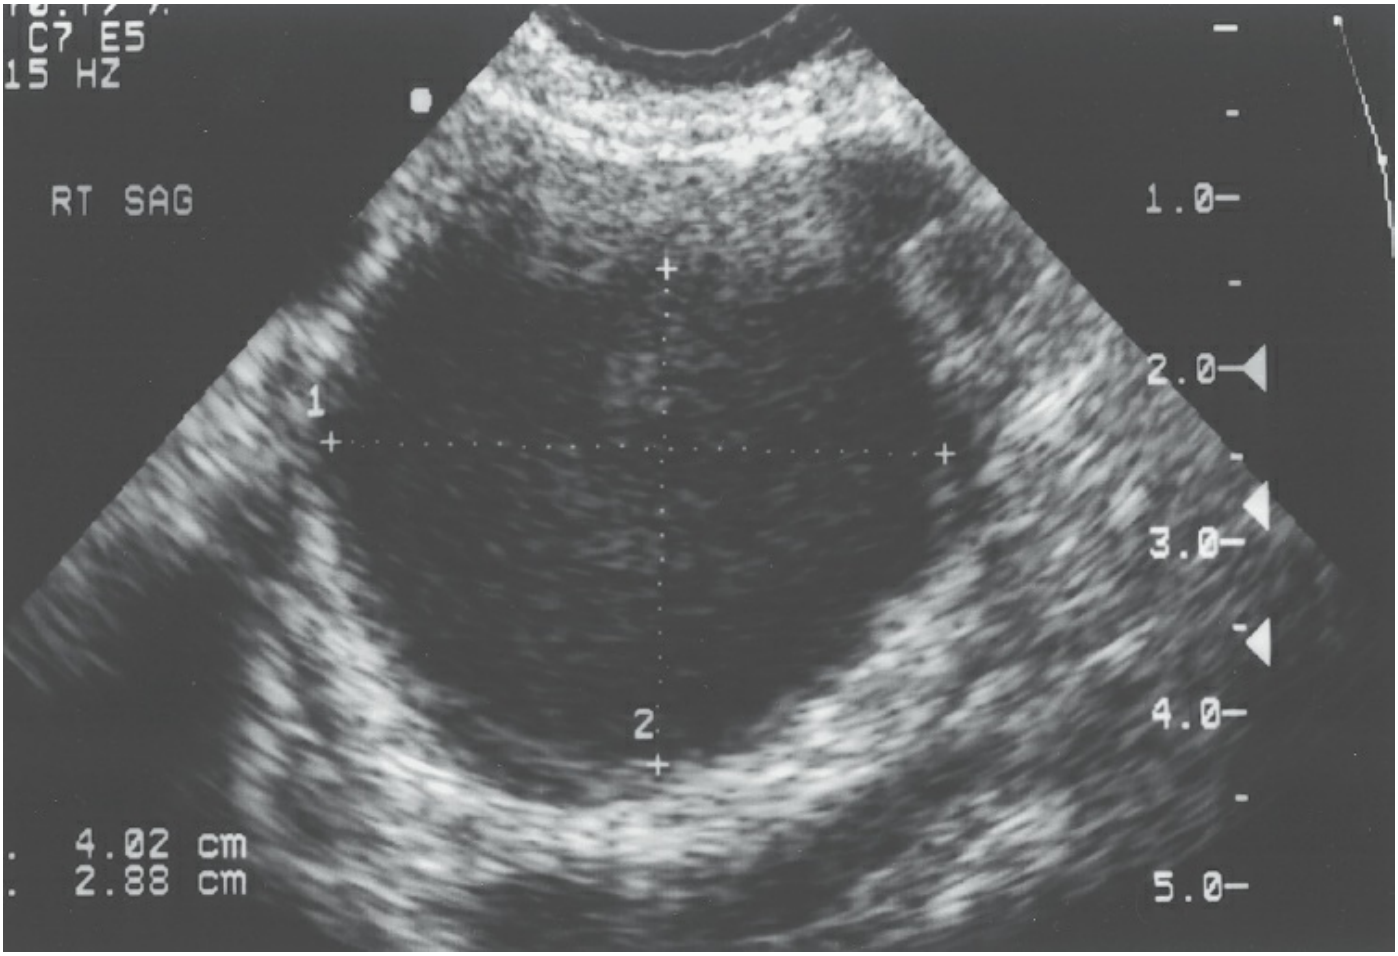

FIGURE 10-9 Transvaginal ultrasonogram of an endometrioma of the ovary.

CT seldom is indicated as a primary diagnostic procedure, although it may be helpful in planning treatment when a malignancy is strongly suspected or when a nongynecologic disorder may be present. Abdominal flat-plate radiography is not a primary diagnostic procedure, although if used for other indications, it may reveal calcifications that can assist in the discovery or diagnosis of a mass. Pelvic calcifications (teeth) consistent with a benign cystic teratoma, a calcified uterine fibroid, or scattered calcifications consistent with psammoma bodies of a papillary serous cystadenoma can be seen with abdominal radiography **(Fig. 10-10)**.

FIGURE 10-10 Benign cystic teratoma (dermoid cyst) of the ovary with teeth seen on abdominal radiograph.

Ultrasonography or CT imaging may be appropriate to demonstrate ureteral deviation, compression, or dilation in the presence of moderately large and laterally located fibroids or other pelvic mass. Such findings rarely provide an indication for surgical intervention for otherwise asymptomatic leiomyomas.

Table 10-10 Ultrasonographic Characteristics of Adnexal Masses That May Be Useful in Predicting Malignancy

Unilocular cyst vs. multilocular vs. solid components
Regular contour vs. irregular border
Smooth walls vs. nodular vs. irregular
Presence or absence of ascites
Unilateral vs. bilateral
Wall thickness

Internal echogenicity and septations (including thickness)
Presence of other intra-abdominal pathology (liver, etc.)
Vascular characteristics and color flow Doppler pattern

Hysteroscopy provides direct evidence of intrauterine pathology or submucous leiomyomas that distort the uterine cavity (see Chapter 26). Hysterosalpingography will demonstrate indirectly the contour of the endometrial cavity and any distortion or obstruction of the uterotubal junction secondary to leiomyomas, an extrinsic mass, or peritubal adhesions. The techniques combining hysterosalpingography, in which fluid is instilled into the uterine cavity, with transvaginal ultrasonography are helpful in the diagnosis of intrauterine pathology. Hysterosalpingography or sonohysterography may be indicated in women with infertility and uterine leiomyoma.

MRI may be most useful in the diagnosis of uterine anomalies, although its value rarely justifies the increased cost of the procedure over ultrasonography for the diagnosis of other pelvic masses (86).

Management of Pelvic Mass

The management of a pelvic mass is based on an accurate diagnosis. An explanation of this diagnosis should be conveyed to the patient, along with a discussion of the likely course of the disease (e.g., growth of uterine leiomyomas, regression of fibroids at menopause, regression of a follicular cyst, the uncertain malignant potential of an ovarian mass). All options for management should be presented and discussed, although it is appropriate for the physician to state a recommended approach with an explanation of the reasons for the recommendation. Management should be based on the primary symptoms and may include observation with close follow-up, temporizing surgical therapies, medical management, or definitive surgical procedures.

Leiomyomas

[5] The management of uterine leiomyomas is dependent on the patient's age and proximity to anticipated menopause, symptoms, patient preference, and the experience and skills of the clinician. Variability in reporting data regarding the severity of symptoms, uterine anatomy, and response to therapy makes it difficult to compare different types of therapies, which include observation, medical, surgical, and radiologic-based techniques (see Chapter 11 for discussion of uterine fibroids).

Ovarian Masses

The now-routine application of ultrasound technology to gynecologic examinations led to the more frequent detection of ovarian cysts, sometimes as an incidental finding. Ultrasonography is a relatively easy diagnostic study to perform, but this ease led to the

labeling of physiologic ovarian morphology and cystic follicles, as pathologic and the subsequent referral of patients for therapies, including surgery, without indications. **Treatment of ovarian masses that are suspected to be functional tumors is expectant (Fig. 10-2). A number of randomized prospective studies showed no acceleration of the resolution of functional ovarian cysts** (some of which were associated with the use of *clomiphene citrate* or human menopausal gonadotropins) **with oral contraceptives compared with observation alone** (66). **Oral contraceptives are effective in reducing the risk of subsequent ovarian cysts and may be appropriate for women who desire both contraception and their noncontraceptive benefits.**

Symptomatic cysts should be evaluated promptly, although mildly symptomatic masses suspected to be functional should be managed with analgesics rather than surgery to avoid the risk of surgical complications, including the development of adhesions that may impair subsequent fertility. Surgical intervention is warranted in the presence of severe pain or the suspicion of malignancy or torsion.

[4] On ultrasonography, ascites, cysts greater than 10 cm and those that have multiloculations are concerning for malignancy (81). **If a malignant mass is suspected at any age, surgical evaluation should be performed promptly.**

Simple cysts up to 10 cm in size are likely benign and can be managed expectantly at any age, if asymptomatic (81).

Ovarian or adnexal torsion is suspected on the basis of peritoneal signs and the acuity of onset, often accompanied by nausea and vomiting. Doppler flow studies suggesting abnormal flow are predictive of torsion, although torsion can be seen with normal flow (87). The absence of internal ovarian flow is not specific to torsion and may be seen with cystic lesions, although in these situations peripheral flow usually can be visualized.

The management of suspected ovarian torsion, which can occur at any age from prepubertal to postmenopausal, is surgical. When torsion is confirmed by laparoscopy, untwisting of the mass and ovarian preservation rather than extirpation are generally indicated (88). The value of oophoropexy in preventing recurrent torsion is not well established.

Ultrasonographic or CT-directed aspiration procedures of ovarian masses should not be used in women in whom there is a suspicion of malignancy. In the past, laparoscopic surgery for ovarian masses was reserved for diagnostic or therapeutic purposes in patients at very low risk for malignancy. With the recent advancements in minimally invasive surgery the current recommendation is for **laparoscopic management of suspected benign adnexal masses (Fig. 10-11)**, even those greater than 10 cm. Rates of intraoperative rupture were found to be similar between the open and laparoscopic approaches in three randomized trials made up of 394 patients. The

benefits of laparoscopy included decreased operative time, hospital stay, postoperative pain, and perioperative morbidity. The conversion rate to laparotomy was less than 2% (81).

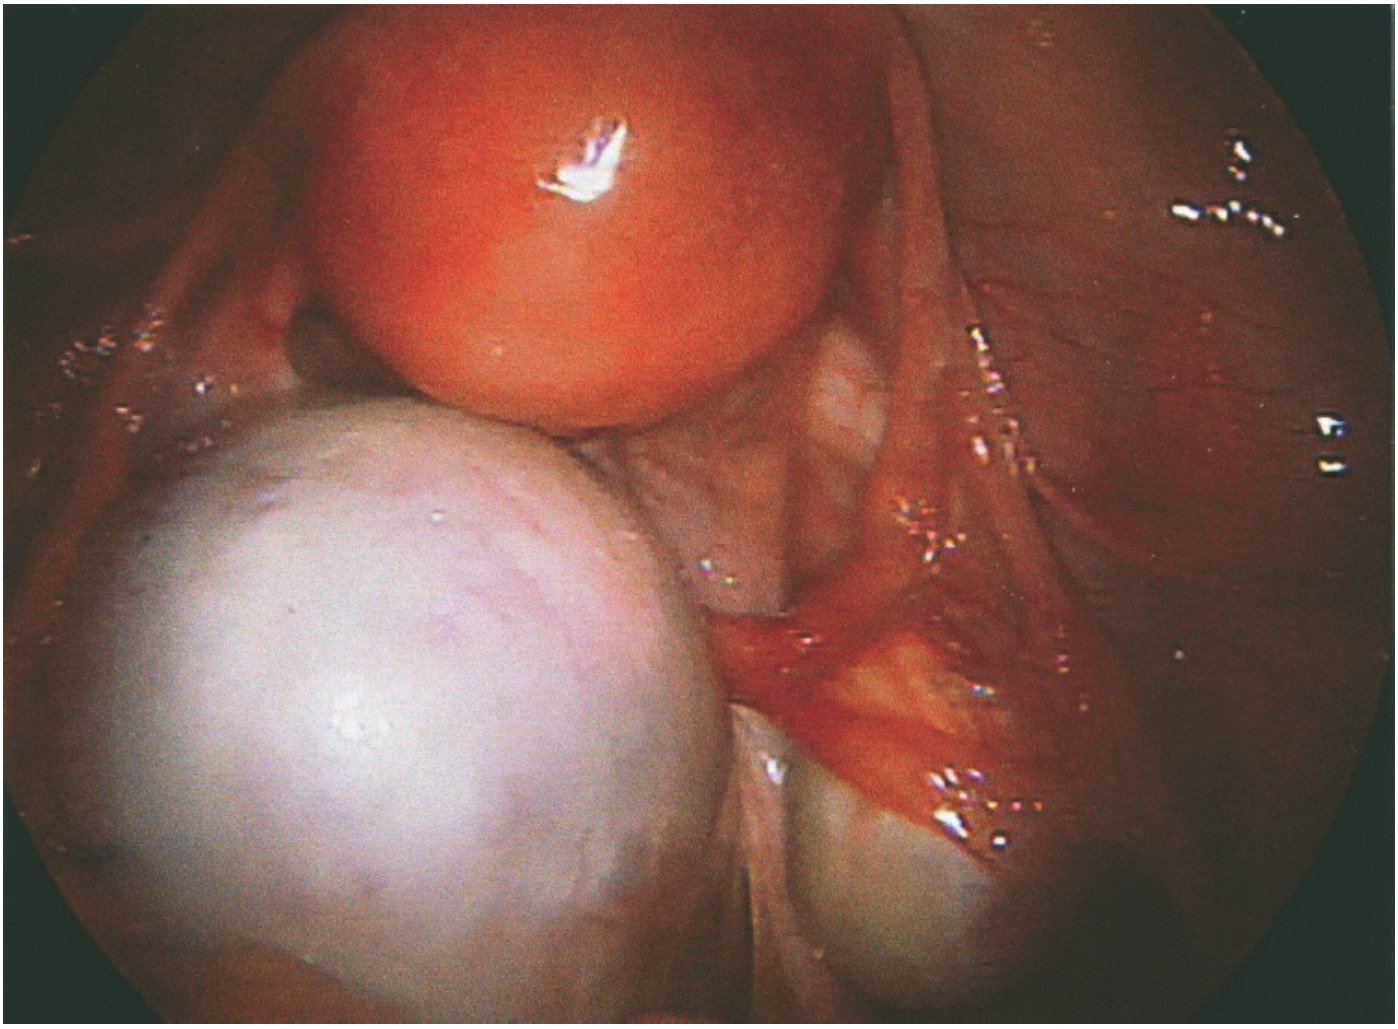

FIGURE 10-11 Laparoscopic appearance of benign ovarian mass (dermoid cyst).

Vulvar Conditions

In postmenarchal individuals, vulvar symptoms are most often related to a primary vaginitis and a secondary vulvitis. The mere presence of vaginal discharge can lead to vulvar irritative symptoms, or candidal vulvitis may be present **(Fig. 10-12)**. The causes of vaginitis and cervicitis are covered in Chapter 15. Adult women describe vulvar symptoms using a variety of terms (itching, pain, discharge, discomfort, burning, external dysuria, soreness, pain with intercourse or sexual activity). **Burning with urination from noninfectious causes may be difficult to distinguish from a urinary tract infection, although some women can distinguish pain when the urine hits the vulvar area (an external dysuria) from burning pain (often suprapubic in location)**

during urination. Itching is a very common vulvar symptom. A variety of vulvar conditions and lesions can present with pruritus. Vulvovaginal symptoms may be caused by STDs, nonsexually transmitted vaginitis, or UTIs. The distinction between symptoms related to a UTI and those of vaginitis is difficult, and consideration should be given to testing for both *C. trachomatis* and obtaining a urine culture, particularly in young reproductive age women (89).

FIGURE 10-12 Candidal vulvitis.

A number of skin conditions that occur on other areas of the body may occur on the vulvar area. Table 10-11 contains a list of these conditions classified by either infectious or noninfectious causes. Whereas the diagnosis of some of these conditions is apparent from inspection alone (e.g., a skin tag), any lesions that appear atypical or in which the diagnosis is not clear should be analyzed by biopsy, because the risks of malignant lesions increases with age (Fig. 10-13).

Pigmented vulvar lesions include benign nevi, lentigines, melanosis, seborrheic keratosis, condyloma, and some vulvar intraepithelial neoplasias (VINs), especially

multifocal VIN-3 **(Fig. 10-14)**. **Suspicious pigmented vulvar lesions in particular should warrant biopsy to rule out VIN or malignant melanoma** (90). Approximately 10% of white women have a pigmented vulvar lesion; some of these lesions may be malignant (see Chapter 40) or have the potential for progression (VIN) (see Chapter 16). There is an increase in rates of VIN in women younger than age 50, along with increasing rates of vulvar squamous cell carcinoma *in situ,* possibly related to increasing rates of human papillomavirus (HPV) infection. Heightened awareness among clinicians may play a role in the increasing frequency of diagnosis; suspicious lesions warrant vulvar biopsy. Pigmented lesions include common nevi, lentigines, melanomas, dysplastic nevi, blue nevi, and a lesion termed atypical melanocytic nevi of the genital type (AMNGT) (91). AMNGTs have some histologic features that may overlap with those of melanoma, but with a benign prognosis.

Table 10-11 Subacute and Chronic Skin Recurrent Conditions of the Vulva

Noninfectious	Infectious
Acanthosis nigricans	Cellulitis
Atopic dermatitis	Folliculitis
Behçet disease	Furuncle/carbuncle
Contact dermatitis	Insect bites (e.g., chiggers, fleas)
Crohn disease	Necrotizing fasciitis
Diabetic vulvitis[a]	Pubic lice
Hidradenitis suppurativa[a]	Scabies
	Tinea
Lichen sclerosus	Condyloma
Paget disease	Vulvar candidiasis
“Razor bumps”—folliculitis or pseudofolliculitis	HSV
Psoriasis	
Seborrheic dermatitis	
Vulvar aphthous ulcer	
Vulvar intraepithelial neoplasia	

[a]Etiology unknown, often secondarily infected.

FIGURE 10-13 Large benign skin tag from left labium majus.

FIGURE 10-14 Pigmented vulvar lesion.

Vulvar Biopsy

A vulvar biopsy is essential for distinguishing benign from premalignant or malignant vulvar lesions, especially because many types of lesions may have a somewhat similar appearance. Vulvar biopsies should be performed liberally in women of reproductive age to ensure that these lesions are diagnosed and treated appropriately. A prospective study of vulvar lesions evaluated by biopsy in a gynecologic clinic found lesions occurring in the following order of frequency: epidermal inclusion cyst, lentigo, Bartholin duct obstruction, carcinoma *in situ,* melanocytic nevi, acrochordon, mucous cyst, hemangiomas, postinflammatory hyperpigmentation, seborrheic keratoses, varicosities, hidradenomas, verruca, basal cell carcinoma, and unusual tumors such as neurofibromas, ectopic tissue, syringomas, and abscesses (92). The frequency with which a lesion would be reported after a tissue biopsy is related to the frequency with which all lesions of a given pathology are evaluated in this manner. This listing probably underrepresents such common lesions as condylomata **(Fig. 10-15)**.

FIGURE 10-15 Extensive vulvar condyloma.

Biopsy is easily performed in the office using a local anesthetic. Typically, 1% *lidocaine* is infiltrated beneath the lesion using a small (25- to 27-gauge) needle. Disposable punch biopsy instruments come in a variety of sizes from 2 to 6 mm in diameter. These skin biopsy instruments, along with fine forceps, scissors, and a scalpel, should be available in all outpatient gynecologic settings. For smaller biopsies, it is usually not necessary to place a suture. Topical *silver nitrate* can be used for hemostasis. Multiple tissue samples may be appropriate to obtain representative areas of a lesion if the lesion has a variable appearance or is multifocal. Although the vulvar biopsy procedure involves minimal discomfort during the procedure, the biopsy sites will be painful for several days after the procedure. The prescription of a topical anesthetic such as 2% *lidocaine* jelly, to be applied periodically and before urinating, is appreciated by patients who require this procedure. Infection of the site can occur, and patients should be cautioned to report excessive erythema or purulent drainage.

Other Vulvar Conditions

Classification and description of intraepithelial lesions of the vulva are presented in Chapter 16.

Pseudofolliculitis or Mechanical Folliculitis

This is similar to what is described as pseudofolliculitis barbae (razor bumps) and may occur in women who follow the popular practice of shaving pubic hair (93). **Pseudofolliculitis consists of an inflammatory reaction surrounding an ingrown hair and occurs most commonly among individuals with curly hair, particularly African Americans.**

Infectious Folliculitis

Shaving may be associated with an infectious folliculitis, commonly caused by *Staphylococcus aureus* and *Streptococcus pyogenes*. Shaving and other methods of pubic hair removal are associated with razor burn, contact dermatitis, and the transmission of other infectious agents such as *Molluscum contagiosum,* HPV, and herpes simplex along with other bacteria including *Pseudomonas aeruginosa* (93).

Fox–Fordyce Disease

This condition is characterized by a chronic, pruritic eruption of small papules or cysts formed by keratin-plugged apocrine glands. It is commonly present over the lower abdomen, mons pubis, labia majora, and inner portions of the thighs. **Hidradenitis suppurativa is a chronic condition involving the apocrine glands with the formation of multiple deep nodules, scars, pits, and sinuses that occur in the axilla, vulva, and perineum.** Hyperpigmentation and secondary infection are often seen. Hidradenitis suppurativa can be extremely painful and debilitating. It has been treated with antibiotics, isotretinoin, or steroids; surgical therapy with wide local excision may be necessary (94).

Acanthosis Nigricans

This disease involves widespread velvety pigmentation in skin folds, particularly the axillae, neck, thighs, submammary area, and vulva and surrounding skin **(Fig. 10-16)**. It is of particular interest to gynecologists because of its association with hyperandrogenism and PCOS; as such, it is associated with obesity, chronic anovulation, acne, glucose intolerance, insulin resistance, and cardiovascular disease (95). Topical and oral retinoids are used to treat the acanthosis nigricans, along with management of the underlying conditions including obesity and insulin resistance or diabetes.

FIGURE 10-16 Acanthosis nigricans of the neck.

Extramammary Paget Disease

This is an intraepithelial neoplasia containing vacuolated Paget cells (see Chapter 16). Clinically, the appearance of Paget disease is variable, and it may have an appearance varying from moist, oozing ulcerations to an eczematoid lesion with scaling and crusting to a grayish lesion (96). It may be confused with candidiasis, psoriasis, seborrheic dermatitis, contact dermatitis, and VIN. A biopsy to confirm the diagnosis is mandatory. Treatment has traditionally been surgery, although recurrences are very common; topical therapies including imiquimod are being used (97).

Vulvar Intraepithelial Neoplasia

VIN is associated with HPV infection and is increasing in frequency, particularly among young women (see Chapter 16). Diagnosis requires biopsy of any suspicious vulvar lesions, particularly those that are pigmented or discolored. The increasing frequency of this entity dictates a careful vulvar inspection during annual gynecologic examinations.

Vulvar Tumors, Cysts, and Masses

Condylomata Acuminata

These are very common vulvar lesions and are usually easily recognized. They may resolve spontaneously; treatment is guided by wart number, size, and anatomic site; patient preference; cost of treatment; convenience; adverse effects; and provider experience (98). **Treatments may be patient-applied or provider-administered. Other sexually transmitted organisms, such as the virus responsible for *M. contagiosum* and the lesions of syphilis and condylomata lata, may occasionally be mistaken for vulvar condylomata acuminata caused by HPV** (see Chapter 15). A summary of benign vulvar tumors is listed in **Table 10-12**. There is an argument regarding whether sebaceous cysts exist on the vulva or whether these lesions are histopathologically epidermal or epidermal inclusion cysts (99). The so-called sebaceous cysts are clinically indistinguishable from epidermal inclusion cysts that may result from the burial of fragments of skin after the trauma of childbirth or episiotomy or that arise from occluded pilosebaceous ducts. These cysts are seldom symptomatic, although if infection develops, incision and drainage may be required acutely, and ultimately complete excision is indicated.

Table 10-12 Types of Vulvar Tumors

1. *Cystic lesions*
Bartholin duct cyst
Cyst in the canal of Nuck (hydrocele)
Epithelial inclusion cyst
Skene duct cyst
2. *Solid tumors*
Acrochordon (skin tag)
Angiokeratoma
Bartholin gland adenoma
Cherry angioma
Fibroma
Hemangioma
Hidradenoma
Lipoma

Granular cell myoblastoma
Neurofibroma
Papillomatosis
3. *Anatomic*
Hernia
Urethral diverticulum
Varicosities
4. *Infections*
Abscess—Bartholin, Skene, periclitoral, other
Condyloma lata
Molluscum contagiosum
Pyogenic granuloma
5. *Ectopic*
Endometriosis
Ectopic breast tissue

Bartholin Duct Cysts

These are common vulvar lesions in reproductive age women. They result from occlusion of the duct with accumulation of mucus and may be asymptomatic. Infection of the gland can result in the accumulation of purulent material, with the formation of a rapidly enlarging, painful, inflammatory mass (a Bartholin abscess). An inflatable bulb-tipped catheter was described by Word and is quite easy to use (100). The small catheter is inserted through a small stab wound into the abscess after infiltration of the skin with local anesthesia; the balloon of the catheter is inflated with 2 to 3 mL of saline and the catheter remains in place for 4 to 6 weeks, allowing epithelialization of a tract and the creation of a permanent gland opening.

Skene Duct Cysts

These are cystic dilations of the Skene glands, typically located adjacent to the urethral meatus within the vulvar vestibule. Although most are small and often asymptomatic, they may enlarge and cause urinary obstruction, requiring excision **(Fig. 10-17)**.

FIGURE 10-17 The Skene gland cyst.

Painful Intercourse

Painful intercourse (dyspareunia) may be caused by many different vulvovaginal conditions, including common vaginal infections and vaginismus (see Chapters 15 and 17). A careful sexual history is essential, as is a careful examination of the vulvar area and vagina. *Vulvodynia* is the term used to describe unexplained vulvar pain, sexual dysfunction, and the resultant psychological disability (101,102). **The term *vulvar vestibulitis* was previously used to describe a situation in which there is pain during intercourse or when attempting to insert an object into the vagina; pain on pressure to the vestibule on examination and vestibular erythema (known as the Friedrich triad); this entity is now described as localized vulvodynia, which may be provoked or spontaneous, primary or secondary, and intermittent, persistent, constant, immediate, or delayed** (see Chapter 12) (102,103). A number of studies failed to demonstrate a consistent relationship with any genital infectious organism, including *C. trachomatis*, gonorrhea, *Trichomonas*, mycoplasma, *Ureaplasma*,

Gardnerella, candida, or HPV, and the condition has been characterized as multifactorial, with inflammatory, neuropathic, and functional components (104). Although the symptoms of dyspareunia with insertion can be disabling, no curative therapies were found. Medical and behavioral therapies are of some benefit, and some authors encourage surgery, but the role of this treatment and newer therapies such as the injection of botulinum toxin A is not well established (104).

Vulvar Ulcers

A number of STDs can cause vulvar ulcers, including herpes simplex virus, syphilis, lymphogranuloma venereum, and granuloma inguinale (see Chapter 15). *Crohn disease* can include vulvar involvement with abscesses, fistulae, sinus tracts, fenestrations, and other scarring. Medical treatment with systemic steroids and other systemic agents is the standard therapy; surgical therapy for intestinal and vulvar disease may be required.

The Behçet Disease

This systemic condition is characterized by genital and oral ulcerations with ocular inflammation and many other manifestations (105). The cause and the most effective therapy are not well established, although anti-inflammatory, immunomodular, and immunosuppressive therapies may be effective (106).

Lichen Planus

This condition causes oral and genital ulcerations. Typically, there is desquamative vaginitis with erosion of the vestibule. Treatment is based on the use of topical and systemic steroids. Plasma cell mucositis appears as erosions in the vulvar area, particularly the vestibule. Biopsy is essential in establishing the diagnosis.

Vaginal Conditions

Vaginal discharge is one of the most common vaginal symptoms. Conditions ranging from vaginal candidiasis to chlamydia cervicitis to bacterial vaginosis to cervical carcinoma may cause vaginal discharge. Infectious vaginal conditions are addressed more completely in Chapter 15. Vaginal lesions may occasionally be palpable to a woman. More commonly, vaginal lesions are discovered on examination by a clinician. They may contribute to symptoms (such as bleeding or discharge) or they may be entirely asymptomatic. Vaginitis, cervicitis, and vaginal or cervical lesions (including malignancies) can be causes of vaginal discharge. Other noninfectious causes of discharge are as follows:

1. **Retained foreign body—tampon, pessary**
2. **Ulcerations—tampon-induced, lichen planus, herpes simplex infection**
3. **Malignancy—cervical, vaginal**

Some vaginal lesions are asymptomatic and are noted incidentally on examination. Fibroepithelial polyps consist of polypoid folds of connective tissue, capillaries, and stroma covered by vaginal epithelium. Although they can be excised easily in the office, their vascularity can be troublesome, and excision is not necessary unless the diagnosis is in question. **Cysts of embryonic origin can arise from mesonephric, paramesonephric, and urogenital sinus epithelium. Gartner duct cysts are of mesonephric origin and are usually present on the lateral vaginal wall.** They rarely cause symptoms and do not require treatment. Other embryonic cysts can arise anterior to the vagina and beneath the bladder. Cysts that arise from the urogenital sinus epithelium are located in the area of the vulvar vestibule. Vaginal adenosis, the presence of epithelial-lined glands within the vagina, is associated with *in utero* exposure to *diethylstilbestrol*. No therapy is necessary other than close observation and periodic palpation to detect nodules that may need to be evaluated by biopsy to rule out vaginal clear cell adenocarcinoma (see Chapter 38).

Women will sometimes describe a bulging lesion of the vagina and vulvar area, variably associated with symptoms of pressure or discomfort. The most common cause of such a lesion is one of the disorders of vaginal support. Management of these conditions is discussed in Chapter 30. Other genital lesions, such as urethral diverticula or embryonic cysts, may cause similar symptoms.

POSTMENOPAUSAL AGE GROUP

Abnormal Bleeding

Differential Diagnosis

[1] The causes of postmenopausal bleeding and the percentage of patients who seek treatment for different conditions are presented in Table 10-13.

Table 10-13 Etiology of Postmenopausal Bleeding

Factor	Approximate Percentage
Exogenous estrogens	30
Atrophic endometritis/vaginitis	30
Endometrial cancer	15
Endometrial or cervical polyps	10
Endometrial hyperplasia	5
Miscellaneous (e.g., cervical cancer, uterine sarcoma, urethral caruncle, trauma)	10

From **Hacker NF, Moore JG.** *Essentials of Obstetrics and Gynecology*. 3rd ed. Philadelphia, PA: WB Saunders; 1998:635, with permission.

Benign Disorders

Hormone therapy (HT) may be used to manage troublesome menopausal symptoms including vasomotor and genitourinary symptoms. The North American Menopause Society has issued a statement noting that HT is the most effective treatment for these symptoms, and has been shown to prevent bone loss and fracture; the society noted that the risks of HT depend on the type, dose, duration, route of administration, timing of initiation, and concurrent use of a progestogen, thus requiring individualization of use, with periodic revaluation of the benefits versus the risks (107). Long-term combined HT has been associated with increased risks of venous thromboembolism, stroke, breast cancer, coronary events, gallbladder disease, and death from lung cancer (108). Women who are taking HT during menopause may be using a variety of hormonal regimens that can result in bleeding. Because unopposed estrogen therapy can result in endometrial hyperplasia, various regimens of progestins are typically added to the estrogen regimen; they are given in a continuous fashion, although they may be given in a sequential fashion for women within 1 year of menopause. Endometrial sampling is indicated for any unexpected bleeding that occurs with hormonal therapy. **A significant change in withdrawal bleeding or breakthrough bleeding (e.g., absence of withdrawal bleeding for several months followed by resumption of bleeding or a marked increase in the amount of bleeding) should prompt endometrial sampling.**

Patient adherence to hormonal regimens is a significant issue with HT, with the challenges of oral therapy mitigated by nonoral routes of administration (109). Missed doses of oral medication and failure to take the medication in the prescribed fashion can lead to irregular bleeding or spotting that is benign in origin but that can result in patient dissatisfaction.

The problems that women most often report with HT include vaginal bleeding and weight gain. The use of a continuous low-dose combined regimen has the advantage that for many women, bleeding will ultimately cease after several months, during which irregular and unpredictable bleeding may occur (110). Some women are unable to tolerate these initial months of irregular bleeding. The risk of endometrial hyperplasia or neoplasia with this regimen is low.

Other benign causes of bleeding include atrophic vaginitis and endometrial and cervical polyps, which may become apparent as postcoital bleeding or spotting. Women who experience bleeding after menopause may attempt to minimize the extent of the problem; they may describe it as “spotting” or “pink or brownish discharge.” However, any indication of bleeding or spotting should be evaluated. **[1] In the absence of HT, any bleeding after menopause (classically defined as absence of menses for 1 year) should prompt evaluation with endometrial sampling.** Studies of transvaginal

ultrasonography revealing an endometrial thickness 4 mm or less correlate with a low risk of endometrial malignancy, and thus endometrial sampling is not required (111). Endometrial polyps and other abnormalities can be seen in women who are taking *tamoxifen.* These polyps are more likely to involve cystic dilation of glands, stromal condensation around the glands, and squamous metaplasia of the overlying epithelium. These polyps can be benign, although they must be distinguished from endometrial malignancies, which may occur when taking *tamoxifen.* **[2]** The incidence of endometrial polyps not associated with *tamoxifen* increases with age during the reproductive years; it is not clear whether the incidence subsequently peaks or decreases during the postmenopausal years (12). Endometrial polyps are more likely to be malignant in postmenopausal women, and hypertension is associated with an increased risk of malignancy (112).

Neoplasia

Endometrial, cervical, and ovarian malignancies must be ruled out in the presence of postmenopausal bleeding. One series found a malignancy (endometrial or cervical) in approximately 10% of women with postmenopausal bleeding (113). **Cervical cytology testing is essential when postmenopausal bleeding is noted, although cytologic testing is an insensitive diagnostic tool for detecting endometrial cancer.** The cytology test results are negative in some cases of invasive cervical carcinoma because of tumor necrosis.

Cervical malignancy is diagnosed by cervical biopsy of grossly visible lesions and colposcopically directed biopsy for women with abnormal Pap test results (see Chapter 16). **Functional ovarian tumors may produce estrogen and lead to endometrial hyperplasia or carcinoma, which may cause bleeding.**

Diagnosis of Postmenopausal Abnormal Bleeding

Pelvic examination to detect local lesions and a Pap test to assess the cytology are essential first steps in finding the cause of postmenopausal bleeding. Pelvic ultrasonographic examination and, in particular, transvaginal ultrasonography or sonohysterography can suggest the cause of bleeding (111,114). **Endometrial sampling, through office biopsy, hysteroscopy, or D&C, is usually considered essential.** An endometrial thickness of less than 5 mm measured by transvaginal ultrasonography is unlikely to indicate endometrial cancer, and some authors suggest that the diagnostic accuracy is overestimated and recommend a cutoff of 3 mm (115).

Management of Postmenopausal Abnormal Bleeding

Benign Disorders

The management of bleeding caused by atrophic vaginitis includes topical (vaginal) or systemic use of estrogens after other causes of abnormal bleeding are excluded. Such therapy can provide significant benefits in terms of the quality of life, but must be weighed with each individual, considering contraindications and patient preferences (107). Serum levels appear to be lower with vaginal administration using creams, tablets, or rings (116). Cervical polyps can easily be removed in the office.

Endometrial Hyperplasia

The terminology used to describe endometrial hyperplasia is confusing, and the clinician must consult with the pathologist to ensure an understanding of the diagnosis to dictate correct management. In 2015, the ACOG and the Society of Gynecologic Oncology recommended that the **World Health Organization (WHO) system be replaced with the endometrial intraepithelial neoplasia (EIN) schema as described in Table 10-14 to distinguish benign lesions from those that are premalignant and should be managed more conservatively.**

Table 10-14 Nomenclature for Endometrial Hyperplasia

Class	Nomenclature	Treatment
Benign	Benign endometrial hyperplasia	Medical
Premalignant	Endometrial intraepithelial neoplasia (EIN), replaces atypical hyperplasia	Surgical vs. medical (desires fertility or poor surgical candidate)
Malignant	Endometrial adenocarcinoma, endometrioid type, well differentiated	Surgical +/– staging

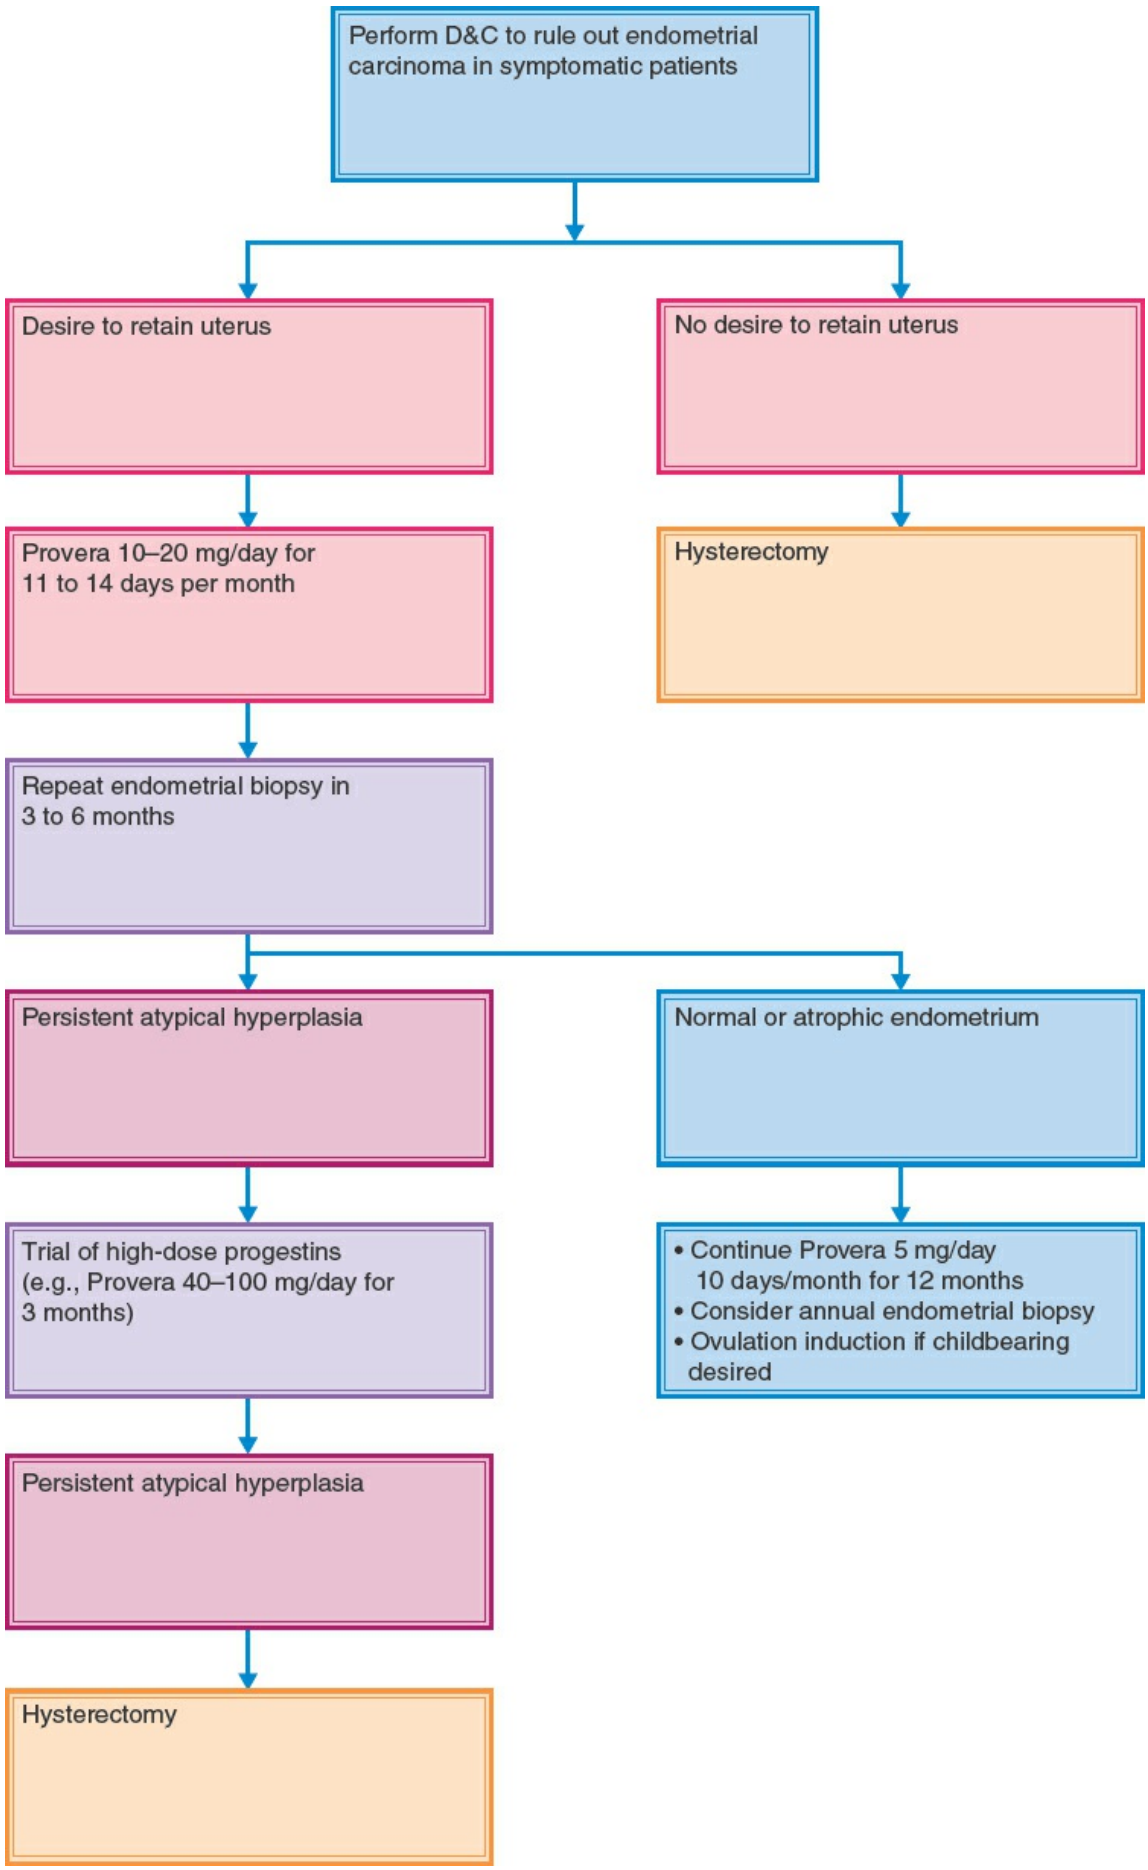
The new nomenclature has three categories:

1. **Benign = Benign endometrial hyperplasia**
2. **Premalignant = EIN, replaces atypical hyperplasia**
3. **Malignant = Endometrial adenocarcinoma, endometrioid type, well differentiated**

Many pathologists still use the WHO system, which classifies endometrial hyperplasia as simple hyperplasia, complex hyperplasia, simple atypical hyperplasia, and complex atypical hyperplasia (117). Approximately 40% to 50% of women with atypical hyperplasia or EIN have concurrent carcinoma. **The management of endometrial hyperplasia is based on an understanding of the natural history of the lesion involved.** The risk of progression of hyperplasia without atypia is low but is approximately 30% among those with atypical hyperplasia (117). Hysterectomy is recommended as definitive treatment of EIN in postmenopausal women, and rules out

possible concurrent carcinoma. Management of endometrial cancer with surgical staging and multidisciplinary review of pathology and treatment planning is addressed in Chapter 37.

Progestin therapy (oral, parenteral, or intrauterine device delivery) has been used in women with EIN or endometrial cancer who are poor operative candidates (29,118). These women should have an endometrial biopsy every 3 months to check for recurrence, with recurrence risks approaching 50% (118). A suggested scheme of management is outlined in **Figure 10-18**. This treatment is discussed in more detail in Chapter 37.



Perform D&C to rule out endometrial carcinoma in symptomatic patients
Desire to retain uterus
No desire to retain uterus
Provera 10–20 mg/day for 11 to 14 days per month
Hysterectomy
Repeat endometrial biopsy in 3 to 6 months
Persistent atypical hyperplasia
Normal or atrophic endometrium
Trial of high-dose progestins (e.g., Provera 40–100 mg/day for 3 months)
• Continue Provera 5 mg/day 10 days/month for 12 months
• Consider annual endometrial biopsy
• Ovulation induction if childbearing desired
Persistent atypical hyperplasia
Hysterectomy

FIGURE 10-18 Management of endometrial hyperplasia. (From **Hacker NF, Friedlander ML**. Uterine cancer. In: Berek JS, Hacker NF. *Berek & Hacker's Gynecologic Oncology*. 6th ed. Philadelphia, PA: Wolters Kluwer; 2014: 404.)

Pelvic Masses

Differential Diagnosis

Ovarian Masses

During the postmenopausal years, the ovaries become smaller. Ovarian volume is related to age, menopausal status, weight, height, and the use of exogenous hormones (119). A large body habitus and uterine size make it more difficult to palpate and assess the ovarian size, particularly among postmenopausal women, and transvaginal ultrasonography is significantly more accurate than clinical examination. Transvaginal ultrasonography is suggested in addition to annual pelvic examination among overweight postmenopausal women (120). **[3]** Although ovarian cancer is notoriously difficult to diagnose at any early stage, the concept that it is frequently asymptomatic has been challenged. Symptoms may include back pain, fatigue, bloating, constipation, abdominal pain, and urinary symptoms; these symptoms are of greater severity and more recent onset in women with ovarian malignancy (121). It is argued that among primary clinicians, the possibility of an ovarian mass (either benign or malignant) in women with these symptoms warrants further diagnostic investigation. The positive predictive value of these symptoms is not high for the prediction of early-stage disease, and the use of symptoms to trigger an evaluation for ovarian cancer is noted to result in diagnosis of the disease in only 1 in 100 women in the general population with such symptoms (122). **[3]** Ovarian cancer is predominantly a disease of postmenopausal women; the incidence increases with age, and the average patient age is about 56 to 60 years (see Chapter 39).

With increased use of pelvic ultrasonographic evaluation, a new problem arose in postmenopausal women: the discovery of a small ovarian cyst. This is particularly troublesome in a woman who is entirely asymptomatic and whose ultrasonographic examination was performed for indications unrelated to pelvic pathology. It is suggested that **when the cyst is asymptomatic, small (<10 cm in diameter), unilocular, and thin walled, with a normal CA125 level, the risk of malignancy is extremely low and these masses can be followed conservatively, without surgery** (81,123,124). Surgery may be indicated in some women with a strong family history of ovarian, breast, endometrial, or colon cancer, or with a mass that appears to be enlarging (see Chapter 39). The addition of color flow Doppler examination and other ultrasonographic characteristics may be helpful in distinguishing benign from malignant masses, although the role of Doppler ultrasonography remains somewhat controversial **(Table 10-10)** (81).

[5] Many postmenopausal women have not had regular gynecologic care, and the discovery of a pelvic mass may reflect the persistence of a uterine leiomyoma that previously was not discovered. The possibility of transient ovarian cysts is noted above, and it may be difficult to distinguish an ovarian from a uterine mass. Some women may not remember having been told they had a pelvic mass. Thus, **a review of medical records may be helpful in determining the pre-existence of a benign pelvic mass.** Uterine leiomyomas are hormonally responsive and typically decrease in size or resolve after menopause (see Chapter 11).

Diagnosis of Postmenopausal Pelvic Mass

A personal and family medical history is helpful in detecting individuals at increased risk for the development of ovarian cancer. Several hereditary family cancer syndromes involve ovarian neoplasms (see Chapter 39). **Patients with hereditary forms of epithelial ovarian cancer account for only a small percentage of all cases; 90% to 95% of cases of ovarian cancer are sporadic and without identifiable heritable risk.**

In postmenopausal women with a pelvic mass, a CA125 measurement may be helpful in predicting a higher likelihood of a malignancy, which may guide decisions regarding management, consultation, or referral. A high index of suspicion by women and their clinicians represents the best way to detect early ovarian cancer. Persistent symptoms such as an increase in abdominal size, bloating, fatigue, abdominal pain, indigestion, inability to eat normally, urinary frequency, pelvic pain, constipation, back pain, new onset of urinary incontinence, or unexplained weight loss require evaluation and consideration of the possibility of ovarian cancer. **A normal CA125 level does not rule out ovarian cancer; up to 50% of early-stage ovarian malignancies and 20% to 25% of advanced cancers have normal values of CA125** (125).

Management of Postmenopausal Pelvic Mass

The use of improved imaging techniques may allow the nonoperative management of ovarian masses that are probably benign **(Table 10-10)**. **A suspicious or persistent complex mass requires surgical evaluation. Patients with masses that are clinically suspicious for cancer should be offered the opportunity of a preoperative consultation with a gynecologic** oncologist, a physician trained to appropriately stage and debulk ovarian cancer to optimize the patient's outcome (126). Comprehensive surgical staging facilitates appropriate therapy and optimizes prognosis.

Vulvar Conditions

Anatomic changes that occur in postmenopausal women include atrophy of the labia majora and increasing prominence of the labia minora. The epithelium of the hymen and vestibule become thin; there is a shift in vaginal cellular maturation in response to estrogen deprivation, with resultant thinning. Although these changes lead to minimal symptoms in most women, external dysuria, pruritus, tenderness, dyspareunia, and bleeding can result from fissuring and excoriations. **Because of the risk of VIN and malignancy, suspicious lesions require vulvar biopsy.**

Vulvar Dermatoses

Several vulvar conditions occur most commonly in postmenopausal women. Symptoms are primarily itching and vulvar soreness, in addition to dyspareunia.

In the past, numerous terms were used to describe disorders of vulvar epithelial growth that produce a number of nonspecific gross changes. These terms included *leukoplakia, lichen sclerosus,* and *atrophicus, atrophic* and *hyperplastic vulvitis,* and *kraurosis vulvae.* The ISSVD in 2006 recommended a classification of vulvar dermatoses based on histologic patterns, listed with the likely clinical diagnoses, rather than on the basis of clinical morphology as in the previous categorization (see Chapter 12) (127). This classification system excludes neoplastic and infectious conditions. Vulvar conditions that are described in this classification system include atopic, allergic, and irritant contact dermatitis, psoriasis, lichen simplex chronicus, lichen sclerosus, lichen planus, pemphigoid, aphthous ulcers, Behçet disease, and Crohn disease.

Lichen Sclerosus

Lichen sclerosus is the most common white lesion of the vulva. Lichen sclerosus can occur at any age, although it is most common among postmenopausal women and prepubertal girls (Fig. 10-19). The symptoms are pruritus, dyspareunia, and burning. Lichen sclerosus characteristically is associated with decreased subcutaneous fat to the extent that the vulva is atrophic, with small or absent labia minora, obliteration of the anatomic landmarks, thin labia majora, and sometimes phimosis of the prepuce. The surface is pale with a shiny, crinkled pattern (described as having characteristics like “cigarette paper”), often with fissures and excoriation. The lesion tends to be symmetric and often extends to the perineal and perianal areas. The diagnosis is confirmed by biopsy. Invasive cancer is associated with lichen sclerosus, although the significance of this association is unclear in terms of causation (128).

FIGURE 10-19 Prepubertal lichen sclerosus.

Treatment is with an ultrapotent topical steroid such as 0.05% *clobetasol.* Approximately 96% of patients respond satisfactorily (129). Maintenance therapy is frequently required, and a graduated reduction from ultrapotent to medium- and low-potency topical steroids can help to maintain remission of symptoms (130). The topical calcineurin inhibitors *pimecrolimus* and *tacrolimus* were effective in individuals not responding to topical steroids, although the FDA approved a warning suggesting possible risk of cancer from this class of drugs and caution is advised with long-term use avoided (131).

Premalignant Vulvar Lesions

Squamous VIN is seen most often in postmenopausal women but may occur during the reproductive years. Pruritus is the most common symptom, although "lumps" may be described and are sometimes confused with condyloma (132). Current terminology describes two types of VINs: VIN, usual type, that is typically HPV-related and encompassing former VIN-2 and -3 with warty, basaloid, and mixed types; and VIN, differentiated type (133). The lesion appears thickened and hyperkeratotic, and there may be excoriation. Lesions may be discrete but may be symmetric and multiple. About one-third of women will have a history of HPV-related cervical disease or condyloma (132). Most women with VIN are smokers. Biopsy is necessary to confirm the diagnosis and to exclude malignancy. See Chapter 16 for management of VIN.

Urethral Lesions

The urethra and vagina have a common embryonic origin and are steroid-dependent tissues. Urethral caruncles and prolapse of the urethral mucosa are examples of vulvar lesions that may be seen in other age groups but that occur more commonly among older women. Both conditions can be treated with topical or systemic estrogen preparations. Various vulvar skin lesions, including seborrheic keratoses and cherry hemangiomas (senile hemangiomas), occur more commonly on aging skin.

Vaginal Conditions

Up to half of postmenopausal women have symptoms of atrophic vaginitis, although many do not seek therapy. Symptoms include an external dysuria, pruritus, tenderness, dyspareunia, and bleeding from fissuring or ulcerations. In addition to the clinical findings of a shiny, flat, thin-appearing vaginal mucosa without rugae, microscopic examination of vaginal secretions reveals an increased number of white blood cells. **Treatment with local or systemic estrogens effectively manages the symptoms and restores normal pH levels with ongoing therapy** (134). Systemic absorption does occur with topical estrogen therapy, and rates of absorption differ depending on the

degree of atrophy. Topical emollients may be helpful if estrogens are not desired or are contraindicated. Vaginal lubricants are universally useful in minimizing symptoms of dyspareunia for postmenopausal women (135).

Management Summary

KEY POINTS

1 Fibroids are very common; most are asymptomatic and can be managed expectantly.

2 There is no definite relationship between oral contraceptives and the presence of fibroids.

3 First-degree relatives of women with fibroids have a 2.5 times increased risk of developing fibroids.

4 The risk of having fibroids is 2.9 times greater in African American women than in white women.

5 Women with fibroids are only slightly more likely to experience pelvic pain than women without fibroids.

6 Rapid uterine growth is not well defined, and almost never indicates sarcoma in premenopausal women; sarcomas are rare and more likely occur in postmenopausal women with symptoms of pain and bleeding.

7 Sonography is the most readily available and least costly imaging technique to differentiate fibroids from other pelvic pathology; however, MRI permits more precise evaluation of the number, size, and position of fibroids, including the proximity to the endometrial cavity.

8 The presence of submucosal fibroids decreases fertility and removing them can increase fertility; subserosal fibroids do not affect fertility and removing them does not increase fertility; intramural fibroids may slightly decrease fertility, but removal does not increase fertility.

9 Most fibroids do not increase in size during pregnancy.

10 For women who are mildly or moderately symptomatic with fibroids, watchful waiting may allow treatment to be deferred, perhaps indefinitely.

11 As women approach menopause, watchful waiting may be considered because there is limited time to develop new symptoms, and after menopause bleeding stops and fibroids decrease in size.

12 Surgical treatment options include abdominal myomectomy, laparoscopic myomectomy, laparoscopic radiofrequency ablation, hysteroscopic myomectomy, endometrial ablation, and abdominal, vaginal, or laparoscopic hysterectomy.

13 An inability to evaluate the ovaries on pelvic examination is not an indication for surgery.

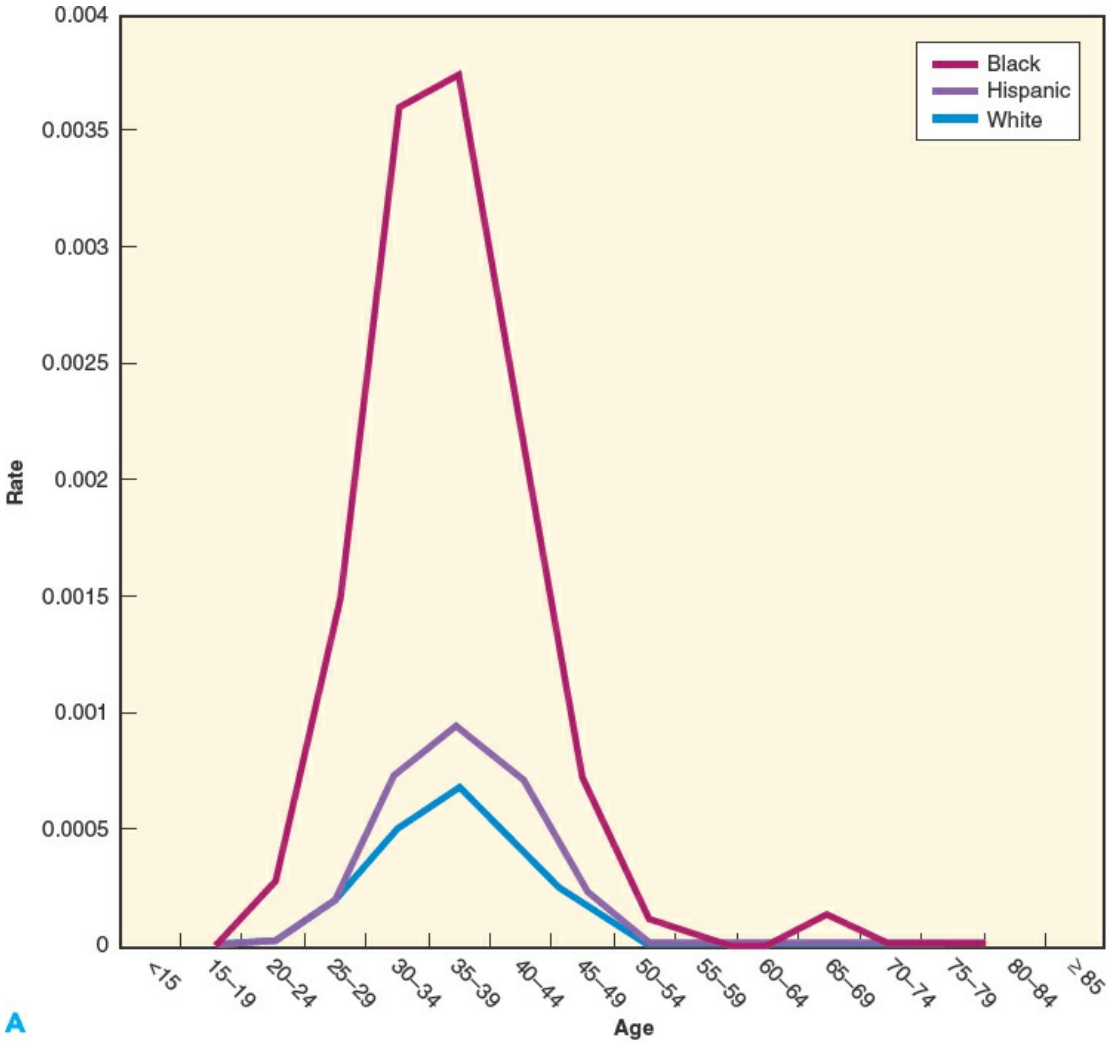
14 Myomectomy should be considered as a safe alternative to hysterectomy, even for those women

who have large uterine fibroids and wish to retain their uterus.

15 Submucous fibroids, sometimes associated with increased menstrual bleeding or infertility, often can be removed hysteroscopically.

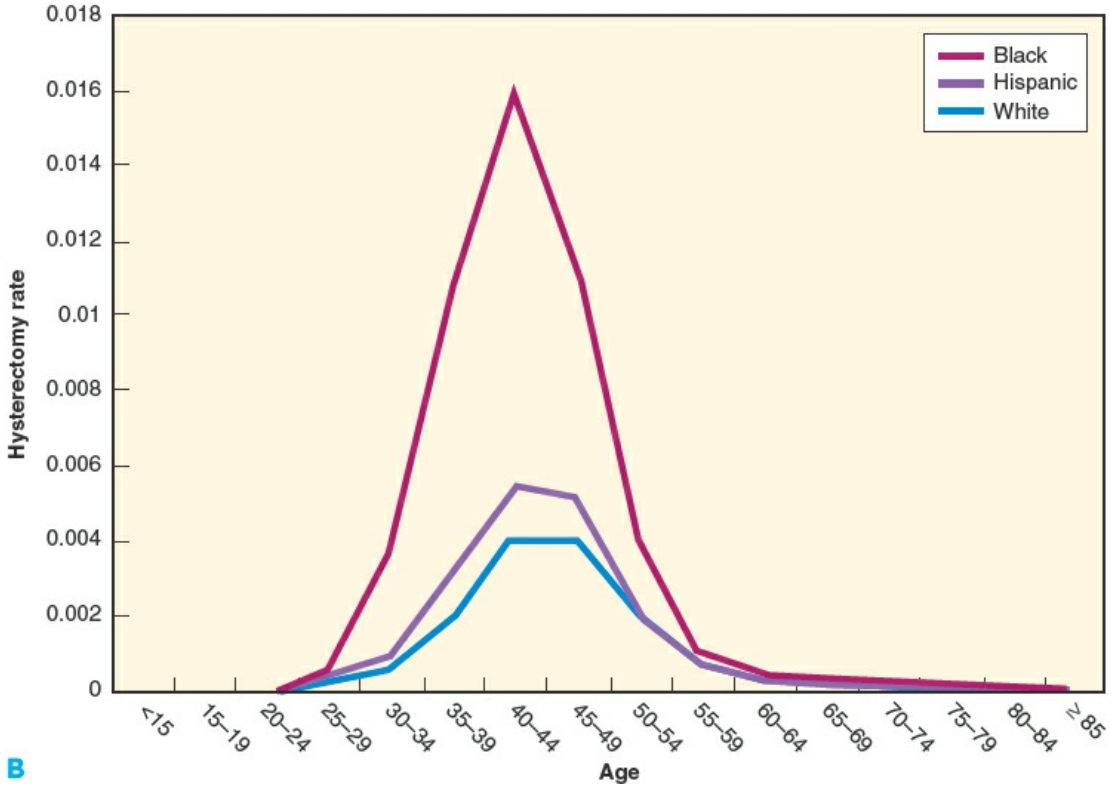
16 Routine ultrasound follow-up is sensitive, and may detect many clinically insignificant fibroids.

17 Uterine artery embolization (UAE) is an effective treatment for selected women with uterine fibroids. The effects of UAE on early ovarian failure, fertility, and pregnancy are unclear.



Fibroids (leiomyomas, myomas) are an important health care concern because they are the most frequent indication for the performance of hysterectomy, accounting for nearly 240,000 such procedures in the United States (1). In comparison, approximately 30,000 myomectomies are performed every year. Inpatient surgery for fibroids costs $2.1 billion per year in the United States, and the cost of outpatient surgeries, medical and nonmedical costs, and time away from work or family add significantly to these expenditures (2).

ORIGINS OF UTERINE FIBROIDS



Fibroids **are benign, monoclonal tumors of the smooth muscle cells of the myometrium** and contain large aggregations of extracellular matrix composed of collagen, elastin, fibronectin, and proteoglycan (3).

Incidence

[1] Fibroids are remarkably common. Fine serial sectioning of uteri from 100 consecutive women subjected to hysterectomy discovered fibroids in 77%, some as small as 2 mm (4). A random sampling of women aged 35 to 49, screened by self-report, medical record review, and sonography, found that among African American women by age 35 the incidence of fibroids was 60%, and it was over 80% by age 50 **(Fig. 11-1)**. White women have an incidence of 40% at age 35 and almost 70% by age 50 (5).

(From Health Services/Technology Assessment Tests [HSTAT]. Available online at http://www.ncbi.nlm.nih.gov/books/bv.fcgi?rid=hstat1.section.48317.)

Etiology

Although the precise causes of fibroids are unknown, advances have been made in understanding the molecular biology of these benign tumors and their hormonal, genetic, and growth factors (6).

Genetics

Fibroids are monoclonal and are made up of concentric smooth muscle fibers and fibrous connective tissue surrounded by a vascular pseudocapsule. Some authors postulate that hypoxic conditions, perhaps associated with menstruation, induce mutations in a single myometrial smooth muscle stem cell. Approximately 40% to 50% of fibroids display nonrandom and tumor-specific chromosome rearrangements involving mostly deletions, duplications, and translocations of chromosomes 6, 7, 12, and 14. These complex molecular changes affect energy metabolism, extracellular matrix remodeling, and estrogen and progesterone receptor status.

Growth factors, small proteins that act as signaling molecules, interact with specific receptors on the cell surface and are important for the development of fibroids. Transforming growth factor-β (TGF-β), basic fibroblast growth factor (bFGF), vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and insulinlike growth factor (IGF) modulate cellular growth, proliferation, and differentiation. The TGF-β family upregulates the synthesis of many extracellular matrix components that increase the fibrous component of fibroids. Proliferation of smooth muscle cells are induced by bFGF, which promotes angiogenesis. Estrogen and progesterone influence fibroid development by regulating growth factors and their signaling pathways. Fibroids may be affected by environmental chemicals, which can increase or decrease estrogen and/or progesterone receptors.

Genetic differences between fibroids and leiomyosarcomas (LMSs) indicate that LMSs do not result from the malignant degeneration of fibroids. Cluster analysis of 146 genes found that the majority are downregulated in LMSs but not in fibroids or myometrium. Comparative genomic hybridization did not find specific anomalies shared by fibroids and LMSs (7).

Hormones

Estrogen and progesterone appear to promote the development of fibroids.

Fibroids are rarely observed before puberty, are most prevalent during the reproductive years, and regress after menopause. Factors that increase overall lifetime exposure to estrogen, such as obesity and early menarche, increase the incidence. Decreased exposure to estrogen found with smoking, exercise, and increased parity is protective (8).

Serum levels of estrogen and progesterone are similar in women with and without clinically detectable fibroids. As a result of increased levels of aromatase within fibroids, *de novo* production of estradiol is higher than in normal myometrium (8). Progesterone is important in the pathogenesis of fibroids, which have increased concentrations of progesterone receptors A and B compared with normal myometrium (9,10). The highest mitotic counts are found in fibroids at the peak of progesterone production (11). Gonadotropin-releasing hormone (GnRH) agonists decrease the size of fibroids, but progestin given concurrently with GnRH prevents a decrease in size (12).

Human fibroid tissue, grafted to immunodeficient mice, increased in size in response to estradiol plus progesterone, but the growth was blocked by the antiprogestin *RU486* (12). The volume of grafted fibroid tissue decreased after progesterone withdrawal. Treatment with estradiol alone did not increase the graft size, but did induce expression of progesterone receptors and supported the action of progesterone on the grafts (12).

Growth Factors

Growth factors, proteins, or polypeptides, produced locally by smooth muscle cells and fibroblasts, appear to stimulate fibroid growth primarily by increasing extracellular matrix (6). Many of these growth factors are overexpressed in fibroids and either increase smooth muscle proliferation (TGF-β, bFGF), increase DNA synthesis (epidermal growth factor [EGF], PDGF), stimulate synthesis of extracellular matrix (TGF-β), promote mitogenesis (TGF-β, EGF, IGF, prolactin [PRL]), or promote angiogenesis (bFGF, VEGF).

Risk Factors

Prospective, longitudinal studies characterize the factors that influence the development of uterine fibroids (4,13,14). Although selection bias may limit epidemiologic studies, risk factors are considered.

Age

The incidence of fibroids increases with age, 4.3 per 1,000 woman-years for 25 to 29 year olds and 22.5 for 40 to 44 year olds. African American women develop fibroids at an earlier age than white women (13).

Endogenous Hormonal Factors

Greater exposure to endogenous hormones, as found with early menarche (younger than 10 years of age), increases and late menarche decreases the likelihood of having uterine fibroids (14). Fibroids are smaller, less numerous, and have smaller cells in hysterectomy specimens from postmenopausal women, when endogenous estrogen levels are low (4,15).

Family History

[3] First-degree relatives of women with fibroids have a 2.5 times increased risk of developing fibroids (26). Monozygous twins are reportedly hospitalized for treatment of fibroids more often than heterozygous twins, but these findings may be the result of reporting bias (27).

Ethnicity

[4] African American women have a 2.9 times greater risk of having fibroids than white women, unrelated to other known risk factors (28). African American women have fibroids develop at a younger age and have more numerous, larger, and more symptomatic fibroids (29). It is unclear whether these differences are genetic or result from known differences in circulating estrogen levels, estrogen metabolism, diet, or environmental factors.

Weight

A prospective study found that the risk of fibroids increased 21% with each 10 kg increase in body weight, and with increasing body mass index (BMI) (20). Similar findings were reported in women with greater than 30% body fat (21). Obesity increases conversion of adrenal androgens to estrone and decreases the sex hormone–binding globulin (SHBG). The result is an increase in biologically available estrogen, which may explain the increase in fibroid prevalence and/or growth.

Diet

Few studies examined the association between diet and the presence or growth of fibroids (22). A diet rich in beef, other red meat, and ham increased the incidence of fibroids, while a diet rich in green vegetables decreased this risk. These findings are difficult to interpret because calorie and fat intake were not measured.

Exercise

Women in the highest category of physical activity (approximately 7 hours per week) were significantly less likely to have fibroids than women in the lowest category (less than 2 hours per week) (23).

Oral Contraceptives

[2] There is no definite relationship between oral contraceptives and the presence

of fibroids. An increased risk of fibroids with oral contraceptive use was reported, but a subsequent study found no increased risk with the use or duration of use (24,25). Studies in women with known fibroids who were prescribed oral contraceptives showed no increase in fibroid growth (20,26). The formation of new fibroids does not appear to be influenced by oral contraceptive use (27).

Menopausal Hormone Therapy

For the majority of postmenopausal women with fibroids, hormone therapy will not stimulate fibroid growth. If fibroids do grow, progesterone is likely to be the cause (28). One study evaluated postmenopausal women with fibroids who were given 2 mg of oral *estradiol* daily and randomized to 2.5 or 5 mg of *medroxyprogesterone acetate* (*MPA*) per day (28). One year after starting treatment, 77% of women taking 2.5-mg *MPA* had either no change or a decrease in fibroids diameters and 23% had a slight increase. However, 50% of women taking 5-mg *MPA* had an increase in fibroid size (mean diameter increase of 3.2 cm).

Postmenopausal women with fibroids treated with 0.625 of *conjugated equine estrogen* (*CEE*) and 5-mg *MPA* were compared over 3 years to a similar group of women not taking hormone therapy (29). By the end of the third year, only 3 of 34 (8%) treated and 1 of 34 (3%) untreated women had any increase in fibroid volume over baseline (28). Postmenopausal women with known fibroids, followed with sonography, were noted to have an average 0.5-cm increase in the diameter of fibroid after using transdermal *estrogen* patches plus oral *progesterone* for 12 months (29). Women taking oral *estrogen* and *progesterone* had no increase in fibroid size (34).

Pregnancy

Increasing parity decreases the incidence and number of clinically apparent fibroids (31–33). The remodeling process of the postpartum myometrium, a result of apoptosis and dedifferentiation, may be responsible for the involution of fibroids (34). Another theory postulates that the vessels supplying fibroids regress during involution of the uterus, depriving fibroids of their source of nutrition (35).

Smoking

Smoking reduces the incidence of fibroids. Reduced conversion of androgens to estrone, caused by inhibition of aromatase by nicotine, increased 2-hydroxylation of estradiol, and stimulation of higher levels of SHBG decrease bioavailability of estrogen (36–38).

Tissue Injury

Cellular injury or inflammation resulting from an environmental agent, infection, or hypoxia was proposed as a mechanism for initiation of fibroid formation (39). Repetitive tissue injury to the endometrium and endothelium might promote the development of monoclonal smooth muscle proliferations in the muscular wall.

Frequent mucosal injury with stromal repair (menstruation) may release growth factors that promote the high frequency of uterine fibroids (39).

No increased incidence was found in women with prior sexually transmitted infections, prior intrauterine device (IUD) use, or prior talc exposure (31). Herpes simplex virus (HSV) I or II, cytomegalovirus (CMV), Epstein–Barr virus (EBV), and chlamydia were not found in fibroids.

SYMPTOMS

Fibroids are almost never associated with mortality, but they may cause morbidity and significantly affect the quality of life (40). **Women who have hysterectomies because of fibroid-related symptoms have significantly worse scores on SF-36 quality-of-life questionnaires than women diagnosed with hypertension, heart disease, chronic lung disease, or arthritis** (40).

Of 116 women with fibroids larger than 5 cm on sonographic examination and uterine size greater than 12 cm on pelvic examination, 42% were satisfied with their initial level of symptoms, including stress, bleeding, and pain (41). Most of the 48 women who chose to have treatment within 1 year were more likely to have higher scores on bleeding and pain scales and be more concerned about their symptoms. Most women chose myomectomy ($n = 20$), hysterectomy ($n = 15$), or hysteroscopic myomectomy ($n = 4$), and symptom scores improved markedly during the 7.5 months (mean) of follow-up.

Abnormal Bleeding

The association of fibroids with heavy menstrual bleeding is not clearly established. Therefore, other possible etiologies, including coagulopathies such as the von Willebrand disease, should be considered in a woman with heavy menstrual bleeding (42).

Type 0 and 1 fibroids have been associated with anemia. Of 1,665 women having office hysteroscopic evaluation for heavy menstrual bleeding, 259 women had a submucous fibroid diagnosed; 63 were type 0, 110 type 1, and 52 were type 2 (25 were not documented). Hemoglobin concentrations below 12 were significantly associated with submucous fibroids and most strongly correlated with type 0 fibroids (43).

Another study found that women with fibroids used 7.5 pads or tampons on the heaviest day of bleeding compared with 6.1 pads or tampons used by women without fibroids (44). Women with fibroids larger than 5 cm had slightly more gushing and used about 3 more pads or tampons on the heaviest day of bleeding than women with smaller fibroids.

Pain

[5] Women with fibroids are only slightly more likely to experience pelvic pain than women without fibroids. Transvaginal sonography (TVS) was performed on a population-based cohort of 635 non–care-seeking women with an intact uterus to determine the presence of uterine fibroids (45). Dyspareunia, dysmenorrhea, or noncyclic pelvic pain was measured by visual analog scales. The 96 women found to have fibroids were only slightly more likely to report moderate or severe dyspareunia or noncyclic pelvic pain and had no higher incidence of moderate or severe dysmenorrhea than women without fibroids. Neither the number nor the total volume of fibroids was related to pain. However, women who present for clinical evaluation for fibroid-associated pain may be different from those in the general population (45).

Fibroid degeneration may cause pelvic pain. As fibroids enlarge, they may outgrow their blood supply, with resulting cell death (46). Types of degeneration determined both grossly and microscopically include hyaline degeneration, calcification, cystic degeneration, and hemorrhagic degeneration. The type of degeneration appears to be unrelated to the clinical symptoms (46). Pain from fibroid degeneration is often successfully treated with analgesics and observation. Torsion of a pedunculated subserosal fibroid may produce acute pelvic pain that requires surgical intervention (47).

Urinary Symptoms

Fibroids may cause urinary symptoms, although few studies examined this association. Following uterine artery embolization (UAE) with a 35% reduction in the mean uterine volume, frequency and urgency were greatly or moderately improved in 68% of women, slightly improved in 18%, and unchanged or worse in only 14% (48). This finding suggests that **increased uterine volume associated with fibroids is related to urinary symptoms.**

Fourteen women with large fibroids and urinary symptoms were given six monthly injections of GnRH agonist (GnRH-a) with a resulting 55% decrease in uterine volume (49). Following therapy, urinary frequency, nocturia, and urgency decreased. There were no changes in urge or stress incontinence as measured by symptoms or urodynamic studies. It is not clear whether these findings are related to a decrease in uterine volume or to other effects of GnRH treatment.

NATURAL HISTORY OF FIBROIDS

Most fibroids grow slowly. A prospective, longitudinal study of 72 premenopausal women (38 African American, 34 white) using computer analysis of serial MRI found that the median growth rate was 9% over 12 months (13). Multiple fibroids in the same individual were found to have highly variable growth rates, suggesting that growth

results from factors other than hormone levels. After age 35, growth rates declined with age for white women but not for African American women, which likely explains the increased fibroid-related symptoms noted in African American women. Seven percent of fibroids regressed over the study period. Continued follow-up of these women is planned and may provide a better understanding of this issue.

Rapid Fibroid Growth

[6] In premenopausal women, "rapid uterine growth" almost never indicates the presence of uterine sarcoma. One study found only 1 sarcoma among 371 (0.26%) women operated on for rapid growth of presumed fibroids (50). No sarcomas were found in the 198 women who had a 6-week increase in uterine size over 1 year, which is the definition of rapid growth that was used in the past.

Uterine Sarcoma

Women found to have uterine sarcoma are often clinically suspected of having a pelvic malignancy (50,51). **Women with pain and bleeding and who are closer to menopause or postmenopausal may have a rare sarcoma. Of nine women found to have uterine sarcomas, all were postmenopausal and eight were admitted with abdominal pain and vaginal bleeding** (51). All eight had presumed gynecologic malignancies: uterine sarcoma in four, endometrial carcinoma in three, and ovarian cancer in one. One additional woman had surgery for prolapse and a sarcoma was found incidentally (51).

The Surveillance, Epidemiology, and End Results (SEER) database identified 13,089 patients diagnosed with uterine sarcoma in the period from 2000 to 2012. The mean age of patients with sarcomas was 68 for carcinosarcoma; 55 for LMS; 54 for stromal sarcoma; and 59 for adenosarcoma (52). A literature review found a mean age of 36 years in women subjected to myomectomy (50).

DIAGNOSIS

Pelvic Examination

Clinically significant subserosal and intramural fibroids can usually be diagnosed by pelvic examination based on findings of an enlarged, irregularly shaped, firm, and nontender uterus. Uterine size assessed by bimanual examination, even for most women with BMI greater than 30, correlates well with uterine size and weight at pathologic examination (53). Routine sonographic examination is not necessary when the diagnosis is almost certain. A definite diagnosis of submucous fibroids often requires saline-infusion sonography (SIS), hysteroscopy, or magnetic resonance imaging

(MRI) (54).

Fibroid Location

The FIGO fibroid classification system categorizes submucous, intramural, subserosal, and transmural fibroids.

***Type 0*—intracavitary (e.g., a pedunculated submucosal fibroid entirely within the cavity)**

***Type 1*—less than 50% of the fibroid diameter within the myometrium**

***Type 2*—50% or more of the fibroid diameter within the myometrium**

***Type 3*—abut the endometrium without any intracavitary component**

***Type 4*—intramural and entirely within the myometrium, without extension to either the endometrial surface or to the serosa**

***Type 5*—subserosal at least 50% intramural**

***Type 6*—subserosal less than 50% intramural**

***Type 7*—subserosal attached to the serosa by a stalk**

***Type 8*—no involvement of the myometrium; includes cervical lesions, those in the round or broad ligaments without direct attachment to the uterus, and "parasitic" fibroids**

Transmural fibroids are categorized by their relationship to both the endometrial and the serosal surfaces, with the endometrial relationship noted first, for example, types 2 to 3 (Table 11-1; Fig. 11-2) (55).

Table 11-1 FIGO Leiomyoma Classification System

SM—submucosal	0	Pedunculated intracavitary
	1	<50% intramural
	2	≥50% intramural
O—other	3	Contacts endometrium; 100% intramural
	4	Intramural
	5	Subserosal ≥50% intramural
	6	Subserosal <50% intramural
	7	Subserosal pedunculated
	8	Other (specify, e.g., cervical, parasitic)
Hybrid leiomyomas		Two numbers are listed separated by a hyphen. By convention, the first refers to the relationship with the endometrium while the second refers

(impact both endometrium and serosa)		to the relationship to the serosa. One example is given below.
	2–5	Submucosal and subserosal, each with less than half the diameter in the endometrial and peritoneal cavities, respectively.

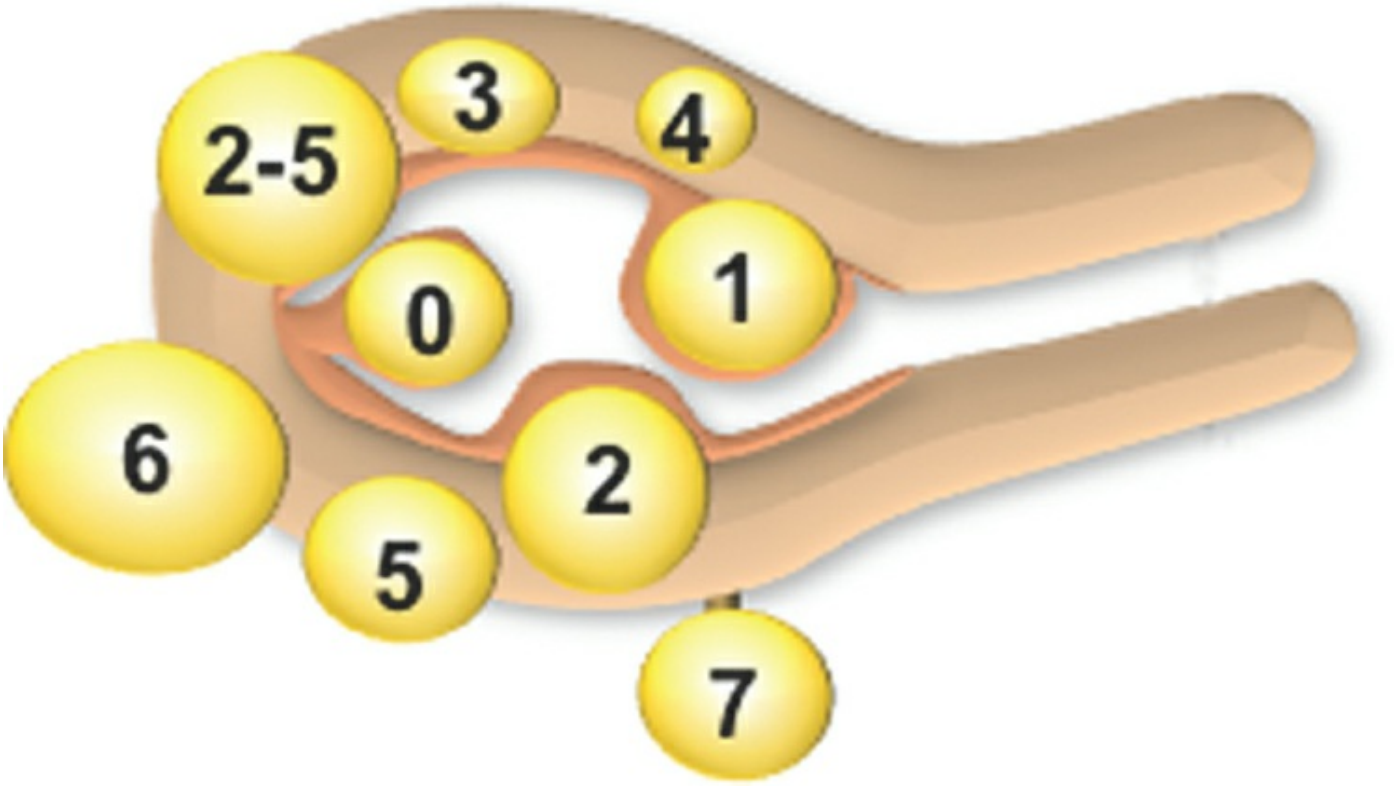

FIGURE 11-2 FIGO leiomyoma classification system.

Fibroid Variants

A number of benign uterine smooth muscle tumors have been defined according to histologic criteria issued by the World Health Organization. Mitotically active leiomyoma is defined by the presence of 10 to 15 mitoses/10 high-power fields (hpf) and may be seen in patients who are pregnant or are using exogenous hormones.

Increased cellularity, higher than that of nearby myometrium, is defined as a cellular leiomyoma. Taran et al. reported a series of women treated for cellular leiomyomas and 2 of 99 patients (2%) had recurrent disease (56). One study suggested that cellular leiomyomas exhibiting chromosome 1p deletions, a genetic alteration found in LMS, may be clinically more aggressive and require more intense surveillance (57).

Leiomyoma with bizarre nuclei (also called atypical or symplastic) shows scattered large atypical cells. Ly et al. described 34 patients with atypical leiomyomas undergoing hysterectomy and 4 had recurrent disease (12%) (58).

Smooth muscle tumors of uncertain malignant potential (STUMP) show atypical histologic features that range between leiomyoma and LMS, uncertain types of necrosis,

the presence of focal or diffuse cytologic atypia but the mitotic count is less than 10/10 hpf, the presence of coagulative tumor necrosis but mitosis is less than 10/10 hpf, and cellular tumors with more than 15 mitoses/10 hpf. Rarely STUMPs, mostly those that are p53 and p16 positive, have been found to exhibit malignant potential to develop a low-grade LMS (not high-grade). Guntupalli et al. reported a series of 41 patients with STUMPs: three (7.3%) had recurrence (all local and distant) after undergoing a total abdominal hysterectomy, and one of the recurrences was an LMS (59).

LMSs exhibit hypercellularity, diffuse moderate-to-marked nuclear atypia, a high mitotic rate (≥10/hpf), and tumor cell necrosis. LMS is an aggressive cancer and has a poor prognosis caused by early hematogenous spread, even in early-stage disease. The 5-year survival for stage I LMS is 61% and for stages III and IV is about 30%. Pritts et al. published a rigorous meta-analysis of 133 studies of women having surgery for presumed fibroids and determined that the prevalence of LMS was 1 in 1,960, or 0.051% (60). The Agency for Healthcare Research and Quality (AHRQ) of the U.S. Department of Health and Human Services updated the analysis, added 91,294 more surgeries, and calculated a prevalence of LMS of 1 in 1,429 (0.07%) cases of surgery for presumed fibroids (61).

There is no reliable method of preoperative diagnosis of LMS available and it is difficult to differentiate this disease from benign fibroids.

Imaging

For symptomatic women, consideration of medical therapy, noninvasive procedures, or surgery often depends on an accurate assessment of the size, number, and position of fibroids. TVS, SIS, hysteroscopy, and MRI were all performed on 106 women scheduled for hysterectomy and the findings were compared to pathologic examination (54). **[7]** Submucous fibroids were best identified with MRI (sensitivity 100%, specificity 91%). Identification was about equal with TVS (sensitivity 83%, specificity 90%), SIS (sensitivity 90%, specificity 89%), and hysteroscopy (sensitivity 82%, specificity 87%). MRI is not technique dependent and has low interobserver variability for diagnosis of submucous fibroids, intramural fibroids, and adenomyosis when compared with TVS, SIS, and hysteroscopy (62,63).

The presence of adenomyosis is associated with junctional zone thickness of more than 15 mm (or 12 mm in a nonuniform junctional zone). Focal, not well-demarcated, and high- or low-intensity areas in the myometrium correlate with adenomyosis (65).

MRI allows evaluation of the number, size, and position of submucous, intramural, and subserosal fibroids and can evaluate their proximity to the bladder, rectum, and endometrial cavity. MRI helps define what can be expected at surgery and may help the surgeon avoid missing fibroids during surgery (66). For women who wish to preserve fertility, MRI to document location and position relative to the endometrium may be

helpful prior to hysteroscopic, laparoscopic, or abdominal myomectomy.

[7] Sonography is the most readily available and least costly imaging technique to differentiate fibroids from other pelvic pathology. It is reasonably reliable for evaluation of uterine volume less than 375 cc and containing four or fewer fibroids (62). Sonographic appearance of fibroids can be variable, but often they appear as symmetrical, well-defined, hypoechoic, and heterogeneous masses. Areas of calcification or hemorrhage may appear hyperechoic, while cystic degeneration may appear anechoic. SIS utilizes saline inserted into the uterine cavity to provide contrast and better defines submucous fibroids (62).

Imaging of Uterine Sarcomas

The preoperative diagnosis of LMS may be possible. Diagnosis with total serum lactate dehydrogenase (LDH) and LDH isoenzyme 3 measurements along with gadolinium-enhanced diethylenetriamine pentaacetic acid (Gd-DTPA) dynamic MRI was reported to be highly accurate (66). MRI images are taken during the arterial phase, between 40 and 60 seconds after infusion of gadolinium. Sarcomas have increased vascularity and show increased enhancement with gadolinium, while degenerating fibroids have decreased perfusion and exhibit decreased enhancement. Using LDH measurements and Gd-DTPA, a study of 87 women with uterine fibroids, 10 women with LMSs, and 130 women with degenerating fibroids reported 100% specificity, 100% positive predictive value, 100% negative predictive value, and 100% diagnostic accuracy for LMS **(Fig. 11-3)**.

A form of MRI functional imaging called diffusion-weighted imaging (DWI) has been used to distinguish between malignant and benign tumors. Malignant lesions have higher cellularity and nuclear area, which restrict water diffusion as measured by the apparent diffusion coefficient (ADC). Sixteen patients with uterine LMSs and 26 patients with degenerating fibroids confirmed by surgery and pathology underwent MRI and DWI. The mean ADC in LMSs was significantly lower than that in degenerating fibroids. The sensitivity and specificity were 100% and 90%. Other studies show conflicting results and DWI needs further investigation (67).

FERTILITY

[8] The presence of submucous fibroids decreases fertility rates and removing them increases fertility rates. Subserosal fibroids do not affect fertility rates but removing them does increase fertility. Intramural fibroids may slightly decrease fertility, but removal does not increase fertility (68). A meta-analysis of the effect of fibroids on fertility and the effect of myomectomy on fertility found that submucous fibroids that distort the uterine cavity appear to decrease fertility, with ongoing

pregnancy/live birth rates decreased by about 70% (relative risk [RR] 0.32; 95% confidence interval [CI], 0.12–0.85) (68). Resection of submucous fibroids slightly increased fertility relative to infertile controls without fibroids (ongoing pregnancy/live birth rate, RR 1.13; 95% CI, 0.96–1.33).

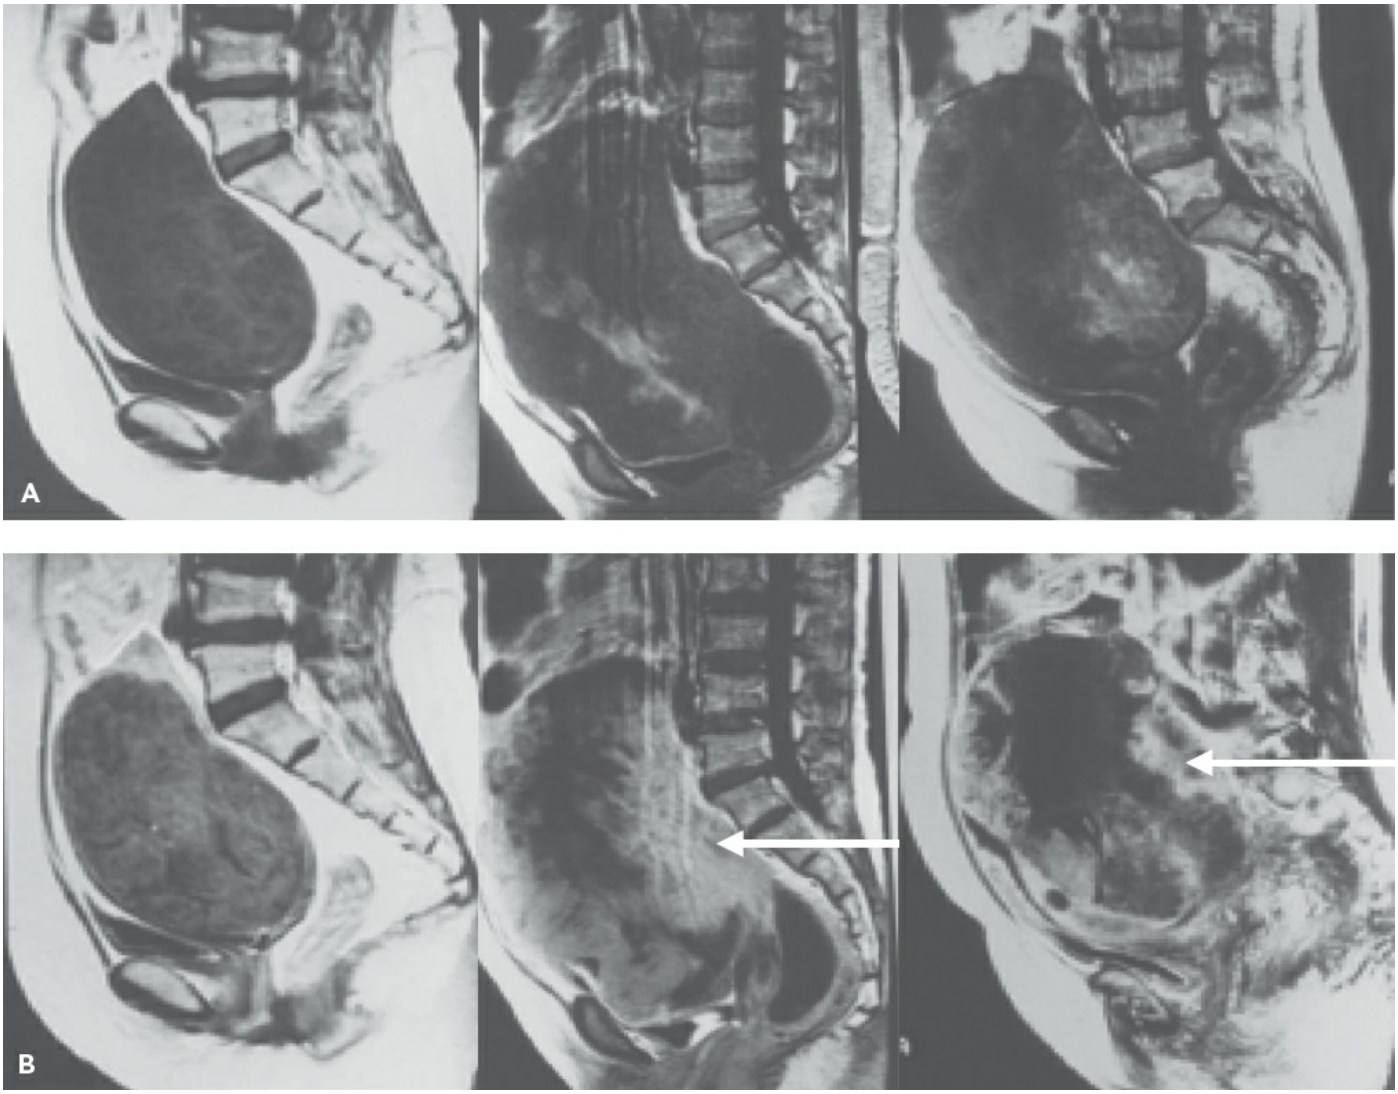

FIGURE 11-3 MR images. **A:** Degenerating fibroid. **Left to right.** Pre-enhanced T1 image, T2 image, and no enhancement on T1 Gd-DTPA at 60 seconds. **B:** Leiomyosarcoma. **Left to right.** Pre-enhanced T1 image, T2 image (*arrow* to dorsal part of tumor), and enhancement of dorsal part of tumor (*arrow*) on T1 Gd-DTPA at 60 seconds. (From **Goto A, Takeuchi S, Sugimura K, et al.** Usefulness of Gd-DTPA contrast-enhanced dynamic MRI and serum determination of LDH and its isozymes in the differential diagnosis of leiomyosarcoma from degenerated leiomyoma of the uterus. Int J Gynecol Cancer 2002;12:354–361.)

Several studies have described the role of HOXA10 and HOXA11 transcription factors on uterine factor infertility associated with endometrial receptivity. In normal endometrium, BMP-2 upregulates HOXA10 expression. This process is absent in endometrial cells of women with submucous fibroids. The result is altered decidualization and inhibition of embryo implantation and decreased uterine factor

fertility (69).

Analysis of studies that routinely used hysteroscopy to confirm clear nondistortion of the cavity by intramural fibroids found ongoing pregnancy/live birth rates were not significantly different compared to controls (RR 0.73; 95% CI, 0.38–1.40) (66). Removal of intramural or subserosal fibroids did not improve ongoing pregnancy/live birth rates (RR 1.67; 95% CI, 0.75–3.72). Another study evaluated pregnancy rates for 102 women undergoing ovarian stimulation—intra-uterine insemination (OS-IUI) for unexplained infertility and who had at least one documented fibroid and a normal uterine cavity determined by hysterosonography or hysterosalpingogram. No differences were observed in conception and live birth rates in women with non–cavity-distorting fibroids and those without fibroids (70).

Myomectomy may involve operative and anesthetic risks, risks of infection or postoperative adhesions, a slight risk of uterine rupture during pregnancy, an increased likelihood that a cesarean section will be recommended for delivery, plus the expense of surgery and time for recovery. Therefore, until intramural fibroids are shown to decrease and myomectomy to increase fertility rates, surgery should be undertaken with reluctance (68). Randomized studies are needed to clarify the RRs and benefits of surgical intervention.

FIBROIDS AND PREGNANCY

Incidence of Fibroids During Pregnancy

The prevalence of fibroids among pregnant women is 18% in African American women, 10% in Hispanic women, and 8% in white women, based on first trimester sonography (71). Mean size of the fibroids was 2.5 cm. Clinical examination detects 42% of fibroids greater than 5 cm during pregnancy, but only 12.5% when they are less than 5 cm (72).

Effect of Pregnancy on Fibroids

[9] Most fibroids do not increase in size during pregnancy. Pregnancy has a variable, and unpredictable, effect on fibroid growth, likely dependent on individual differences in fibroid gene expression, circulating growth factors, and fibroid-localized receptors (72,73). A prospective study of 36 pregnant women with a single fibroid discovered during routine first trimester sonographic screening and examined by sonography at 2- to 4-week intervals found that 69% of the women had no increase in fibroid volume throughout pregnancy (73). In the 31% of women noted to have an increase in volume, the greatest increase occurred before the 10th week of gestation. There was no relationship between initial fibroid volume and fibroid growth during gestational periods. A reduction in fibroid size toward baseline measurements was observed 4

weeks after delivery.

Fibroid Degeneration During Pregnancy

In women noted to have fibroids during pregnancy, clinical symptoms and sonographic evidence of fibroid degeneration occur in about 5% (74). Among 113 women followed during pregnancy with serial sonography, 10 (9%) developed anechoic spaces or coarse heterogeneous patterns consistent with fibroid degeneration. Seven of 10 women had severe abdominal pain requiring hospitalization, consistent with clinical symptoms of degeneration. No sonographic changes were noted in the other 103 women, and only 11.7% had similar abdominal pain. A small study of women with fibroid-associated pain during pregnancy found use of *ibuprofen* shortened the hospital stay and decreased the rate of readmission (75).

Influence of Fibroids on Pregnancy

Very rarely does the presence of a fibroid during pregnancy lead to an unfavorable outcome. Research was conducted on large populations of pregnant women examined with routine second trimester sonography with follow-up care and delivery at the same institution (76,77). In a study of 12,600 pregnant women, the outcomes of 167 women with fibroids were no different with regard to the incidence of preterm delivery, premature rupture of membranes, fetal growth restriction, placenta previa, placental abruption, postpartum hemorrhage, or retained placenta (76). Cesarean section was more common among women with fibroids (23% vs. 12%).

The other study of 15,104 pregnancies, including 401 women with fibroids, found no increased risk of premature rupture of membranes, operative vaginal delivery, chorioamnionitis, or endometritis (77). However, there were increased risks of preterm delivery (19.2% vs. 12.7%), placenta previa (3.5% vs. 1.8%), and postpartum hemorrhage (8.3% vs. 2.9%). Cesarean section was again more common (49.1% vs. 21.4%). A small retrospective study found an association between retroplacental fibroids and placental abruption; 8 of 14 women with retroplacental fibroids developed abruption compared with 2 of 79 women without retroplacental fibroids (78).

Fetal injury attributed to mechanical compression by fibroids is uncommon. A search of the PubMed database from 1980 to 2010 revealed one case of fetal head anomalies with fetal growth restriction, one case of a postural deformity, one case of a limb reduction, and one case of fetal head deformation with torticollis (79–82).

Any decision to perform a myomectomy in order to prevent problems during pregnancy should take into account the risks of surgery, anesthesia, postoperative adhesions, and an increased likelihood of subsequent cesarean delivery, along with concerns about discomfort, expense, and time away from work or family.

Rupture of Myomectomy Scar During Pregnancy

Following abdominal myomectomy, uterine rupture during pregnancy appears to be a rare event.

Trial of labor after myomectomy is associated with a 0.47% risk of uterine rupture. Eleven studies that included 1,034 pregnancies and 756 viable (≥24 weeks) deliveries found 7 uterine ruptures after myomectomy (0.93%); the rate was 0.47% (2/426) in women undergoing trial of labor after myomectomy and 1.52% (5/330) in women before the onset of labor. Five of the seven uterine ruptures occurred before 36 weeks. Size, number, and positions of removed fibroids or the type of myometrial closure was not available to determine specific risk factors for rupture. The 0.47% rate of rupture for women with a trial of labor after myomectomy is similar to the 0.5% to 1% risk of rupture for trial of labor after previous cesarean delivery (83).

Operative techniques, instruments, and energy sources used during laparoscopic myomectomy may differ from those employed during laparotomy. A study of 19 published and unpublished cases of uterine rupture during pregnancy following laparoscopic myomectomy found that almost all cases involved deviations from standard surgical technique as described for abdominal myomectomy (84). In 7 cases, the uterine defect was not repaired; in 3 cases it was repaired with a single suture; in 4 cases it was repaired with only one layer of suture; and in 1 case only the serosa was closed. In only 3 cases was a multilayered closure employed. In 16 of the cases, monopolar or bipolar energy was used for hemostasis.

Although definite conclusions and recommendations regarding appropriate technique for laparoscopic myomectomy must await proper study of myometrial wound healing, it appears prudent for surgeons to adhere to time-tested techniques developed for abdominal myomectomy, including multilayered closure of myometrium (for other than superficial uterine defects) and limited use of electrosurgery for hemostasis. Even with ideal surgical technique, individual wound-healing characteristics may predispose to uterine rupture.

TREATMENT

The development of new treatments for fibroids is slow, perhaps because many women with fibroids are asymptomatic, fibroids are benign, and mortality is very low (84). **If offered hysterectomy as a first, and sometimes only, treatment option, some women choose to accommodate to symptoms and stop seeking treatment.** This may lead physicians to underestimate the true impact of the condition, despite the fact that women who have hysterectomies as a result of fibroid-related symptoms have significantly worse scores on SF-36 quality-of-life questionnaires than women diagnosed with hypertension, heart disease, chronic lung disease, or arthritis (40).

After an exhaustive review of the medical literature published between 1975 and

2000, with evaluation of 637 relevant articles and careful study of 200 articles, the authors found no satisfactory answers to fundamental questions about fibroid treatments (86). Women and their physicians need information on which to base decisions regarding possible treatments.

This section summarizes the literature regarding the management of fibroids. Treatment options include observation, medical therapy, hysteroscopic myomectomy, laparoscopic myomectomy, hysterectomy, UAE, and focused ultrasound.

Watchful Waiting

Not having treatment for fibroids rarely results in harm, except for women with severe anemia from fibroid-related heavy menstrual bleeding or hydronephrosis from ureteric obstruction from a massively enlarged fibroid uterus. Predicting future fibroid growth or onset of new symptoms is not possible (84). During observation, the average fibroid volume increases 9% per year with a range of −25% to +138% (87). A nonrandomized study of women with uterine size 8 weeks or greater who chose watchful waiting found that 77% of women had no significant changes in the self-reported amount of bleeding, pain, or degree of bothersome symptoms at the end of 1 year (88). Furthermore, mental health, general health, and activity indexes were also unchanged. Of the 106 women who initially chose watchful waiting, 23% opted for hysterectomy during the course of the year.

[10] Therefore, for women who are mildly or moderately symptomatic with fibroids, watchful waiting may allow treatment to be deferred, perhaps indefinitely.

[11] As women approach menopause, watchful waiting may be considered, because there is limited time to develop new symptoms and after menopause, bleeding stops and fibroids decrease in size (15). Although not specifically studied, the incidence of hysterectomy for fibroids declines considerably after menopause, suggesting that there is a significant decline in symptoms.

Medical Therapy

Nonsteroidal Anti-Inflammatory Medication

Nonsteroidal anti-inflammatory drugs (NSAIDs) were not shown to be effective for the treatment of heavy menstrual bleeding in women with fibroids. A placebo-controlled, double-blind study of 25 women with menorrhagia, 11 of whom had fibroids, found a 36% decrease in blood loss among women with idiopathic heavy menstrual bleeding, but no decrease in women with fibroids. No other studies examined this treatment (89).

Tranexamic Acid

Tranexamic acid is a synthetic antifibrinolytic medication which can be used for the management of menorrhagia at a dosage of 1.3 g, three times a day for 3 to 5 days during menstrual bleeds. A pooled analysis of two randomized, double-blind, placebo-controlled, parallel-group studies of women with heavy menstrual bleeding and fibroids found mean menstrual blood loss was significantly (p <0.001) reduced compared with placebo maintained across three treatment cycles (90). Adverse events included headache (55%) and nausea (15%). The results of this analysis may not be generalizable to women with markedly enlarged fibroids that require surgical management.

Gonadotropin-Releasing Hormone Agonists

Treatment with GnRH-a decreases uterine volume, fibroid volume, and bleeding. The benefits of GnRH-a are limited by side effects and risks associated with long-term use (91,92). Monthly GnRH-a given for 6 months reduced fibroid volume by 30% and total uterine volume by 35% (91). Reduction in the uterine size occurs mostly within the first 3 months of treatment (92). Heavy menstrual bleeding responds well to GnRH-a; 37 of 38 women had resolution by 6 months. Following discontinuation of GnRH-a, menses returns in 4 to 8 weeks and uterine size returns to pretreatment levels within 4 to 6 months (93). In this study 64% of women remained asymptomatic 8 to 12 months after treatment.

Side effects occur in 95% of women treated with GnRH-a (89). Seventy-eight percent experience hot flushes, 32% vaginal dryness, and 55% have transient frontal headaches. During 6 months of treatment only 8% of women discontinued GnRH-a because of the side effects. Arthralgia, myalgia, insomnia, edema, emotional lability, depression, and decreased libido are reported. **The hypoestrogenic state induced by GnRH-a causes significant bone loss after 6 months of therapy** (94).

In an effort to reduce side effects, inhibit bone loss, and allow long-term use of GnRH-a, low doses of *estrogen* and *progestins* may be added while continuing GnRH-a. A study of long-term use of GnRH-a over 6 years found a wide range of reduction in bone density among women and no difference in bone loss between groups given *estrogen* and *progestin* versus those treated with GnRH-a alone (95).

Gonadotropin-Releasing Hormone Agonist as Temporary Treatment for Perimenopausal Women

Women in late perimenopause who are symptomatic from uterine fibroids may consider short-term use of GnRH-a. Thirty-four perimenopausal women with symptomatic fibroids were treated with GnRH-a for 6 months, 12 of whom required repeat treatment 6 months after discontinuation of the medication (96); 31 women avoided surgery; 15 women went into natural menopause. Although not specifically studied, add-back therapy might be considered in this setting.

Gonadotropin-Releasing Hormone Antagonist

The immediate suppression of endogenous GnRH by daily subcutaneous injection of the GnRH antagonist *ganirelix* results in a 29% reduction in fibroid volume within 3 weeks (97). Treatment is accompanied by hypoestrogenic symptoms. When long-acting compounds are available, a GnRH antagonist might be considered for medical treatment prior to surgery.

Progesterone-Mediated Medical Treatment

The reduction in uterine size following treatment with the progesterone-blocking drug *mifepristone* is similar to that found with GnRH-a (98). A prospective, randomized controlled trial of *mifepristone* treatment found a 48% decrease in the mean uterine volume after 6 months (99). *Mifepristone* blocks progesterone, and the unopposed exposure of the endometrium to estrogen may lead to endometrial hyperplasia. A systematic review found endometrial hyperplasia in 10 of 36 (28%) women screened with endometrial biopsies (100).

Ulipristal Acetate

Ulipristal acetate (UPA) is a selective progesterone receptor modulator with pure antagonist activity. UPA modulates the progesterone signaling pathway and promotes remodeling of the extracellular matrix and reduction of collagen synthesis. UPA is effective for controlling bleeding and reducing the size of fibroids, while increasing the quality of life. The largest study included 451 women with symptomatic uterine fibroids, uterine size less than 16 weeks, and heavy menstrual bleeding (101). Women received four repeated 12-week treatment courses of daily UPA, 5 or 10 mg, given orally. Both doses led to amenorrhea, usually within 1 week, in ≥70% of women and bleeding was controlled in ≥73%. Hemoglobin levels increased over the first two treatment courses and were maintained during follow-up.

By the fourth treatment course, approximately 80% of women had more than 25% reduction in the volume of the three largest fibroids. Patients had significant improvement in pain and quality of life and reached scores reported for healthy individuals. Six cases of hyperplasia were observed, all of which returned to normal endometrium during the study.

Adverse events included headache and hot flushes in 11% of women, almost all of which were mild or moderate. Levels of E2 remained well above postmenopausal levels, suggesting that bone mineral density will not be adversely affected by ulipristal.

Progesterone-Releasing Intrauterine Device

The *levonorgestrel*-releasing intrauterine system (LNG-IUS) may be a reasonable treatment for selected women with fibroid-associated heavy menstrual bleeding.

Evidence from a systematic review of 11 studies of premenopausal women with uterine fibroids using LNG-IUS concluded that they significantly reduced menstrual blood loss and increased hemoglobin and ferritin levels, but did not decrease the

fibroid volume. Device expulsion rates were 15.4% with fibroids larger than 3 cm, but only 6.3% with fibroids smaller than 3 cm and unrelated to fibroid location (102).

Alternative Medicine Treatment

A nonrandomized, nonblinded study compared fibroid growth in 37 women treated with Chinese medicine, body therapy, and guided imagery to 37 controls treated with NSAIDs, progestins, or oral contraceptive pills (103). After 6 months, sonographic evaluation demonstrated that fibroids stopped growing or shrank in 22 of 37 (59%) women treated with Chinese medicine compared to 3 of 37 (8%) controls. Although symptoms responded equally well in both groups, satisfaction was higher in the Chinese medicine group. Participants actively sought alternative therapy and assessment of satisfaction may reflect selection bias.

An uncontrolled study reported treatment of 110 women with fibroids smaller than 10 cm with the Chinese herbal medicine kuei-chih-fu-ling-wan for at least 12 weeks (104). Clinical and sonographic evaluation found complete resolution of fibroids in 19% of women, a decrease in size in 43%, no change in 34%, and an increase in 4%. Heavy menstrual bleeding improved in 60 of 63 (95%) women and dysmenorrhea improved in 48 of 51 (94%). Fifteen of the 110 (14%) women chose to have a hysterectomy during the 4 years of the study.

SURGICAL TREATMENT OPTIONS

[12] Surgical treatment options include abdominal myomectomy, laparoscopic myomectomy, laparoscopic radiofrequency ablation, hysteroscopic myomectomy, endometrial ablation, and abdominal, vaginal, or laparoscopic hysterectomy.

Serious medical conditions, such as severe anemia or ureteral obstruction, often need to be addressed surgically. Pain from fibroid degeneration is usually successfully treated with analgesics until symptoms resolve, but if severe the patient may opt for surgery. Torsion of a pedunculated subserosal fibroid may produce acute pain that requires surgical intervention. Surgical intervention may be indicated in women with fibroids associated with heavy menstrual bleeding, pelvic pain or pressure, urinary frequency, or incontinence that compromises the quality of life (105).

Abdominal myomectomy was long employed as a conservative treatment for uterine fibroids, and much of the literature predates the use of prospective, randomized controlled trials. Although myomectomy is stated to relieve symptoms in 80% of women, there is scant literature documenting its efficacy and many large series have not reported data for relief of symptoms following surgery (105–107). A prospective, nonrandomized study comparing myomectomy with UAE did report that 75% of women in the myomectomy group had a significant decrease in symptom scores after 6 months (108).

Back pain may, on occasion, be related to the presence of fibroids, but other possible causes should be considered. **[13] Inability to evaluate the ovaries on pelvic examination is not an indication for surgery** (109). There is no evidence that pelvic examination increases early detection or decreases the mortality related to ovarian cancer, and sonography can be used to evaluate the adnexa should symptoms develop. Recent evidence that most serous "ovarian" cancers have a tubal origin makes early sonographic diagnosis particularly unlikely.

Treating Preoperative Anemia

In women with significant preoperative anemia, intravenous iron infusions, epoetin, and GnRH agonists have been used to increase hemoglobin levels. A randomized study of women with heavy menstrual bleeding and Hb levels <9.0 g/dL who were scheduled to have surgery received iron either intravenously (based on the calculated total iron deficit, 3 times a week for 3 weeks) or orally (80 mg/day of oral iron protein succinylate daily). The mean increase in hemoglobin was higher in the intravenous iron group than the oral group (3.0 vs. 0.8 g/dL) and there were no severe adverse events in either group (110). A randomized study showed that the use of epoetin, a recombinant form of erythropoietin, 250 IU/kg (approximately 15,000 U) per week for 3 weeks prior to elective surgery increased hemoglobin concentrations by 1.6 g/dL and significantly reduced transfusion rates when compared to controls (111). GnRH-a may be used preoperatively to stop abnormal bleeding, with a resultant increase of hemoglobin concentration. One study of women with fibroids and mean hemoglobin concentrations of 10.2 g who were randomized to GnRH-a plus oral iron or placebo plus oral iron found that after 12 weeks, 74% of the women treated with GnRH-a and iron had hemoglobin greater than 12 g compared with 46% of the women treated with only iron (112).

Abdominal Myomectomy

[14] Myomectomy should be considered a safe alternative to hysterectomy. Victor Bonney, an early advocate of abdominal myomectomy, stated in 1931 that "The restoration and maintenance of physiologic function is, or should be, the ultimate goal of surgical treatment."

Case-controlled studies suggest that there may be less risk of intraoperative injury with myomectomy when compared with hysterectomy (113). A retrospective review of 197 women who had myomectomies and 197 women who underwent hysterectomies with similar uterine size (14 vs. 15 weeks) found operating times were longer in the myomectomy group (200 vs. 175 minutes), but estimated blood loss was greater in the hysterectomy group (227 vs. 484 mL) (113). The risks of hemorrhage, febrile morbidity, unintended surgical procedure, life-threatening events, and rehospitalization were no

different between groups. However, 26 (13%) women in the hysterectomy group suffered complications, including 1 woman with bladder injury, 1 with ureteral injury, 3 bowel injuries, 8 with ileus, and 6 with pelvic abscesses. In contrast, complications occurred in 11 (5%) of the myomectomy patients, including 1 woman with bladder injury, 2 with reoperation for small bowel obstruction, and 6 with ileus.

Hysterectomy, without oophorectomy, may have a more lasting adverse effect on ovarian reserve than myomectomy. Serum AMH was significantly lower 3 months following hysterectomy compared with the preoperative level. Following myomectomy, serum AMH was similar to the preoperative level 3 months after surgery (114).

Myomectomy may be considered even for those women who have large uterine fibroids and wish to retain their uterus. A study of 91 women with uterine size larger than 16 cm (range 16 to 36 cm) reported 1 bowel injury, 1 bladder injury, and 1 reoperation for bowel obstruction, but no women had conversion to hysterectomy (115). The cell saver, which is a device used to collect blood intraoperatively and reinfuse, was used in 70 women, and only 7 required homologous blood transfusion. A retrospective cohort study by Iverson et al. compared 89 women having abdominal hysterectomy for fibroids (mean uterine size 15 cm) to abdominal myomectomy in 103 women (mean uterine size 12 cm) (116). Although selection bias was likely, the hysterectomy group suffered two ureteral, one bladder, one bowel, and one nerve injury and two reoperations for bowel obstruction, while there were no visceral injuries in the myomectomy group. A review of 6 observational studies, which included the patients from the Iverson study, found that among the 1,520 women with uterine size up to 18 weeks, there was no difference in morbidity between those having an abdominal myomectomy compared with those having an abdominal hysterectomy (117).

Cesarean Section and Concurrent Myomectomy

In carefully selected women, myomectomy may be safely accomplished at the time of cesarean section by experienced surgeons. One series reported 25 women with removal of 84 fibroids (2 to 10 cm) at the time of cesarean section without the need for cesarean hysterectomy (118). Estimated blood loss was 876 mL (range 400 to 1,700 mL) and 5 women required blood transfusion. Another study compared 111 women who had myomectomy at the time of cesarean section with 257 women with fibroids who were not subjected to myomectomy during cesarean section (119). Only one of the women in the myomectomy group required transfusion and none required hysterectomy or embolization. There were no differences in mean operative times, incidence of fever, or length of hospital stay between the two groups. Although the cases were likely selected carefully, the authors concluded that, in experienced hands, myomectomy might be safely performed in selected women during cesarean section.

Surgical Technique for Abdominal Myomectomy

Managing Blood Loss

Available surgical techniques allow safe removal of even large fibroids. Tourniquets or vasoconstrictive agents may be used to limit blood loss. *Vasopressin,* an antidiuretic hormone, causes constriction of smooth muscle in the walls of capillaries, small arterioles, and venules.

Significant reductions in blood loss during myomectomy have been found in several interventions: vaginal misoprostol (−98 mL); intramyometrial vasopressin (−246 mL); intravenous tranexamic acid (−243 mL); a Foley catheter secured around the cervix (−240 mL), and a polyglactin suture placed around both the cervix and infundibulopelvic ligaments (−1,870 mL) (120). A significant reduction in the need for blood transfusion has been shown while using vasopressin and tourniquets, but not for misoprostol or tranexamic acid. There are no data regarding whether the combined use of any of these measures decreases blood loss more effectively than individual measures.

Care should be taken to avoid intravascular injection of vasopressin and resultant cardiovascular collapse. Nonetheless, cardiovascular complications have been reported following intramyometrial injection. The maximal safe dose of vasopressin is not well established, but less than 5 units in total is suggested. The half-life of intramuscular vasopressin is 10 to 20 minutes, with a duration of action of 2 to 8 hours. Loss of peripheral pulses and nonmeasurable arterial blood pressure following vasopressin injection have been attributed to cardiovascular collapse or hypotension. Severe peripheral arterial vasospasm and elevated proximal blood pressure may occasionally occur with high-dose vasopressin and should be considered before administering additional vasopressors (121). The use of *vasopressin* to decrease blood loss during

myomectomy is an off-label use of this drug.

Cell savers may be considered for use during myomectomy. Use of the cell saver avoids the risks of infection and transfusion reaction, the oxygen transport capacity of salvaged red blood cells is equal to or better than stored allogeneic red cells, and the survival of red blood cells appears to be at least as good as transfused allogeneic red cells (122). The device suctions blood from the operative field, mixes it with heparinized saline, and stores the blood in a canister. If the patient requires blood reinfusion, the stored blood is washed with saline, filtered, centrifuged to a hematocrit of approximately 50%, and given back to the patient intravenously. Consequently, the need for preoperative autologous blood donation or heterologous blood transfusion often can be avoided (123). In a study of 92 women who had myomectomy for uterine size greater than 16 cm the cell saver was used for 70 women with a mean volume of reinfused packed red blood cells of 355 mL (124).

The cost of using a cell saver compared with donation of autologous blood was not studied for abdominal myomectomy. However, economic models suggest it is cost effective (124). Most hospitals charge a minimal fee for having the cell saver available "on-call" and charge an additional fee if it is used. Assuming that most women who donate autologous blood prior to myomectomy do not require blood transfusion, availability of the cell saver should spare many women the time and expense of donating, storing, and processing autologous blood. For a cohort of women, the cost of using the cell saver should, therefore, be significantly lower than the cost of autologous blood.

When heavy bleeding is anticipated or if copious bleeding is encountered, ligation of both uterine arteries can be performed (125). UAE was used successfully to control bleeding at the time of, or following, myomectomy (126). Because the uterine arteries recannulate, future fertility should not be compromised. These techniques often obviate the need for hysterectomy.

Uterine incisions can be made either vertically or transversely, because fibroids distort normal vascular architecture, making attempts to avoid the arcuate vessels impossible (127). **Careful planning and placement of uterine incisions can avoid inadvertent extension of the incision to the uterine cornua or ascending uterine vessels.**

Based on vascular corrosion casting and examination by electron microscopy, fibroids are completely surrounded by a dense blood supply and no distinct vascular pedicle exists at the base of the fibroid **(Fig. 11-4)** (128). Extending the uterine incisions through the myometrium and entire pseudocapsule until the fibroid is clearly distinguished identifies a less vascular surgical plane, which is deeper than commonly recognized.

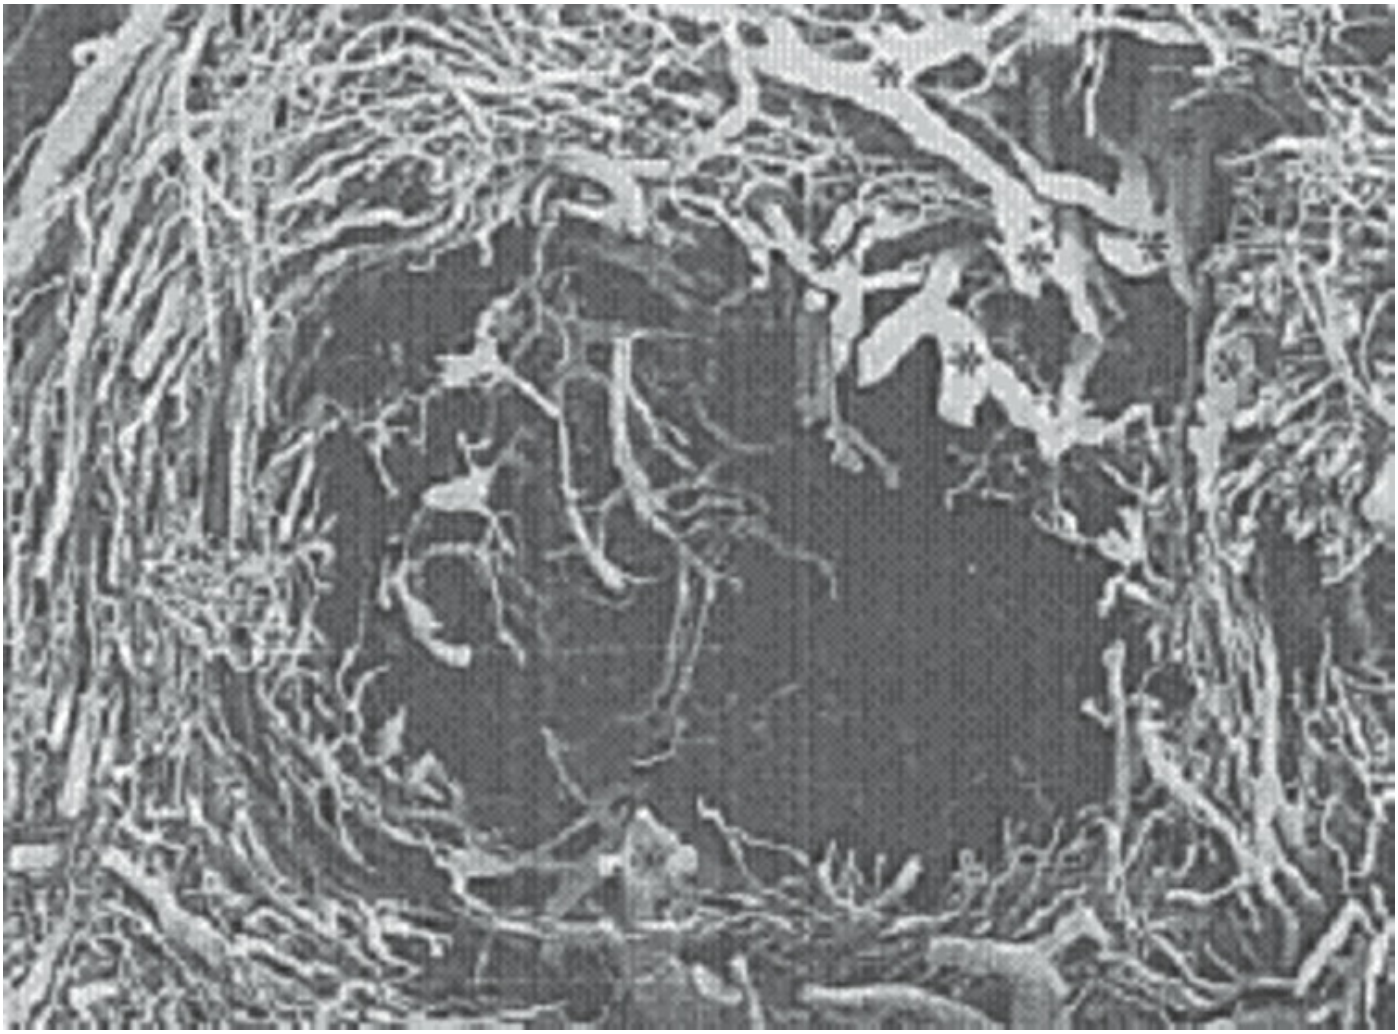

FIGURE 11-4 Corrosion casting of fibroid vessels.

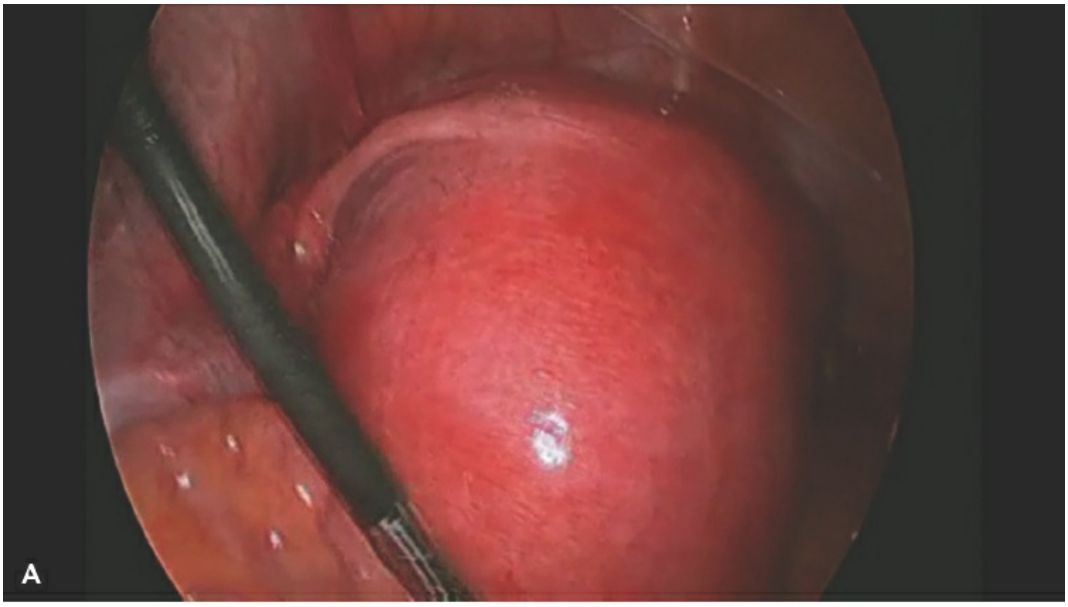
Limiting the number of uterine incisions has been suggested in order to reduce the risk of adhesions to the uterine serosa (129). However, in this manner tunnels must be created within the myometrium in order to extract distant fibroids, making hemostasis more difficult within these defects. Hemostasis is important in order to avoid adhesion formation, and fibrin, leucocytes, and platelets in the presence of erythrocytes leads to adhesion formation. If tunneling incisions are avoided and hemostasis secured immediately, the risk of adhesion formation should be lessened. Therefore, if incisions are made directly over the fibroids and only those fibroids that are easily accessed are removed, the defects can be promptly closed and hemostasis can be secured immediately (115). Multiple uterine incisions may be needed, but adhesion barriers may help limit adhesion formation (130).

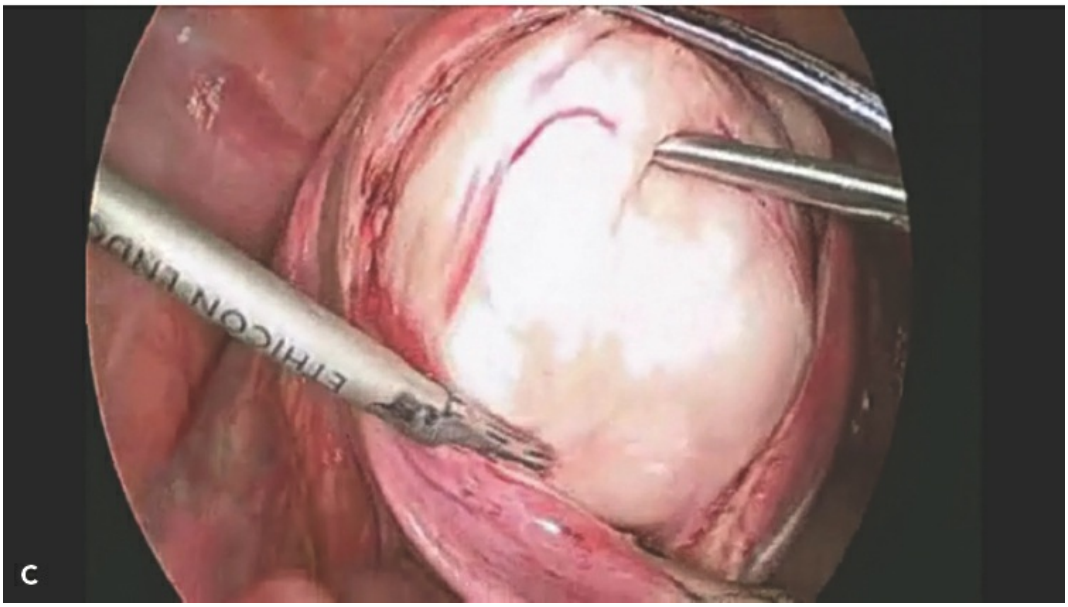
Laparoscopic Myomectomy

Available instruments make laparoscopic myomectomy feasible, although the size and number of fibroids reasonably removed limits the wide application of this approach

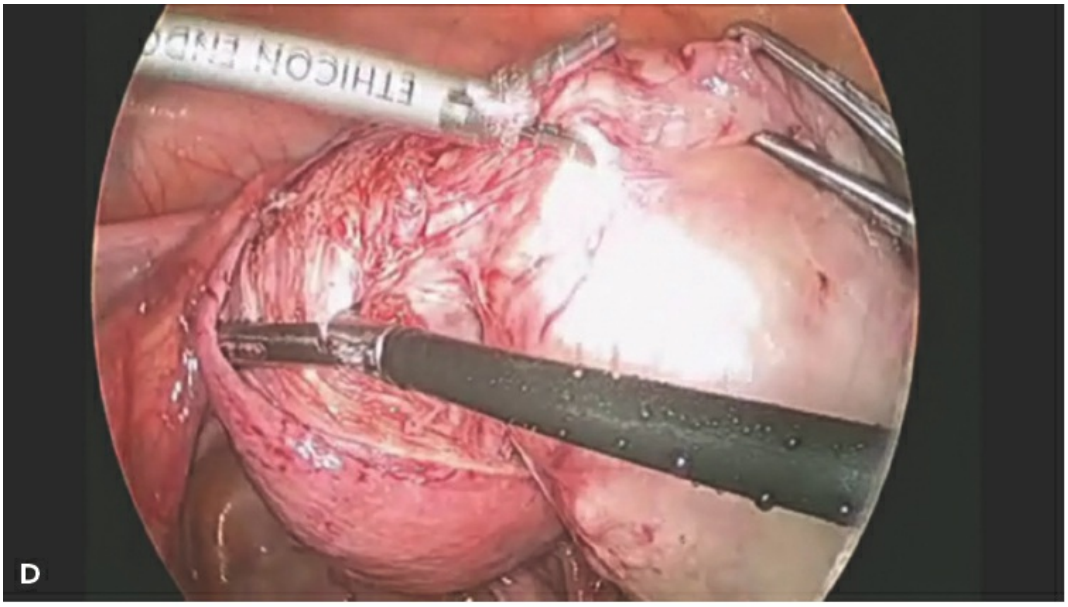


because of the technical difficulty of the procedure and laparoscopic suturing (131). Although microprocessor-assisted myomectomy (robotic) may obviate some of these technical problems, the added cost and longer operating times associated with this approach must be considered (see Chapter 28).

A systematic review of randomized controlled trials of laparoscopic versus open myomectomy included six studies with a total of 576 patients (132). Laparoscopic myomectomy was associated with longer operating times but reduced operative blood loss, less postoperative decline in hemoglobin levels, reduced postoperative pain, more patients fully recuperated at day 15, and fewer overall complications. Major complications, pregnancy rates, and new appearance of fibroids were comparable in the two groups.



Case series without controls show the feasibility of laparoscopic surgery in women with large fibroids. In a series of 144 women with mean fibroid diameter of 7.8 cm (range, 5 to 18 cm), only 2 women required conversion to laparotomy (133). In another series of 332 consecutive women undergoing laparoscopic myomectomy for symptomatic fibroids as large as 15 cm, only 3 women required conversion to laparotomy (134).



Surgical Technique for Laparoscopic Myomectomy

Port placement should be based on the position and size of the fibroids to be removed **(Fig. 11-5)**. Laparoscopic suturing may be more ergonomic if there are two ports on either the patient's right side for right-handed surgeons or left side for left-handed surgeons; a 12-mm port about 2 cm medial to the iliac crest for suture access, and another 5-mm lateral port near the level of the umbilicus (135). A left upper quadrant approach may be used for initial access when the uterine size is near or above the umbilicus (136).

FIGURE 11-5 Laparoscopic myomectomy. **A:** A 7-cm, posterior intramural fibroid. **B:** Transverse incision through myometrium until fibroid reached. **C:** Traction on fibroid and countertraction on myometrium to tease fibroid away from myometrium. **D:** Adherent attachments to myometrium are cut. **E:** Minimal use of bipolar electrosurgery to control larger vessels. **F:** Three-layer suture closure of myometrium. **G:** Morcellator used to remove fibroid from abdominal cavity. **H:** Pelvis irrigated and suctioned. **I:** Adhesion barrier placed over uterine incision.

Vasopressin is injected into the fibroid. An incision is made directly over the fibroid and carried deeply until definite fibroid tissue and the avascular surgical plane is noted. Transverse incisions permit more ergonomic suturing. The fibroid is grasped with a tenaculum for traction and the plane between the myometrium and fibroid is dissected until the fibroid is free. Bleeding vessels in the myometrial defect are desiccated sparingly with bipolar electrosurgical paddles, taking care not to devascularize the myometrium and interfere with wound healing. Delayed absorbable sutures are placed in one, two, or three layers, as needed, adhering to accepted surgical technique at laparotomy. Morcellation of the fibroid with an electromechanical device is accomplished under direct vision. The pelvis and abdomen are irrigated, the fluid suctioned, and an adhesion barrier may be placed.

Tissue Morcellation

Morcellation describes a surgical method of dividing tissue into small sections in order to allow the tissue to be removed from the abdomen or vagina. With laparoscopic myomectomy, morcellation is usually necessary through the vagina, a Mini-laparotomy incision or electromechanical morcellation passed through a laparoscopic port incision. Morcellation allows many women the benefits of minimally invasive surgery: lower mortality rates, fewer intraoperative and postoperative complications, less postoperative pain with less need for narcotic pain medication, shorter hospital stays, and faster return to work and family.

Morcellation should not be performed in the presence of known or suspected uterine or cervical malignancy. Ultrasound or MRI findings of a large irregular vascular mass, often with irregular anechoic (cystic) areas reflecting necrosis or enhancement of uterine masses on MRI with gadolinium imaged in the arterial phase, should raise suspicion of LMS.

There is no evidence that the type of morcellation, electromechanical or scalpel, alters survival for women with LMS. Analysis of 16 studies that included 196 women with sarcomas reported no significant difference in 5-year survival rates between women having electromechanical morcellation, scalpel morcellation, or no tissue morcellation (137). Importantly, laparoscopic-aided morcellation allows the surgeon to inspect the pelvic and abdominal cavities, remove tissue fragments, and copiously irrigate and suction under visual control. In contrast, the possibility of retained tissue

fragments is greater with vaginal or mini-laparotomy morcellation procedures because the surgeon cannot visually inspect the peritoneal cavity.

Laparoscopic Radiofrequency Thermal Ablation

Laparoscopic ultrasound–guided radiofrequency ablation of uterine fibroids can be accomplished via a hand piece coupled to a radiofrequency generator. Health-Related Quality of Life (HRQL) scores showed improvement at 3 months, which was maintained at 36 months. Fourteen of 135 (11%) women required another treatment intervention for fibroid-related symptoms over 3 years of follow-up (138). Larger studies will be needed to assess the effectiveness of this treatment.

Adhesions Following Myomectomy

Adhesion formation after myomectomy is well documented (139). A Cochrane review found that *Interceed* reduced the incidence of adhesion formation, both de novo and reformation, at laparoscopy and laparotomy (140). Data were insufficient to support its use to improve pregnancy rates. There was limited evidence of effectiveness of *Seprafilm* (Genzyme, Cambridge, MA) in preventing adhesion formation in a prospective study that randomized 127 women undergoing abdominal myomectomy to treatment or no treatment with *Seprafilm* (130). During second-look laparoscopy, women treated with *Seprafilm* had significantly fewer adhesions and lower adhesion severity scores than untreated women. This study and others found an increased incidence of adhesions with posterior uterine incisions compared to anterior incisions (141).

Hysteroscopic Myomectomy

[15] Submucous fibroids, sometimes associated with increased menstrual bleeding or infertility, often can be removed hysteroscopically. Classification of submucous fibroids is based on the degree of the fibroid within the cavity; class 0 fibroids are intracavitary; class I have 50% or more of the fibroid within the cavity; and class II have less than 50% of the fibroid within the cavity **(Fig. 11-6)** (55). A meta-analysis of the effect of fibroids on fertility found that submucous fibroids with distortion of the uterine cavity decreased ongoing pregnancy/live birth rates by 70% (RR 0.32; 95% CI, 0.12–0.850) and resection increased ongoing pregnancy/live birth rates (RR 1.13; 95% CI, 0.96–1.33) (68).

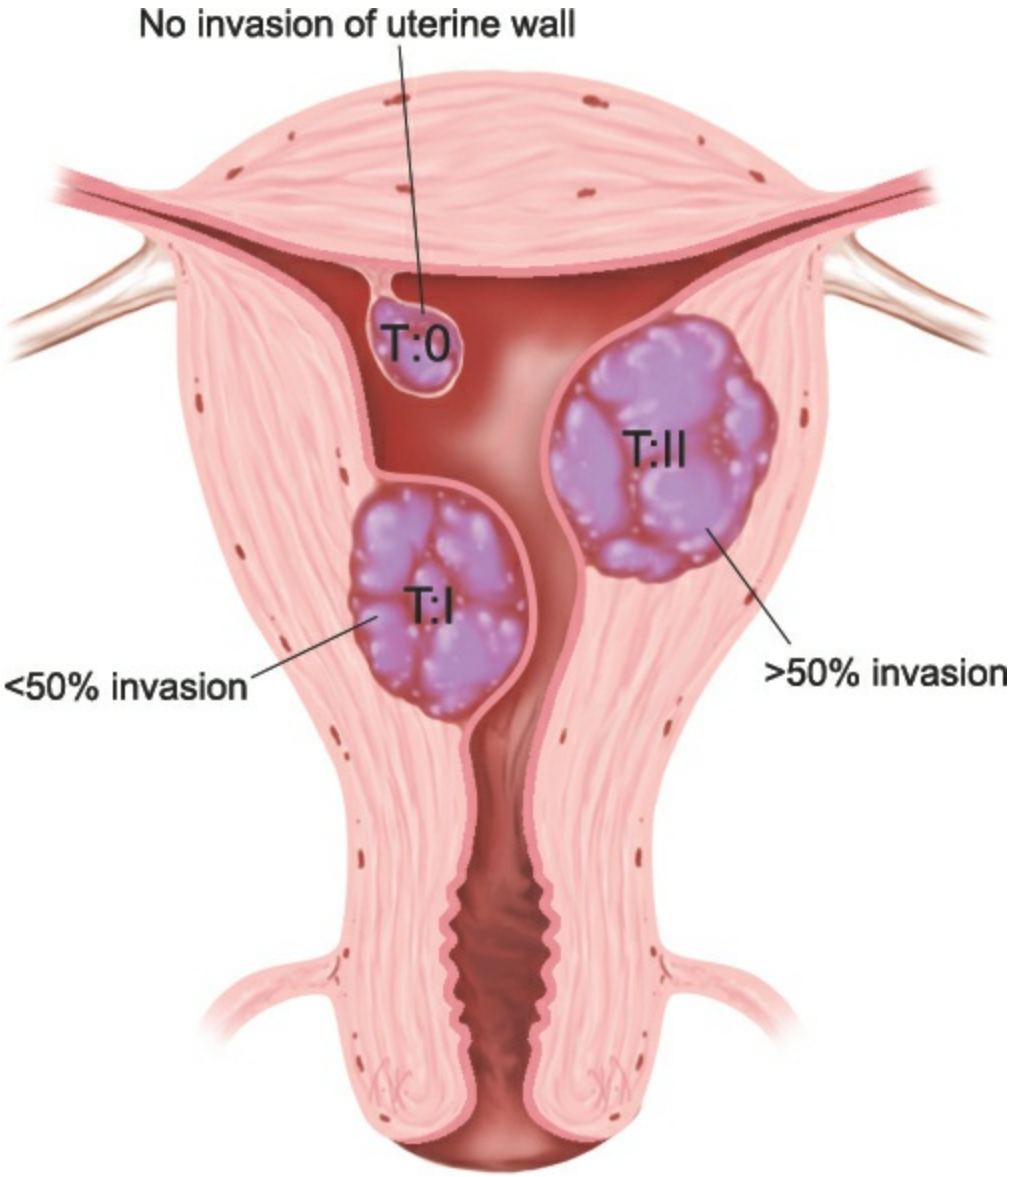

FIGURE 11-6 Fibroid classification. (From **Munro MG, Critchley HO, Broder MS, et al;** FIGO Working Group on Menstrual Disorders. FIGO classification system [PALM-COEIN] for causes of abnormal uterine bleeding in nongravid women of reproductive age. Int J Gynaecol Obstet 2011;113:3–13.)

No meta-analysis of the association of submucous fibroids and abnormal uterine bleeding was performed. However, most studies show a reduction in bleeding following resection. Using pictorial assessment to estimate menstrual blood loss prior to and for 41 months following hysteroscopic resection of submucous fibroids, a significant decrease in bleeding was reported in 42 of 51 (82%) women with submucous pedunculated (type 0), 24 of 28 (86%) with sessile (type 1), and 15 of 22 (68%) with intramural fibroids (type 2) (143). A study of 285 consecutive women with heavy menstrual bleeding or irregular menstrual bleeding who had hysteroscopic resection of submucous fibroid(s) found that additional surgery was required for 9.5% at 2 years, 10.8% at 5 years, and 26.7% at 8 years (144).

Surgical Technique for Hysteroscopic Myomectomy

Hysteroscopic resection of a submucous fibroid can be accomplished under visual control using a telescope and continuous flow of distension fluid through the uterine cavity. The electrosurgical working element uses monopolar or bipolar electrodes. Monopolar electrodes require nonconducting distending solution (sorbitol 5%, sorbitol 3% with mannitol 0.5%, or glycine 1.5%), while bipolar electrodes can be used with saline.

Cervical dilation is usually required prior to insertion of the hysteroscope. *Cytotec* may facilitate easier dilation (145). The cutting loop is passed beyond the fibroid and cutting activated only when the loop is moving toward the surgeon and in direct view. Fibroids should be resected down to the level of the surrounding myometrium and, if fertility is desired, care should be taken to avoid excessive thermal damage to normal myometrium. Often, the remaining portion of the fibroid will be expressed into the uterine cavity by uterine contractions, allowing further resection. Fragments of fibroid are removed from the cavity with a grasping forceps or by capturing the fragments with the loop and extracting the telescope. G0 and G1 fibroids as large as 5 cm may be resected hysteroscopically.

G2 fibroids require careful preoperative evaluation with SIS or MRI to gauge the thickness of normal myometrium between the fibroid and the serosa in order to assess the potential risk of uterine perforation with the loop electrode. The risk of perforation increases with deeper myometrial involvement of the fibroid (146). In some cases, repeat resection may be required after a few weeks, as the remaining portion of the fibroid is expressed into the uterine cavity by uterine contractions.

Hysteroscopic Tissue Removal systems (HTRs) using intrauterine morcellation in physiologic saline solution for distension and irrigation, have been developed for the management of polyps and submucous fibroids. A systematic review of 8 studies included 283 women who underwent intrauterine morcellation of submucous fibroids (147). A deficit of 2,500 mL of isotonic solution is well tolerated by healthy women and no significant intra- or postoperative complications were reported. Complete resection rates were comparable to resectoscopic surgery. There was no significant difference in postoperative hemoglobin levels or patient satisfaction between the resection group compared with HTRs at 3-month follow-up. Uterine Fibroid Symptom-Quality of Life and Health-Related Quality of Life scores improved significantly 12 months after myomectomy using HTRs. As is true with resectoscopic surgery, type 0 and 1 submucous fibroids were found to be easier to manage than type 2.

Procedure-Specific Risks

Cervical dilatation or insertion of the hysteroscope can cause uterine perforation, as can deep myometrial resection. Often the first sign of perforation is a rapid increase in the fluid deficit. Careful inspection of the uterine cavity should be undertaken to look for

brisk bleeding or bowel injury. If no injury is apparent, the procedure should be terminated and the patient should be observed and may be discharged if stable (148). If a perforation occurs during activation of the electrode, then laparoscopy should be performed to carefully inspect for bowel or bladder injury.

Fluid Absorption and Electrolyte Imbalance

Intravascular absorption of distending media is a potentially dangerous complication that can result in pulmonary edema, hyponatremia, heart failure, cerebral edema, and death (149). Careful monitoring of the fluid deficit is important and a fluid deficit of 750 mL during surgery should serve as a warning sign, with planned termination of the procedure. **Many authors suggest termination of the procedure when the fluid deficit exceeds 1,000 mL, although other guidelines suggest termination after introduction of 1,500 mL of a nonelectrolyte solution or 2,500 mL of an electrolyte solution** (149). Electrolytes should be assessed and corrected if necessary and diuretics considered. Risk factors for fluid overload include resection of fibroids with deep intramural extension or prolonged operating time. The use of normal saline combined with bipolar energy reduces the risk of hyponatremia, but a fluid deficit over 1,500 mL can lead to cardiac overload (150).

Endometrial Ablation for Abnormal Bleeding Associated With Fibroids

In selected women not desiring future childbearing, endometrial ablation with or without hysteroscopic myomectomy may be efficacious. Pad counts following ablation with or without fibroid resection found that 48 of 51 (94%) women had resolution of abnormal bleeding after a mean follow-up of 2 years (range, 1 to 5 years) (151). A study of 62 women followed for an average of 29 months (range, 12 to 60 months) found that 74% of the women had hypomenorrhea or amenorrhea, and only 12% required a hysterectomy (152).

Hydrothermal ablation was used to treat 22 women with known submucous fibroids up to 4 cm, with 91% reporting amenorrhea, hypomenorrhea, or eumenorrhea after a minimum of 12 months' follow-up (153). In a study of 65 women with menometrorrhagia and type 1 or 2 submucous myomas up to 3 cm, after treatment with *NovaSure* endometrial ablation device (Hologic, Bedford, MA), normal bleeding or amenorrhea was observed in most women at 1 year (154).

NEW APPEARANCE OF FIBROIDS

Although new fibroids may sometimes develop following myomectomy, most women will not require additional treatment. If the first surgery is performed in the presence of a single fibroid, only 11% of women will need subsequent surgery (155). If multiple fibroids are removed during the initial surgery, only 26% will need subsequent surgery

(mean follow-up 7.6 years). Individual fibroids, once removed, do not grow back. Fibroids detected after myomectomy, often referred to as "recurrence," result either from failure to remove fibroids at the time of surgery or are newly developed fibroids. Perhaps this circumstance is best designated "new appearance" of fibroids (156).

Sonography found that 29% of women had persistent fibroids 6 months after myomectomy (157). In addition, the background formation of new fibroids in the general population should be considered. A hysterectomy study found fibroids in 77% of specimens from women who did not have a preoperative diagnosis of fibroids (4).

Incomplete follow-up, insufficient length of follow-up, the use of either transabdominal or transvaginal sonography (with different sensitivity), detection of very small clinically insignificant fibroids, or use of calculations other than life-table analysis confound many studies of new fibroid appearance (158).

Clinical Follow-Up

Self-reported diagnosis based on symptom questionnaires has reasonably good correlation with sonographic or pathologic confirmation of significant fibroids and may be the most appropriate method of gauging clinical evidence of new appearance (18). One study of 622 patients aged 22 to 44 at the time of surgery and followed over 14 years found the cumulative new appearance rate based on clinical examination and confirmed by ultrasound was 27% **(Fig. 11-7)** (159). An excellent review of life-table analysis studies found a cumulative risk of clinically significant new appearance of 10% 5 years after abdominal myomectomy (160).

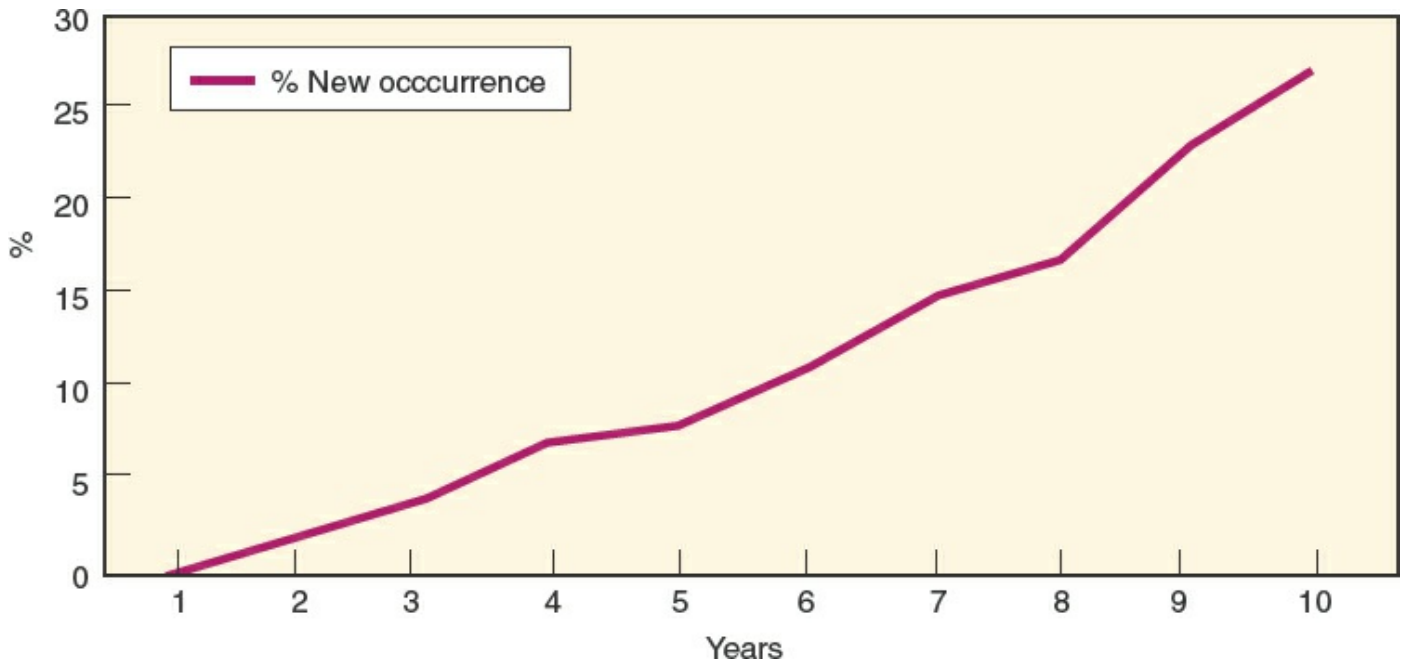

FIGURE 11-7 Overall 10-year new appearance after initial myomectomy. (From **Candiani G, Fedele L, Parazzini F, et al.** Risk of recurrence after myomectomy. Br J Obstet Gynecol 1991;98:385–389.)

Sonographic Follow-Up

[16] Routine ultrasound follow-up is sensitive but detects many clinically insignificant fibroids. One hundred forty-five women, with mean age 38 (ranging from 21 to 52), were followed after abdominal myomectomy with clinical evaluation every 12 months and TVS at 24 and 60 months (sooner, with clinical suspicion of new fibroids) (157). No lower size limit was used for the sonographic diagnosis of fibroids and, thus, the cumulative probability of new appearance was 51% at 5 years. A study of 40 women who had a normal sonogram 2 weeks following abdominal myomectomy found that the cumulative risk of sonographically detected new fibroids larger than 2 cm was 15% over 3 years (161).

Need for Subsequent Surgery

Meaningful information for a woman considering treatment for her fibroids is the approximate risk of developing symptoms that would require yet additional treatment. A study of 125 women followed by symptoms and clinical examination after a first abdominal myomectomy found that a second surgery was required during the follow-up period (average 7.6 years) for 11% of women who had one fibroid removed initially and for 26% of women who had multiple fibroids removed (155). Crude rates of hysterectomy after myomectomy vary from 4% to 16% over 5 years (162,163).

Prognostic Factors Related to New Appearance of Fibroids

Age

Given that the incidence of fibroids increases with increasing age, 4 per 1,000 woman-years for 25 to 29 year olds and 22 per 1,000 for 40 to 44 year olds, new fibroids would be expected to form as age increases, even following myomectomy (13).

Subsequent Childbearing

The 10-year clinical new appearance rate for women who subsequently gave birth was 16%, but for those women who did not the rate was 28% (159).

Number of Fibroids Initially Removed

After at least 5 years of follow-up, 27% of women who initially had a single fibroid removed had clinically detected new fibroids and 59% of women with multiple fibroids initially removed had new fibroids (151).

Gonadotropin-Releasing Hormone Agonists

Preoperative treatment with GnRH-a decreases fibroid volume and may make smaller fibroids harder to identify during surgery. A randomized study found that 3 months following abdominal myomectomy, 5 (63%) of 8 women in the GnRH group had fibroids less than 1.5 cm detected sonographically, while only 2 of 16 (13%) untreated

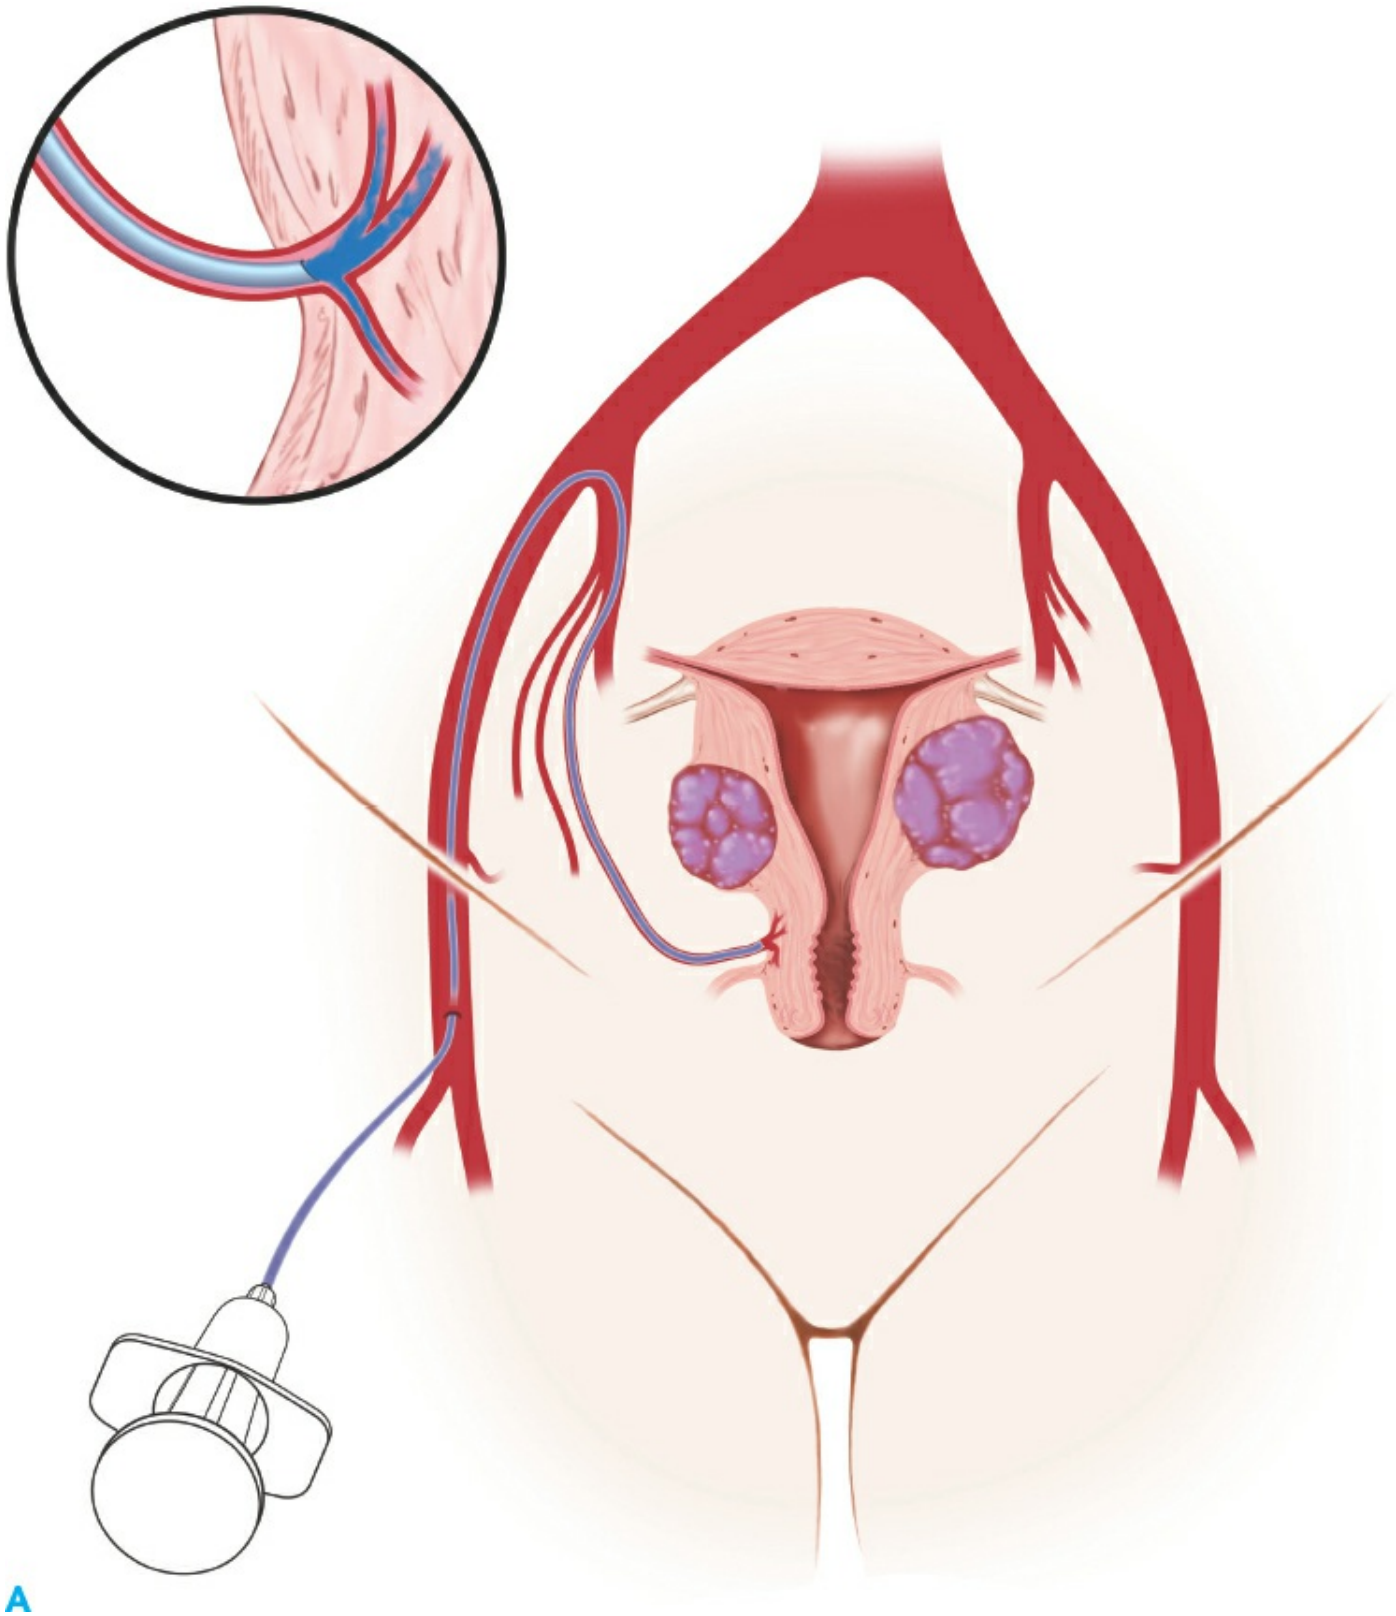
women had small fibroids detected (157).

Laparoscopic Myomectomy

New appearance of fibroids is not more common following laparoscopic myomectomy when compared with abdominal myomectomy. Eighty-one women randomized to either laparoscopic or abdominal myomectomy were followed with TVS every 6 months for at least 40 months (164). Fibroids larger than 1 cm were detected in 27% of women following laparoscopic myomectomy compared to 23% in the abdominal myomectomy group, and no woman in either group required any further intervention.

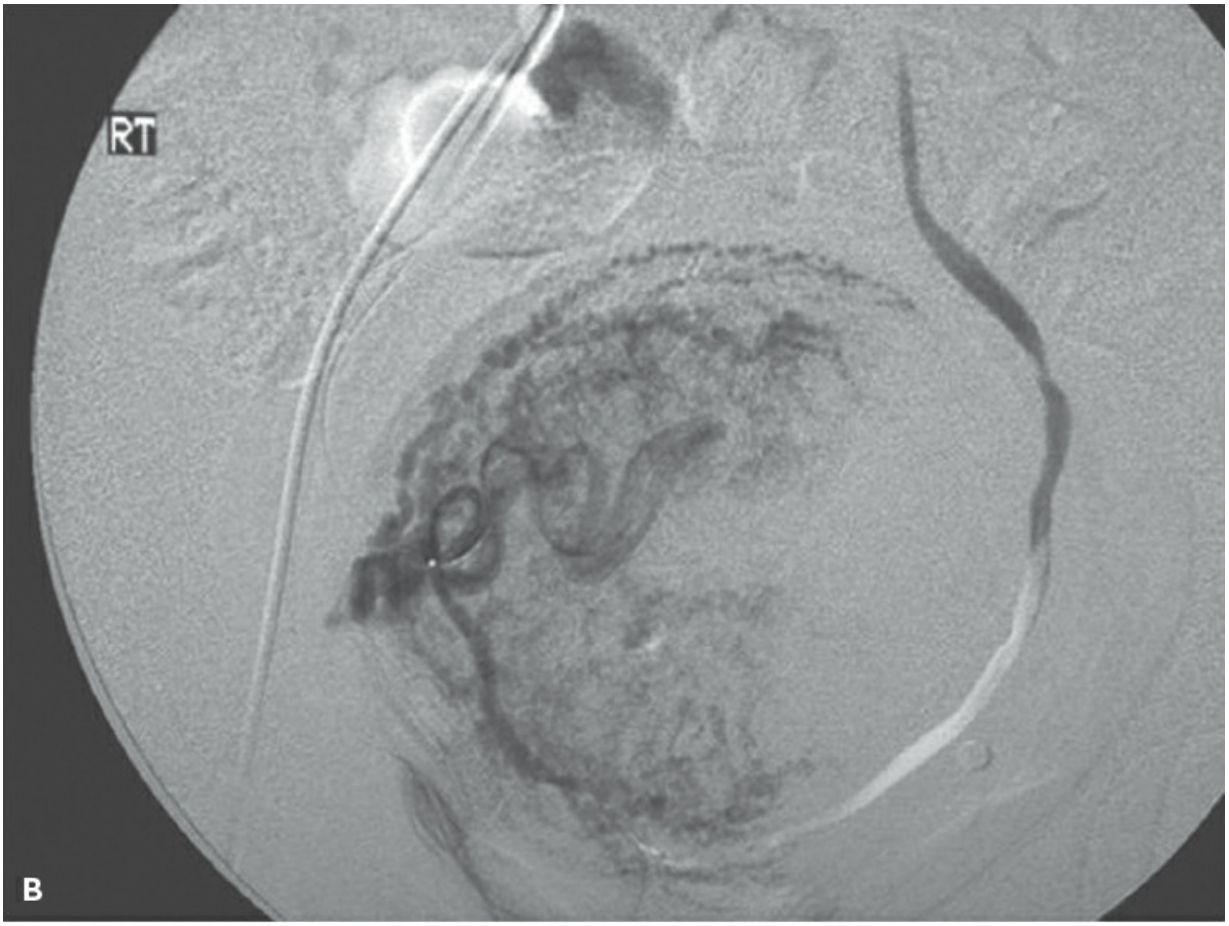
UTERINE ARTERY EMBOLIZATION

[17] Uterine artery embolization (UAE) is an effective treatment for selected women with uterine fibroids. The effects of UAE on early ovarian failure, fertility, and pregnancy are unclear. Therefore, many interventional radiologists advise against the procedure for women considering future fertility. Appropriate candidates for UAE include women who have sufficiently bothersome symptoms to warrant hysterectomy or myomectomy. Although extremely rare, complications of UAE may necessitate life-saving hysterectomy, and women who would not accept hysterectomy, even for life-threatening complications, should not undergo UAE. Contraindications to treatment of fibroids with UAE include women with active genital infection, genital tract malignancy, diminished immune status, severe vascular disease limiting access to the uterine arteries, contrast allergy, or impaired renal function (165). UAE outcomes are well studied and documented.



Fibroid and uterine volume decreased significantly and consistently following UAE and reports from the EMMY trial confirmed that fibroid and uterine volume reductions persisted up to 5 years after UAE (61). However, 28% of women underwent subsequent hysterectomy. Other studies, with length of follow-up ranging from 6 to 60 months, reported the need for subsequent treatment: hysterectomy in 17.5%, myomectomy in 8.8%, repeat embolization in 6.3%, IUD placement in 8%, medical therapy in 6.7%, and endometrial ablation in 1.2%. Decline in bleeding and/or pain were reported in most RCTs. Major procedure-related complication rates ranged from 1.2% to 6.9%.

A Cochrane review found no difference between UAE and myomectomy or hysterectomy in the risk of major complications, but UAE was associated with a higher rate of minor complications (166). UAE had an increased likelihood of requiring surgical intervention within 2 to 5 years of the initial procedure. One small study found that myomectomy was associated with better fertility outcomes than UAE. Patient satisfaction rates at up to 5 years following UAE versus myomectomy or hysterectomy found no difference between the interventions.



The American College of Obstetricians and Gynecologists recommends that women considering UAE have a thorough evaluation with a gynecologist to help facilitate collaboration with the interventional radiologist and that responsibility of caring for the patient be clear (168).

Uterine Artery Embolization Technique

Percutaneous cannulation of the femoral artery is performed by a properly trained and experienced interventional radiologist **(Fig. 11-8)** (169). Embolization of the uterine artery and its branches is accomplished by injecting gelatin sponges, polyvinyl alcohol particles (PVA), or tris-acryl gelatin microspheres via the catheter until occlusion, or slow flow, is documented. Total radiation exposure (approximately 15 cGy) is comparable to one or two computed tomography scans or barium enemas (170).

RT
B

RT
POST
C

FIGURE 11-8 A–C: UAE techniques. **A:** A catheter is threaded to the uterine arteries and embolic material injected to block off blood flow to the uterus. **B:** Contrast dye shows the vessels supplying the fibroid prior to UAE. **C:** Following UAE, embolic material blocks blood flow to the fibroid.

Tissue hypoxia secondary to UAE causes postprocedural pain that usually requires pain management in the hospital for 1 day. NSAID medications are usually taken for 1 to 2 weeks, and many women return to normal activity within 1 to 3 weeks. Approximately 5% to 10% of women have pain for longer than 2 weeks (170). Ten percent of women require readmission to the hospital for postembolization syndrome, characterized by diffuse abdominal pain, nausea, vomiting, low-grade fever, malaise, anorexia, and leukocytosis. Treatment with intravenous fluids, NSAID medications, and pain management usually leads to resolution of symptoms within 2 to 3 days (170). **Persistent fever should be managed with antibiotics. Failure to respond to antibiotics may indicate sepsis, which needs to be aggressively managed with hysterectomy.**

Uterine Artery Embolization Outcomes

The largest prospective study reported to date includes 555 women aged 18 to 59 (mean, 43), 80% of whom had heavy bleeding, 75% had pelvic pain, 73% had urinary frequency or urgency, and 40% of women had required time off work due to fibroid-related symptoms (171). Telephone interviews 3 months after UAE found that heavy menstrual bleeding improved in 83% of women, dysmenorrhea improved in 77%, and urinary frequency in 86%. Mean fibroid volume reduction of the dominant fibroid was 33% at 3 months, but improvement in heavy menstrual bleeding was not related to preprocedural uterine volume (even >1,000 cm^3) or to the degree of volume reduction obtained. Of note, two women (0.4%) had continued uterine growth and worsening pain and were found to have sarcomas. The hysterectomy rate caused by complications was 1.5%. Within the follow-up period, 3% of women under 40, but 41% of women over 50, had amenorrhea.

A prospective, randomized trial comparing hysterectomy and UAE in 177 women with symptomatic fibroids found that major complications were rare. Hospital stay was significantly shorter for UAE (2 vs. 5 days), but UAE was associated with more readmissions (9 vs. 0) for pain and/or fever in the 6-week postoperative period. Significant complications included one woman who required resection of a submucous fibroid, one who had sepsis in the UAE group, and one woman who had a vesicovaginal fistula following hysterectomy.

Early Ovarian Failure

The risk of premature ovarian failure following UAE needs further study. Transient amenorrhea was reported in as many as 15% of women. Ovarian arterial perfusion as

measured by Doppler sonography immediately following UAE shows that 35% of women had decreased ovarian perfusion and 54% had complete loss of perfusion (173). However, basal follicle-stimulating hormone (FSH) and anti-müllerian hormone (AMH) levels indicated decreased ovarian reserve in all women in one study (174).

Kim et al. reported a significant decrease of AMH and antral follicle counts (AFC) at 3 and 12 months after UAE (175). A significant recovery of AMH at the 12-month measurement was seen, but only in patients <40 years of age. These results suggest that ovaries may be damaged following UAE, but they may recover in younger women. A study comparing women who underwent UAE with women having laparoscopic myomectomies found significantly lower AMH levels and AFC in the UAE group (176). Although normal FSH, estradiol, ovarian volume, and AFC were documented in most women following UAE, these tests cannot predict earlier onset of menopause (177). Younger women, whose ovaries contain a large number of follicles, are likely to maintain a normal FSH despite destruction of a significant number of follicles, but it is not clear if future fertility will be impaired. Loss of follicles might cause menopause at an age earlier than would otherwise be expected. Long-term follow-up of women having UAE will be necessary to answer this important question.

Fertility and Pregnancy Following Uterine Artery Embolization

Because of the possibility of decreased ovarian function, and the potential for increased pregnancy complications, women who wish to conceive should not be treated with UAE (178). Although the risk appears to be low for women younger than 40 years old, premature ovarian failure would be devastating in this setting. Potential fertility following UAE is uncertain. A prospective trial of women with intramural fibroids larger than 4 cm, randomly selected for either UAE or myomectomy, reported more pregnancies and fewer spontaneous abortions after surgery than after UAE (176). Obstetrical and perinatal results were similar.

Two hundred twenty-seven completed pregnancies after UAE were compared with pregnancies in untreated women matched for age and fibroid location (controls) (179). Miscarriage rates (35% vs. 17%) and postpartum hemorrhage rates (14% vs. 3%) were higher in UAE pregnancies compared with controls. Rates of preterm delivery, IUGR, and malpresentation were similar in UAE pregnancies and in control pregnancies with fibroids. One small randomized study compared fertility outcomes of UAE with laparoscopic myomectomy (176). Twenty-six patients after UAE and 40 after myomectomy tried to conceive, with a pregnancy rate of 50% vs. 78% (p <0.05) and miscarriage rate of 53% vs. 19% (p <0.05) for UAE and myomectomy, respectively. A Cochrane database review stated that UAE may be associated with less favorable fertility outcomes than myomectomy, but the data is low quality and should be regarded with extreme caution (166).

Another study reported eight term and six preterm deliveries, but two women had

placenta previa and one woman had a membranous placenta. It is not clear whether this high incidence of abnormalities is related to an effect of UAE on the endometrium or a placental problem inherent to women with uterine fibroids. As a result, some authors recommend early-pregnancy sonography to look for placenta accreta (180). Uterine wall defects, necrosis, and fistula have been reported following UAE, and the integrity of the uterine wall during pregnancy and childbirth remains unknown (181).

Uterine Artery Occlusion

Alternative methods of uterine artery occlusion include laparoscopic uterine artery occlusion. Fifty-eight patients were randomized to UAE or laparoscopic uterine artery occlusion (182). After a median follow-up of 48 months, clinical failures and symptom recurrence occurred in 14 women after laparoscopy (48%) and in five women after UAE (17%). Laparoscopic occlusion requires general anesthesia, is invasive, and requires a skilled laparoscopic surgeon.

Magnetic Resonance–Guided Focused Ultrasound

Ultrasound energy can be focused to create sufficient heat at a specific point so that protein is denatured and cell death occurs. Concurrent MRI allows precise targeting of tissue and monitoring of therapy by assessing the temperature of treated tissue (183). The advantages of this procedure are a very low morbidity and a very rapid recovery, with return to normal activity in one day. The procedure is not recommended for women wishing future fertility (183). Initial studies had treatment limited by the U.S. Food and Drug Administration to approximately 10% of fibroid volume, and while a 15% reduction in fibroid size was reported 6 months following treatment, only an additional 4% reduction was noted at 24 months (184). More recent studies with larger treatment areas reported better results; 6 months after treatment, the average volume reduction was 31% (+/−28%) (185).

An evidence-based review found cohort studies involving 1,594 patients with short-term follow-up (<1 year) (186). Twenty-six major complications (1.6%) were reported. MRgHIFU resulted in statistically and clinically significant reductions in fibroid-related symptoms. For women failing medical therapy and seeking alternatives to hysterectomy for symptomatic uterine fibroids, the author concluded that MRgHIFU provides a safe and effective, noninvasive, uterine-preserving treatment with a rapid recovery. Disadvantages of MRgHIFU include restricted eligibility, lengthy procedure time, and availability of an MR device.

A nonrandomized comparative study of 166 patients with uterine fibroids who underwent MRgHIFU (n = 99) and laparoscopic myomectomy (n = 67) reported the laparoscopic myomectomy group showed substantial symptom improvement in 52 patients and partial symptom improvement in 13 (187). In the MRgHIFU group, 6

months after treatment, 62 patients showed complete symptom relief and 36 patients showed partial relief. MRgHIFU requires no general anesthesia or blood loss and leads to quick postoperative recovery. This study had no description of patient or fibroid characteristics and both patient and physician selection bias were likely. The lack of high-quality comparative evidence between MRgHIFU and other, more established uterine-preserving treatments, limits informed decision making among treatment options.

MANAGEMENT SUMMARY

A woman's individual circumstance, including fibroid-related symptoms and their effect on the quality of life, desire (or not) to preserve fertility, and her wishes regarding treatment options should be considered when discussing possible treatments. Multiple treatment options usually exist and the following points should be considered.

For an asymptomatic woman diagnosed with fibroids who desires fertility in the near future, evaluation of the uterine cavity with SIS, hysteroscopy, or MRI provides useful information regarding the presence of submucous fibroids and their potential impact on fertility. If the cavity is not deformed, fibroids need not be treated and conception may be attempted. If the cavity is deformed, myomectomy (hysteroscopic or abdominal) can be considered. An experienced laparoscopic surgeon may offer laparoscopic myomectomy, with a multilayered myometrial closure.

For an asymptomatic woman who does not desire future fertility, observation (watchful waiting) should be considered. A periodic review of the patient's symptoms and a pelvic examination to evaluate the uterine size should be accomplished. In the presence of very large fibroids, renal ultrasound or computed tomography urogram can be considered to rule out significant hydronephrosis.

For a symptomatic woman who desires future fertility and her primary symptom is abnormal bleeding, baseline hemoglobin measurement should be considered because accommodation to anemia can occur. If indicated, further evaluation of the endometrium with endometrial biopsy can be performed. Evaluation of the uterine cavity with SIS, hysteroscopy, or MRI can help determine the appropriate treatment options.

If the cavity is deformed, myomectomy (hysteroscopic or abdominal) should be considered. An experienced laparoscopic surgeon may offer laparoscopic myomectomy. If the symptoms of pain or pressure (bulk symptoms) are present, and if the uterine cavity is not deformed, myomectomy (abdominal or laparoscopic) can be considered.

For a symptomatic woman who does not desire future fertility, observation (watchful waiting) can be considered if no treatment is desired at that time. A

symptomatic perimenopausal woman may desire observation until she enters menopause, when symptoms often diminish. Baseline hemoglobin measurements should be obtained and if a significant anemia exists, treatment should be considered. If irregular menstrual bleeding is present, evaluation of the endometrium with sonography or endometrial biopsy should be considered. If the endometrium is normal, a *levonorgestrel*-IUS or endometrial ablation may be appropriate treatment. Myomectomy (hysteroscopic, abdominal, or laparoscopic), hysterectomy (vaginal, laparoscopic, or abdominal), or UAE can be considered.

For a woman with primarily fibroid-related pain or pressure symptoms (bulk symptoms), myomectomy, hysterectomy, and UAE or focused ultrasound (limited by size and number of fibroids) may be considered.

Hysterectomy

KEY POINTS

1 Acute pelvic pain is rapid in onset, often associated with unstable vital signs and obvious abnormalities on physical examination and laboratory assessment. Improper diagnosis can result in significant morbidity and even mortality.

2 Timely and thorough assessment, guided by organ system (reproductive, gastrointestinal, urinary) and category of pathology, will ensure effective diagnosis and management of infection, obstruction, ischemia (torsion), leakage of irritating substance (viscus or cyst rupture), or pregnancy-related pain.

3 Chronic pelvic pain (CPP) is a multifaceted disorder characterized by changes in the processing of afferent signaling in the pelvic organs, the surrounding somatic tissues, the spinal cord, and the brain. The shared thoracolumbar and sacral innervations of the pelvic structures and the upregulation processing of neural input in the central nervous system account for the multiplicity of somatic and psychological symptoms experienced by women with CPP.

4 A thorough history and physical examination are important for successful management of acute and chronic pain. The ancillary laboratory and diagnostic procedures performed to assess acute, life-threatening processes differ from those focused on chronic pain conditions. CPP requires a multidisciplinary approach for diagnosis and management.

DEFINITIONS

[1] *Acute pain* is intense and characterized by sudden onset, sharp rise, and short course. *Cyclic pain* refers to pain that occurs with a definite association to the menstrual period. *Dysmenorrhea*, or painful menstruation, is the most common

cyclic pain phenomenon and is classified as *primary* or *secondary* on the basis of associated anatomic pathology (1). ***Chronic* pelvic pain (*CPP*) is defined as pain of greater than 3 months in duration, localized to the anatomic pelvis, and sufficiently severe to cause functional disability or necessitate medical care** (2).

Whereas acute pain is generally associated with autonomic reflex responses, such as nausea, emesis, diaphoresis, and apprehension, these autonomic reflex responses are not present in women with CPP. Acute pain is often affiliated with signs of inflammation or infection, such as fever and leukocytosis, which are absent in chronic pain states. The pathophysiology of acute pelvic pain involves mediators of inflammation present in high concentration as a result of infection, ischemia, or chemical irritation.

By contrast, the etiology of CPP often involves changes in modulation or "upregulation" of normally nonpainful stimuli. Pain is out of proportion to the degree of tissue damage (3,4). Chronic pain is characterized by physiologic, affective, and behavioral responses that differ from those associated with acute pain (44). An inflammatory lesion, such as endometriosis, for example, can set up an environment of chronic neurogenic inflammation or stimulation, which can result in "plastic" changes in the peripheral and central nervous system (CNS) and the persistence of chronic pain (5–8). Genetic predisposition, adverse environmental pressures, and hormonal milieu are thought to increase the vulnerability and predisposition for chronic pain disorders (9).

ACUTE PAIN

The differential diagnosis of acute pelvic pain is outlined in Table 12-1. Assessing the character of the pain helps create a differential diagnosis. **[1] Rapid onset of pain is most consistent with perforation or rupture of a hollow viscus or ischemia following the torsion of a vascular pedicle. Colic or severe cramping pain is commonly associated with muscular contraction or obstruction of a hollow viscus, such as the intestine, ureter, or uterus. Pain perceived over the entire abdomen suggests a generalized reaction to an irritating fluid within the peritoneal cavity such as blood, purulent fluid, or contents of an ovarian cyst.**

Table 12-1 Differential Diagnosis of Acute Pelvic Pain

Gynecologic
Acute Pain
1. *Complication of pregnancy* a. Ectopic pregnancy b. Abortion, threatened, or incomplete
2. *Acute infections* a. Endometritis

b. Pelvic inflammatory disease (acute PID) or salpingo-oophoritis c. Tubo-ovarian abscess
3. *Adnexal disorders* a. Hemorrhagic functional ovarian cyst b. Torsion of adnexa c. Rupture of functional, neoplastic, or inflammatory ovarian cyst
Recurrent Pelvic Pain
1. Mittelschmerz (midcycle pain) 2. Primary dysmenorrhea 3. Secondary dysmenorrhea
Gastrointestinal
1. Gastroenteritis 2. Appendicitis 3. Bowel obstruction 4. Diverticulitis 5. Inflammatory bowel disease 6. Irritable bowel syndrome
Genitourinary
1. Cystitis 2. Pyelonephritis 3. Ureteral lithiasis
Musculoskeletal
1. Abdominal wall hematoma 2. Hernia
Other
1. Acute porphyria 2. Pelvic thrombophlebitis 3. Aortic aneurysm 4. Abdominal angina

The first perception of visceral pain is a vague, deep, poorly localizable sensation associated with autonomic reflex responses. When the pain becomes localized to a region of the abdominal wall, the pain is called referred pain. Referred pain is well localized, more superficial, and is appreciated within the nerve distribution or dermatome of the spinal cord segment innervating the involved viscus. The location of the referred pain provides insight into the location of the primary disease process. The innervations of the pelvic organs are outlined in Table 12-2. The upper vagina, cervix, uterus, and adnexa share the same visceral innervations with the large intestine, rectum, bladder, lower ureter, and lower small intestine. Pain from the reproductive organs, genitourinary (GU), and gastrointestinal (GI) tracts are referred to the same dermatomes

(10).

Table 12-2 Nerves Carrying Painful Impulses from the Pelvic Organs

Organ	Spinal Segments	Nerves
Abdominal wall	T12–L1	Iliohypogastric, ilioinguinal, genitofemoral
Lower abdominal wall, anterior vulva, urethra, clitoris	L1–L2	Ilioinguinal, genitofemoral
Lower back	L1–L2	
Pelvic floor, anus, perineum, and lower vagina	S2–S4; L1–L2	Pudendal, inguinal, genitofemoral, posterofemoral cutaneous
Upper vagina, cervix, uterine corpus, inner third of fallopian tubes, broad ligament, upper bladder, terminal ileum, and terminal large bowel	T11–L2; S2–S4	Thoracolumbar autonomics (sympathetics) via hypogastric plexus; sacral autonomics (parasympathetics) via pelvic nerve
Ovaries, outer two-thirds of fallopian tubes, and upper ureter	T9–T10	Thoracic autonomics (sympathetics) via renal and aortic plexus and celiac and mesenteric ganglia, aortic and superior mesenteric plexuses

Evaluation of Acute Pelvic Pain

In the evaluation of acute pelvic pain, early diagnosis is critical because significant delay increases morbidity and mortality. Fundamental to correct diagnosis is an accurate history. The date and character of the last and previous menstrual periods and the presence of abnormal bleeding or discharge should be ascertained. The menstrual, sexual, contraceptive history, and any history of sexually transmitted conditions and previous gynecologic disorders are relevant. Pain history should include how and when the pain started, pregnancy-related symptoms (amenorrhea, irregular bleeding, nausea, breast tenderness), GI symptoms (anorexia, nausea, vomiting, constipation, obstipation, absence of flatus, hematochezia), urinary symptoms (dysuria, urgency frequency, hesitancy, hematuria), signs of infection (fever, chills, purulent vaginal discharge), and symptoms attributable to a hemoperitoneum (dizziness, syncope, abdominal distention, and right upper quadrant or shoulder pain). Document any past medical and surgical history, and current medications.

Baseline laboratory studies will include, at minimum, a complete blood count (CBC) with differential, clean catch midstream routine urine analysis (RUA), sensitive urine or serum pregnancy test, gonorrhea and chlamydia screening, and a transvaginal pelvic ultrasound. Other tests such as computerized tomography (CT) with and without contrast, chemistry panel, or blood type and screen (if transfusion is likely) may be

indicated depending on the patient's symptoms and the specific differential diagnosis.

Reproductive Tract Causes of Acute Pelvic Pain

Ectopic Pregnancy

[2] All reproductive-aged women presenting with acute pain should be screened for pregnancy.

An ectopic pregnancy is defined as implantation of the fetus in a site other than the uterine cavity (see Chapter 32).

Symptoms

Ectopic pregnancies can implant anywhere other than inside the uterus including the abdomen, cervix, ovary, or cornua of the uterus. Nearly all ectopic pregnancies (98%) are found within the fallopian tube, which will be discussed in this section (11).

Implantation of the fetus in the fallopian tube produces pain with acute dilation of the tube. If tubal rupture occurs, localized abdominal pain tends to be temporarily relieved and is replaced by generalized pelvic and abdominal pain and dizziness with the development of a hemoperitoneum. A period of amenorrhea followed by irregular bleeding and acute onset of pain compose the classic triad of symptoms. A mass in the cul-de-sac may produce an urge to defecate. Referred pain to the right shoulder often develops if the intra-abdominal blood collection transverses the right colic gutter and irritates the diaphragm (C3–C5 innervation).

Signs

Vital signs often reveal orthostatic changes in the case of a ruptured ectopic. Orthostasis is diagnosed by obtaining a patient's pulse and blood pressure while they are supine, after sitting for 3 minutes, and finally after standing for 3 minutes. If the systolic blood pressure decreases by 20 mmHg or the diastolic blood pressure decreases by 10 mmHg when standing from a supine position, orthostasis is confirmed. Although pulse rate is not specifically included in the definition of orthostasis, it is easy to obtain and an increase in pulse rate can be suggestive of orthostasis. Elevated temperature is generally absent with an ectopic.

Abdominal examination is notable for tenderness and guarding in one or both lower quadrants. With the development of hemoperitoneum, generalized abdominal distention and rebound tenderness are prominent and bowel sounds are decreased. Pelvic examination generally reveals mild tenderness on the motion of the cervix. Adnexal tenderness is present, usually more pronounced on the side of the ectopic pregnancy, and a mass may be palpated. Positive pregnancy test and transvaginal ultrasound are usually confirmatory. Ultrasound findings can include an adnexal mass, pseudosac in the endometrium, and an extrauterine sac with a yolk sac within the embryo in the fallopian

tube. If the patient has intra-abdominal bleeding, peritoneal free fluid can be seen on the ultrasound. The diagnostic approach and the medical and surgical management of ectopic pregnancy are discussed in Chapter 32 (12,13).

Leaking or Rupture of an Ovarian Cyst

Functional cysts (e.g., follicle or corpus luteum) are the most common ovarian cysts and are more likely to rupture than benign or malignant neoplasms. The pain associated with the rupture of the ovarian follicle at the time of ovulation is called *mittelschmerz*. The small amount of blood leaking into the peritoneal cavity and high concentration of follicular fluid prostaglandins contribute to this midcycle pelvic pain. The pain is usually mild to moderate and self-limited, and with an intact coagulation system, hemoperitoneum is unlikely.

Normal menstrual cycles produce follicles which mature to release an ovum, which becomes the corpus luteum that eventually involutes. When the follicle does not rupture to release an ovum it can become a follicular or physiologic cyst and continue to grow. Likewise, the corpus luteum fails to involute and continues to grow after ovulation. Both of these can become hemorrhagic cysts. Uncomplicated ruptured ovarian cysts which are hemodynamically stable can be managed with close observation, hospitalization, or repeat imaging.

[2] A hemorrhagic cyst can become symptomatic, causing worsening vital signs, and require surgery. The rapidly expanding ovarian capsule or, with rupture, the blood in the peritoneal cavity is responsible for the acute pain. Rupture of this cyst can produce either a small amount of intraperitoneal bleeding or frank hemorrhage, resulting in significant blood loss and hemoperitoneum. Cystic ovarian neoplasms or inflammatory ovarian masses, such as endometriomas or abscesses, can leak or rupture. A history of a dermoid cyst or endometrioma that has not yet undergone surgical extirpation is not uncommon. **Surgical exploration is indicated if the rupture leads to significant hemoperitoneum (corpus luteum) or chemical peritonitis (endometrioma or dermoid), which could impair future fertility, or an acute abdomen (abscess), which is life-threatening.**

Symptoms

An ovarian cyst that is not undergoing torsion, rapidly enlarging, infected, or leaking does not usually cause acute pain. **A corpus luteum cyst is the most common cyst to rupture and leads to hemoperitoneum. Symptoms of a ruptured corpus luteum cyst are similar to those of a ruptured ectopic pregnancy.** The patient is in the luteal phase or can have delayed menses as a result of the persistently functioning corpus luteum. The onset of pain is usually sudden and is associated with increasing pelvic pain, which becomes generalized abdominal pain and dizziness or syncope with the development of significant hemoperitoneum.

A ruptured endometrioma or benign cystic teratoma (dermoid cyst) produces similar symptoms; however, dizziness and signs of hypovolemia are not present because blood loss is minimal.

Signs

Orthostasis resulting from hypovolemia is present only when there is intravascular volume depletion, such as with a hemoperitoneum. Fever is rare. **The most important sign is the presence of significant abdominal tenderness, often associated with localized or generalized lower quadrant rebound tenderness because of peritoneal irritation.** The abdomen can be moderately distended with decreased bowel sounds. On pelvic examination, a mass is often palpable if the cyst is leaking and has not completely ruptured.

Diagnosis

The diagnosis and the type of ruptured cyst are ascertained by blood tests and transvaginal ultrasound. Pregnancy test, CBC, and, if orthostasis is present, type and screening should be ordered. Leukocytosis is uncommon. The hematocrit is decreased if active bleeding is present. If orthostasis is absent and the peripheral hematocrit is relatively normal, clinically significant hemoperitoneum is unlikely. Culdocentesis was used historically to support findings by aspirating clear, blood tinged, or purulent fluid in helping with diagnosis. It has largely been replaced by improvements in pelvic imaging, image-guided aspiration, or diagnostic laparoscopy.

A skillful reading of transvaginal ultrasound images can help characterize a cystic structure in the pelvis as a dermoid, endometrioma, corpus luteum, or pelvic abscess and quantify the amount of intraperitoneal fluid.

Management

Orthostasis, significant anemia, or a large amount of free peritoneal fluid on ultrasound suggests significant hemoperitoneum and usually requires surgical management by laparoscopy or laparotomy. Patients who are not orthostatic or febrile, not pregnant or anemic, and have only a small amount of fluid in the cul-de-sac can often be observed in the hospital, with surgical intervention, or discharged home from the emergency room after observation.

Adnexal Torsion

[2] Torsion (twisting) of the vascular pedicle of an ovary, ovary with cyst, fallopian tube, paratubal cyst, or rarely a pedunculated uterine myoma results in ischemia of the structures distal to the twisted pedicle and acute onset of pain. A benign cystic teratoma is the most common neoplasm to undergo torsion. Because of adhesions, ovarian carcinoma and inflammatory masses such as endometriomas or abscesses rarely undergo torsion. It is unusual for a normal tube and ovary to torque, although a

polycystic ovary can undergo torsion. Diagnosis of adnexal torsion is challenging. The clinician must base the diagnosis on history, clinical examination, and additional investigations such as pelvic ultrasound (14). There is no specific size criteria for ovarian torsion, but one study found that 83% of torsion occurred in ovaries that were 5 cm or larger (15). In the pediatric population, the clinician should be aware that torsion can happen with no ovarian lesion or mass.

Symptoms

The pain of torsion is usually severe and constant or, if the torsion is partial and intermittent, the pain can wax and wane. The onset of the torsion and subsequent abdominal pain frequently coincides with activities such as lifting, exercise, or intercourse. Autonomic reflex responses (e.g., nausea, emesis, tachycardia, and apprehension) are usually present.

Signs

Mild temperature elevation, tachycardia, and leukocytosis may accompany the necrosis of tissue. Pregnancy test is negative unless there is a coexistent pregnancy. The diagnosis must be suspected in any woman with acute pain and unilateral adnexal mass.

On examination, the localized direct and rebound tenderness can be noted in the lower quadrant(s). Another important sign is the presence of a large pelvic mass on bimanual examination.

Diagnosis

The process of torsion occludes the lymphatic and venous drainage of the involved adnexa; therefore, the torqued viscus rapidly increases in size and can be easily palpated on examination or visualized by ultrasound. The presence of Doppler blood flow to the ovary on ultrasound does not definitely rule out torsion. CT has been shown to have low overall sensitivity and is not recommended for the workup for suspected ovarian torsion in one meta-analysis (16) However, in another case-control study, CT was not shown to be significantly different from ultrasound in identifying ovarian torsion (17).

The ovarian torsion composite index (OT-CI) is a scoring system that combines clinical and radiologic findings to accurately predict ovarian torsion. Scores greater than or equal to 3 had 100% sensitivity and 65.3% specificity and could be considered for surgical interventions (18).

The diagnosis of ovarian torsion is challenging as clinical symptoms are neither sensitive nor specific and there are no definitive criteria with imaging. Surgical diagnosis (laparoscopy or laparotomy) remains the diagnostic and therapeutic method of choice if there is suspicion of ovarian torsion.

Management

Adnexal torsion must be treated surgically. The adnexa may be untwisted and a cystectomy performed if appropriate. Even when it appears that necrosis occurred, there is evidence that it remains functional and sparing the adnexa can preserve its hormonal and reproductive function. Treatment can be accomplished by laparoscopy or laparotomy, depending on the size of the mass.

Acute Salpingo-Oophoritis and Pelvic Inflammatory Disease

The diagnosis and management of acute salpingo-oophoritis and pelvic inflammatory disease (PID) are discussed in Chapter 15.

Symptoms

[2] All cases of PID are polymicrobial, involving gram-negative and gram-positive aerobic and anaerobic bacteria. PID initiated by *Neisseria gonococcus* or chlamydia is manifested by the acute onset of pelvic pain that increases with movement, fever, purulent vaginal discharge, and sometimes nausea and emesis. Subclinical PID can be seen with chlamydial salpingo-oophoritis, with more insidious symptoms that can be confused with the symptoms of irritable bowel syndrome (IBS) (19).

Signs

Elevated temperature and tachycardia are typical. Abdominal examination may show distention and decreased bowel sounds caused by secondary ileus. Direct and rebound abdominal tenderness with palpation are marked. **The most important signs of acute salpingo-oophoritis are cervical motion tenderness and bilateral adnexal tenderness.** Evaluation of the pelvis may be difficult because of pain and guarding, but lack of a discrete mass or masses differentiates acute salpingo-oophoritis from tubo-ovarian abscess (TOA) or torsion. Right upper quadrant can be a distinct sign of PID-related perihepatitis involving the liver capsule and peritoneal surfaces, called Fitz-Hugh–Curtis syndrome.

Diagnosis

Leukocytosis and elevated erythrocyte sedimentation rate (ESR), a nonspecific, although more sensitive, sign of inflammation, are found in patients with acute PID. Pregnancy test is usually negative because PID as coexistent with intrauterine pregnancy (IUP) is rare. If the pregnancy test is positive, an infected or very inflamed ectopic pregnancy, or instrumented IUP, or infected, incomplete abortion should be suspected. Appendicitis and diverticulitis can be mistaken for PID. Laparoscopy can be useful if the diagnosis is uncertain. The Centers for Disease Control and Prevention (CDC) guidelines for diagnosing PID state that PID should be suspected and treatment started if the patient is at risk for PID and she has uterine, cervical motion, or adnexal tenderness without any apparent cause (20). Findings that support the diagnosis include cervical or vaginal

mucopurulent discharge, elevated ESR or C-reactive protein (CRP), laboratory confirmation of gonorrhea or chlamydia, oral temperature of 38.3°C or higher, or white blood cells (WBCs) on wet mount of vaginal secretions. One study showed that an ESR >19.5 mm per 1/2 h and CRP >11.5 mg/L were predictors of TOA where below these cutoffs were predictors of PID without TOA (21). Most specific criteria for the diagnosis include endometritis on endometrial biopsy, laparoscopic evidence of PID (tubal edema, erythema, and purulent discharge), or thickened, fluid-filled fallopian tubes on pelvic ultrasound or magnetic resonance imaging (MRI).

Tubo-Ovarian Abscess

[2] TOA, a complication of acute salpingo-oophoritis, is usually bilateral but can be unilateral (20). The symptoms and signs are similar to those of acute salpingitis. A ruptured TOA is a life-threatening surgical emergency because gram-negative endotoxic shock can develop rapidly.

Signs

Vital signs reveal fever, tachycardia, and low blood pressure if the patient is septic. TOAs can often be palpated on bimanual examination as firm, exquisitely tender, bilateral fixed masses. The abscesses can be palpated or "pointed" in the pelvic cul-de-sac and are appreciated on rectovaginal examination. Approximately 90% of patients will have abdominal or pelvic pain and 60% to 80% will present with fever and/or leukocytosis.

Diagnosis

The diagnostic imaging of choice for TOAs is ultrasound. CT with and without contrast can be used to establish the diagnosis (22). The differential diagnosis of a unilateral mass includes TOA and adnexal torsion, ectopic pregnancy, endometrioma, leaking ovarian cyst, and periappendiceal or diverticular abscess. If physical and ultrasound examination results are not definitive, laparoscopy or laparotomy must be performed.

Management

TOAs should always be treated as an inpatient, and conservative medical therapy with intravenous broad-spectrum antibiotics can be attempted (see Chapter 15) (23). If the patient is persistently febrile or not improving clinically, CT or ultrasound-guided drainage of the abscesses should be undertaken. CT-guided percutaneous drainage can be achieved transabdominally or transvaginally. Drainage along with intravenous antibiotics is considered first-line therapy (23,24). If fertility is not desired, bilateral salpingo-oophorectomy (BSO) and hysterectomy will provide definitive therapy.

[2] A ruptured TOA rapidly leads to diffuse peritonitis, evidenced by tachycardia

and rebound tenderness in all four quadrants of the abdomen. With endotoxic shock, hypotension and oliguria ensue, and the result can be fatal. Exploratory laparotomy with resection of infected tissue is mandatory (see Chapter 15).

According to the CDC, women should show clinical improvement in regards to pelvic pain and vital signs within 3 days of initiation of therapy. If there is no improvement, additional diagnostics should be performed, such as diagnostic laparoscopy and other imaging for alternative diagnoses. Women who receive a diagnosis of chlamydia or gonorrhea should be retested 3 months after treatment and their partner should also be treated (20).

Uterine Leiomyomas

Leiomyomas (fibroids) are uterine smooth muscle tumors, as discussed in detail in Chapter 11. **Discomfort may be present when myomas are in the broad ligament or encroaching on adjacent bladder, rectum, or supporting ligaments of the uterus**. The discomfort is usually reported as noncyclic pressure or pain symptoms and less often, urinary frequency, dysmenorrhea, dyspareunia, or constipation (25). **There is no association between the degree of pain and fibroid volume or number** (26). A retrospective review of patients who had **[2]** symptomatic fibroids were diagnosed with histology-proven endometriosis (27).

Acute pelvic pain caused by uterine leiomyomas is rare but can develop if the myoma undergoes degeneration or torsion (27). Rare cases of uterine rupture have been documented which require prompt treatment (28). Degeneration of myomas occurs secondary to loss of blood supply, usually attributable to rapid growth associated with pregnancy. **In a nonpregnant woman, degenerating uterine leiomyoma is often a misdiagnosis, because it can be confused with subacute salpingo-oophoritis.** A pedunculated subserosal leiomyoma can undergo torsion with ischemic necrosis and can be associated with pain similar to that of adnexal torsion. When a submucous leiomyoma becomes pedunculated within the endometrial cavity, the uterus contracts forcefully as if to expel a foreign body and the resulting pain is similar to that of labor. The cramping pain is usually associated with vaginal hemorrhage.

Signs

Vital signs are usually normal, although a low-grade temperature and mild tachycardia can be present with degeneration. Abdominal or bimanual examination and ultrasound reveal an irregular solid mass or masses arising from the uterus. If degeneration occurs, the inflammation can cause abdominal tenderness in response to palpation and mild localized rebound tenderness.

Diagnosis and Management

With degeneration there is usually leukocytosis. **Ultrasound can distinguish adnexal**

from uterine etiology of an eccentric mass. If diagnosis is still uncertain, a pelvic MRI is more accurate (29). The fibroid can be excised laparoscopically; however, surgery is not mandatory. A submucosal leiomyoma with pain and hemorrhage should be excised transcervically with hysteroscopic guidance.

Endometriosis-Related Acute Pain

In women with endometriosis, endometrial glands and stroma implant outside the uterine cavity, most commonly at the cul-de-sac, ovaries, or pelvic visceral and parietal peritoneum. Each menstrual cycle potentially results in further proliferation, causing inflammation, scarring, fibrosis, and adhesion formation. Women with endometriosis often experience dysmenorrhea, dyspareunia, and dyschezia, irregular bleeding, or subfertility. Acute pain attributable to endometriosis is usually premenstrual and menstrual; if nonmenstrual acute generalized pain occurs, a ruptured endometrioma (chocolate endometrial cyst within the ovary) should be considered. The management of endometriosis is discussed under dysmenorrhea and CPP (see also Chapter 13).

Diagnosis

The abdomen is often tender in one or both the lower quadrants. Significant distention or rebound tenderness may be present if there is there is a ruptured endometrioma. **Bimanual and rectovaginal examinations can reveal a fixed, retroverted uterus with tender nodules in the uterosacral region or thickening of the cul-de-sac.** An adnexal mass, if present, usually is fixed to the broad ligament and cul-de-sac. **The clinical diagnosis of endometriosis is accurate approximately 50% of the time. Definitive diagnosis is made by laparoscopy or laparotomy.** In the setting of chronic pain symptoms with an acute exacerbation, a leaking endometrioma should be suspected. If there is a characteristic mass on ultrasound, laparoscopy is indicated.

Gastrointestinal Tract Causes of Acute Pelvic Pain

Appendicitis

[2] The most common intestinal source of acute pelvic pain in women is appendicitis. Lifetime incidence in the United States is 7%, and it is the most common cause of emergent abdominal surgery (30). **The symptoms and signs of appendicitis can be similar to those of PID, but the nausea and emesis are often more prominent with appendicitis.**

Symptoms

The first symptom of appendicitis is typically diffuse abdominal pain, periumbilical pain, followed by anorexia, nausea, and vomiting. Within a matter of hours, the pain

generally shifts to the right lower quadrant. Fever, chills, emesis, and obstipation (no flatus or stool per rectum) may ensue. However, this classic symptom pattern is often absent. Atypical abdominal pain can occur when the appendix is retrocecal or entirely within the true pelvis (which occurs in 15% of the population). In this setting, tenesmus and diffuse suprapubic pain may occur.

Signs

A low-grade fever is generally present, but the temperature may be normal. High temperatures are typically seen with appendiceal perforation. **Local tenderness is usually elicited on palpation of the right lower quadrant (McBurney point). The appearance of severe generalized muscle guarding, abdominal rigidity, rebound tenderness, right-sided mass, tenderness on rectal examination, positive psoas sign (pain with forced hip flexion or passive extension of hip), and obturator signs (pain with passive internal rotation of flexed thigh) indicate appendicitis.** The pelvic examination usually does not show cervical motion or bilateral adnexal tenderness, but right-sided unilateral adnexal area tenderness can be present.

Diagnosis

Many patients with acute appendicitis have normal total leukocyte counts but a left shift is usually present. The mean platelet volume has been shown to be helpful in diagnosis; a decrease in MPV was noted with patients with acute appendicitis (31). **Ultrasound examination of the pelvic organs is normal, whereas the appendix may appear abnormal on ultrasound or CT with contrast. CT with oral contrast with normal filling of the appendix rules out appendicitis.** Diagnostic laparoscopy can be useful to rule out other sources of pelvic pathology, but it may be difficult to visualize the appendix sufficiently to rule out early appendiceal inflammation, so appendectomy can be indicated if the diagnosis is uncertain.

Management

Initial management is intravenous administration of fluids, strict restriction of any oral intake, and preoperative antibiotics followed by laparoscopy or laparotomy. **Surgery with a false-positive rate of 15% is considered acceptable and is preferable to prolonged observation with the risk of rupture and peritonitis. A ruptured appendix is life-threatening and can have profound consequences for the fertility of women of reproductive age. With the advent of imaging, negative appendectomy rates are less than 10%** (32).

Acute Diverticulitis

[2] Acute diverticulitis is a condition in which there is inflammation of a diverticulum or outpouching of the wall of the colon, usually involving the sigmoid colon. Diverticulitis typically affects postmenopausal women but can occur in women

during their 30s and 40s.

Symptoms

The severe, left lower quadrant pain of diverticulitis can occur following a long history of symptoms of irritable bowel (bloating, constipation, and diarrhea), although diverticulosis usually is asymptomatic. Diverticulitis is less likely to lead to perforation and peritonitis than is appendicitis. Fever, chills, and constipation typically are present, but anorexia and vomiting are uncommon.

Signs

Bowel sounds are hypoactive and are substantially decreased with peritonitis related to a ruptured diverticular abscess. Abdominal examination reveals distention with left lower quadrant tenderness on direct palpation and localized rebound tenderness. Abdominal and bimanual rectovaginal examinations may reveal a poorly mobile, doughy inflammatory mass in the left lower quadrant. Leukocytosis and fever are common. Stool guaiac may be positive as a result of inflammation of the colon or microperforation. Hemodynamic instability can be seen with perforation.

Diagnosis and Management

CT with and without contrast is an important adjunct to history and physical examination (33). It will reveal a swollen, edematous bowel and can rule out an abscess. A barium enema is contraindicated. Diverticulitis is initially managed medically with intravenous administration of fluids, strict restriction of oral intake, and broad-spectrum intravenous antibiotics. A diverticular abscess, obstruction, fistula, or perforation requires general surgical intervention.

Intestinal Obstruction

The most common causes of intestinal obstruction in women are postsurgical adhesions, hernia, inflammatory bowel disease, or carcinoma of the bowel or ovary.

Symptoms

[2] Intestinal obstruction is heralded by the onset of colicky abdominal pain followed by abdominal distention, vomiting, constipation, and obstipation. Higher and more acute obstruction results in early vomiting. Colonic obstruction presents with a greater degree of abdominal distention and obstipation. Initially vomiting consists of gastric contents, followed by bile, then material with feculent odor, depending on the level of obstruction.

Signs

Fever is often present in the late stages. At the onset of mechanical obstruction, bowel sounds are high pitched and maximal during an episode of colicky pain. As the obstruction progresses, bowel sounds decrease and, when absent, suggest ischemic

bowel. Marked abdominal distention often ensues.

Diagnosis and Management

An upright abdominal x-ray series shows a characteristic gas pattern, distended loops of bowel, and air–fluid levels; and it helps to determine whether obstruction is partial or complete (no colonic gas seen). CT can be useful. WBC count will be elevated in patients with ischemic bowel. **Complete obstruction requires surgical management, whereas partial obstruction often can be managed with intravenous fluids, bowel rest, and selective use of nasogastric suction.** A water-soluble contrast such as Gastrografin has been shown to be therapeutic and shown in studies to improve bowel function, decreased hospital stay, and lower rate of surgery (34). The cause of the obstruction should be determined and treated, if possible. Underlying GI or reproductive tract malignancy may be present.

Urinary Tract Causes of Acute Pelvic Pain

Ureteral colic resulting from ureteral lithiasis is caused by a sudden increase in intraluminal pressure and associated inflammation. Urinary tract infections (UTIs) producing acute pain include cystitis and pyelonephritis. The most common microbes causing UTIs are *Escherichia coli* followed by *Proteus*, *Klebsiella*, and *Pseudomonas* (35).

Symptoms and Signs

[2] The pain of lithiasis is typically severe and crampy; it can radiate from the costovertebral angle (CVA) to the groin. Hematuria is often present. UTI comprises bladder or kidney infection. Cystitis is associated with dull suprapubic pain, urinary frequency, urgency, dysuria, and occasionally hematuria. Pyelonephritis is associated with flank and CVA pain, although lateralizing lower abdominal pain occasionally is present. Urethritis caused by chlamydia or gonorrhea infection can have similar symptoms to those of a UTI. These infections must be ruled out, if relevant.

Diagnosis

The diagnosis of stone can be made by urinalysis revealing red blood cells and demonstration of the stone via abdominal ultrasound, CT urography, or intravenous pyelography (uric acid stones may not be detected by CT). There is pain with firm pressure over the CVA in the case of lithiasis or pyelonephritis. Peritoneal signs are absent. Suprapubic tenderness may accompany cystitis.

The diagnosis of UTI is based on RUA revealing bacteria and leukocytes with or without leukocyte esterase and nitrites, in the absence of significant squamous epithelial cells. Findings can subsequently be confirmed by culture. The diagnostic

thresholds for WBC and vaginal squamous cells vary with each laboratory. An elevated number of squamous cells in the urinary specimen suggests contamination of the urine specimen with vaginal secretions and can result in false-positive urine analysis and culture.

Management

Expectant medical treatment consists of oral hydration or intravenous fluids (if the patient is unable to tolerate oral intake), antibiotics for UTI, and pain control. Surgical management, such as lithotripsy or open surgery, is an option for renal and urethral lithiasis. Nonpregnant women (and pregnant women who are afebrile with a normal WBC count) with pyelonephritis and all women with cystitis can be treated on an outpatient basis. **Nonpregnant women with pyelonephritis can be treated with a 14-day course of a *fluoroquinolone* or *trimethoprim/sulfamethoxazole*** (some sources recommend one intravenous dose of a third-generation cephalosporin before discharging patients with oral antibiotics) (see Chapter 15) (36). Caution should be used with *trimethoprim/sulfamethoxazole* given the rising resistance patterns**. It is important to follow up urine culture sensitivities and treat accordingly.** If there is no improvement, raising concerns for patient compliance, inability to tolerate oral medications and fluids, or whether the patient may be immunocompromised as related to AIDS, intravenous drug use/abuse, diabetes, pregnancy, or chronic steroid use, then the patient should be hospitalized and given intravenous antibiotics.

Tuberculosis should be excluded as a cause of pyelonephritis if the characteristic sterile pyuria is present and the patient's condition does not improve with antibiotics.

Acute Pelvic Pain: Summary

[1] All women of reproductive age with acute pelvic pain should have a CBC with differential, ESR, urinalysis, and a sensitive qualitative urine or serum pregnancy test. If not diagnosed expeditiously, an acute process can often result in significant morbidity or mortality. For patients who have CPP and develop acute exacerbation, it is important to rule out a superimposed acute process. Symptoms of fever, chills, diaphoresis, abnormal vaginal bleeding, dizziness, syncope, emesis, significant diarrhea, obstipation, dysuria, hematuria, hematochezia, and signs of elevated temperature, tachycardia, orthostasis, abdominal distention, abnormal bowel sounds, ascites, peritonitis, or abnormal pregnancy are all indicative of an acute process.

[1] Laboratory tests for the evaluation of acute pelvic pain include a CBC with differential, ESR, clean catch midstream RUA, gonorrhea and chlamydia nucleic acid amplification testing (NAAT) from cervix or urine, and urine or serum pregnancy test. The sedimentation rate is nonspecific, but often is the only abnormal laboratory finding in women with subacute PID. **[1]** If the pregnancy test is positive, a quantitative β-

human chorionic gonadotropin (βhCG) should be ordered. Other studies that are recommended include transvaginal pelvic ultrasound. CT with and without contrast, abdominal x-rays, or upper or lower Gastrografin studies help rule out gastrointestinal pathology when gastrointestinal symptoms predominate. CT is useful for evaluation of retroperitoneal masses or abscesses related to the gastrointestinal tract. Pelvic MRI can be diagnostic if the pelvic ultrasound cannot determine whether a mass is uterine or adnexal.

[1] Diagnostic laparoscopy is reserved for establishing the diagnosis in patients who have acute abdomen of uncertain cause, for elucidating the nature of an ambiguous adnexal mass, or for delineating whether a pregnancy is intrauterine or extrauterine (if ultrasound results and βhCG are equivocal). Visualization is hampered if diagnostic laparoscopy is performed for a large pelvic mass (>12 cm) and is relatively contraindicated in patients with peritonitis, severe ileus, or bowel obstruction. In these settings, laparotomy is preferable. The majority of patients with pelvic pain and a normal pelvic ultrasound have improvement or resolution of symptoms with conservative therapy and do not require surgical intervention (37).

CYCLIC PAIN: PRIMARY AND SECONDARY DYSMENORRHEA

[3] **Dysmenorrhea is a common gynecologic disorder affecting as many as 60% of menstruating women (38). Primary dysmenorrhea refers to menstrual pain without pelvic pathology, whereas secondary dysmenorrhea is defined as painful menses associated with underlying pathology.** Primary dysmenorrhea usually appears within 1 to 2 years of menarche, when ovulatory cycles are established. The disorder affects younger women but may persist into their 40s. Secondary dysmenorrhea usually develops years after menarche and can occur with anovulatory cycles. The differential diagnosis of secondary dysmenorrhea is outlined in Table 12-3.

Primary Dysmenorrhea

[3] **The etiology of primary dysmenorrhea includes excessive or imbalanced amount of prostanoids secreted from the endometrium during menstruation. The prostanoids result in increased uterine contractions with a dysrhythmic pattern, increased basal tone, and increased active pressure. Uterine hypercontractility, decreased uterine blood flow, and increased peripheral nerve hypersensitivity contribute to pain** (39). Prostaglandin compounds are found in higher concentrations in secretory endometrium than in proliferative endometrium. The decline of progesterone levels in the late luteal phase triggers lytic enzymatic action, resulting in a release of phospholipids with the generation of arachidonic acid and activation of the cyclooxygenase (COX) pathway. The biosynthesis and metabolism of prostaglandins

and thromboxane derived from arachidonic acid are depicted in Figure 12-1. Increased synthesis of prostanoids in women with primary dysmenorrhea results in higher uterine tone with high-amplitude contractions causing dysmenorrhea (40). It is theorized that women suffering from dysmenorrhea have upregulated COX enzyme activity and prostanoid synthase activity. This led to the use of nonsteroidal anti-inflammatory drugs (NSAIDs), which act as COX enzyme inhibitors, for therapy (41).

Symptoms

The pain of primary dysmenorrhea usually begins a few hours before or just after the onset of a menstrual period and may last 48 to 72 hours. The pain is similar to labor, with suprapubic cramping, and may be accompanied by lumbosacral backache, pain radiating down the anterior thigh, nausea, vomiting, diarrhea, and rarely syncopal episodes. The pain of dysmenorrhea is colicky in nature and, unlike abdominal pain that is caused by chemical or infectious peritonitis, is relieved by abdominal massage, counterpressure, or movement of the body.

Table 12-3 Differential Diagnosis of Chronic Pelvic Pain

Gynecologic	Genitourinary
Noncyclic	Recurrent or relapsing cystourethritis
Adhesions	Urethral syndrome
Endometriosis	Interstitial cystitis/painful bladder syndrome
Salpingo-oophoritis	Ureteral diverticuli or polyps
Ovarian remnant or retained ovary syndrome	Carcinoma of the bladder
Pelvic congestion	Ureteral obstruction
Ovarian neoplasm benign or malignant	**Neurologic**
Pelvic relaxation	Nerve entrapment syndrome, neuroma, or other neuropathies
Cyclic	Trigger points
Primary dysmenorrhea	**Musculoskeletal**
Mittelschmerz	Myofascial pain and trigger points

Secondary dysmenorrhea	**Low-back pain syndrome**
Endometriosis/adenomyosis	Congenital anomalies
Uterine or vaginal anomalies with obstruction of menstrual outflow	Scoliosis and kyphosis
Intrauterine synechiae (Asherman syndrome)	Spondylolysis
Endometrial polyps or nonhormonal intrauterine device (IUD)	Spondylolisthesis
Uterine leiomyomata	Spinal injuries
Pelvic congestion syndrome	Inflammation
Gastrointestinal	Tumors
Irritable bowel syndrome	Osteoporosis
Ulcerative colitis	Degenerative changes
Crohn disease	Coccydynia
Carcinoma	Myofascial syndrome
Infection	**Systemic**
Recurrent partial bowel obstruction	Fibromyalgia
Diverticulitis	Acute intermittent porphyria
Hernia	Abdominal migraine
Abdominal angina	Connective tissue disease including systemic lupus erythematosus
	Lymphoma
	Neurofibromatosis

Signs

On examination, the vital signs are normal. The suprapubic region may be tender to palpation. Bowel sounds are normal, and there is no upper abdominal tenderness and no abdominal rebound tenderness. **Bimanual examination at the time of the dysmenorrheic episode often reveals uterine tenderness; severe pain does not occur with movement of the cervix or palpation of the adnexal structures.** The pelvic organs are normal in primary dysmenorrhea.

Diagnosis

[3] To diagnose primary dysmenorrhea, it is necessary to clinically rule out

underlying pelvic pathology and confirm the cyclic nature of the pain. History taking is important to rule out abnormal uterine bleeding, presence of dyspareunia, or nonmidline focal pelvic pain that can point to other causes of pain. During the pelvic examination, the size, shape, and mobility of the uterus; the size and tenderness of adnexal structures; and the nodularity or fibrosis of uterosacral ligaments or rectovaginal septum should be assessed. NAAT for gonorrhea and chlamydia and if relevant, CBC and ESR, help rule out endometritis and subacute PID. Pelvic ultrasound should be performed if symptoms do not resolve with NSAIDs. If no abnormalities are found, a tentative diagnosis of primary dysmenorrhea can be established. Laparoscopy is not necessary at this point.

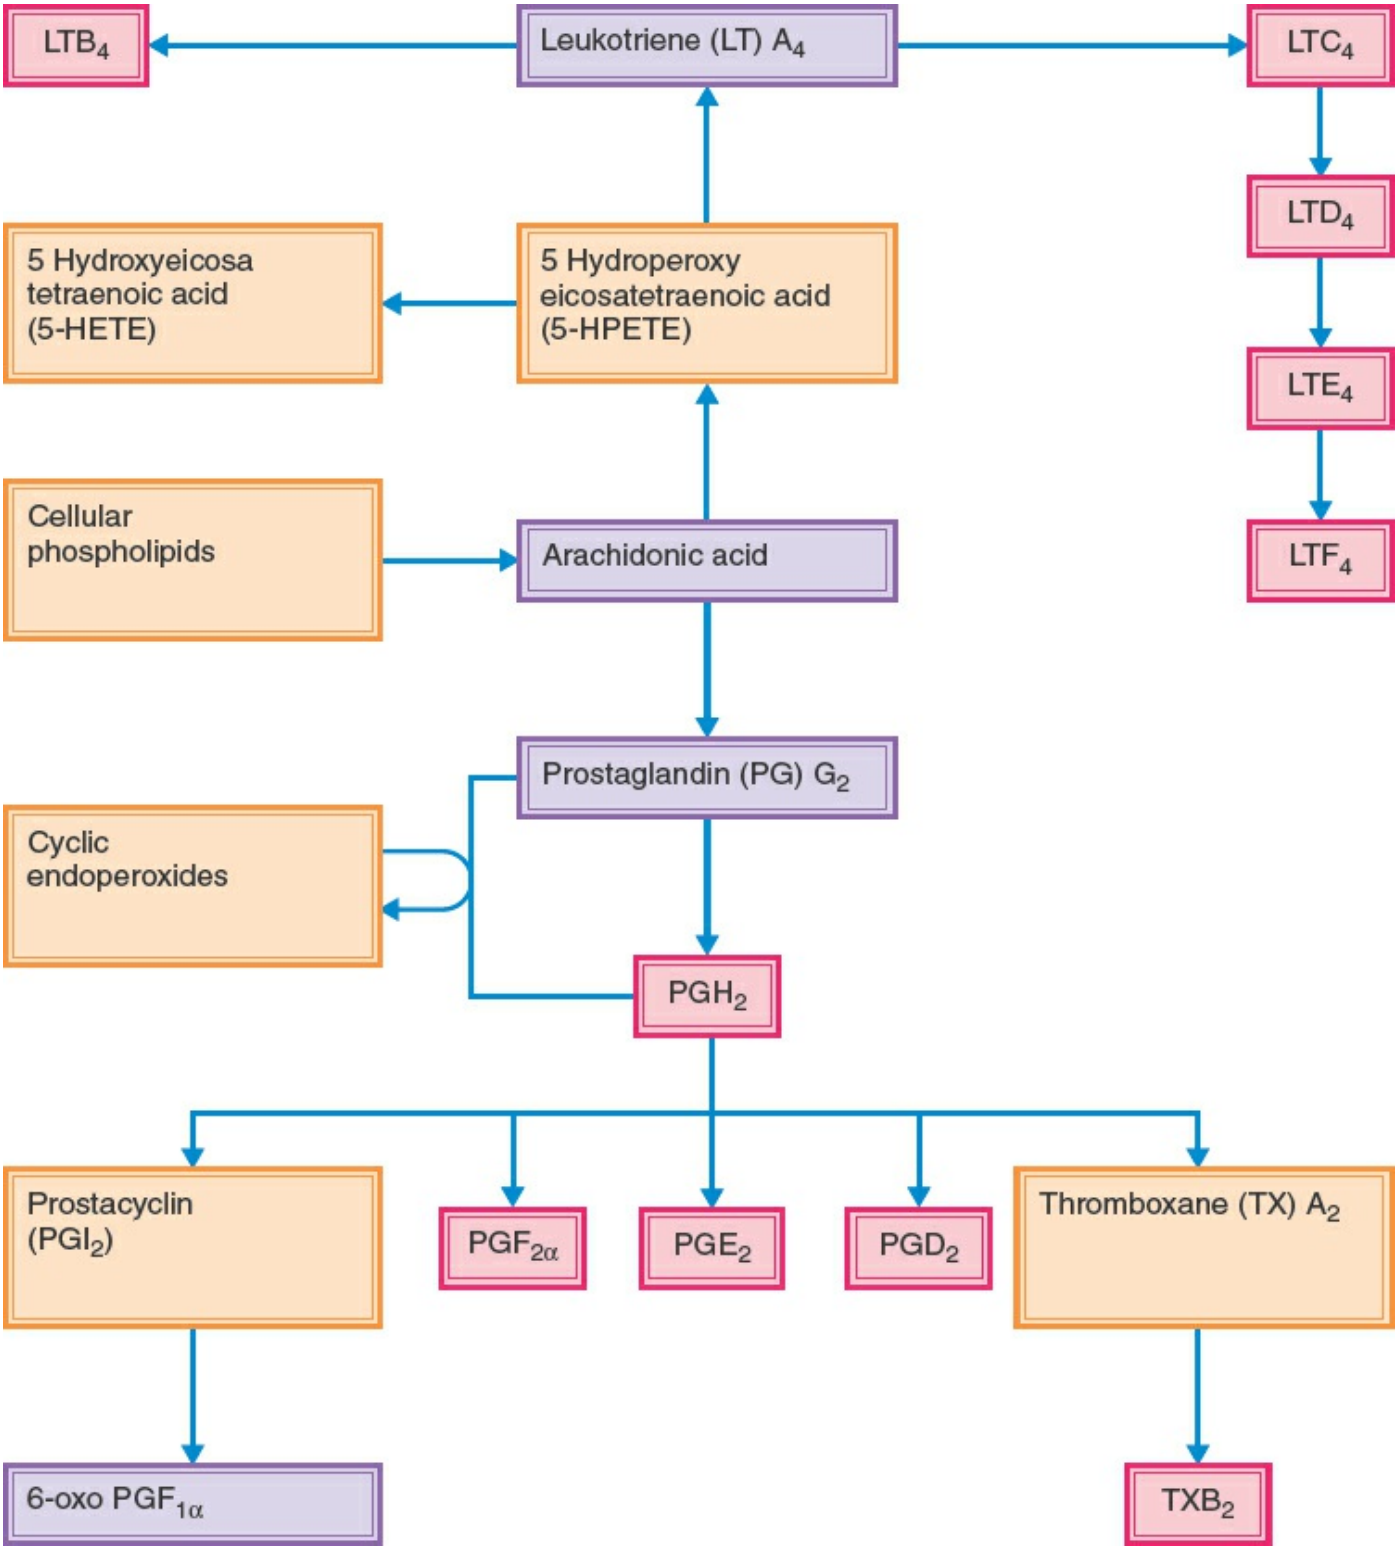

FIGURE 12-1 The biosynthesis and metabolism of prostaglandins and thromboxane derived from arachidonic acid. (From **Chaudhuri G.** Physiologic aspects of prostaglandins and leukotrienes. *Semin Reprod Endocrinol* 1985;3:219, with permission.)

Management

[3] Prostaglandin synthase inhibitors, also called NSAIDs, are effective for the

treatment of primary dysmenorrhea (42). **The inhibitors should be taken up to 1 to 3 days before or, if menses are irregular, at the first onset of minimal pain or bleeding and continuously every 6 to 8 hours to prevent reformation of prostaglandin byproducts.** The medication should be taken for the first few days of menstrual flow. A 4- to 6-month course of therapy is warranted to determine whether the patient will respond to treatment. Changes in dosages and types of NSAIDs should be attempted if initial treatment is not successful. The medication may be contraindicated in patients with gastrointestinal ulcers or bronchospastic hypersensitivity to aspirin. Side effects are usually mild and include nausea, dyspepsia, diarrhea, and occasionally fatigue.

Hormonal contraceptives have been shown to be equally effective to NSAIDs. They are indicated for patients with primary dysmenorrhea who have no contraindications to hormonal contraceptives and who desire contraception. Hormonal contraceptive agents (such as combined estrogen and progestin) or progesterone-only oral contraceptives (OCs) (either cyclic or continuous regimens), transdermal patch, vaginal ring, injectable progestin preparations, or levonorgestrel-releasing intrauterine devices are more effective than placebo alone and result in less absence from work or school (43). Continuous or extended cycle combined OC pills are just as efficacious for this pain syndrome (44). Hormonal contraceptives inhibit ovulation, decrease endometrial proliferation, and create an endocrine milieu similar to the early proliferative phase of the menstrual cycle, when prostaglandin levels are lowest. Decreased prostaglandin levels result in less uterine cramping.

Treatment with both NSAIDs and hormonal contraception may be more effective than either one alone. If the patient does not respond to this regimen for 2 to 3 months, hydrocodone or codeine may be added for 2 to 3 days per month; before addition of the narcotic medication, psychological factors should be evaluated, and diagnostic laparoscopy to rule out pathology should be considered.

Nonpharmacologic pain management, in particular heat, acupuncture, or transcutaneous electrical nerve stimulation (TENS), may be useful (45–47). Acupuncture is thought to excite receptors or nerve fibers, blocking pain impulses through interactions with mediators like serotonin and endorphins. The perception of pain signals is altered with TENS. It does not directly affect uterine contractions. Abdominal electrical or chemical heating pads are effective in treating primary dysmenorrhea. There is insufficient data to support any herbal or vitamin regimen.

Methods rarely used to treat primary dysmenorrhea include surgical laparoscopic uterine nerve ablation and presacral neurectomy and hysterectomy (48).

Secondary Dysmenorrhea

[3] Secondary dysmenorrhea is cyclic menstrual pain that occurs in association with underlying pelvic pathology. The pain of secondary dysmenorrhea often begins 1 to 2 weeks before menstrual flow and persists until a few days after the cessation of bleeding. [3] Underlying causes include endometriosis, adenomyosis, subacute endometritis and PID, copper intrauterine devices (IUDs), ovarian cysts, congenital pelvic malformations, and cervical stenosis. Whereas the diagnosis of primary dysmenorrhea is based on the history and presence of a normal pelvic examination and ultrasound, the diagnosis of secondary dysmenorrhea may require review of a pain diary to confirm cyclicity, and transvaginal ultrasound examination, laparoscopy, and hysteroscopy may be indicated.

[3] The most common cause of secondary dysmenorrhea is endometriosis, followed by adenomyosis and nonhormonal intrauterine devices. NSAIDs and hormonal contraceptives are less likely to provide pain relief in women with secondary dysmenorrhea than in those with primary dysmenorrhea. The differential diagnosis of secondary dysmenorrhea is outlined in Table 12-3. The management of secondary dysmenorrhea is treatment of the underlying disorder.

Endometriosis

[3] In women with endometriosis, endometrial glands and stroma are found outside the uterine cavity, especially at the cul-de-sac, ovaries, and pelvic visceral and parietal peritoneum. They can occur outside the pelvis such as the bowel, diaphragm, and even the pleural cavity. There are several theories of pathogenesis, but none explains all the different types of endometriosis. Given that confirmation requires visual diagnosis, the prevalence of endometriosis is unknown. It is thought to occur in approximately 10% of the general female population, 15% to 20% of infertile women, and more than 30% of women with CPP. In some cases, regression can occur spontaneously (see the section on endometriosis under the heading of chronic pelvic pain and Chapter 13) (49).

Symptoms

Patients typically complain of severe dysmenorrhea and cyclic pelvic pain that starts up to 2 weeks prior to menses. Symptoms depend on the site of endometriosis. The pain can be sharp or pressure-like, localized to the midline or involving the lower abdomen, back, and rectum. Other symptoms include deep thrust dyspareunia, subfertility, irregular bleeding despite ovulatory cycles, and nongynecologic symptoms such as cyclic dyschezia, urinary urgency, frequency, bloating, and rarely hematochezia or hematuria. Patients with thoracic endometriosis can have symptoms of chest pain, pneumothorax, and hemothorax that coincides with menses (50).

Signs

Bimanual and rectovaginal examinations may reveal uterosacral nodularity and focal tenderness. Fibrosis resulting from endometriosis can cause a fixed retroverted uterus or laterally deviated cervix or uterus. Bimanual examination can demonstrate a fullness consistent with ovarian cystic endometrioma. Patients can have focal uterosacral or broad ligament area tenderness. Abdominal wall endometriosis implants can present with a cyclically painful discrete abdominal mass on examination.

Diagnosis

Diagnosis of endometriosis is categorized by nonsurgical or surgical diagnosis. The clinical, or nonsurgical, diagnosis of endometriosis is accurate in approximately 50% of cases. Though a definitive diagnosis of endometriosis cannot be made on imaging studies, endometriomas are generally distinguishable from hemorrhagic corpus lutea by the appearance on ultrasound. Homogeneous hemorrhagic-appearing cysts that fail to resolve after one to two menstrual cycles are suspicious for endometriomas. CA125 can be elevated but is a nonspecific and nonsensitive marker for endometriosis. **Definitive or surgical diagnosis is made by direct operative visualization either laparoscopically or via laparotomy with histologic confirmation.** Active red flame, or colorless vesicles, or petechial lesions usually indicate early disease, while powder-burn, fibrotic lesions suggest more longstanding lesions. Suspicious findings should be biopsied for confirmation. Deep infiltrating lesions and peritoneal windows are most often found within the posterior cul-de-sac, especially at the uterosacral ligaments, and may cause pain by penetrating the many nerve endings in this area (51). Patients with endometriosis have nerve fibers in their endometrial tissue, and studies show endometrial biopsy is a potential, but as yet unproven, diagnostic tool. A double-blind study of 99 women undergoing laparoscopy and endometrial biopsy for evaluation of endometrial nerve fibers found that the biopsy was just as effective as laparoscopy for diagnosing endometriosis (52).

Management of Secondary Dysmenorrhea Caused by Endometriosis: Pharmacologic

Medications can be used to reduce the cyclic hormonal stimulation of these lesions and eventually decidualize or atrophy the lesions. Surgical resection of endometriosis has surgical risks but can reduce pain by removing implants. One study showed short-term improvement in dyspareunia and quality of sex life in patients up to 12 months after radical resection of endometriosis (53). Given the excellent response rate, relatively low cost, and fair tolerability with medical hormonal therapy, an expert consensus panel recommended that women with suspected endometriosis who are not actively trying to conceive and who do not have an adnexal mass start with first-line medical management before laparoscopy. **First-line treatment consists of a trial of combined estrogen–progestin formulations with or without NSAIDs** (54). Both cyclic and continuous combined OCs can be used with equal efficacy (55). Most studies

used OCs containing low-dose estrogen and more androgenic progestins; newer-generation progestins are also effective. Continuous rather than cyclic OC regimens can be tried, without a hormonal break or with menstruation every 3 months. Two reviews have shown that continuous OCs may be more effective at reducing pain symptoms than cyclic regiments in maintaining symptoms after initial surgery (56,57).

Second-line medical therapy involves high-dose progestins or gonadotropin-releasing hormone (GnRH) analogs. This can be initiated for refractory symptoms or for patients with contraindication to estrogen. Progestins alone are associated with few metabolic concerns and are safe and inexpensive alternatives to surgical intervention. Progestins or progestins plus estrogen effectively manage pain symptoms in approximately three-quarters of the women with endometriosis (58). High-dose *medroxyprogesterone acetate* and *norethindrone acetate* are equally effective to the GnRH analogs (59). **Progestins should be given at a dose to achieve amenorrhea, then the dose can be tapered to control symptoms.**

A randomized controlled trial comparing *levonorgestrel* intrauterine system (LNG-IUS) with depot GnRH for the treatment of endometriosis-related chronic pain found that both were effective treatments (60). Etonogestrel implants are shown to be as effective as medroxyprogesterone acetate (61).

GnRH agonist and add-back treatment can be used as pharmacologic treatments for endometriosis (62). A randomized controlled trial of GnRH agonist therapy for 6 months in cases of confirmed endometriosis showed decreased size of endometriotic lesions and pain symptoms. Side effects are related to the hypoestrogenic state and include vasomotor symptoms, mood swings, vaginal dryness, decreased libido, myalgias, and, eventually, bone loss. These side effects can be reduced with supplemental calcium and hormonal add-back therapy with *norethindrone acetate* 2.5 to 5 mg daily with or without low-dose estrogen (0.625 mg of conjugated estrogen or 1 mg of 17 β-estradiol) (62). Given the side effects, GnRH agonists usually are not used for more than 8 to 12 months, but with add-back hormones and/or bisphosphonate, GnRH therapy can be considered for use for more than 1 year. Recurrence of symptoms after discontinuation of GnRH agonist ranges from 36% to 70%, 5 years after completion of treatment.

Androgenic hormones such as danazol are thought to inhibit the luteinizing hormone surge and steroidogenesis and may have anti-inflammatory effects. These medications increase free testosterone, resulting in possible side effects such as deepening of voice, weight gain, acne, and hirsutism. Vaginal *danazol* in lower doses may be effective.

Aromatase p-450 and prostaglandin E2 (PgE_2) pathways are thought, to be involved in the genesis of endometriotic implants. Aromatase plays an important role in estrogen biosynthesis by catalyzing the conversion of androstenedione and testosterone to estrone

and estradiol. Although aromatase activity is not detectable in normal endometrium, it is found in eutopic endometrium and endometriotic lesions. **Thus, aromatase inhibitors (AIs) are being used as adjunctive therapy with medical therapies in refractory cases** (63). A 2008 review of eight studies evaluated AIs for management of endometriosis and found that AIs combined with progestins or OCs or GnRH analogs decreased mean pain scores and lesion size and improved the quality of life. In the only randomized controlled trial (97 women) evaluated in this meta-analysis, AI (*anastrozole*) in combination with GnRH agonist significantly improved pain ($p < 0.0001$) compared with GnRH agonist alone at 6-month follow-up, and there was no significant reduction in the spine or hip bone density (64).

Management of Endometriosis: Surgical

Laparoscopy and laparotomy are appropriate for some patients, and can be considered for treatment in the management of secondary dysmenorrheal pain related to endometriosis that is unresponsive to hormonal agents (see also Chapter 13). Excellent operative skill is required to manage endometriosis surgically. Endometriotic lesions should be ablated or resected. Endometriomas must be removed with their capsule. Resection of endometriomas by ovarian cystectomy improves pain and fertility in women with CPP and endometriosis when compared to fenestration, drainage, and coagulation. In a randomized controlled trial of laser ablation for minimal to moderate endometriosis, over 90% of women felt improved at 1-year follow-up, and 87% of women with stage III to IV endometriosis were satisfied with the results at 1-year follow-up. Recurrent pain after 24 months is close to 50% (65). A meta-analysis found that there was no difference in pain levels when comparing patients with surgical and medical management of endometriosis (66). Given these findings, the risks and benefits of surgical management should be thoroughly discussed with patients when coming up with a treatment plan.

In women who no longer desire fertility with severe secondary dysmenorrhea, hysterectomy with BSO and removal of endometriosis lesions is the preferred treatment. Hysterectomy without BSO results in a higher rate of disease recurrence and a 30% reoperation rate. The risk of recurrent endometriosis with hormone replacement is small if combined estrogen–progestin preparations are used and unopposed estrogen is avoided.

There are limited data regarding outcomes for repeated conservative surgical procedures, including pelvic denervation procedures (65). Although reoperation is often considered the best option, the long-term outcome appears suboptimal with a cumulative probability of recurrent pain between 20% and 40%, and of further surgical procedure at least 20%. Hysterectomy with BSO decreased the need for reoperation to treat pelvic pain by sixfold. Postoperative medical treatment with OCs can be effective (67). Reoperation in a symptomatic patient after previous conservative surgery should take

into account the psychological state of the patient, desire for future fertility, and whether the pain responded to prior surgical therapy with at least 1, but preferably 3 to 5 years of pain relief.

Rectovaginal endometriosis is often deeply infiltrating, highly innervated, and associated with severe cyclic pelvic pain and dyspareunia (see also Chapter 13). These lesions can be surgically challenging for laparoscopic resection. Hormonal therapy can be effective. One study reviewed hormonal therapy in 217 patients: 68 in 5 observational studies, 59 in a cohort study, and 90 in a randomized controlled trial (68). The study compared AI, vaginal *danazol*, GnRH agonist, intrauterine progestin, and two estrogen–progestin combinations, transvaginally or transdermally, and an oral progestin. With the exception of an AI used alone, the pain relief with medical therapies was satisfactory over the 6- to 12-month course of the treatment, with 60% to 90% of women reporting substantial decrease or complete relief from pain symptoms.

Adenomyosis

[3] Adenomyosis is defined as the presence of endometrial stroma and glands within the myometrium, at least one low-power field from the basis of the endometrium, whereas endometriosis is characterized by ectopic endometrium appearing within the peritoneal cavity. Adenomyosis, endometriosis, and uterine leiomyomas frequently coexist. Although occasionally noted in women in their younger reproductive years, the average age of symptomatic women is usually older than 40 years. Increasing parity, early menarche, and shorter menstrual cycles may all be risk factors according to one study (69–71).

Symptoms

Symptoms typically associated with adenomyosis include excessively heavy or prolonged menstrual bleeding, dyspareunia, and dysmenorrhea. Symptoms often begin up to 2 weeks before the onset of a menstrual flow and may not resolve until after the cessation of menses. Patients may present with CPP.

Signs

The uterus is typically diffusely enlarged, although usually less than 14 cm in size, and is often soft and tender, particularly at the time of menses. Mobility of the uterus is not restricted, and there is no associated adnexal pathology (72).

Diagnosis

Adenomyosis is a clinical diagnosis. Definitive diagnosis can only be made histologically. Imaging studies including pelvic ultrasound or MRI, although helpful, are not definitive. Because of the cost of MRI and negligible improvement in diagnostic accuracy, this study is not recommended routinely. Transvaginal ultrasound has been shown to have an accuracy rate of 68% to 86% in diagnosing adenomyosis. The

accuracy decreases in women who have coexisting fibroids or who have focal adenomyosis (73). In women with diffuse uterine enlargement and negative pregnancy test results, secondary dysmenorrhea may be attributed to adenomyosis; **however, the pathologic confirmation of suspected adenomyosis can be made only at the time of hysterectomy.**

Management

The management of adenomyosis depends on the patient's age and desire for future fertility. **Relief of secondary dysmenorrhea caused by adenomyosis can be ensured after hysterectomy, but less invasive approaches can be tried initially. NSAIDs, hormonal contraceptives, and menstrual suppression using oral, intrauterine, or injected progestins or GnRH agonists are all useful.** Treatment follows the same protocol as treatment for endometriosis. Uterine artery embolization can be effective (74).

CHRONIC PELVIC PAIN

[3] CPP is defined as pelvic pain that persists in the same location for greater than 6 months' duration, causing functional disability or requiring treatment. CPP is an inclusive, general term that encompasses many more specific causes, ranging from reproductive, gastrointestinal, and urinary tract etiologies to myofascial pain and nerve entrapment syndromes. CPP affects 12% to 20% of women in the United States. The differential diagnosis of CPP is outlined in Table 12-3. **[3] Nongynecologic causes of pain, such as IBS, interstitial cystitis (IC)/bladder pain syndrome (BPS), abdominal wall or pelvic floor myofascial syndrome, or neuropathy, are frequently overlooked but common causes of CPP.** This can in part explain why 60% to 80% of patients undergoing laparoscopy for CPP have no intraperitoneal pathology (2).

Patients with CPP are often anxious and depressed. Their marital, sexual, social, and occupational lives are disrupted. While some patients with CPP present with psychiatric comorbidities, some women develop secondary symptoms as a result of CPP. These patients frequently have poor treatment outcomes from traditionally effective gynecologic and medical therapy and may undergo multiple unsuccessful surgical procedures for pain. About 12% to 19% of hysterectomies are performed for pelvic pain, and 30% of patients who present to pain clinics have had a hysterectomy (75).

CPP states are characterized by upregulation of CNS responsiveness to peripheral stimuli. **[3] The relationship between the pain and pathology, such as endometriosis, adhesions, or venous congestion, is inconsistent and treatment is associated with pain recurrence. Recent investigations suggest that "plasticity" of the nervous system or alterations in signal processing may be involved in the maintenance of**

chronic pain states (2,6). Maladaptive changes within the peripheral and CNS predispose to allodynia (pain with usually nonpainful stimuli), hyperalgesia (excessive pain with a potentially painful stimulus), widening of the receptive field (pain experienced over a larger territory), and abnormal reflex responses in surrounding musculature (5–7,76).

The spinal cord is not a simple conduit between the periphery and the brain. It is an important site of "gating" mechanisms, such as excitation, inhibition, convergence, and summation of neural stimuli (77). With visceral tissue injury, a subset of nociceptive C-fibers that are usually dormant, called "silent" afferents, can become activated. The dorsal horn of the spinal cord is then flooded with noxious chemical stimuli that, over time, can lead to upregulation of the signaling in the dorsal horn and brain, and pain sensation can be persistent and amplified, even after the peripheral pathology has resolved. The dorsal horn neurons demonstrate a number of electrophysiologic changes in this setting, such as the development of spontaneous activity, enlarged receptive fields, and lowered threshold for firing.

[3] In chronic pain states, the pain is no longer adaptive. The initial painful input produces a persistent abnormal state of increased responsiveness called central sensitization (8). It is not known why in some individuals or in certain settings, prolonged stimuli or injury will result in sensitization. Different regions of the CNS are important in modulating the sensory and affective components of the pain response. Pain persistence is fostered by adverse or traumatic early experience, conditioning, fear, arousal, depression, and anxiety.

Evaluation of Chronic Pelvic Pain

[4] On the first visit, a thorough pain history should be performed, taking into consideration the nature of each pain symptom: location, radiation, severity, aggravating and alleviating factors; effect of menstrual cycle, stress, work, exercise, intercourse, and orgasm; the context in which pain arose; and the social and occupational toll of the pain (Table 12-4). A visual or verbal analog pain scale to record pain severity 0 through 10 and stating "no pain" and "worst possible pain" is important in assessing the severity of pain and comparing the changes in severity over subsequent visits. **[4]** The evaluation should include a comprehensive questionnaire that addresses depression, anxiety, emotional, physical and sexual trauma, quality of life, and criteria to assist with the diagnosis of IBS and IC/BPS. The International Pelvic Pain Society published a comprehensive pain assessment tool in order to facilitate the history and physical examination, which can be found on the International Pelvic Pain Society's Web site and reprinted or reproduced (78).

Diagrams of a woman's abdomen, back, and genital area should be used to help the patient define the location of pain (2). The patient should be questioned about symptoms

specific to the types of pathology listed in Table 12-3.

1. [4] **Genital (abnormal vaginal bleeding, abnormal vaginal discharge, dysmenorrhea, dyspareunia, sub-fertility, sexual functioning)**
2. **Enterocoelic (constipation, diarrhea, flatulence, hematochezia, and relationship of pain to times of altered bowel function or form and pain relief with bowel movements)**
3. **Musculoskeletal/neuropathic (physical trauma—surgical or injury, exacerbation with exercise or postural changes, weakness, numbness, lancinating pain)**
4. **Urologic (urgency, frequency, nocturia, hesitancy, dysuria, hematuria, incontinence)**
5. **Psychological (previous diagnoses, hospitalizations, and medications, current depression, anxiety, panic, including suicidal ideation, past and current emotional, physical, or sexual trauma)**

Record a thorough gynecologic, medical, and surgical history; medication, ethanol, or recreational drug intake; prior evaluations for pain with outcome; and review prior operative and pathology reports. Prior physical, emotional, and sexual trauma or abuse should be ascertained (79–81). The attitude of the patient and her family toward the pain, resultant behavior of the patient and her family, and current upheavals in the patient's life should be discussed. The part of the history relating to sensitive issues may have to be revisited after establishing rapport with the patient.

Table 12-4 Pain History Mneumonic

OLD CAARTS	Pain History
Onset	When and how did pain start? Did it change over time?
Location	Localize specifically. Can you put a finger on it?
Duration	How long does it last?
Characteristic	Cramping, aching, stabbing, burning. "like lightening," tingling, itching
Alleviating/Aggravating factors	What makes it better (medication, stress reduction, heat/ice, position change) or worse (specific activity, stress, menstrual cycle)?
Associated symptoms	Gynecologic (dyspareunia, dysmenorrhea, abnormal bleeding, discharge, infertility), GI (constipation, diarrhea, bloating, gas, rectal bleeding), GU (frequency, dysuria, urgency, incontinence), neurologic (specific nerve distribution)
Radiation	Does it move to other areas (dermatomal)?

Temporal	What time of day (elation to menstrual cycle and activities of daily living)?
Severity	Scale of 0–10

GI, gastrointestinal; GU, genitourinary.
From Rapkin AJ, Howe CN. Chronic pelvic pain: A review. Part 2. In: *Family Practice Recertification*. Monroe Township, New Jersey: Medical World Communications, 2006;28:59–67.

Whatever the original cause of the pain, when pain has persisted for any length of time, it is likely that other psychosocial factors are now contributing to the maintenance of the pain. Pain is commonly accompanied by anxiety and depression, and these conditions need to be carefully assessed and treated (2,82,83). In a typical gynecologic setting, referral to a psychologist or psychiatrist for parallel evaluation can evoke resistance. The inference is drawn that the referring physician is ascribing the pain to psychological causes. The patient needs to understand the reason for this referral and to be reassured that it is a routine and necessary part of the evaluation. **A psychologist is one of the key personnel in a multidisciplinary pain clinic.**

[4] A complete physical examination should be performed, with particular attention directed to the abdominal and lumbosacral areas, vulva, pelvic floor, and internal organs via vaginal, bimanual, and rectovaginal examination. The examination should include the *Carnett test,* which is an evaluation of the painful sites on the abdominal wall before and after tensing of the abdominal muscles (head raised off the table or with bilateral straight leg raise) to differentiate abdominal wall and visceral sources of pain. Abdominal wall pain is augmented and visceral pain is diminished with palpating the tender points during these maneuvers (84). While standing, the patient should be examined for hernias, both abdominal (inguinal and femoral) and pelvic (cystocele and enterocele). An attempt should be made to locate by palpation the tissues that reproduce the patient's pain. If abdominal wall sources of pain are noted, it is useful to block these areas with injection of local anesthetics and then perform the pelvic examination (84). Neuropathic symptoms (sharp or lancinating or electrical pain, burning, or tingling sensations) should be localized to the peripheral nerve subserving the involved area.

Reproductive Tract

The most common findings noted at the time of laparoscopy for CPP are endometriosis and adhesions. Patients with other gynecologic pathologies, such as benign or malignant ovarian cysts, uterine leiomyomas of a size sufficient to encroach on supporting ligaments or other somatic structures, or significant pelvic relaxation should be evaluated and treated in a manner that is appropriate for the underlying condition. Pain associated with these latter conditions is generally not severe, and appropriate surgical management is therapeutic.

Endometriosis

See the section on secondary dysmenorrhea above and for a more thorough discussion of the diagnosis and management of endometriosis refer to Chapter 13.

[4] Endometriosis can be demonstrated in 15% to 40% of patients undergoing laparoscopy for CPP. Endometriosis is a surgical diagnosis based on identification and histology of characteristic lesions (85). Endometriosis produces a low-grade inflammatory reaction; over time this results in adhesions between confluent pelvic organs (86). However, the cause of the pain is not well established. **[4] There is no correlation between the location of disease and pain symptoms.** (87,88). **There appears to be no relationship between the incidence and severity of pain or the stage of the endometriotic lesions, and as many as 30% to 50% of patients have no pain regardless of stage. Similarly, 40% to 60% of patients have no tenderness on examination regardless of stage** (88). Deeply infiltrating endometriosis lesions that involve the rectovaginal septum and the bowel, ureters, and bladder are strongly associated with pain (86,89,90) Pelvic adhesions related to endometriosis are a predictor of pelvic pain (91). Vaginal and uterosacral deep lesions are associated with dyspareunia and dyschezia.

Prostaglandin E and $F_{2\alpha}$ production from explants of petechial lesions present in mild, low-stage disease was found to be significantly greater than from the explants of powder-burn or black lesions, which are more common in patients with higher-stage endometriosis. Prostaglandin and cytokine production may account for severe pain in some patients with mild disease. More importantly, endometriotic implants acquire a vascular and nerve supply that may contribute to peripheral and CNS sensitization and persistence of pain even after surgical therapy (92–94).

Endometriosis-related pain syndrome is a new and evolving concept that is defined as pain that does not respond adequately to appropriate medical and surgical therapy, especially in the setting of minimal or mild disease. In this situation, neural plasticity results from central sensitization, hypothetically initiated by the peripheral inflammatory insult (93). The disease is no longer just the endometriosis, but is fostered by the alterations in the peripheral and CNS. Endometriosis-related pain syndrome is often co-existent or "comorbid" with other chronic conditions such as IC/PBS, IBS, myofascial pain, fibromyalgia and vulvodynia, and anxiety disorders. These disorders need to be managed concurrently.

Adhesions

[4] Adhesions noted at the time of laparoscopy may be in the same general region of the abdomen as the source of the pelvic pain; however, neither the specific location (i.e., adnexa structures, parietal, visceral peritoneum, or bowel) nor density of the adhesions correlates consistently with the presence of pain symptoms (95,96). In one nonrandomized, noncontrolled study of adhesion lysis, a

subgroup of women with anxiety, depression, multiple somatic symptoms, and social and occupational disruption responded poorly to adhesiolysis. The group without these characteristics had significant improvement in pain (97). Prospective randomized controlled trials do not support adhesiolysis for women with CPP. A randomized controlled trial of laparoscopic adhesiolysis showed an improvement in both the groups (i.e., laparoscopy with and laparoscopy without lysis of adhesions), suggesting a large placebo effect (98–100). One randomized controlled trial that did not consistently demonstrate a significant long-term reduction in pain did find some improvement if the adhesions were dense and involved the small bowel (101). In a nonrandomized study of patients who underwent adhesiolysis for pelvic pain, 41% of patients still had residual abdominal symptoms during a 15 year follow up (102).

Most women with adhesions had a prior surgical procedure with possible injury to abdominal wall nerves, such as the iliohypogastric or ilioinguinal nerves, and those are more likely to be the cause of the pain. The abdominal wall must be carefully evaluated for myofascial or nerve injury, or entrapment, as the source of pain before assuming that adhesions contribute to the genesis of pain.

Diagnosis

Diagnostic laparoscopy is recommended if GI, GU, and myofascial and neuropathic causes are ruled out or treated and the results of the psychological evaluation are negative. Mini-laparoscopy using local anesthesia and conscious sedation is used to perform "conscious pain mapping," whereby specific adhesions are tweaked and pelvic pain response is recorded (103). In an observational study of 50 women using local anesthesia, manipulation of appendiceal and pelvic adhesions contributed to pelvic pain. However, lysis of these adhesions did not improve outcomes over traditional laparoscopic therapy (2,104).

Management

The causal role of adhesions in the genesis of pelvic pain is uncertain, and surgery will lead to further adhesion formation and perhaps organ injury. Therefore, lysis is not recommended unless there is intermittent partial bowel obstruction or infertility. Although some observational studies showed that laparoscopic lysis of adhesions can alleviate CPP, randomized controlled trials have not revealed any long-term benefit. If surgery is performed, barrier materials such as oxidized regenerated cellulose or hyaluronic acid with carboxymethyl cellulose have been shown in meta-analysis studies to be effective for prevention of adhesion reformation (105). Repeated surgical procedures for lysis of adhesions are not indicated.

Pelvic Congestion

Pelvic congestion syndrome involves congestion or dilation of uterine and/or ovarian venous plexuses (106–110). First proposed in the 1950s, this condition was a

suggested result of emotional stress that could lead to smooth muscle spasm and congestion of ovarian and uterine pelvic venous plexuses. A subsequent blind study was undertaken to compare results of transuterine venography in patients with unexplained CPP and negative laparoscopy with controls. This study demonstrated that women with CPP had a larger mean ovarian vein diameter, delayed disappearance of contrast medium, and greater ovarian plexus congestion compared to controls. The existence of this condition is controversial as this condition does not have definitive diagnostic criteria (110).

Pelvic congestion syndrome results from compression of the left renal vein at the origin of the superior mesenteric artery (also known as "nutcracker syndrome"). This leads to pelvic venous congestion.

Signs and Symptoms

[4] Pelvic congestion affects women of reproductive age. Typical symptoms include bilateral lower abdominal and back pain that is increased with standing for long periods, secondary dysmenorrhea, dyspareunia, abnormal uterine bleeding, chronic fatigue, and irritable bowel symptoms (110). Pain usually begins with ovulation and lasts until the end of menses. The uterus is often bulky, and the ovaries are enlarged with multiple functional cysts. The uterus, parametria, and uterosacral ligaments are tender.

Diagnosis

Diagnosis can be made clinically. However, imaging can be used to help diagnosis and aid in therapy. Transuterine venography or MRI are the primary method for diagnosis, although other modalities, such as pelvic ultrasound and laparoscopy, may disclose varicosities (106,110). Because of the cost and possible side effects of treatment, further management should be based on related symptoms and not solely on the presence of varicosities.

Management

Treatment of suspected pelvic congestion ranges from the less invasive hormonal suppression and cognitive–behavioral pain management to the more invasive ovarian vein embolization or hysterectomy and salpingo-oophorectomy (106–110). Low-estrogen, progestin-dominant continuous OCs, high-dose progestins, and GnRH analogs often provide pain relief (107). Hormonal suppression should be the initial mode of treatment for women with suspected pelvic congestion. *Medroxyprogesterone acetate,* 30 mg daily, is useful (108). Goserelin acetate (3.5 mg a month for 6 months) has been shown to be effective in treating pelvic congestion in pelvic venography improvements and in symptom improvement (107). A multidisciplinary approach incorporating psychotherapy, behavioral pain management, or both is highly recommended. Percutaneous transcatheter embolization can be considered for women who do not respond to medical or hormonal therapy (109,110). Technically more

invasive, transcatheter embolotherapy selectively catheterizes the ovarian and internal iliac veins, followed by contrast venography and embolization. This treatment showed some promise in small uncontrolled studies, but larger randomized controlled trials are necessary to validate its benefits. For women who have completed their childbearing, hysterectomy with oophorectomy is a reasonable option if multidisciplinary management has failed (110).

Subacute Salpingo-Oophoritis

Patients with salpingo-oophoritis usually present with symptoms and signs of acute infection. Atypical or partially treated infection may not be associated with fever or peritoneal signs. **Subacute or atypical salpingo-oophoritis is often a sequel of chlamydia or mycoplasma infection.** Abdominal tenderness, cervical motion, and bilateral adnexal tenderness are typical of pelvic infection (see Chapter 15).

Ovarian Remnant and Residual Ovary Syndromes

[4] In a reproductive-aged patient who has had a BSO, with or without a hysterectomy, for severe endometriosis or PID, CPP may be caused by ovarian remnant syndrome (111). **This syndrome results from residual ovarian cortical tissue that is left in situ after a difficult dissection in an attempt to perform an oophorectomy. This tissue can become encased in adhesions and result in painful cysts.** Often, the patient had multiple pelvic operations with the uterus and adnexa removed sequentially. Laparoscopic oophorectomy, combined with a difficult dissection, is a strong risk factor.

Residual ovary syndrome is uncommon considering the number of women undergoing hysterectomy with ovarian preservation. **Theoretically, after a hysterectomy with one or both ovaries intentionally left in situ, adhesions develop and encase the ovaries, then cyclical expansion of the ovaries can result in pain and, in some cases, a tender persistent mass. This can be seen in patients with endometriosis in which ovarian implants are left in place.**

Symptoms

The patient usually reports lateralizing pelvic pain, often cycling with ovulation or the luteal phase that is described as sharp and stabbing or constant, dull, and nonradiating, occasionally with associated genitourinary or gastrointestinal symptoms. Symptoms tend to arise 2 to 5 years after initial oophorectomy. A tender mass in the lateral region of the pelvis is pathognomonic. The patient may report deep dyspareunia, constipation, or flank pain.

Diagnosis

Ultrasonography usually confirms a mass with the characteristics of ovarian tissue.

The accuracy of ultrasound can be improved by treating the patient with a 5- to 10-day course of *clomiphene citrate,* 100 mg daily, to stimulate follicular development. In a patient who has had BSO and is not taking hormone therapy, estradiol and follicle-stimulating hormone (FSH) assays reveal a characteristic premenopausal picture (FSH <40 mIU/mL and estradiol >20 pg/mL), although on occasion the remaining ovarian tissue may not be active enough to suppress FSH levels (111). The patient may have a persistent estrogenized state based on the vulvar and vaginal examination and lack postmenopausal symptoms such as hot flashes, night sweats, and mood changes. **Medical therapy that suppresses ovarian function can be diagnostic and therapeutic.** Imaging with pelvic ultrasound can be used if pelvic mass is found on exam.

Management

Patients who are not candidates for, or decline, surgery can be managed through medical treatment such as high-dose progestins or OCs, which usually provides good results. Patients experience pain relief with a GnRH agonist, although these medications are impractical for long-term therapy. Those who achieve relief with GnRH agonists also experience relief with subsequent surgery (112). Laparoscopic examination usually is not productive because the ovarian mass may be missed or adhesions may prevent accurate diagnosis. A few articles documented successful laparoscopic treatment of this condition (113,114). **Removal of the remnant ovarian tissue is necessary for treatment, and the corrective surgery tends to be arduous, with risks of cystotomy, enterotomy, and postoperative small bowel obstruction** (111). Surgical pathology usually reveals the presence of ovarian tissue, sometimes with endometriosis, corpus lutea or follicle cysts, and fibrous adhesions. *Clomiphene citrate* can be used 7 to 10 days before surgery to induce folliculogenesis, allowing ovarian tissue to be more easily detected.

Gastroenterologic Etiology

The uterus, cervix, and adnexa share visceral innervation with the lower ileum, sigmoid colon, and rectum. These pain signals travel through sympathetic nerves to spinal cord segments T10 to L1. [4] It is often difficult, therefore, to determine whether lower abdominal pain is of gynecologic or enterocoelic origin. Skillful medical history and examination are necessary to distinguish gynecologic from gastrointestinal causes of pain. Inflammatory bowel disease, such as Crohn disease or ulcerative colitis, infectious enterocolitis, intestinal neoplasms, appendicitis, and hernia must be ruled out with appropriate history and physical examination, complete blood cell count, and stool cultures and visualization of colonic mucosa when appropriate.

Irritable Bowel Syndrome

[4] IBS is one of the more common causes of lower abdominal pain and may account for up to 60% of referrals to the gynecologist for CPP. An estimated 35% of patients with CPP have a concurrent diagnosis of IBS (115,116). Women who had a hysterectomy for CPP are twice as likely to have IBS. Women are at a slightly higher risk of IBS than men (117). The pathophysiology of IBS appears to be influenced by CNS sensitization and decreased descending inhibition, which ultimately leads to visceral hypersensitivity. Visceral hypersensitivity and abnormal reflex responses, demonstrated in both animal and human studies, result in an increased intensity of pain, lowered threshold for sensation, and an enlarged viscera-somatic region of pain referral, all of which lead to the IBS symptoms (118,119).

Symptoms

The predominant symptom of IBS is abdominal pain. Other symptoms include abdominal distention, excessive flatulence, alternating diarrhea and constipation, increased pain before a bowel movement, decreased pain after a bowel movement, and pain exacerbated by events that increase gastrointestinal motility, such as eating, stress, anxiety, depression, and menses. The pain is usually intermittent, occasionally constant, cramp-like, and more likely to occur in the left lower quadrant. The patient with IBS can be placed into one of three categories: constipation-predominant, diarrhea-predominant, and pain-predominant (alternating bowel habits) depending on their main symptoms. The new Rome IV criteria for diagnosis (Table 12-5) includes at least 3 days of recurrent abdominal pain or discomfort per month over the past 3 months with at least two of the following features: relief with defecation, onset associated with change in stool frequency, or onset associated with change in the form and appearance of stool (120).

Table 12-5 Rome IV Criteria for Irritable Bowel Syndrome

Recurrent abdominal pain for at least 1 day per week (on average) for the previous 3 months with onset of symptoms at least 6 months before the diagnosis and associated with two of three features:
1. Related to defecation
2. Associated with a change in frequency of stool
3. Associated with a change in form (appearance) of stool

Signs

On physical examination, the findings of a palpable tender sigmoid colon or discomfort during insertion of the finger into the rectum and hard feces in the rectum are suggestive of IBS.

Diagnosis

The diagnosis of IBS is usually based on history and physical examination, and although suggestive, especially in young women, the findings are not specific. A CBC, thyroid function study, stool sample to test for white cells and occult blood, and sigmoidoscopy or colonoscopy or barium enema are usually required, particularly in older individuals and in young individuals who have not responded to initial treatment. The results of these studies are all normal in patients with IBS.

Management

Treatment consists of reassurance, education, stress reduction, bulk-forming agents and other symptomatic treatments, and low-dose tricyclic antidepressants (TCAs). A multidisciplinary management approach consisting of medical and psychological approaches is recommended. Patients should eliminate triggers in their diet, such as food containing lactose, sorbitol, alcohol, fat, and fructose. Products that contain caffeine can cause abdominal bloating, cramping, and more frequent bowel movements. After the patient has tried these lifestyle changes, if she remains symptomatic, a short-term trial of antispasmodics such as *dicyclomine* or *hyoscyamine* can be given (117–119). Multidisciplinary therapy addresses the cognitive, affective, and behavioral components of the pain. Therapy may decrease the intensity of nociceptor stimulation and change the patient's interpretation of the meaning of pain (119).

Antispasmodic agents relax the smooth muscle and reduce contractility of the gastrointestinal tract. While antispasmodics and laxatives may produce symptomatic relief of bowel symptoms, the pain symptoms of IBS may respond to antidepressants. **Low-dose TCAs can alleviate the pain of IBS as shown in a number of randomized controlled trials. TCAs can reduce excessive gastrointestinal contractility and are approved for use as antispasmodics.** TCAs may be used for women with moderate to severe pain, who were refractory to other therapies. Although the dose to achieve the analgesic response is much lower than that used for antidepressive effects, TCAs may be increased to higher dosages in patients with coexisting depression. **Selective serotonin reuptake inhibitors (SSRIs) and serotonin/norepinephrine reuptake inhibitors (SNRIs) were used successfully in the treatment of IBS and can be used in those patients failing TCA treatment or those who are depressed or are unable to tolerate the side effects of TCAs** (117–119).

Urologic Etiology

[4] CPP of urologic origin may be related to recurrent cystourethritis, urethral syndrome, sensory urgency of uncertain cause, and IC/PBS. With an appropriate diagnostic workup, infiltrating bladder tumors, ureteral obstruction, renal lithiasis, and endometriosis can easily be ruled out as possible causes.

Urethral Syndrome

Urethral syndrome is defined as a symptom complex including dysuria, frequency and urgency of urination, suprapubic discomfort, and often dyspareunia in the absence of any abnormality of the urethra or bladder (121). The cause of urethral syndrome is uncertain and is attributed to a subclinical infection, urethral obstruction, and psychogenic and allergic factors. The symptoms of urethral syndrome may evolve into the initial stages of IC/PBS.

Symptoms

Urinary urgency, frequency, suprapubic pressure, and other less frequent symptoms such as bladder or vaginal pain, urinary incontinence, postvoid fullness, dyspareunia, and suprapubic pain are commonly observed. According to the American Urological Association, these symptoms must be present for at least 6 weeks.

Signs

Physical and neurologic examinations should be performed. Anatomic abnormalities, including pelvic relaxation, urethral caruncle, and hypoestrogenism, should be evaluated. The patient should be evaluated for vaginitis. The urethra should be carefully palpated to detect purulent discharge.

Diagnosis

A clean catch or catheterized urine specimen for RUA and culture should be obtained to rule out UTI. Urine cytology can help exclude malignancy or hematuria. A postvoid residual can easily be done in clinic to check for urinary retention. As indicated, urethral and cervical studies for chlamydia should be obtained, and a wet prep for vaginitis should be performed. Urethral syndrome should be considered if infection is ruled out, the evaluation does not disclose vulvovaginitis, and no allergic phenomenon causing contact dermatitis of the urethra can be detected. The possibility of ureaplasma, chlamydia, candida, trichomonas, gonorrhea, and herpes should be eliminated. Cystoscopic evaluation should be performed to rule out urethral diverticulum, stones, and cancer. Pelvic floor muscles should be evaluated, as spasm of these muscles can lead to urethral pain and tenderness. The urethral pain can be a manifestation of IC/PBS.

Management

Various forms of therapy are suggested for urethral syndrome. **Those patients in whom no infectious agent is present but who have sterile pyuria may respond to a 2- to 3-week course of *doxycycline* or *erythromycin.*** Long-term, low-dose antimicrobial prophylaxis often is used in women with urgency and frequency symptoms who had careful documentation of recurrent UTIs. Some of these women may continue to have symptoms when their urine is not infected, and bacterial infection redevelops over time.

Posttreatment test of cure cultures are useful. **It is recommended that all postmenopausal women with this condition be given a trial of local estrogen therapy for at least 2 months.** If there is no improvement after antibiotic or estrogen therapy, physical therapy (PT), and cognitive–behavioral therapy, then urethral dilation can be considered but recent studies are lacking. Positive results were noted with biofeedback techniques. Other treatments including acupuncture and laser therapy proved successful (122). Psychological support is very important in this group of women. **Management requires a multidisciplinary approach, as is true of CPP in general.**

Interstitial Cystitis/Bladder Pain Syndrome or Painful Bladder Syndrome

IC/BPS occurs more often in women than men. Most patients are between 40 and 60 years of age. In 2002, painful bladder disorders were defined by the International Continence Society (ICS) in a set of new recommendations (123). The most widely used definition, **painful bladder syndrome (PBS) is described as a clinical syndrome (i.e., a complex of symptoms) consisting of "suprapubic pain related to bladder filling, accompanied by other symptoms, such as increased daytime and nighttime frequency in the absence of proven infection or other obvious pathology." By comparison, the term "IC" refers to patients who have PBS symptoms, but who also have "typical cystoscopic and histologic features" during bladder hydrodistention** (123).

The etiology of IC/PBS is unknown, but several hypotheses exist. A defective glycosaminoglycan (GAG) epithelial layer, which allows irritating substances in the urine to penetrate the urothelium to the subepithelial nerve endings, may be responsible for the syndrome (124). This theoretical mechanism is based on the fact that many IC sufferers are sensitive to certain foods and beverages. Immunologic mechanisms were proposed because abnormal mast cell activity, increased substance P–expressing nerve fibers and increased nerve growth factor, were all found in bladder biopsies of IC-affected individuals (124). Autoimmune mechanisms may be responsible in some individuals given that there is a higher incidence of systemic lupus erythematosus, allergies, inflammatory bowel and IBD, and fibromyalgia in patients with bladder symptoms. Another possible mechanism is central sensitization with altered sympathetic and hypothalamic adrenal axis, substantiated by the existence of "phantom" bladder pain even after surgical removal of the bladder (125).

Symptoms

Symptoms include pain and severe and disabling urinary frequency and urgency, nocturia, and occasional dysuria and hematuria. Suprapubic, pelvic, urethral, vaginal, vulvar, or perineal pain is common and can be relieved to some extent by emptying of the bladder (125).

Signs

Pelvic examination usually reveals anterior vaginal wall and suprapubic tenderness. Pelvic floor muscles are invariably involved, and tender to palpation. Urinalysis may reveal microhematuria without pyuria, although results are usually normal.

Diagnosis

The diagnosis is one of exclusion and is no longer based on cystoscopy. Definitions and diagnostic criteria continue to change. **In 2011, the American Urological Association defined criteria as an unpleasant sensation perceived to be related to the urinary bladder, associated with lower urinary tract symptoms of more than 6 weeks' duration, in the absence of infection or other identifiable causes.**

National Institutes of Health (NIH) Consensus Criteria for diagnosis of IC states that patients must have at least two of the following: (1) pain on bladder filling relieved by emptying; (2) pain in suprapubic, pelvic, urethral, vaginal, or perineal region; (3) glomerulations on endoscopy or decreased compliance on cystometrogram (126).

Patients can be evaluated with cystoscopy with hydrodistention and biopsy. Petechial bladder mucosal hemorrhages (glomerulations) are characteristic of IC. The use of a pelvic pain and urgency or frequency symptom scale and a bladder potassium intravesical test can promote early diagnosis (127); it is debatable whether a positive potassium test is definitive for IC or if a positive test is a manifestation of bladder hyperalgesia (126).

Management

Although there is no definitive cure for IC/PBS, patients can achieve remission with multidisciplinary therapy. First-line treatments are primarily behavioral modification such as bladder training and stress management, cognitive–behavioral therapy, dietary modifications or restriction of acidic, spicy, and fermented foods, and pelvic floor muscle PT. These first-line treatments are individually specific. For example, studies have shown that the foods that can cause irritation differ between individuals (128). Urinary alkalinization can be useful (129). TCAs have been efficacious. *Amitriptyline* 10 mg can be taken at bedtime and titrated as tolerated up to 150 mg or to relief of symptoms. *Amitriptyline* has antihistaminic, anticholinergic, and sodium channel blocking properties that are potentially therapeutic for opposing the histamine from mast cell degranulation, urinary frequency, and neuropathic pain, respectively (129). Oral *pentosan polysulfate sodium* (PPS) is the only U.S. Food and Drug Administration (FDA)-approved oral therapy for IC and is modestly beneficial (129,130). *Pentosan polysulfate* is a heparin-like moiety that resembles the GAG layer, but should not be used with NSAIDs because of the bleeding risk.

Intravesical therapy can be first- or second-line. With an intravesical mixture of *lidocaine,* bicarbonate, and *heparin* instilled three times a week for 3 weeks, 57% of

women reported resolution of pain (131). *Dimethyl sulfoxide* (*DMSO*) is the only FDA-approved intravesical treatment of IC. Intravesical 50% *DMSO* showed significant symptomatic improvement compared to placebo in two randomized controlled trials. Intravesical solutions containing dissolved PPS showed some promise but are not FDA approved and are under investigation (132). Hydrodistention of the bladder to maximum capacity under epidural anesthesia has been used to treat ICS/PBS and has shown to be helpful in improving symptoms (133,134).

Sacral neuromodulation is an invasive, yet promising, technique under investigation for treatment of refractory IC (135). Sacral neuromodulation is not FDA approved for IC, and larger studies are required to confirm efficacy.

Treatments that require more data to support safety and efficacy include intravesical instillation of GAGs and intradetrusor botulinum toxin.

Neurologic and Musculoskeletal Causes

Nerve Entrapment

[4] Abdominal cutaneous nerve injury or entrapment of the iliohypogastric or ilioinguinal nerves can occur with transverse suprapubic laparotomy incisions or laparoscopy incisions placed inferior to the anterior superior iliac spine. Injury can follow heavy lifting or traumatic injury, such as with a motor vehicle accident. The ilioinguinal (thoracic 12, lumbar 1 and lumbar 2, T12, L1, L2) or iliohypogastric (T12 and L1, L2) nerves may become trapped between the transverse and internal oblique muscles, especially when the muscles contract. Alternatively, the nerve may be ligated or traumatized during the surgery (136). **Localized pain in the L1–L2 dermatome lateral to the rectus muscle immediately following surgery should be evaluated expeditiously, as removal of the offending fascial suture will be curative. Neuropathic pain may not begin until weeks after surgery or even years following surgery, following vigorous abdominal wall stress with lifting or reinjury.**

Femoral nerve injury can result when deep lateral retractor blades compress the nerve between the blade and the lateral pelvic side wall (137). Femoral nerve damage results in an inability to flex at the hip joint or to extend at the knee.

Symptoms of nerve entrapment or injury include sharp, burning, aching pain, and paresthesia in the dermatomal distribution of the involved nerve. With nerve entrapment, hip flexion and exercise or activity exacerbates pain and rest or infiltration with a local anesthetic relieves pain. The pain is usually judged as coming from the abdomen, not the skin (138).

Pudendal neuropathy can result from vaginal surgery (especially with lateral mesh attachments), childbirth, exercise, and chronic constipation or pelvic floor muscle abnormalities. Vulvar surgical procedures including episiotomies, laser hair

removal, and Bartholin gland removal can lead to injury of the vestibular, rectal, or clitoral nerves, terminal branches of the pudendal nerve (139**)**.

Nantes criteria for pudendal nerve entrapment in and around the Alcock canal are: (1) pain in the sacral 2–4 dermatomal area innervated by the pudendal nerve (i.e., ipsilateral clitoris/ penis, distal urethra, labia/scrotum, perineum, and anus); (2) pain is increased while sitting; (3) patient is not awakened by pain; (4) no sensory loss on clinical examination (sensory deficits are suggestive of a sacral nerve root lesion); (5) resolution of pain with administration of pudendal nerve block (140). Entrapment can potentially be relieved by surgical release but neuralgia caused by nerve injury will not recover from surgery. It is not possible with examination or imaging to completely differentiate pudendal entrapment from neuralgia related to nerve injury.

Signs

On examination, the point of maximal tenderness or pain should be localized with the fingertip. The maximal point of tenderness in an iliohypogastric or ilioinguinal injury is at the rectus margin, medial and inferior to the anterior iliac spine. Carnett test will be positive with increased pain over the area of entrapment or injury. Carnett test involves palpation of the tender area followed by repalpation during an abdominal wall tensing maneuver, that is abdominal crunch (3/4 "sit up") or bilateral straight leg raise. Abdominal wall pain is more severe with palpation during muscle contraction in the setting of L1, L2 nerve entrapment, injury, hernia, or myofascial pain. For the pudendal nerve, the maximal tenderness is near the ischial spine and the Alcock canal.

A tentative diagnosis or neuropathy can be confirmed by a diagnostic nerve block with 3 to 5 mL of 0.25% *bupivacaine*. Patients usually report immediate relief of symptoms after injection, and at least 50% of patients experience relief lasting longer than a few hours over the following weeks.

Management

Many patients may require no further intervention after a series of weekly nerve blocks and avoiding activities that lead to compression of the nerve. Many patients require PT or medications that downregulate nerve firing. Medications for neuropathic pain include topical local anesthetics, oral anticonvulsants, or antidepressants. PT can be helpful in cases of pudendal neuropathy involving abnormal functioning of levator or obturator internus muscles. If injection and other pharmacologic approaches produce only limited pain relief and there are no contributory visceral or psychological factors, surgical decompression of the involved nerve may be recommended.

Myofascial Pain

Myofascial pain of the abdominal wall or pelvic floor muscles are commonly overlooked in the evaluation of CPP. **[4]** **Myofascial pain syndrome (MPS) consists of pain originating from muscle trigger points in the skeletal muscle and fascia. By**

definition, a myofascial trigger point is a "hyperirritability focus within a tender, taut band-like hardness within one or more skeletal muscles or the associated fascia" (141). Intra-abdominal pathology, muscular overload, and direct trauma can result in the development of trigger points but are not required for development or perpetuation.

Depending on the study, 13% to 75% of women with CPP have myofascial pelvic tenderness and/or trigger points (142). **Pelvic floor muscle pain can result from surgical trauma, poor posture, severe constipation, or viscerosomatic reflex responses.** The muscles sharing thoracolumbar and sacral nerve supply with the reproductive, gastrointestinal, and urinary systems can lead to pelvic floor and abdominal wall muscle pain (143). Trigger points can develop in muscles in the zone of the referred pain from the underlying organ and in turn the trigger point can lead to abdominal fullness, bloating, swelling, and gas. IC/PBS, IBS, endometriosis, and vulvodynia are associated with pelvic floor dysfunction and trigger points and many women with these diagnoses have, or will develop, generalized chronic myofascial pain and fibromyalgia (143). Trigger points in the lower rectus abdominis between the umbilicus and symphysis can develop in women with severe dysmenorrhea.

Symptoms

History should investigate overuse, repetitive strains, injuries, and dysfunctional posturing which can result in myofascial trigger points in the abdominal wall, back, and pelvic floor. History of IBS, IC/PBS, or endometriosis should prompt a search for abdominal wall and pelvic floor myofascial pain. **Abdominal wall and pelvic floor myofascial pain is exacerbated by activity, or by stimuli to the dermatome of trigger points** (e.g., full bladder, bowel, luteal phase, or menses; any stimulation to organs that share the dermatome of the involved nerve) (144).

Signs

Pelvic muscle assessment should include both external and internal muscles. In addition to testing for tenderness, muscle strength, for which both the squeeze and lift components are essential, and function testing are important (145). Unfortunately, techniques for the discovery of pelvic floor trigger points are not standardized, making it difficult to describe the musculoskeletal system for the diagnostic workup.

Management

Massage therapy can help relieve the pain in some cases. "Myofascial release" is a special vigorous message that can be effective (141). Depending on the location of the myofascial trigger points, pelvic floor PT is indicated (145,146).

PT entails manual techniques to inactivate trigger points, restore muscle length, and correct predisposing factors. Pelvic floor PT involves a variety of muscle relaxation and lengthening exercises to pelvic floor muscles as well as releasing trigger

points by connective tissue release. A retrospective chart review of 75 women with chronic myofascial pelvic pain noted significantly improved pain scores proportional to the number of PT visits completed (144). A randomized study noted 57% patients with CPP benefited from myofascial PT (147,148). The response rate was significantly greater with PT compared to therapeutic massage. Sustained pressure with adequate force to a trigger point for a specified period or injection can inactivate the irritable point (149).

NSAIDs, gabapentin, pregabalin, low-dose TCAs, SNRIs, and benzodiazepines may be useful in patients requiring pharmacologic interventions. Injection of the trigger point with 3 mL of 0.25% bupivacaine provides relief that usually outlasts the duration of the anesthetic action. After four to five biweekly injections, the procedure should be abandoned if long-lasting relief is not obtained. A 60-patient randomized controlled trial compared lidocaine patch and placebo patch versus anesthetic injection for the treatment of Myofascial Pain Syndrome (MPS). The study revealed similar efficacy of anesthetic patch to the gold standard treatment with trigger point injection and was associated with less discomfort than injection therapy (151). Acupuncture can be effective (152). Concomitant with injection at trigger points; relaxation, stress reduction, and cognitive–behavioral pain management should be undertaken, especially if anxiety, depression, history of emotional trauma, physical or sexual abuse, sexual dysfunction, or social or occupational disruption are present.

Fibromyalgia

[4] Fibromyalgia is an *MPS*, made up of the triad of diffuse pain, fatigue, and nonrestorative sleep. Women with abdominal wall or pelvic floor myofascial pain, IC/PBS, and IBS often have comorbid *fibromyalgia*. Women are affected more commonly than men. To diagnose the syndrome, the patient must have tender points in all four quadrants. The cause is thought to be a CNS sensitization that results in abnormal perception of chronic pain. Fibromyalgia is closely associated with *chronic fatigue syndrome,* a combination of regional myofascial problems including infections and autoimmune disorders or dysautonomias. The management includes education, environmental changes (well-balanced diet, adequate time for sleep, and an environment conducive to restful sleep), exercise and stretching, and counseling or cognitive behavioral therapy for relaxation and maximizing coping mechanisms. Medications used include NSAIDs, low-dose TCAs, selective SNRIs, anticonvulsants, and benzodiazepines to improve sleep (150).

Low-Back Pain Syndrome

In women who experience lower-back pain without pelvic pain, gynecologic pathology rarely is the cause of their pain. However, low-back pain may accompany gynecologic pathology. Back pain may be caused by gynecologic, vascular,

neurologic, psychogenic, or spondylogenic (related to the axial skeleton and its structure) pathology (153).

Symptoms

Women with low-back pain syndrome often have pain occurring after trauma or physical exertion, in the morning on arising, or with fatigue. Nongynecologic low-back pain can intensify with the menstrual cycle.

Signs

Examination consists of inspection, evaluation with movement, and palpation. Various anatomic structures in the spine should be considered as sources of pain. Muscles, vertebral joints, and discs (including the lumbosacral junction, paravertebral sacrospinal muscles, and sacroiliac joints) are common sources of spondylogenic pain that must be examined carefully (2).

Diagnosis

Diagnostic imaging studies performed while the patient is standing, lying, and sitting with maximal flexion can be helpful. An elevated ESR suggests pain of inflammatory or neoplastic origin. Though most patients with acute back pain do not require imaging, plain films can be obtained to evaluate for infection, fracture, malignancy, spondylolisthesis, degenerative changes, disc space narrowing, and prior surgery. For patients who require advanced imaging, MRI without contrast is considered to be the best imaging modality.

Management

Consultation with the patient's primary care provider should be sought before initiating management for back pain unless the source could be referred gynecologic pain. For more complex cases, an orthopedic or neurosurgery consult may be required.

Vulvodynia

[4] Vulvodynia has a prevalence of 15% and is classified as vulvar pain for at least 3 months without a clear source (154). Specific causes of vulvar pain must be excluded before a diagnosis of vulvodynia can be made. **Specific causes of vulvar pain that should be ruled out include inflammatory conditions (dermatitis, dermatoses), malignancy, neuralgia, trauma, iatrogenic causes (e.g., chemotherapy, radiation, surgery), infection (candida, herpes), and hormonal deficiency.** Factors that can initiate or maintain vulvodynia include comorbid pain or psychiatric disorders, genetic predisposition to pain or inflammation, sex steroid hormone deficiency, pelvic floor musculoskeletal abnormalities, relevant neurologic changes in the pudendal or sacral 2–4 nerves, and psychosocial issues. **Vulvodynia is classified by pain localization,**

triggers, and timing of onset. If there is localized pain of the vulvar vestibule (vestibulodynia) or clitoris (clitorodynia), vulvodynia is classified as localized. Pain over the entire vulva is called generalized vulvodynia. Mixed vulvodynia refers to pain that is localized and generalized. Pain is further classified as provoked which means pain with genital contact or spontaneous, whereby the pain occurs without contact. Pain can be provoked and spontaneous. If the pain occurs from the first genital penetration attempt, it is classified as primary. If the pain starts after a period of painless genital contact, it is classified as secondary.

The pathophysiology of vulvodynia is unclear but likely complex and multifactorial. **Provoked vestibular pain, the most common type of vulvodynia, has been hypothesized to start with a chronic inflammatory process or immunologic challenge such as yeast infection or injury.** Proliferation of nociceptive nerve fibers, increased inflammatory infiltrate dominated by mast cells, and increased neuroinflammatory neurokines, cytokines, chemokines, and prostanoids can develop in predisposed individuals (155). Altered pelvic floor musculature contractility often is associated but may be etiologic. There is evidence for central and peripheral sensitization with hypersensitivity to tactile, thermal, and chemical stimuli.

A history and examination are adequate for the diagnosis of vulvodynia. Patients should be questioned about their medical, psychological, sexual, and pain history (156). **The vulva and vagina should be examined for any lesions, infections, or dermatoses. A cotton swab is used to test the vestibule for pain at 12, 2, 5, 6, 7, and 10 o'clock. Pain of at least 4/10 on a numeric rating scale when the swab is pressed to a depth of 1/3 of the cotton tip for 1 second is consistent with provoked vestibulodynia.** Pelvic floor muscle tone and tenderness should be ascertained with a single lubricated finger in the vagina. A wet mount of vaginal discharge should be performed to look for yeast or bacterial vaginosis and for signs of inflammation (excessive white blood cells) or estrogen deficiency (multiple parabasal or intermediate cells). Imaging studies can be considered to diagnose the pain if not limited to vestibule.

The treatment of vulvar pain is multifactorial. Address any underlying disorder which may be causing the pain such as infection, dermatoses, psychological, or hormonal issues. Long-term hormonal contraceptives may contribute to vestibular thinning and pain. Vulvar hygiene is an important part of the treatment. Patients should be taught to eliminate pads, allergens, fabric softeners, soaps, and other potentially irritating chemicals. **The pharmacologic treatments of vulvodynia can include topical lidocaine 5%, anticonvulsants such as gabapentin topical (6% compounded) or oral, TCAs either as a topical or oral formulation, botulinum toxin injections, hormonal therapy if estrogen deficiency is noted, and injections of local anesthetic with or without steroid. Pelvic floor PT is usually recommended for treatment of**

vulvodynia. Further treatments include surgery (vestibulectomy) for provoked vestibulodynia, psychological (cognitive–behavioral, psychotherapy, mindfulness-based relaxation therapy), EMG biofeedback, and complementary/alternative treatments such as acupuncture or hypnotherapy (157–161).

Psychological Factors

[3] Psychological factors that increase pain vulnerability and lower resilience promote the chronicity of pain (162). The meaning attached to the pain, pain-related catastrophizing, low self-efficacy in managing pain, poor pain coping, anxiety, negative affect, childhood emotional, physical or sexual traumatic experiences, and poor social support all play a role in maintaining and amplifying chronic pain (163–165). Recent investigations are beginning to shed light on how current and previous psychological, behavioral, and psychosocial factors affect chronic pain. Crucial are the changes in brain networks concerning reward, motivation, learning, and pathways descending from the brain to the periphery that modulate pain (162). **[3] There is a close relationship between depression and pain**. The Beck Depression Inventory can be used as a tool for evaluation; a score over 12 suggests dysphoria and over 18, depression (166). Antidepressants, particularly SNRIs often relieve depression and pain.

[3] Childhood physical abuse has been noted to be more prevalent in women with CPP than in those with other types of pain (39% vs. 18.4%) (81). In a comparison of women with CPP, women with nonpelvic chronic pain (headache), and pain-free women, a higher lifetime prevalence of major sexual abuse and physical abuse was found in the CPP group. Childhood traumas may lead to an increased vulnerability to psychosocial stress and impaired coping strategies and promote chronicity of pain after an injury.

If patients are taught self-efficacy and adaptive pain coping skills through psychological treatment interventions, pain can be reduced and functioning improved. Cognitive-behavioral therapy can be useful in treating CPP (167). Dramatizing the pain is a coping mechanism that is used by pain sufferers to generate support from others around them (168). This practice, combined with pain-related anxiety and fear, propagates pain.

Management of Chronic Pelvic Pain

Multidisciplinary Approach

[3] The multidisciplinary management approach recognizes the importance of cognitive, psychological, and myofascial contributions to chronic pain. The treatment milieu for women with chronic pain must be therapeutic, optimistic, and supportive. The patient should be instructed to complete a daily pain rating form

for two menstrual cycles and bring to her subsequent visit. This form provides the clinician and patient with important information for pain diagnosis and management. Each day, the average pain level (0 to 10), mood (0 to 10), vaginal bleeding (yes or no), and briefly, events that trigger pain such as stress, foods, and physical activities should be recorded. The pain ratings can encourage the patient's sense of control and decrease feelings of helplessness. Daily recording improves self-efficacy and compliance, and help the patient to recognize the connection between pain and stressors. The ratings reveal the relationship of the pain to the menstrual cycle. Cyclical pain associated with ovulation, premenstrual, or menstrual phase can be improved with hormonal suppression.

[3] Offering regular follow-up appointments is preferable to asking the patient to return only if pain persists because the latter reinforces pain behavior. Specific pain management skills should be taught using cognitive–behavioral approaches by a psychologist or with techniques as mindfulness-based meditation or yoga. **Patients should be instructed in ways to enhance opportunities for control of pain.** Various strategies, including cognitive-behavioral therapy, mindfulness-based relaxation techniques, stress management, hypnosis, and other psychotherapeutic approaches affect CNS pain networks and increase descending inhibition of peripheral pain signals. **Psychological group treatment is a very cost-effective approach for helping patients learn stress reduction techniques and develop coping behavioral mechanisms** (169). Psychotherapy is indicated for women who have pronounced depression, sexual difficulties, or previous trauma. Acupuncture can be helpful. Myofascial evaluation can be supplemented by PT evaluation and if appropriate, PT treatment should be initiated.

Various studies of multidisciplinary pain management in CPP were performed in the past (170). This approach incorporates the skills of the gynecologist, psychologist, and physical therapist, and may include an anesthesiologist for specialized nerve blocks. Retrospective, uncontrolled studies revealed relief of pain in 85% of the participants (171). One prospective randomized study revealed a similar response rate, which was significantly better than that of traditional therapy for pain and associated symptom reduction, improvement of daily functioning, and the quality of life (170).

[3] The following groups of patients should be considered for multidisciplinary therapy early in the management process: (1) no obvious pathology; (2) pathology that has an equivocal role in pain production; (3) poor response to traditionally effective medical or surgical management; (4) more than one visceral or somatic structure involved in the production of pain (i.e., more than one "pain generator"); (5) significant stress, anxiety, posttraumatic stress disorder, or depression; (6) history of past or current physical, emotional, or sexual trauma. There is a dearth of evidence based on controlled trials for the treatment of noncyclic pelvic pain (172).

Pharmacologic Interventions

Any patients with dysmenorrhea or pain that worsens in the luteal or menstrual phase should be given pre-emptive NSAIDs in adequate doses and/or hormonal agents to suppress ovulation and/or menses. The choice of the hormonal agent used to suppress the menstrual cycle will vary with patient preference, concurrent medical conditions, and side effects.

Patients with neuropathic pain or those with evidence of central sensitization or myofascial pain benefit from agents that alter neural processing (173). **A low dose of a TCA, most anticonvulsants, and selective SNRIs are often effective, especially if combined with cognitive-behavioral therapy or mindfulness.** These pharmacologic agents lower the threshold for nerve firing and can help reduce reliance on narcotic pain medication, increasing activity, and relieving the impact the pain has on women's lifestyle (104).

Anticonvulsants such as *gabapentin* or *pregabalin* are useful for treatment of CPP. *Gabapentin* plus *amitriptyline* can be more efficacious than *amitriptyline* alone (173). The anticonvulsants likely impact pain via blockade of calcium channels.

Local anesthetics are sodium channel blockers and they downgrade nerve firing. Ilioinguinal, iliohypogastric, pudendal nerve blocks and trigger point injections can be easily learned by the gynecologist and used liberally where appropriate to downregulate neural signaling.

Women with significant depression or anxiety should be treated with an appropriate therapeutic dose of antidepressant or anxiolytic medication. Psychiatry can be consulted in this setting.

The role of opioid therapy in chronic pain is controversial and randomized controlled trials are lacking. Long-term management of CPP with narcotic medications is considered a last resort after failure of all other treatment modalities. Opioids should be given on a scheduled basis, and patients should have consistent follow-up with evaluation of the extent of pain relief, level of function, and quality of life. Physicians should carefully document failure of other treatment options and patient counseling. Narcotics should be prescribed only with a narcotic contract. The patient should sign a written contract agreeing to obtain pain medications from only one provider and describing other expectations with respect to treatment. Some other points that the patient should agree to include no early refills or increasing dosage of medication without discussion with the doctor, no alcohol or illegal drugs, random blood or urine drug screens if needed, and psychiatric or psychological evaluation if needed. Updated opioid guidelines for chronic noncancer pain are available (174,175).

Physical Therapy

PT procedures restore tissue and joint flexibility, improve posture and body mechanics, restore strength and coordination, reduce nervous system irritability, and restore function (175). **PT is an important component of the management of patients with myofascial pain in the abdominal wall, pelvic floor, or lower back or fibromyalgia** (146).

Laparoscopy

Women with disabling pain that is premenstrual and/or menstrual and that does not respond to NSAIDs or hormonal contraceptives should be considered for laparoscopic evaluation. Diagnostic laparoscopy is a standard procedure in the evaluation of patients with chronic noncyclic pelvic pain; however, laparoscopy is generally withheld until other nongynecologic somatic or visceral causes of pain are excluded. During diagnostic laparoscopy, endometriotic lesions should be excised for biopsy, and if infection is suspected, cultures should be performed. The laparoscopy is essentially a debulking procedure, and all visible endometriosis may not be able to be removed safely; but if possible the implants should be excised or electrocoagulated.

Presacral neurectomy and laparoscopic uterosacral nerve ablation (LUNA) are techniques to interrupt the nerve supply to the uterus. A large study showed that LUNA was no more effective for CPP than laparoscopy alone (176). A 2007 review revealed that there is insufficient evidence to recommend pelvic nerve disruption for the treatment of dysmenorrhea (177).

The role of pelvic adhesions in pain is unclear, and the efficacy of lysis of adhesions is even more in doubt. Adhesiolysis, even via laparoscopy, is frequently complicated by adhesion reformation and may not be effective for relief of pain in controlled trials (96–102). Other causes must be treated first, and psychological consultation and management should precede or accompany the lysis of adhesions.

Hysterectomy

Although 19% of hysterectomies are performed to cure pelvic pain, 30% of patients presenting to pain clinics have already undergone hysterectomy without experiencing pain relief. A multidisciplinary approach including a gynecologist, physical therapist, and a psychologist decreased the frequency of hysterectomy in one study from 16.3% of patients with CPP to 5.8% (178).

[4] Hysterectomy is particularly useful for women who have completed childbearing and have secondary dysmenorrhea or chronic pain related to endometriosis, uterine pathology, such as adenomyosis, or pelvic congestion. However, hysterectomy is generally not indicated for patients with CPP (179–181). Before recommending hysterectomy for pain or unilateral adnexectomy for unilateral pain, it is useful to apply the **PREPARE** mnemonic in discussions with the patient (182): the ***P*rocedure** that is being done, ***R*eason** or indication, ***E*xpectation** or desired

outcome of the procedure, ***P*robability** that the outcome will be achieved, ***A*lternatives** and nonsurgical options, and ***R*isks** as well as ***E*xpense** (see Chapter 3). Hysterectomy for central pelvic pain in women with dysmenorrhea, dyspareunia, and uterine tenderness provided relief of pain in 77% of women in one retrospective study and in 74% of women in one prospective cohort study (183). Nevertheless, 25% of women in the retrospective study noted that pain persisted or worsened at 1-year follow-up (183). Persistent pain in the prospective study was associated with multiparity, prior history of PID, absence of pathology, and Medicaid payer status. The Maine Women's Health Study, a prospective cohort study, studied outcomes of 199 women with frequent pain at baseline who underwent hysterectomy. In this cohort, only 11% reported persistent symptoms after their surgery (184).

The American College of Obstetricians and Gynecologists outlined criteria that should be met before performing a hysterectomy for pelvic pain (185). **They require at least 6 months of pelvic pain without any otherwise correctable pathology.** When deciding on the surgical approach, consideration should be given to a vaginal or laparoscopic hysterectomy over an abdominal approach, if there are no extensive adhesions expected or large uterine/fibroid size does not preclude it. There are many studies that confirm less morbidity and shorter hospital stays with vaginal compared with abdominal hysterectomies (186). A prospective study of abdominal versus vaginal versus laparoscopically assisted surgery did not find any statistical difference or worsening of outcomes of urinary or sexual function between the different approaches at 6 months (186).

KEY POINTS

1 Endometriosis is diagnosed by visualization of lesions during laparoscopy, ideally with histologic confirmation; positive histology confirms the diagnosis, but negative histology does not exclude it.

2 Endometriosis can be associated with infertility, pelvic pain, that is, dysmenorrhea, dyspareunia and nonmenstrual pain, and reduced quality of life.

3 Severe or deep endometriosis should be managed in a facility with the necessary expertise to provide treatment in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy.

4 The American Society for Reproductive Medicine (ASRM) staging system for endometriosis is subjective and correlates poorly with pelvic pain and infertility.

5 The Endometriosis Fertility Index (EFI) predicts non-in vitro fertilization (IVF) pregnancy rates after surgical treatment of endometriosis.

6 Suppression of ovarian function reduces pain associated with endometriosis. Different classes of hormonal drugs—combination oral contraceptives, progestins, gonadotropin-releasing hormone (GnRH) agonists—are equally effective in reducing pain but have differing side effects and costs.

7 Ablation or resection of endometriotic lesions plus adhesiolysis in minimal to mild endometriosis is more effective than diagnostic laparoscopy alone in improving fertility.

8 Suppression of ovarian function is not effective in improving subsequent fertility in patients with endometriosis.

Endometriosis is defined as the presence of endometrial-like tissue (glands and/or stroma) outside the uterus. The most frequent sites of implantation are the pelvic viscera and the peritoneum but, although rare, it can also be found in the pericardium, pleura, lung, and even the brain. Endometriosis varies in appearance from a few minimal lesions on otherwise intact pelvic organs, to deep infiltrating nodules and massive ovarian endometriotic cysts with extensive adhesions involving bowel, bladder, and ureter resulting in significant distortion of the pelvic anatomy. It is estimated to occur in 10% of reproductive-age women and is associated with pelvic pain and infertility. Considerable progress in understanding the pathogenesis, spontaneous evolution, diagnosis, and treatment of endometriosis has occurred. **The European Society for Human Reproduction and Embryology (ESHRE) guidelines for the clinical management of endometriosis are published and regularly updated to present emerging clinical evidence** (1).

EPIDEMIOLOGY

Prevalence

Endometriosis is found predominantly in women of reproductive age but is reported in adolescents and in postmenopausal women receiving hormonal replacement therapy (2). It is found in women of all ethnic and social groups. **Estimates of the frequency of endometriosis vary widely, but the prevalence of the condition is assumed to be around 10% women of reproductive age** (3,4). Although no consistent information is available on the incidence of the disease, temporal trends suggest an increase among women of reproductive age (4). The World Endometriosis Research Foundation (WERF) EndoCost study calculated the costs of women with histologically proven endometriosis treated in referral centers (5). The study showed that the costs to women with endometriosis are substantial, resulting in an economic burden similar to the estimated annual health care costs for diabetes mellitus, Crohn disease, and rheumatoid arthritis (5).

In women with pelvic pain or infertility, a high prevalence of endometriosis (from a low of 20% to a high of 90%) is reported (6,7). **In women with unexplained infertility (regular menstrual cycle, normal pelvic imaging, normospermic partner) with or without pain, the prevalence of endometriosis is reported to be as high as 50%** (8). **In asymptomatic women undergoing tubal ligation (women of proven fertility), the prevalence of endometriosis ranges from 3% to 43%** (9–14). This variation in the reported prevalence may be explained by several factors. First, it may vary with the diagnostic method used: laparoscopy, the operation of choice for diagnosis, is a better method than laparotomy for diagnosing minimal to mild endometriosis. Second, minimal or mild endometriosis may be more thoroughly evaluated in asymptomatic patients than in asymptomatic patients during tubal sterilization. Third, the interest and experience of the surgeon has relevance because there is a wide variation in the appearance of subtle endometriosis implants, cysts, and adhesions. Most studies that evaluate the prevalence of endometriosis in women of reproductive age lack histologic confirmation (9–11,15–20).

Risk and Protective Factors

The following are possible risk factors for endometriosis: infertility, red hair, early age at menarche, shorter menstrual cycle length, hypermenorrhea, nulliparity, müllerian anomalies, low birth weight (less than 7 pounds), being one of multiple fetal gestation, *diethylstilbestrol* (DES) exposure, endometriosis in first-degree relative, tall height, dioxin or polychlorinated biphenyls (PCB) exposure, a diet high in fat and red meat, and prior surgeries or medical therapy for endometriosis (21,22). Prior use of contraception or intrauterine device (IUD), or smoking is not associated with increased risk of endometriosis (23,24). **Protective factors against the development of endometriosis include multiparity, lactation, tobacco exposure *in utero,* increased body mass index, increased waist-to-hip ratios, and diet high in vegetables and fruits** (21,25). Some evidence suggests that women with a "pinpoint cervix" have an increased risk for endometriosis, but more studies are needed to confirm this observation (26).

Endometriosis and Cancer

Several publications link endometriosis with an increased risk for certain gynecologic and nongynecologic cancers (27,28). These associations are controversial and no good data exist to inform clinicians regarding the best management of patients who might be at risk of developing such cancers (1). Endometriosis should not be considered a medical condition associated with a clinically relevant risk of any specific cancer (29). **Data from large cohort and case-control studies indicate an increased risk of**

ovarian cancers in women with endometriosis. The observed effect sizes are modest, varying between 1.3 and 1.9 (30). **Evidence from clinical series consistently demonstrates that the association is confined to the endometrioid and clear-cell histologic types of ovarian cancer** (31). A causal relationship between endometriosis and these specific histotypes of ovarian cancer should be recognized, but the low magnitude of the risk observed is consistent with the view that ectopic endometrium undergoes malignant transformation with a frequency similar to its eutopic counterpart (32). Evidence for an association with melanoma and non-Hodgkin lymphoma has been reported but needs to be verified, whereas an increased risk for other gynecologic cancer types is not supported (31).

ETIOLOGY

Although signs and symptoms of endometriosis have been described since the 1800s, its widespread occurrence was acknowledged only during the 20th century. **Endometriosis is an estrogen-dependent disease. Three theories were proposed to explain the pathogenesis of endometriosis:**

1. **Ectopic transplantation of endometrial tissue**
2. **Coelomic metaplasia**
3. **The induction theory**

No single theory can account for the location of endometriosis in all cases.

Transplantation Theory

The transplantation theory, originally proposed by Sampson in the mid-1920s, is based on the assumption that endometriosis is caused by the seeding and implantation of endometrial cells by transtubal regurgitation during menstruation (33). **Substantial clinical and experimental data support this hypothesis** (6,34). Retrograde menstruation occurs in 70% to 90% of women, and it may be more common in women with endometriosis than in those without the disease (9,35). The presence of endometrial cells in the peritoneal fluid, indicating retrograde menstruation, is reported in 59% to 79% of women during menses or in the early follicular phase, and these cells can be cultured in vitro (36,37). The presence of endometrial cells in the dialysate of women undergoing peritoneal dialysis during menses supports the theory of retrograde menstruation (38). Endometriosis is most often found in dependent portions of the pelvis —the ovaries, the anterior and posterior cul-de-sac, the uterosacral ligaments, the posterior uterus, and the posterior broad ligaments (39). The menstrual reflux theory combined with the clockwise peritoneal fluid current explains why endometriosis is predominantly located on the left side of the pelvis (refluxed endometrial cells implant

more easily in the rectosigmoidal area) and why diaphragmatic endometriosis is found more frequently on the right side (refluxed endometrial cells implant there by the falciform ligament) (40,41).

Endometrium obtained during menses can grow when injected beneath abdominal skin or into the pelvic cavity of animals (42,43). Endometriosis was found in 50% of *Rhesus* monkeys after surgical transposition of the cervix to allow intra-abdominal menstruation (44). Increased retrograde menstruation by obstruction of the outflow of menstrual fluid from the uterus is associated with a higher incidence of endometriosis in women and in baboons (45–47). Women with shorter intervals between menstruation and longer duration of menses are more likely to have retrograde menstruation and are at higher risk for endometriosis (48). Menstruation is associated with intraperitoneal inflammation in women and baboons, but a limited quantity of endometrial cells can be identified in peritoneal fluid during menstruation in women, possibly because endometrial–peritoneal attachment is reported to occur within 24 hours (49–51). Ovarian endometriosis may be caused by either retrograde menstruation or by lymphatic flow from the uterus to the ovary; metaplasia and bleeding from a corpus luteum may be a critical event in the development of some endometriomas (52–54).

Deep endometriosis, with a depth of at least 5 mm beneath the peritoneum, can present as nodules in the cul-de-sac, rectosigmoid, and bladder area and occurs with other forms of peritoneal or ovarian endometriosis (55). According to anatomic, surgical, and pathologic findings, deep endometriotic lesions originate intraperitoneally rather than extraperitoneally. The lateral asymmetry in the occurrence of ureteral endometriosis is compatible with the menstrual reflux theory and with the anatomic differences of the left and right hemipelvis (40). Adolescents and young women can have peritoneal disease (56). This observation, together with evidence from the development and spontaneous evolution of endometriosis in baboons, supports the notion that endometriosis starts as peritoneal disease and that the three different phenotypes and locations of endometriosis (peritoneal, ovarian, and deep) represent a homogeneous disease continuum with a single origin (i.e., regurgitated endometrium), rather than three different disease entities (40,57,58).

Extrapelvic endometriosis, although rare (1% to 2%), may result from vascular or lymphatic dissemination of endometrial cells to many gynecologic (vulva, vagina, cervix) and nongynecologic sites. The latter include bowel (appendix, colon, small intestine, hernia sacs), lungs and pleural cavity, skin (cesarean section, episiotomy or other surgical scars, inguinal region, extremities, umbilicus), lymph glands, nerves, and brain (59).

Coelomic Metaplasia

The transformation (metaplasia) of coelomic epithelium into endometrial tissue is a proposed mechanism for the origin of endometriosis. One study evaluating structural

and cell surface antigen expression in the rete ovarii and epoophoron reported little commonality between endometriosis and ovarian surface epithelium, suggesting that serosal metaplasia is unlikely in the ovary (60). The results of another study involving the genetic induction of endometriosis in mice suggest that ovarian endometriotic lesions may arise directly from the ovarian surface epithelium through a metaplastic differentiation process induced by activation of an oncogenic *K-ras* allele (53).

Induction Theory

The induction theory is an extension of the coelomic metaplasia theory. It proposes that an endogenous (undefined) biochemical factor can induce undifferentiated peritoneal cells to develop into endometrial tissue. This theory is supported by experiments in rabbits but is not substantiated in women or nonhuman primates (61,62).

Genetic Factors

Endometriosis is a complex disorder caused by a combination of multiple genetic and environmental factors. These genetic factors need to be divided into germline and somatic genetic variants. The former is inherited and results in a higher chance of developing endometriosis, the latter are somatic alterations that possibly play a role in the pathophysiology of endometriosis.

Germline Variants

Inherited genetic variants associated with endometriosis confer a genetic susceptibility to develop the disease but represent only approximately 50% of the risk associated with the disease (63). The heritable component of endometriosis is demonstrated by familial clustering in humans and in *Rhesus* monkeys, a founder effect detected in the Icelandic population, higher concordance in monozygotic versus dizygotic twins, a similar age at onset of symptoms in affected nontwin sisters, an increased prevalence of endometriosis among first-degree relatives and a 15% prevalence of magnetic resonance imaging (MRI) findings suggestive of endometriosis in the first-degree relatives of women with ASRM stage III or IV disease (64). The induction of human-like endometriosis in mice by genetic activation of an oncogenic *K-ras* allele lends further support to the genetic basis of this disorder (53).

The risk of endometriosis is seven times greater if a first-degree relative is affected by endometriosis (65). **Because no specific mendelian inheritance pattern is identified, multifactorial inheritance is postulated.** Family linkage studies and genome-wide association studies (GWAS) have provided insights on the genetic variants contributing to the hereditary risk of endometriosis. Family linkage studies identify genetic variants that lead to clustering of endometriosis in certain families, but these variants are often rare in the general population. GWAS studies uncover common genetic variants in the general population related to an increased risk of endometriosis

(63).

A meta-analysis of 11 GWAS identified 19 independent single nucleotide polymorphisms associated with endometriosis (66). However, all these polymorphisms combined explain only approximately 5% of variance in endometriosis. These genetic variants are located in or near a wide variety of genes with functions in diverse pathways: sex steroid hormone signaling (FSHB, ESR1), inflammation (NFE2L3), oncogenesis (ID4), uterine development (HOXA10, HOXA11), WNT signaling (WNT4, MIR148), estrogen responsive genes (GREB1, KDR) and genes involved in the actin cytoskeleton or cellular adhesion (FN1, VEZT, ANRIL). Large genome-wide linkage studies, including more than 1,300 families with multiple women affected by endometriosis, have identified three linkage regions of endometriosis: on chromosome 10q26, chromosome 20p13, and chromosome 7p13-15 (63,67,68). The genes in these linkage regions have roles in estrogen metabolism (CYP2C19 in the 10q26 region) and in endometrial or uterine development (INHBA, SFRP4 and HOXA10 in the 7p13-15 region).

Functional studies of the genes in these endometriosis risk loci are needed to elucidate their precise role and determine the effects of the variants in underlying pathways. These targeted functional gene studies have the potential to provide us with important new insights on the pathogenesis of endometriosis.

Somatic Alterations

Aneuploidy

Epithelial cells of endometriotic cysts are monoclonal on the basis of phosphoglycerate kinase gene methylation, and normal endometrial glands are monoclonal (69,70). In a comparison of endometriotic tissue with eutopic endometrium, flow cytometric DNA analysis failed to show aneuploidy (71). Studies using comparative genomic hybridization, or multicolor *in situ* hybridization, showed aneuploidy for chromosomes 11, 16, and 17, increased heterogeneity of chromosome 17 aneuploidy, and losses of 1p and 22q (50%), 5p (33%), 6q (27%), 70 (22%), 9q (22%), and 16 (22%) of 18 selected endometriotic tissues (72–74). In another study, trisomies 1 and 7, and monosomies 9 and 17 were found in endometriosis, ovarian endometrioid adenocarcinoma, and normal endometrium (75). The proportions of aneusomic cells were significantly higher in ovarian endometriosis compared with extragonadal endometriosis and normal endometrium (p <0.001), suggesting a role of the ovarian stromal milieu in the induction of genetic changes, which may lead to invasive cancer in isolated cases (75).

Microsatellite DNA assays reveal an allelic imbalance (loss of heterozygosity) in *p16 (Ink4), GALT, p53,* and *APOA2* loci in patients with endometriosis and in stage II of endometriosis (76). Another report found a loss of heterozygosity in 28% of endometriotic lesions at one or more sites: chromosomes 9p (18%), 11q (18%), and

22q (15%) (70).

Somatic Mutations

Somatic mutations in genes or chromosomes are, by definition, never passed on to progeny but can play an important role in pathogenesis of diseases such as cancer. **The role of somatic mutations in endometriosis is not well understood.**

Patients with clear cell ovarian carcinoma or endometrioid ovarian carcinoma often have concomitant endometriosis and endometriosis is well recognized as a risk factor for these types of ovarian cancer. Investigation of endometriosis lesions occurring synchronously with clear cell ovarian carcinoma or endometrioid ovarian carcinoma showed somatic mutations in ARID1A, PIK3CA, and in the MET oncogenes (77–79). However, data on the presence of somatic alterations in noncancer-associated endometriosis are very limited. One study revealed the presence of somatic mutations in noncancer-associated deep endometriotic lesions in 19 of 24 patients (79%) (80). Five patients harbored known cancer driver mutations in ARID1A, PIK3CA, KRAS, or PPP2R1A although deep infiltrating endometriosis has virtually no risk for malignant transformation. All the tested somatic mutations appeared to be confined to the epithelial compartment of endometriotic lesions.

Immunologic Factors and Inflammation

Retrograde menstruation appears to be a common event in women and not all women who have retrograde menstruation develop endometriosis. The immune system may be altered in women with endometriosis, and it is hypothesized that the disease may develop as a result of reduced immunologic clearance of viable endometrial cells from the pelvic cavity (81,82). Endometriosis can be caused by decreased clearance of peritoneal fluid endometrial cells resulting from reduced natural killer (NK) cell activity or decreased macrophage activity (83). Decreased cell-mediated cytotoxicity toward autologous endometrial cells is associated with endometriosis (83–87). These studies used techniques that have considerable variability in target cells and methods (88,89). Whether NK cell activity is lower in patients with endometriosis than in those without endometriosis is controversial. Some reports demonstrate reduced NK activity and others found no increase in NK activity in women with moderate to severe disease (85–87,90–95). There is great variability in NK cell activity among normal individuals that may be related to variables such as smoking, drug use, and exercise (88).

In contrast, endometriosis can be considered a condition of immunologic tolerance, as opposed to ectopic endometrium, which essentially is self-tissue (81). It can be questioned why viable endometrial cells in the peritoneal fluid would be a target for NK cells or macrophages. Autotransplantation of blood vessels, muscles, skin grafts,

and other tissues is extremely successful (84–86). There is no in vitro evidence that peritoneal fluid macrophages actually attack and perform phagocytosis of viable peritoneal fluid endometrial cells. High-dose immunosuppression can slightly increase the progression of spontaneous endometriosis in baboons (96). There is no clinical evidence that the prevalence of endometriosis is increased in immunosuppressed patients. The fact that women with kidney transplants, who undergo chronic immunosuppression and are not known to have increased infertility problems can be considered indirect evidence that these patients do not develop extensive endometriosis.

Substantial evidence suggests that endometriosis is associated with a state of subclinical peritoneal inflammation, marked by an increased peritoneal fluid volume, increased peritoneal fluid white blood cell concentration (especially macrophages with increased activation status), and increased inflammatory cytokines, growth factors, and angiogenesis-promoting substances. It is reported in baboons that subclinical peritoneal inflammation occurs during menstruation and after intrapelvic injection of endometrium (94). A higher basal activation status of peritoneal macrophages in women with endometriosis may impair fertility by reducing sperm motility, increasing sperm phagocytosis, or interfering with fertilization, possibly by increased secretion of cytokines such as tumor necrosis factor α (TNF-α) (97–101). Tumor necrosis factor may facilitate the pelvic implantation of ectopic endometrium (100,101). The adherence of human endometrial stromal cells to mesothelial cells in vitro is increased by the pretreatment of mesothelial cells with physiologic doses of TNF-α (102). Macrophages or other cells may promote the growth of endometrial cells by secretion of growth and angiogenetic factors such as epidermal growth factor (EGF), macrophage-derived growth factor (MDGF), fibronectin, and adhesion molecules such as integrins (102–108). After attachment of endometrial cells to the peritoneum, subsequent invasion and growth appear to be regulated by matrix metalloproteinases (MMP) and their tissue inhibitors (109,110).

There is increasing evidence that local inflammation and secretion of prostaglandins (PGs) is related to differences in endometrial aromatase activity between women with and without endometriosis. Expression of aromatase cytochrome P450 protein and mRNA is present in human endometriotic implants but not in normal endometrium, suggesting that ectopic endometrium produces estrogens, which may be involved in the tissue growth interacting with the estrogen receptor (111). Inactivation of 17β-estradiol is impaired in endometriotic tissues because of deficient expression of 17β-hydroxysteroid dehydrogenase type 2, which is normally expressed in eutopic endometrium in response to progesterone (112). The inappropriate aromatase expression in endometriosis lesions can be stimulated by prostaglandin E_2 (PGE_2). This reaction leads to local production of E_2, which stimulates PGE_2 production, resulting in a positive-feedback system between local inflammation and estrogen-driven local

growth of ectopic endometrium (113).

The subclinical pelvic inflammatory status associated with endometriosis is reflected in the systemic circulation. Increased concentrations of C-reactive protein, serum amyloid A (SAA), TNF-α, membrane cofactor protein-1, interleukin-6 (IL-6), IL-8, and chemokine (C-C motif) receptor 1 (CCR1) are observed in peripheral blood samples of patients with endometriosis when compared with controls (114). This observation offers a basis for the development of noninvasive diagnostic tests.

Both hypothesis-driven research and system biology approaches using mRNA microarray and proteomic techniques studies show that eutopic endometrium is biologically different in women with endometriosis when compared to controls with respect to proliferation, apoptosis, angiogenesis, and inflammatory pathways (115–118). Several studies show a higher prevalence of nerve fibers and neurotrophic factors in the eutopic endometrium from women with endometriosis when compared to controls (49,119).

Environmental Factors and Dioxin

There is an increasing awareness of potential links between reproductive health, infertility, and environmental pollution. Attention was directed toward the potential role of dioxins in the pathogenesis of endometriosis, but the issue remains controversial. A meta-analysis concluded that there is insufficient evidence in women or in nonhuman primates that endometriosis is caused by dioxin exposure (120).

Human Data

A 1976 explosion of a factory in Seveso, Italy, resulted in the highest recorded levels of dioxin exposure in humans, but data are not published (121). The Seveso Women's Health Study will correlate prospective individual data on exposure to dioxin with reproductive endpoints such as the incidence of endometriosis, infertility, and decreased sperm quality. One case-control study failed to show an association in the general population between endometriosis and exposure to PCB and chlorinated pesticides during adulthood. No differences in mean plasma concentrations of 14-PCB and 11-chlorinated pesticides were found between women with and those without endometriosis (122). In another study, increased exposure to dioxin-like compounds is associated with (moderate to severe) endometriosis in a case-control study in women (123). Genetic mechanisms may play a role in dioxin exposure and the development of endometriosis. Transcripts of the *CYP1A1* gene, a dioxin-induced gene, are significantly higher (nine times higher) in endometriotic tissues than in eutopic endometrium (113). Other investigators report a similar expression of aryl hydrocarbon receptor and dioxin-related genes (using semiquantitative reverse transcriptase polymerase chain reaction) in the endometrium from women with or without endometriosis (124). In Japanese women, no association was found between endometriosis prevalence or severity and

polymorphisms for aryl hydrocarbon receptor repressor, aryl hydrocarbon (x2) receptor, and aryl hydrocarbon nuclear translocator or *CYP1A1* genes (125). Based on these data, there is insufficient evidence supporting the association between endometriosis and dioxin exposure in humans.

Nonhuman Primates

An initial retrospective case-control study reported that the prevalence of endometriosis was not statistically different ($p = 0.08$) between monkeys chronically exposed to dioxin for 4 years (11 of 14, 79%) and unexposed animals (2 of 6, 33%) after a period of 10 years. A positive correlation was found between the severity of endometriosis and dioxin dose, serum levels of dioxin, and dioxin-like chemicals (126,127). Two prospective studies evaluated the association between dioxin exposure and development of endometriosis in *Rhesus* monkeys. In one study, monkeys exposed for 12 months to low-dose dioxin (0.71 ng/kg/day) had endometriosis implants with smaller maximal and minimal diameters and similar survival rate when compared with endometriotic lesions in unexposed controls, suggesting no effect of dioxin on endometriosis (128). After 12 months of exposure to high-dose dioxin (17.86 ng/kg/day), larger diameters and a higher survival rate of endometriosis implants were observed in exposed *Rhesus* monkeys compared with unexposed controls. The second randomized study performed in 80 *Rhesus* monkeys compared those with no treatment with those treated with 0, 5, 20, 40, and 80 µg of *aroclor* (1,254 kg/day) for 6 years. Endometriosis occurred in 37% of controls and in 25% of treated monkeys as determined by laparoscopy and necropsy data (129). No association was observed between endometriosis severity and PCB exposure. These data question the importance of dioxin exposure, except at high doses, in the development of endometriosis in primates.

Rodents

Continuous exposure to 2,3,7,8-tetrachlorodibenzo-P-dioxin inhibited the growth of surgically induced endometriosis in ovariectomized mice treated with high-dose estradiol. No correlation was observed between the dose of dioxin and survival of endometrial implants, adhesions, and serum E_2 levels (130). In ovariectomized mice induced with endometriosis, similar stimulating effects of estrone and 4-chlorodiphenyl ether (4-CDE) were observed on survival rates of endometriotic mice, suggesting an estrogen-like effect of 4-CDE (131). Potential mechanisms mediating dioxin action to promote endometriosis in rodents are complex and probably different in rats and mice, and furthermore in women. The mouse appears to be a better model to elucidate these mechanisms, but both models have important limitations (132,133).

Stem Cells

In 2004 the first evidence for the presence of adult stem cells in endometrium was published (134). In one study, stem cells were identified in endometrium isolated from hysterectomy tissue. Concurrently, it was reported that some epithelial and stromal cells in human endometrium of bone marrow transplant recipients were of donor origin (135). In the next decade, a key role of adult stem cells in normal endometrial physiology was discovered (136).

Following the discovery of endometrial stem cells, it was proposed that these stem cells play a role in the pathogenesis of endometriosis. The first hypothesis is an extension of Sampson theory of retrograde menstruation: endometrial stem cells, with intrinsic abnormalities such as germline or somatic mutations, may have increased propensity to implant on the peritoneum after retrograde menstruation. Studies showed that women with endometriosis shed basalis endometrium at menstruation, increasing the likelihood of endometrial epithelial progenitor cells gaining access to the peritoneal cavity and stem cells have been identified in endometriotic lesions (136). However, the presence of endometrial stem/progenitor cells in peritoneal fluid has not yet been reported, which is crucial for identifying their role in the pathogenesis of endometriosis. A second hypothesis focuses on abnormal stem cell recruitment in patients with endometriosis (137). Stem cells from the bone marrow or alternate sources could be preferentially recruited in ectopic over eutopic endometrium through altered expression of chemotactic ligands such as CXCL12 (137). Abnormal endometrial function caused by impaired recruitment of stem cells to the eutopic endometrium could be a contributing endometrial factor to endometriosis-associated infertility (137).

Several studies have addressed the role of stem cells in endometriosis, but **no strong direct evidence for the role of endometrial stem/progenitor cells in the pathogenesis of endometriosis has been reported.**

Future Research

The study of endometriosis is compounded by the need to determine the presence or absence of pathology. The pathogenesis of endometriosis, the pathophysiology of related infertility, and the spontaneous evolution of endometriosis are being studied. At the time of diagnosis, most patients with endometriosis had the disease for an unknown period, making it difficult to initiate clinical experiments that would determine the etiology or progression of the disease (34). Because endometriosis occurs naturally only in women and nonhuman primates, and invasive experiments cannot be performed easily, it is difficult to undertake properly controlled studies.

There is a need for the development of good in vitro and in vivo models for endometriosis. The main advantage of the rodent models used to study endometriosis is their low cost relative to nonhuman primates, but the disadvantages are numerous (138–141). First of all, in these models, the type of lesion appears to be quite different from

the variety of pigmented and nonpigmented lesions observed in women (138–140). Secondly, there is a lack of standardization in rodent endometriosis models and no consensus on relevant outcome measures. Nonhuman primates are phylogenetically close to humans, have a comparable menstrual cycle, are afflicted with spontaneous endometriosis, and when induced with endometriosis, develop macroscopic lesions that are similar to those found in human disease (44,142–146). Spontaneous endometriosis in the baboon is minimal and disseminated, similar to the different stages of endometriosis in women (142,147–149).

The techniques for in vitro experiments have significantly improved, including the development of endometrial organoids (150,151). Application of these promising new techniques on endometriotic tissue and further improvement of in vitro models for endometriosis hold great potential for future research.

DIAGNOSIS

Clinical Presentation

[2] Endometriosis should be suspected in women with infertility, dysmenorrhea, dyspareunia, or chronic pelvic pain, although these symptoms can be associated with other diseases. Endometriosis may be asymptomatic, even in women with more advanced disease (i.e., ovarian endometriosis or deep endometriosis).

Endometriosis can be associated with significant gastrointestinal symptoms (pain, nausea, vomiting, early satiety, bloating and distention, altered bowel habits). A characteristic motility change (ampulla of Vater–duodenal spasm, a seizure equivalent of the enteric nervous system, along with bacterial overgrowth) is documented in most women with the disease (152). Women of reproductive age with endometriosis are not osteopenic (153).

The average delay between onset of pain symptoms and surgically confirmed endometriosis is quite long: 8 years or longer in the United Kingdom and 9 to 12 years in the United States (154). Similar durations were observed in Scandinavia and in Brazil (155,156). A delay in diagnosis of endometriosis of 6 and 3 years in women with pain and women with infertility, respectively, was reported. Over previous decades, there was a steady decrease in the delay in diagnosis and a decline in the prevalence of advanced endometriosis at first diagnosis (157). Patient awareness of endometriosis was increased. Many patients' quality of life is affected by pain, emotional impact of infertility, anger about disease recurrence, and uncertainty about the future regarding repeated surgeries or long-term medical therapy and its side effects (158). **Endometriosis should be perceived as a chronic disease, at least in a subset of highly symptomatic women, and quality-of-life should be evaluated using reliable and validated questionnaires** (159).

Pain

[3] In adult women, dysmenorrhea may be especially suggestive of endometriosis if it begins after years of pain-free menses. Dysmenorrhea often starts before the onset of menstrual bleeding and continues throughout the menstrual period. In adolescents, the pain may be present after menarche without an interval of pain-free menses. Evidence suggests that absenteeism from school and the incidence and duration of oral contraceptive (OC) use for severe primary dysmenorrhea during adolescence is higher in women who later develop deep endometriosis than in women without deep endometriosis (160).

The distribution of pain is variable but most often is bilateral. Local symptoms can arise from rectal, ureteral, and bladder involvement, and lower back pain can occur. Some women with extensive disease have no pain, whereas others with only minimal to mild disease may experience severe pelvic pain. **All endometriosis lesion types are associated with pelvic pain, including minimal to mild endometriosis** (161). Endometriomas are not associated with dysmenorrheal severity, and dysmenorrhea is less frequent in women with only ovarian endometriomas compared with other locations (162,163). Endometriomas can be considered a marker for greater severity of deep lesions (164). Deep lesions are consistently associated with pelvic pain, gastrointestinal symptoms, and painful defecation (165). The role of adhesions in pain and endometriosis is poorly understood (166).

Many studies failed to detect a correlation between the degree of pelvic pain and the severity of endometriosis (12,163,167). **Some studies reported a positive correlation between endometriosis stage and endometriosis-related dysmenorrhea or chronic pelvic pain** (168,169). In one study, a significant but weak correlation was observed between endometriosis stage and severity of dysmenorrhea and nonmenstrual pain, whereas a strong association was found between posterior cul-de-sac lesions and dyspareunia (170).

Possible mechanisms causing pain in patients with endometriosis include local peritoneal inflammation, deep infiltration with tissue damage, adhesion formation, fibrotic thickening, and collection of shed menstrual blood in endometriotic implants, resulting in painful traction with the physiologic movement of tissues (171,172). The character of pelvic pain is related to the anatomic location of deep endometriotic lesions (165). Severe pelvic pain and dyspareunia may be associated with deep endometriosis (7,171,173). In rectovaginal endometriotic nodules, a close histologic relationship was observed between nerves and endometriotic foci and between nerves and the fibrotic component of the nodule (174). Increasing evidence suggests a close relationship between the density of innervation of endometriotic lesions and pain symptoms (170).

Infertility

Many arguments support the hypothesis that there is a causal relationship between the presence of endometriosis and infertility (175). The following factors have been reported:

1. Increased prevalence of endometriosis in infertile women (33%) when compared to women of proven fertility (4%), a reduced monthly fecundity rate (MFR) in baboons with mild to severe (spontaneous or induced) endometriosis when compared to those with minimal endometriosis or a normal pelvis.
2. Trend toward a reduced MFR in infertile women with minimal to mild endometriosis when compared to women with unexplained infertility.
3. Endometriotic ovarian cysts that negatively affect the rate of spontaneous ovulation (176).
4. Dose–effect relationship: A negative correlation between the r-AFS stage of endometriosis and the MFR and cumulative pregnancy rate (175,177).
5. Reduced MFR and cumulative pregnancy rate after donor sperm insemination in women with minimal to mild endometriosis when compared to those with a normal pelvis.
6. Reduced MFR after husband sperm insemination in women with minimal to mild endometriosis when compared to those with a normal pelvis.
7. Reduced implantation rate per embryo after in vitro fertilization (IVF) in women with endometriosis when compared to women with tubal factor infertility (175,178).
8. Increased MFR and cumulative pregnancy rate after surgical removal of minimal to mild endometriosis.

When endometriosis is moderate or severe, involving the ovaries and causing adhesions that block tubo-ovarian motility and ovum pickup, it is associated with infertility (176,179). This effect was shown in primates, including cynomolgus monkeys and baboons (145,180). Numerous mechanisms (ovulatory dysfunction, luteal insufficiency, luteinized unruptured follicle syndrome, recurrent abortion, altered immunity, and intraperitoneal inflammation) are proposed as explanations, but an association between fertility and minimal or mild endometriosis remains controversial (181).

Spontaneous Abortion

A possible association between endometriosis and spontaneous abortion was suggested in uncontrolled or retrospective studies. Some controlled studies evaluating the association between endometriosis and spontaneous abortion have important methodologic shortcomings: heterogeneity between cases and controls, analysis of the abortion rate before the diagnosis of endometriosis, and selection bias of study and control groups (81,182,183). **Based on controlled prospective studies, there is no**

evidence that endometriosis is associated with (recurrent) pregnancy loss or that medical or surgical treatment of endometriosis reduces the spontaneous abortion rate (184–186). Some data suggest that miscarriage rates may be increased after treatment with assisted reproductive technology (187).

Endocrinologic Abnormalities

Endometriosis is associated with anovulation, abnormal follicular development with impaired follicle growth, reduced circulating E_2 levels during the preovulatory phase, disturbed luteinizing hormone (LH) surge patterns, premenstrual spotting, luteinized unruptured follicle syndrome, and galactorrhea, and hyperprolactinemia (188). Increased incidence and recurrence of the luteinized unruptured follicle syndrome is reported in baboons with mild endometriosis, but not in primates with minimal endometriosis or a normal pelvis (189). Luteal insufficiency with reduced circulating E_2 and progesterone levels, out-of-phase endometrial biopsies, and aberrant integrin expression was reported in the endometrium of women with endometriosis by some researchers, but these findings were not confirmed by other investigators (188,190,191). No convincing data exist to conclude that the incidence of these endocrine abnormalities is increased in women who have endometriosis.

Extrapelvic Endometriosis

Extrapelvic endometriosis, although often asymptomatic, should be suspected when symptoms of pain or a palpable mass occur outside the pelvis in a cyclic pattern. Endometriosis involving the intestinal tract (especially colon) is the most common site of extrapelvic disease and may cause abdominal and back pain, abdominal distention, cyclic rectal bleeding, constipation, and obstruction. Ureteral involvement can lead to obstruction and result in cyclic pain, dysuria, and hematuria. Endometriosis lesions on the diaphragm often result in cyclic shoulder pain. Pulmonary endometriosis can manifest as pneumothorax, hemothorax, or hemoptysis during menses. Umbilical endometriosis should be suspected when a patient has a palpable mass and cyclic pain in the umbilical area (59).

Clinical Examination

In many women with endometriosis, no abnormality is detected during the clinical examination. However, the vulva, vagina, and cervix should be inspected for any signs of endometriosis, although the occurrence of endometriosis in these areas is rare (e.g., episiotomy scar). The presence of a narrow pinpoint cervical ostium can be a risk factor for endometriosis (26). **Other signs of possible endometriosis include uterosacral or cul-de-sac nodularity, lateral or cervical displacement caused by uterosacral scarring, painful swelling of the rectovaginal septum, and unilateral**

ovarian cystic enlargement (192). In more advanced disease, the uterus is often in fixed retroversion, and the mobility of the ovaries and fallopian tubes is reduced ("frozen pelvis"). Evidence of deep endometriosis (deeper than 5 mm under the peritoneum) in the rectovaginal septum with cul-de-sac obliteration or cystic ovarian endometriosis should be suspected when there is clinical documentation of uterosacral nodularities during menses (193–195). In these cases, black-blue–colored lesions can sometimes be observed in the vagina during speculum examination.

Imaging

Based on the symptoms at presentation and the clinical examination the diagnosis of endometriosis can be suspected. However, endometriosis symptoms are not specific and the clinical examination may have false-negative results. The next step in the diagnostic workup is medical imaging. However, **no imaging modality detects endometriosis accurately enough to replace surgical visual detection and biopsy for diagnosis** and thus the gold standard for diagnosis of endometriosis remains laparoscopic visualization of lesions with histologic confirmation (196).

Ultrasound

The guidelines from the European Society of Human reproduction and Embryology (ESHRE) and American College of Obstetricians and Gynecology (ACOG) recommend transvaginal ultrasound (TVUS) as a first imaging step in the diagnostic work up of women with suspected endometriosis. However, **the sensitivity and specificity of TVUS for diagnosis of endometriosis are strongly dependent on the interest and experience of the sonographer and on the quality of the ultrasound equipment.**

In a systematic review the accuracy of TVUS for detecting the different phenotypes of endometriosis (peritoneal, endometrioma, deep infiltrating) was assessed (196). **TVUS could not reliably visualize peritoneal endometriosis (sensitivity = 65%, specificity = 95%). Compared to laparoscopy, TVUS has no value in diagnosing peritoneal endometriosis. However, TVUS is reliable in detecting or excluding the presence of an endometrioma (sensitivity = 93%, specificity = 96%). The typical ultrasound features of an endometriotic ovarian cyst in premenopausal women were described as "ground-glass echogenicity of the cyst fluid, one to four locules and no solid parts" (197). Studies evaluating the accuracy of TVUS for diagnosis of deep endometriosis mainly focus on rectovaginal or bladder nodules. TVUS can detect these deep endometriotic lesions with moderate reliability (sensitivity = 79%, specificity = 94%).** The role of TVUS in diagnosis of deep endometriosis in more distant locations is limited.

In summary, the main role of TVUS in the diagnostic workup of endometriosis is detecting the presence of an endometrioma or deep endometriotic nodule because it

establishes the diagnosis with high certainty. Moreover, **an endometrioma or a deep nodule are very rarely isolated findings.** Patients with an endometrioma or a deep nodule often have other endometriotic lesions and adhesions. Identification of an endometrioma or a deep nodule on TVUS should always be followed by a detailed investigation for other (peritoneal and deep) endometriotic lesions.

Local guidelines for the management of suspected ovarian malignancy should be followed in cases of ovarian endometrioma (1). Ultrasound scanning with or without serum CA125 testing is usually used to identify rare instances of ovarian cancer; however, CA125 levels are frequently elevated in the presence of endometriomas (1).

The absence of endometriosis on TVUS does not rule out the presence of peritoneal or deep endometriosis. Based on the patients' symptoms and clinical examination further investigation and a diagnostic laparoscopy should be considered.

Other Imaging Techniques

Other imaging techniques, including **computed tomography (CT) and MRI,** can be used to provide additional and confirmatory information, but they are not considered first line imaging modalities because of the high costs and their added value is unclear (1). Moreover, CT results in an important radiation dose, which should be avoided as much as possible in a population of young reproductive women.

MRI has a good sensitivity and specificity for the diagnosis of deep endometriosis and endometriomas, but the value in addition to TVUS is limited. A growing number of studies suggest that MRI has a role in the diagnosis of endometriosis because of a greater ability to detect small lesions and lesions on distant locations (extrapelvic endometriosis) (196). However, **a negative MRI does not rule out peritoneal endometriosis** because lesions are identified only if they are hemorrhagic, greater than 5 mm or when associated with extensive adhesions distorting the normal anatomy. **Hysterosalpingography is not recommended as a diagnostic test for endometriosis,** although the presence of filling defects (presence of hypertrophic or polypoid endometrium) has a significant positive correlation with endometriosis (positive and negative predictive values of 84% and 75%, respectively) (198).

Assessment of Intestinal and Urologic Involvement

Medical imaging plays an important role in establishing the diagnosis of endometriosis and imaging-based mapping of the extent of endometriosis is indispensable for appropriate planning of surgical management. **If there is clinical evidence of deep endometriosis, ureteral, bladder, and bowel involvement should be assessed.** Ureteral involvement may be asymptomatic in up to 50% of patients with deep endometriosis (199). Consideration should be given to performing ultrasound (transrectal, transvaginal, or renal), a CT urogram, or an MRI. A barium enema study

might be useful, depending on the individual circumstances, to map the extent of disease present, which may be multifocal (1). There is no proof that one technique is superior to another; it is recommended that the technique that is most familiar to the radiologist involved be used.

Blood and Other Tests

There is no specific blood test for the diagnosis of endometriosis. A general endometriosis screening test may be neither appropriate (risk for overdiagnosis) nor feasible. A blood test with a high sensitivity would be useful if that would identify women with symptomatic endometriosis (pelvic pain, infertility) that is not detectable by ultrasound imaging (200). This would include all cases of minimal to mild endometriosis and those cases of moderate to severe endometriosis without detectable ovarian endometriotic cysts or nodules (201). These are patients who could benefit from laparoscopic surgery to reduce endometriosis-associated pain and infertility or to diagnose and treat other pelvic causes of pelvic pain or infertility, like pelvic adhesions. From that perspective, a lower specificity would be acceptable because the main goal of such a test would be to rule in all women with potential endometriosis or other pelvic diseases who might benefit from surgery (202).

CA125

Levels of CA125, a glycoprotein from coelomic epithelium and common to most nonmucinous epithelial ovarian carcinomas, are significantly higher in women with moderate or severe endometriosis and normal in women with minimal or mild disease (203,204). It is presumed that endometriosis lesions produce peritoneal irritation and inflammation and this leads to an increased shedding of CA125 (204). During menstruation, an increase in CA125 levels was shown in women with and without endometriosis (205–209). Other studies did not find an increase during menses, or found an increase only with moderate to severe endometriosis (210–213). The levels of CA125 vary widely: in patients without endometriosis (8 to 22 U/mL in the nonmenstrual phase), in those with minimal to mild endometriosis (14 to 31 U/mL in the nonmenstrual phase), and in those with moderate to severe disease (13 to 95 U/mL in the nonmenstrual phase). **Compared with laparoscopy, measurement of serum CA125 levels has no value as a diagnostic tool** (214).

Laparoscopy

General Considerations

Unless disease is visible in the vagina or elsewhere, laparoscopy is the standard technique for visual inspection of the pelvis and establishment of a definitive

diagnosis (1). There is insufficient evidence to justify timing the laparoscopy at a specific time in the menstrual cycle. Laparoscopic recognition of endometriosis will vary with the experience of the surgeon, especially for subtle bowel, bladder, ureteral, and diaphragmatic lesions (1). A meta-analysis of its value against a histologic diagnosis showed (assuming a 10% pretest probability of endometriosis) that a positive laparoscopy increases the likelihood of disease to 32% (95% confidence interval [CI], 21–46) and a negative laparoscopy decreases the likelihood to 0.7% (95% CI, 0.1–5.0) (1,215). Diagnostic laparoscopy is associated with an approximately 3% risk of minor complications (e.g., nausea, shoulder tip pain) and a risk of major complications (e.g., bowel perforation, vascular damage) of 0.6 to 1.8 per 1,000 cases (1,216,217). Endometriosis can be treated during laparoscopy, thus combining diagnosis and therapy.

Laparoscopic Technique

During diagnostic laparoscopy, the pelvic and abdominal cavity should be systematically investigated for the presence of endometriosis. This examination should include a complete inspection and palpation with a blunt probe to check for nodularity as a sign of deep endometriosis of the bowel, bladder, uterus, tubes, ovaries, cul-de-sac, or broad ligament (Fig. 13-1). The type, location, and extent of all lesions and adhesions should be documented in the operative notes; ideally, the findings should be recorded with photographs or on video (1).

Laparoscopic Findings

The laparoscopic findings of endometriosis include peritoneal lesions, ovarian endometriotic cysts, and deep endometriosis invading the peritoneal surface with a depth of at least 5 mm. **Most patients with ovarian endometriotic cysts or deep endometriosis also have peritoneal disease.**

Peritoneal Endometriosis

Characteristic findings include typical ("powder-burn" or "gunshot") lesions on the serosal surfaces of the peritoneum. These lesions are black, dark brown, or bluish nodules or small cysts containing old hemorrhage surrounded by a variable degree of fibrosis (Fig. 13-2). Endometriosis can appear as subtle lesions, including red implants (petechial, vesicular, polypoid, hemorrhagic, red flame-like), serous or clear vesicles, white plaques or scarring, yellow-brown discoloration of the peritoneum, and subovarian adhesions **(Fig. 13-3)** (139,140,142,218,219). Histologic confirmation of the laparoscopic impression is essential for the diagnosis of endometriosis, for subtle lesions, and for the typical lesions reported to be histologically negative in 24% of cases (220,221).

Deep Endometriosis

Mild forms of deep endometriosis may be detected only by palpation under an

endometriotic lesion or by discovery of a palpable mass beneath visually normal peritoneum, most notably in the posterior cul-de-sac (Fig. 13-4) (194). **At laparoscopy, deep endometriosis may have the appearance of minimal disease, resulting in an underestimation of disease severity** (194). Reduced size of the cul-de-sac in women with deep endometriosis suggests that such lesions develop not in the rectovaginal septum but intraperitoneally and that burial of anterior rectal wall adhesions creates a false bottom, giving an erroneous impression of extraperitoneal origin (222).

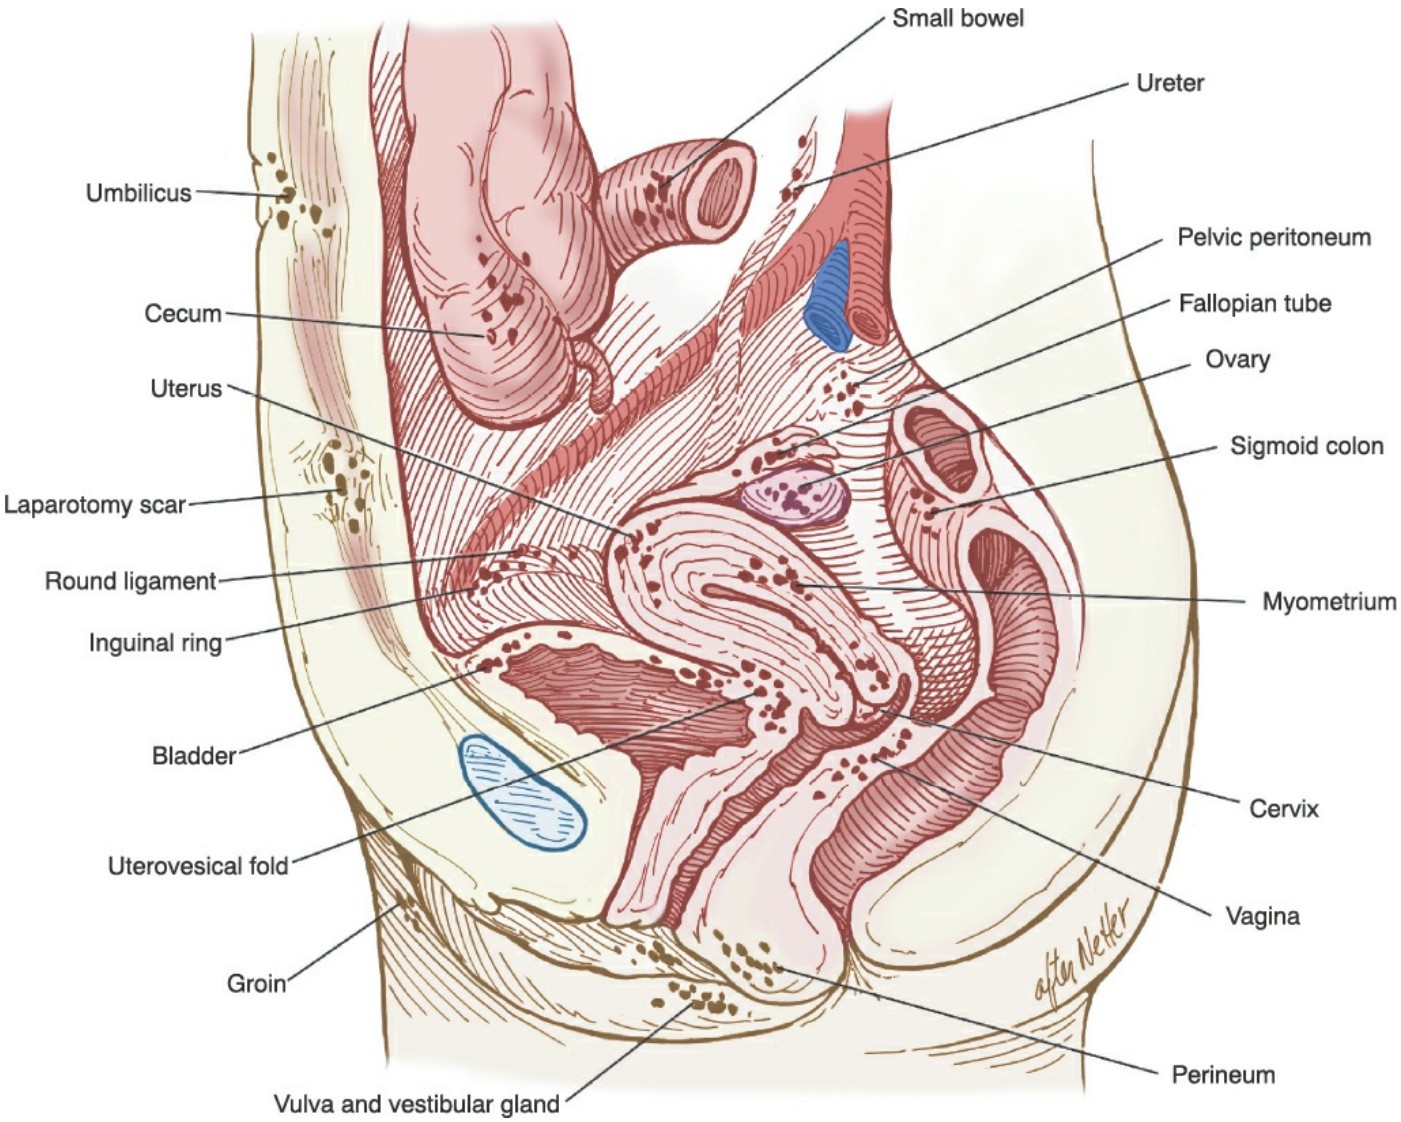

FIGURE 13-1 Pelvic endometriosis.

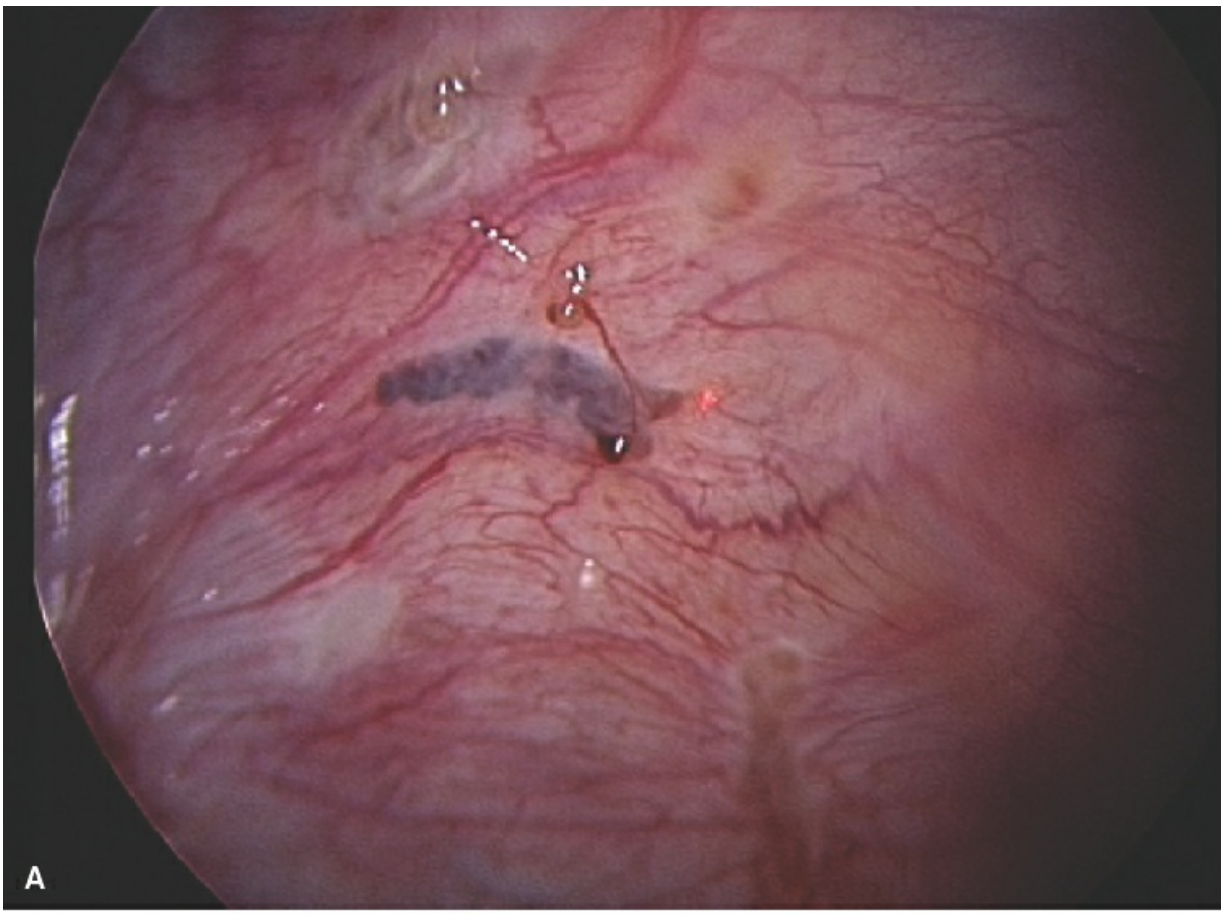

Ovarian Endometriosis

The diagnosis of ovarian endometriosis is facilitated by careful inspection of all sides of both ovaries, which may be difficult when adhesions are present in more advanced stages of disease (Fig. 13-5). With superficial ovarian endometriosis, lesions can be both typical and subtle. Larger ovarian endometriotic cysts (i.e.,

endometriomas) usually are located on the anterior surface of the ovary and are associated with retraction, pigmentation, and adhesions to the posterior peritoneum. **These ovarian endometriotic cysts often contain a thick, viscous dark brown fluid (i.e., "chocolate fluid"), composed of hemosiderin derived from previous intraovarian hemorrhage.** Because this fluid may be found in other conditions, such as in hemorrhagic corpus luteum cysts or neoplastic cysts, **biopsy and preferably removal of the ovarian cyst for histologic confirmation are necessary for the diagnosis** in the revised endometriosis classification of the American Society for Reproductive Medicine (ASRM). If that is not possible, the presence of an ovarian endometriotic cyst should be confirmed by the following features: cyst diameter of less than 12 cm, adhesion to pelvic sidewall or broad ligament, endometriosis on the surface of the ovary, and tarry, thick, chocolate-colored fluid content (223). Ovarian endometriosis appears to be a marker for more extensive pelvic and intestinal disease. Exclusive ovarian disease is found in only 1% of endometriosis patients, with the remaining patients having extensive pelvic or intestinal endometriosis (224).

Histologic Confirmation

[1] Positive histology confirms the diagnosis of endometriosis; negative histology does not exclude it (1). **Whether histology should be obtained when peritoneal disease alone is present is controversial; visual inspection is usually adequate but histologic confirmation of at least one lesion is ideal** (1). **In cases of ovarian endometrioma (>4 cm in diameter) and in deep endometriosis, histology is recommended to exclude rare instances of malignancy** (1).

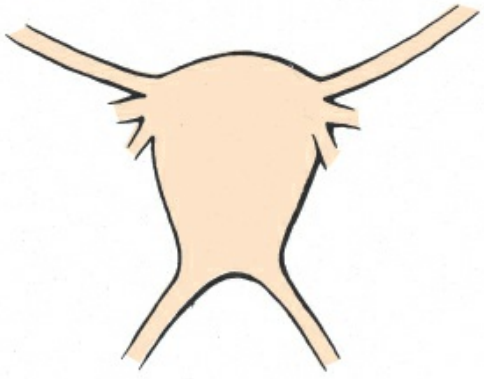

FIGURE 13-5 Revised American Society for Reproductive Medicine Classification. (From the American Society for Reproductive Medicine. Revised American Society for Reproductive Medicine classification of endometriosis. Am Soc Reprod Med 1997;5:817–821.)

In a study of 44 patients with chronic pelvic pain, endometriosis was laparoscopically diagnosed in 36%, but histologic confirmation was obtained in only 18%. This approach resulted in a low diagnostic accuracy of laparoscopic inspection with a positive predictive value of only 45%, explained by a specificity of only 77% (225).

Microscopically, endometriotic implants consist of endometrial glands and/or stroma, with or without hemosiderin-laden macrophages (Fig. 13-6). It is suggested that using these stringent and unvalidated histologic criteria may result in significant underdiagnosis of endometriosis (6). Problems in obtaining biopsies (especially small vesicles) and variability in tissue processing (step or partial instead of serial sectioning) may contribute to false-negative results. Endometrioid stroma may be more characteristic of endometriosis than endometrioid glands (226). The presence of stromal endometriosis, which contains endometrial stroma with hemosiderin-laden macrophages or hemorrhage, was reported in women and in baboons and may represent a very early event in the pathogenesis of endometriosis (148,220,221). Isolated endometrial stromal cell nodules, immunohistochemically positive for vimentin and estrogen receptor, can be found in the absence of endometrial glands along blood or lymphatic vessels (227).

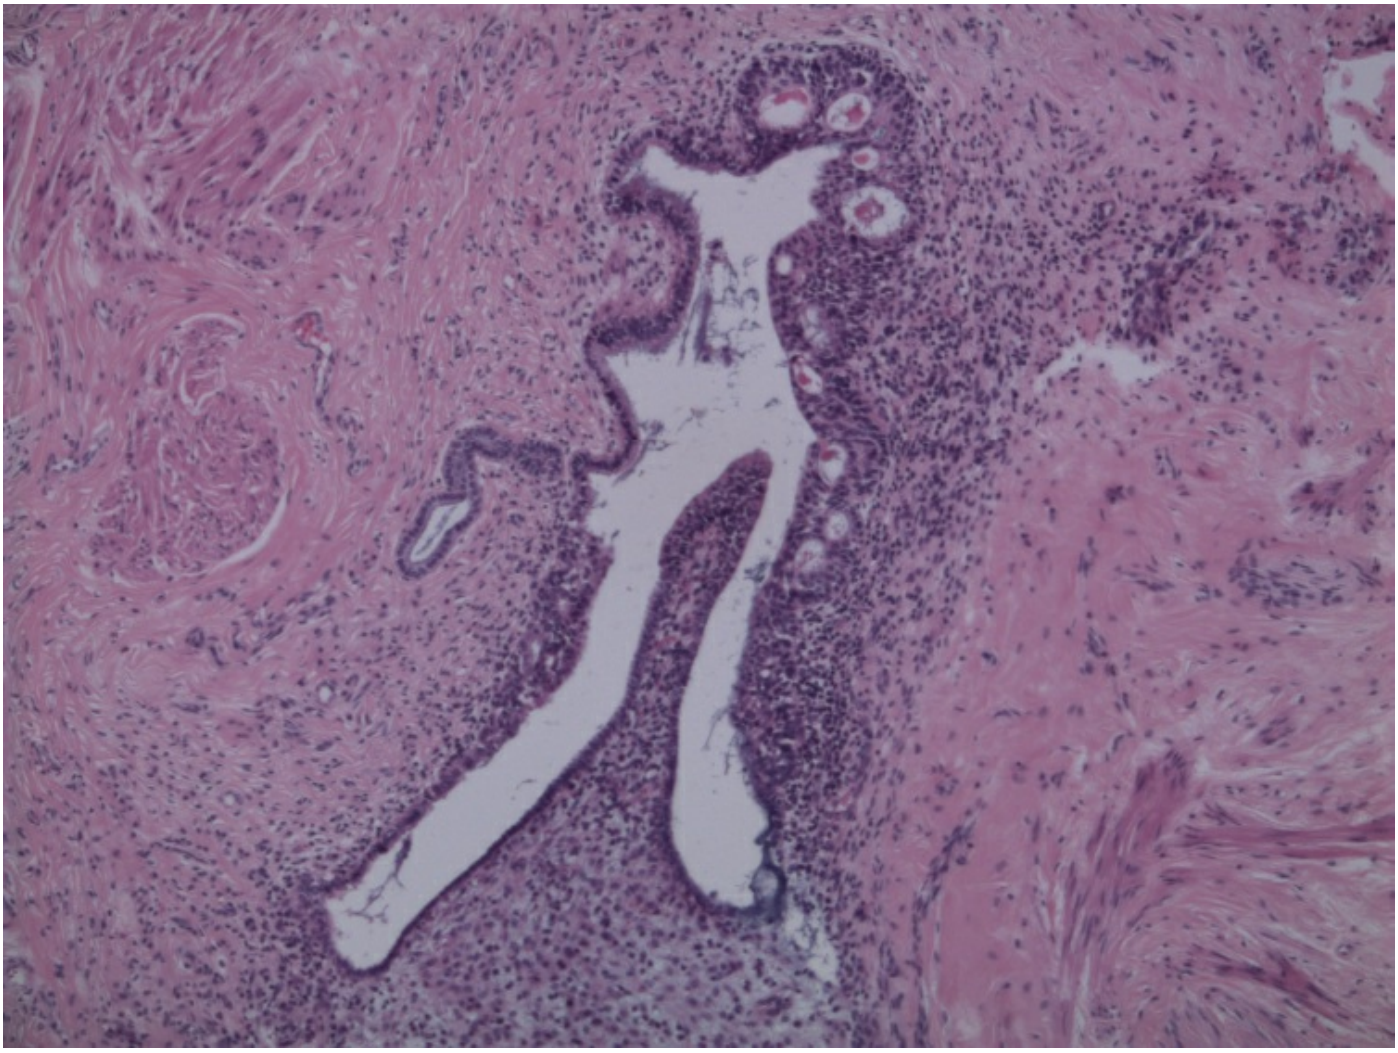

FIGURE 13-6 Histologic appearance of endometriosis: endometrial glandular epithelium, surrounded by stroma in typical lesion and clear vesicle.

Different types of lesions may have different degrees of proliferative or secretory glandular activity (226). Vascularization, mitotic activity, and the three-dimensional structure of endometriosis lesions are key factors (171,228,229). **Deep endometriosis is described as a specific type of pelvic endometriosis characterized by proliferative strands of glands and stroma in dense fibrous and smooth muscle tissue** (20). Smooth muscles are frequent components of endometriotic lesions on the peritoneum, ovary, rectovaginal septum, and uterosacral ligaments (174).

Microscopic endometriosis is defined as the presence of endometrial glands and stroma in macroscopically normal pelvic peritoneum. It is important in the histogenesis of endometriosis and its recurrence after treatment (230,231). The clinical relevance of microscopic endometriosis is controversial because it is not observed uniformly. Using undefined criteria for what constitutes normal peritoneum, peritoneal biopsy specimens of 1 to 3 cm were obtained during laparotomy from 20 patients with moderate to severe endometriosis (231). Examination of the biopsy results with low-

power scanning electron microscopy revealed unsuspected microscopic endometriosis in 25% of cases not confirmed by light microscopy. Peritoneal endometriotic foci were demonstrated by light microscopy in areas that showed no obvious evidence of disease (232).

In serial sections of laparoscopic biopsies of normal peritoneum, 10% to 15% of women had microscopic endometriosis, and endometriosis was found in 6% of those without macroscopic disease (219,233,234). Other studies were unable to detect microscopic endometriosis in 2-mm biopsy specimens of visually normal peritoneum (235–238). Examination of larger samples (5 to 15 mm) of visually normal peritoneum revealed microscopic endometriosis in only 1 of 55 patients studied (239). A histologic study of serial sections through the entire pelvic peritoneum of visually normal peritoneum from baboons with and without disease indicated that microscopic endometriosis is a rare occurrence (96). **Macroscopically appearing normal peritoneum rarely contains microscopic endometriosis** (239).

Laparoscopic Classification

Endometriosis is a complex disease and at present there is no perfect staging system available. **The most widely used staging system is the revised American Society for Reproductive Medicine classification (rASRM).** The Endometriosis Fertility Index (EFI) has been shown to predict non-IVF pregnancy rates for patients following surgical staging and treatment of endometriosis (177,240). To supplement the rASRM classification with regard to the description of deep endometriosis, the ENZIAN score was introduced (241–243). Although the ENZIAN score appears to be a good complement to the rASRM score for morphologic description of deep endometriosis and planning of surgery, it is not widely used. Recently the World Endometriosis Society (WES) published a consensus statement in which they recommend that **all women undergoing surgery should have the rASRM classification completed, women with deep endometriosis should additionally have ENZIAN completed, and women for whom future fertility is a concern should additionally have the EFI completed** (244).

American Society for Reproductive Medicine Staging

The revised ASRM staging system, is based on the appearance, size, and depth of peritoneal and ovarian implants; the presence, extent, and type of adnexal adhesions; and the degree of cul-de-sac obliteration (179,201). **In this classification system, the morphology of peritoneal and ovarian implants should be categorized as red (red, red-pink, and clear lesions), white (white, yellow-brown, and peritoneal defects), and black (black and blue lesions), according to color photographs provided by ASRM.**

This system reflects the extent of endometriotic disease but has considerable

intraobserver and interobserver variability (245,246). **[4] The ASRM classification for endometriosis is subjective and correlates poorly with pain and fertility outcomes** (175). Despite these important shortcomings the WES recommends its use because of two important reasons: it is the most widely used staging system in clinical practice and endometriosis research, and it is the rASRM system (partially) incorporated in the EFI and ENZIAN.

Endometriosis Fertility Index

[5] The EFI staging system predicts non-IVF pregnancy rates after surgical staging and treatment of endometriosis (Fig. 13-7) (177). **The EFI is based on historical and surgical factors. The historical factors are age, years of infertility, and prior pregnancies. The surgical factors consist of the total ASRM score, the ASRM endometriosis score, and the least function score, which describes functionality of the fallopian tubes, fimbriae, and ovaries.**

The EFI was designed specifically for infertility patients who have had surgical staging and treatment of their disease. It is not intended to predict any aspect of endometriosis associated pain. It is required that the male and female gametes are sufficiently functional to enable attempts at non-IVF conception. Severe uterine abnormality that is clinically significant is not included in the EFI. However, when this condition is found it does need to be taken into account in predicting pregnancy rates.

ENZIAN Classification

The ENZIAN staging system supplements the rASRM staging with a precise description of the location and extent of deep endometriosis lesions and the involvement of retroperitoneal structures or other organs.

The anatomic location of the deep endometriotic lesions is described in three compartments: A = rectovaginal septum and vagina; B = sacrouterine ligament to pelvic wall; and C = rectum and sigmoid colon. The depth of invasion is rated for all compartments (grade 1 = invasion <1 cm; grade 2 = invasion 1 to 3 cm; grade 3 = invasion >3 cm). Deep endometriotic lesions outside the pelvis and invasion of organs is registered separately: FA = adenomyosis; FB = bladder; FU = intrinsic involvement of the ureter; FI = intestinal disease cranial to the rectosigmoid junction; and FO = other locations, such as abdominal wall endometriosis. The ENZIAN classification seems to be useful in planning endometriosis surgery, but more research is needed on the correlation with pain or infertility and clinical relevant outcomes.

Spontaneous Evolution

Endometriosis appears to be a progressive disease in a significant proportion (30% to 60%) of patients. During serial observations, deterioration (47%), improvement (30%), or elimination (23%) was documented over a 6-month period (247,248). In

another study, endometriosis progressed in 64%, improved in 27%, and remained unchanged in 9% of patients over 12 months (249). A third study of 24 women reported 29% with disease progression, 29% with disease regression, and 42% with no change over 12 months. Follow-up studies in both baboons and women with spontaneous endometriosis over 24 months demonstrated disease progression in all baboons and in 6 of 7 women (250–252). Several studies reported that subtle lesions and typical implants may represent younger and older types of endometriosis, respectively. In a cross-sectional study, the incidence of subtle lesions decreased with age (253). This finding was confirmed by a 3-year prospective study that reported that the incidence, overall pelvic area involved, and volume of subtle lesions decreased with age, but in typical lesions, these parameters and the depth of infiltration increased with age (7). Remodeling of endometriotic lesions (transition between typical and subtle subtypes) is reported to occur in women and in baboons, indicating that endometriosis is a dynamic condition (254,255). Several studies in women, cynomolgus monkeys, and rodents showed that endometriosis is ameliorated after pregnancy (255–258).

The characteristics of endometriosis are variable during pregnancy, and lesions tend to enlarge during the first trimester but regress thereafter (259). Studies in baboons revealed no change in the number or surface area of endometriosis lesions during the first two trimesters of pregnancy (260). These results do not exclude a beneficial effect that may occur during the third trimester or in the immediate postpartum period. Establishment of a "pseudopregnant state" with exogenously administered estrogen and progestins is based on the belief that symptomatic improvement may result from decidualization of endometrial implants during pregnancy (261). This hypothesis is not substantiated, and it is possible that amenorrhea can explain the beneficial effect of pregnancy and lactation on endometriosis-associated pain symptoms.

MANAGEMENT

Primary Prevention

No strategies to prevent endometriosis are uniformly successful. A reduced incidence of endometriosis was reported in women who engaged in aerobic activity from an early age, but the possible protective effect of exercise was not investigated thoroughly (48). There is insufficient evidence that OC use offers protection against the development of endometriosis. One report showed an increased risk for endometriosis in a select population of women taking OCs, possibly explained by the observation that dysmenorrhea as a reason to initiate estroprogestins is significantly more common in women with endometriosis than in women without the disease (262,263). OCs inhibit ovulation, substantially reduce the volume of menstrual flow, and may interfere with implantation of refluxed endometrial cells, but the hypothesis of recommending OCs for primary prevention of endometriosis is not sufficiently substantiated (264). Although the

risk of endometriosis appears reduced during OC use, it is possible that this effect results from postponement of surgical evaluation caused by temporary suppression of pain symptoms (265). Confounding by selection and indication biases may explain the trend toward an increase in risk of endometriosis observed after discontinuation, but further clarification is needed (265).

ENDOMETRIOSIS FERTILITY INDEX (EFI) SURGERY FORM

LEAST FUNCTION (LF) SCORE AT CONCLUSION OF SURGERY

Score		Description
4	=	Normal
3	=	Mild Dysfunction
2	=	Moderate Dysfunction
1	=	Severe Dysfunction
0	=	Absent or Nonfunctional

	Left	Right		
Fallopian Tube				
Fimbria				
Ovary				
Lowest Score		+		=
	Left	Right		LF Score

To calculate the LF score, add together the lowest score for the left side and the lowest score for the right side. If an ovary is absent on one side, the LF score is obtained by doubling the lowest score on the side with the ovary.

ENDOMETRIOSIS FERTILITY INDEX (EFI)

Principles of Treatment

Treatment of endometriosis must be individualized, taking into consideration the clinical problem in its entirety, including the impact of the disease and the effect of its treatment on quality of life. Evidence-based recommendations that are continuously updated can be found in the ESHRE guidelines for the clinical management of endometriosis (1).

In most women with endometriosis, preservation of reproductive function is desirable (1). **Many women with endometriosis have pain and infertility at the same time or may desire children after sufficient pain relief, which complicates the choice of treatment.** Endometriosis surgery should be considered as reproductive surgery, defined by the World Health Organization (WHO) as "all surgical procedures carried out to diagnose, conserve, correct and/or improve reproductive function" (266). The least invasive and least expensive approach that is effective with the least long-term risks should be chosen (1). **Symptomatic endometriosis patients can be treated with analgesics, hormones, surgery, assisted reproduction, or a combination of these modalities** (1). **Regardless of the clinical profile (infertility, pain, asymptomatic findings), treatment of endometriosis may be justified because endometriosis appears to progress in 30% to 60% of patients within a year of diagnosis and it is not possible to predict in which patients it will progress** (249). Elimination of the endometriotic implants by surgical or medical treatment often provides only temporary relief. In addition to eliminating the endometriotic lesions, the goal should be to treat the sequelae (pain and infertility) often associated with this disease and to prevent recurrence of endometriosis (1). **Endometriosis is a chronic disease and the recurrence rate is high after both hormonal and surgical treatment** (1).

Treatment of extragenital endometriosis will depend on the site. If complete excision is possible, this is the treatment of choice; when this is not possible, long-term medical treatment is necessary using the same principles of medical treatment for pelvic endometriosis (1).

It is important to involve the patient in all decisions, to be flexible in considering diagnostic and therapeutic approaches, and to maintain a good relationship. It may be appropriate to seek advice from more experienced colleagues or to refer the patient to a center with the necessary expertise to offer treatments in a multidisciplinary context, including advanced laparoscopic surgery and laparotomy (1,267). Because the management of severe or deep endometriosis is complex, referral is strongly

recommended when disease of such severity is suspected or diagnosed (1).

Treatment of Endometriosis-Associated Pain

Pain may persist despite seemingly adequate medical or surgical treatment of the disease. A multidisciplinary approach involving a pain clinic and counseling should be considered early in the treatment plan. The least invasive and least expensive approach that is effective should be used (1).

Surgical Treatment

Depending on the severity of disease, diagnosis and removal of endometriosis should be performed simultaneously at the time of surgery, provided that preoperative consent was obtained (1,268–271). **The goal of surgery is to excise all visible endometriotic lesions and associated adhesions—peritoneal lesions, ovarian cysts, deep rectovaginal endometriosis—and to restore normal anatomy** (1). **Laparoscopy is preferred over laparotomy because the two techniques are equally effective and laparoscopy is associated with quicker recovery, better cosmesis, less postoperative pain, decreased costs, lower morbidity, and fewer postoperative adhesions** (1). Laparotomy is only indicated in the rare cases of advanced-stage disease where laparoscopy is impossible.

Conservative Surgery

Peritoneal Endometriosis

Endometriosis lesions can be removed during laparoscopy by surgical excision with scissors, bipolar coagulation, or laser methods (CO_2 laser, potassium-titanyl-phosphate laser, or argon laser). Some surgeons claim that the CO_2 laser is superior because it causes only minimal thermal damage, but **no evidence is available to show the superiority of one technique over another.** Surgical ablation of peritoneal endometriosis is considered equally effective as surgical excision. However, surgical excision of lesions could be preferred because it allows histologic analysis and confirmation of endometriosis.

Ovarian Endometriosis

Superficial ovarian lesions can be vaporized. The surgical management of pain associated with ovarian endometriotic cysts is controversial. The most common procedures for the treatment of ovarian endometriomas are either excision of the cyst wall or drainage and ablation of the cyst wall. During excision, the ovarian endometrioma is aspirated, followed by incision and removal of the cyst wall from the ovarian cortex with maximal preservation of normal ovarian tissue. During drainage and ablation, the ovarian endometrioma is aspirated and irrigated. Its wall can be inspected

with ovarian cystoscopy for intracystic lesions, and it is vaporized to destroy the mucosal lining of the cyst.

According to a systematic review, there is good evidence that excisional surgery for endometriomas with a diameter of 3 cm provides a more favorable outcome than drainage and ablation with regard to the recurrence of the endometrioma, recurrence of pain symptoms, and in women who were previously subfertile or had subsequent spontaneous pregnancy (272). Laparoscopic excision of the cyst wall of the endometrioma was associated with a reduced recurrence rate of the symptoms of dysmenorrhea (odds ratio [OR] 0.15; 95% CI, 0.06–0.38), dyspareunia (OR 0.08; 95% CI, 0.01–0.51), and nonmenstrual pelvic pain (OR 0.10; 95% CI, 0.02–0.56), a reduced rate of recurrence of the endometrioma (OR 0.41; 95% CI, 0.18–0.93), and with a reduced requirement for further surgery (OR 0.21; 95% CI, 0.05–0.79) than surgery to ablate the endometrioma. For those women subsequently attempting to conceive, it was associated with an increased spontaneous pregnancy rate in women who had documented prior infertility (OR 5.21; 95% CI, 2.04–13.29).

Based on this evidence, the **ESHRE guideline recommends cystectomy over drainage and coagulation because a cystectomy reduces endometriosis-associated pain and has a lower recurrence rate.** In case of very large endometriomas where excision is technically difficult without removing a large part of the ovary, a three-step procedure (marsupialization and rinsing followed by hormonal treatment with GnRH analogs and cyst wall electrocoagulation or laser vaporization 3 months later) can be considered (1,273).

It is possible that the surgical techniques used to treat ovarian endometriotic cysts may influence postoperative adhesion formation and/or ovarian function. In a randomized study comparing surgical methods to achieve ovarian hemostasis after laparoscopic endometriotic ovarian cystectomy, closure of the ovary with an intraovarian suture resulted in a lower rate and extension of postsurgical ovarian adhesions at 60 to 90 days follow-up when compared to only bipolar coagulation on the internal ovarian surface (274).

Deep Endometriosis

Deep endometriosis is usually multifocal and complete surgical excision must be performed in a one-step surgical procedure in order to avoid more than one surgery, provided the patient is fully informed (1,173,269). Because management of deep endometriosis is complex, referral to a center with sufficient expertise to offer all available treatments in a multidisciplinary approach is strongly recommended (1). Surgical management is only for symptomatic deep endometriosis. Asymptomatic patients must not undergo surgery, except for cases with complete obstruction of a ureter resulting in asymptomatic loss of renal function. Progression of the disease and appearance of specific symptoms rarely occurred in patients with asymptomatic

rectovaginal endometriosis (270). When surgical treatment is decided, the treatment must be radical with excision of all lesions (1). It is difficult to perform randomized studies to detect the best surgical technique to treat deep endometriosis because these severe cases are all managed individually and not all surgeons are familiar with all treatment options (1). Complete excision while preserving the uterus and ovarian tissue might include the resection of the uterosacral ligaments, the resection of the upper part of the posterior vaginal wall, and urologic and bowel operations.

The patients' surgical agreement must be obtained preoperatively to perform this difficult and high-risk procedure, especially in cases of expected or possible bowel or urologic surgery. Preoperative imaging is necessary to assess bowel and urologic impact of deep endometriosis. As endometriosis sometimes involves nongynecologic organs (i.e., the bowel, the urinary tract, or pelvic bones), other surgical specialists should be consulted as appropriate. These severe cases should be handled in centers with special expertise. Preoperative intestinal preparation may be recommended. Placement of ureteric catheters may facilitate the excision of periureteral endometriosis to facilitate ureterolysis and end-to-end ureteral reanastomosis that may be needed in cases of infiltrative periureteral endometriosis. The pattern of pain in endometriosis is complicated and pain does not always respond to treatment, so consultation with pain specialists may be useful.

In patients with severe endometriosis, it is common clinical practice that surgical treatment be preceded by a 3-month course of medical treatment (194). It is believed that this facilitates surgery by reducing inflammation and vascularization of lesions. The role of preoperative hormonal treatment was evaluated in a Cochrane review that concluded that there was no evidence of a benefit of preoperative medical therapy on the outcome of surgery. Therefore, although common clinical practice, the ESHRE guideline does not recommend preoperative hormonal therapy.

Surgical treatment of bladder endometriosis is usually in the form of excision of the lesion and primary closure of the bladder wall. Removal of full-thickness bladder detrusor endometriosis entails excision of the bladder dome or posterior wall, generally well above the trigone. Transurethral resection is contraindicated. Ureteral lesions may be excised after stenting the ureter. In the presence of intrinsic lesions or significant obstruction, segmental excision with end-to-end anastomosis or reimplantation with antireflux vesicoureteral plasty may be necessary (275).

Surgical excision of deep rectovaginal and rectosigmoidal endometriosis is difficult and can be associated with major complications such as bowel perforations with resulting peritonitis (276). It is debated whether this type of endometriosis is best treated by shaving, conservative excision, or resection reanastomosis, by laparoscopy and laparotomy, or laparoscopically assisted vaginal technique (277). Appendicular endometriosis is usually treated by appendectomy.

In a randomized study comparing colorectal resection for endometriosis by

laparoscopy or laparotomy, clinical outcome was similar with respect to dyschezia, bowel pain and cramping, and dysmenorrhea and dyspareunia, but laparoscopy was associated with less blood loss, fewer complications, and a higher pregnancy rate than laparotomy (278).

There are very few methodologically valid studies evaluating clinical outcome after surgery for deep endometriosis with colorectal extension, as demonstrated in a systematic review (279). In a review on the clinical outcome of surgical treatment of deep endometriosis with colorectal involvement, most of the 49 reviewed studies included complications (94%) and pain (67%); few studies reported recurrence (41%), fertility (37%), and quality of life (10%); only 29% reported (loss of) follow-up. Of 3,894 patients, 71% underwent bowel resection and anastomosis, 10% had full-thickness excision, and 17% were treated with superficial surgery. Comparison of clinical outcome between different surgical techniques was not possible. Postoperative complications were present in 0% to 3% of the patients. Although pain improvement was reported in most studies, pain evaluation was patient based in less than 50% (visual analog scale [VAS] in only 18%). Although quality of life was improved in most studies, prospective data were available for only 149 patients. Pregnancy rates were 23% to 57% with a cumulative pregnancy rate of 58% to 70% within 4 years. The overall endometriosis recurrence rate in studies (longer than 2 years follow-up) was 5% to 25%, with most of the studies reporting 10%.

Because high quality prospective studies reporting standardized and well-defined clinical outcomes after surgical treatment of deep endometriosis with long-term follow-up are needed, the Consensus On Recording Deep Endometriosis Surgery (CORDES) statement was published in 2016 (280). This consensus statement provides definition and standards for recording deep endometriosis surgery and outcome reporting in clinical trials on the surgical management of deep endometriosis.

Adhesiolysis

Endometriosis is often associated with pelvic adhesions, which can be very extensive and result in severe distortion of the pelvic anatomy. The removal of endometriosis-related adhesions (adhesiolysis) should be performed carefully and focused at restoration of the normal anatomy. However, adhesions lysed at surgery can form again. Cutting, surgical denudation, ischemia, desiccation, or abrasion can cause peritoneal trauma during surgery and the subsequent healing mechanism in the peritoneal cavity can result in adhesion formation between damaged serosal surfaces. Minimally invasive techniques such as laparoscopy reduce the risk of adhesion formation but do not eliminate it entirely.

Several barrier agents have been tested for adhesion prevention during surgery. The ESHRE guideline acknowledges that clinicians can consider the use of oxidized regenerated cellulose and potentially other barrier agents. However, **a recent**

systematic review including 18 randomized controlled trials (RCTs) with a total of 1,262 enrolled women found no effects of any barrier agent used during pelvic surgery on either pain or fertility outcomes (281). Low-quality evidence suggests that oxidized regenerated cellulose, expanded polytetrafluoroethylene and sodium hyaluronate with carboxymethylcellulose may all be more effective than no treatment in reducing the incidence of adhesion formation following pelvic surgery.

Based on this systematic review, routine use of barrier agents to prevent postoperative adhesions after pelvic surgery can be considered but cannot be recommended.

Interruption of Pelvic Nerve Pathways

Surgical interruption of pelvic nerve pathways has been suggested as an additional procedure to conservative surgery for endometriosis. Two techniques have been suggested for endometriosis-associated pain: laparoscopic uterine nerve ablation (LUNA) and presacral neurectomy (PSN). The effectiveness of LUNA and PSN was evaluated in several clinical trials and data of six RCTs were analyzed in a Cochrane review (282). Based on the systematic review it can be concluded that laparoscopic excision or ablation of endometriosis should not be combined with LUNA because this procedure offers no additional benefit. PSN is effective as an additional procedure, but it requires a high degree of surgical skill and is associated with increased adverse effects such as bleeding, constipation, urinary urgency, and less pain during the first stage of labor (1).

Outcome of Conservative Surgery

The outcome of surgical therapy in patients with endometriosis and pain is influenced by many psychological factors relating to personality, depression, and marital and sexual problems. It is difficult to evaluate scientifically the objective effect of different surgical approaches because the extirpation and destruction of the pathologic tissue can impact the results as can surgery per se, the doctor–patient relationship, complications, and other factors. There is a significant placebo response to surgical therapy: diagnostic laparoscopy without complete removal of endometriosis may alleviate pain in 50% of patients (283–285). Similar results were reported using oral placebos (286). Although some reports claimed pain relief with laser laparoscopy in 60% to 80% of patients with very low morbidity, none were prospective or controlled or allowed a definitive conclusion regarding treatment efficacy (194,287–290). The longstanding effect of surgery on pain is difficult to evaluate because the follow-up time is too short, usually just a few months. The major shortcoming of surgical treatment in endometriosis-related pain is the lack of prospective randomized studies with sufficient follow-up time to draw clear clinical conclusions.

In a systematic review assessing the efficacy of laparoscopic surgery in the treatment of pelvic pain associated with endometriosis and including five randomized controlled studies, meta-analysis demonstrated an advantage of laparoscopic surgery when compared to diagnostic laparoscopy only at 6 months (OR 5.72; 95% CI, 3.09–10.60; 171 participants, three trials) and 12 months (OR 7.72; 95% CI, 2.97–20.06; 33 participants, one trial) after surgery (291). Few women diagnosed with severe endometriosis were included in the meta-analysis and any conclusions from this meta-analysis regarding treatment of severe endometriosis should be made with caution. It was not possible to draw conclusions from the meta-analysis in which specific laparoscopic surgical intervention was most effective (291).

The extent and duration of the therapeutic benefit of surgery for endometriosis-related pain are poorly defined, and the expected benefit is operator dependent (292). In a systematic review based on three randomized controlled studies, the absolute increased benefit from destruction of lesions compared with diagnostic only operation in terms of proportion of women reporting pain relief was between 30% and 40% after short follow-up periods (292). The pain relief tended to decrease with time, and the reoperation rate, based on long-term follow-up studies, was as high as 50% (292). In most case series on excisional surgery for rectovaginal endometriosis, substantial short-term pain relief was experienced by approximately 70% to 80% of the patients who continued the study. At 1-year follow-up, approximately 50% of the women needed analgesics or hormonal treatments (292). Medium-term recurrence of lesions was observed in approximately 20% of the cases, and approximately 25% of the women underwent repetitive surgery (292). It appears that pain recurrence and reoperation rates after conservative surgery for symptomatic endometriosis are high and probably underestimated (292).

Prevention of Recurrence After Conservative Surgical Treatment

The addition of postoperative hormonal therapy to conservative surgery for endometriosis has been suggested for two main reasons. First, short-term postoperative hormonal therapy (up to 6 months after the operation) could potentially improve the outcomes of the operation through their effect on any residual endometriosis. Secondly, long-term hormonal therapy after surgery could be prescribed for secondary prevention: suppression of ovarian function and menstruation could prevent the development of new lesions.

Systemic Medical Therapy

In a systematic review published in 2004 to determine the effectiveness of systemic medical therapies used for hormonal suppression before or after surgery for endometriosis, or before and after surgery for the eradication of endometriosis, improvement of symptoms, pregnancy rates, and overall tolerability, by comparing them with no treatment or placebo, 11 trials were included (293). **Five trials compared**

postsurgical medical therapy with surgery alone (without medical therapy) and assessed the outcomes of pain recurrence, disease recurrence, and pregnancy rates (294–297). There was no statistically significant reduction in pain recurrence at 12 months (relative risk [RR] 0.76; 95% CI, 0.52–1.10), but the difference at 24 months approached statistical significance (RR 0.70; 95% CI, 0.47–1.03). **There was no statistically significant difference between the use of these medical therapies after surgery compared to surgery alone with regard to disease recurrence** (RR 1.02; 95% CI, 0.27–3.84) or pregnancy rates (RR 0.78; 95% CI, 0.50–1.22). Postsurgical medical therapy was compared to surgery plus placebo in three studies (295,298,299). There was no difference between medical therapy and placebo with regard to the measures for pain; multidimensional pain score (WMD −0.40; 95% CI, −2.15–1.35); linear scale score (0.10; 95% CI, −2.24–2.44); or change in pain (−0.40; 95% CI, −1.48–0.68). There was no difference between medical therapy and placebo for pregnancy rates (RR 1.05; 95% CI, 0.44–2.51) or total AFS scores (WMD −2.10; 95% CI, −4.56–0.36). There was no significant difference between preoperative hormonal suppression and postoperative hormonal suppression for the outcome of pain in one trial (300).

These results were confirmed in another RCT with 5 years of follow-up, showing that GnRH analog treatment with *triptorelin* depot 3.75 intramuscular after operative laparoscopy for stages III and IV endometriosis was comparable to placebo injections with respect to time to relapse of endometrioma, pain recurrence, and time to pregnancy (301).

There is circumstantial evidence that regular postoperative use of OCs effectively prevents endometrioma recurrence (302). In a prospective controlled cohort study with a median follow-up of 28 months after laparoscopic excision of ovarian endometriomata, the 36-month cumulative proportion of subjects free from endometrioma recurrence was 94% in women who always used cyclic oral contraception compared with 51% in those who never used it (p <0.001; adjusted incidence rate ratio [IRR] 0.10; 95% CI, 0.04–0.24) (302).

Some randomized controlled studies suggest that postoperative hormonal treatment can be useful in delaying the recurrence of endometriosis and/or pelvic pain. One study supported the long-term postoperative use of OCs to reduce the frequency and the severity of recurrent endometriosis-related dysmenorrhea (303). The prevention of endometriosis-related pain recurrence by postoperative long-term (24 months) cyclic and continuous administration of OCs was compared to no treatment in women after surgery for ovarian endometrioma. A significant reduction in recurrence rate and VAS scores for dysmenorrhea was evident in the continuous users versus the other groups at 6 months, and in cyclic users versus nonusers at 18 months postoperatively. No significant differences in recurrence rate and VAS scores for dyspareunia and chronic pelvic pain were demonstrated among the groups. The increase of VAS scores for

dysmenorrhea, dyspareunia, and chronic pelvic pain during the postoperative follow-up of 6 to 24 months was significantly higher in nonusers than in the users (303).

In a second study, **long-term cyclic and continuous postoperative use of OCs was shown to effectively reduce and delay endometrioma recurrence** (304). The crude recurrence rate within 24 months was significantly lower in cyclic (14.7%) and continuous users (8.2%) compared with nonusers (29%). The recurrence-free survival was significantly lower in nonusers compared with cyclic and continuous users. The mean recurrent endometrioma diameter at first observation and the mean diameter increase every 6 months of follow-up were significantly lower in cyclic and continuous users compared with nonusers, whereas **no significant differences between cyclic users and continuous users in terms of endometrioma recurrence were demonstrated** (304).

In a third study, women who underwent conservative pelvic surgery for symptomatic endometriosis stages III and IV (r-AFS) were treated postoperatively during 6 months with either placebo, GnRH agonist (*triptorelin* or *leuprorelin,* 3.75 mg every 28 days), continuous estroprogestin (*ethinylestradiol,* 0.03 mg plus *gestodene,* 0.75 mg) or dietary therapy (vitamins, minerals salts, lactic ferments, fish oil) (305). At 12 months after surgery, patients treated with postoperative hormonal suppression therapy showed a lower VAS score for dysmenorrhea than patients in the other groups. Hormonal suppression therapy and dietary supplementation were equally effective in reducing nonmenstrual pelvic pain. **Postoperative medical and dietary therapy allowed a better quality of life when compared to placebo treatment** (305).

In a systematic review to determine whether postoperative use of an *levonorgestrel* intrauterine system in women with endometriosis improves pain symptoms associated with menstruation and reduces recurrence compared with surgery only, placebo, or systemic hormones, one small RCT was identified showing a statistically significant reduction in the recurrence of painful periods in the *levonorgestrel* intrauterine system treated group compared with the control group receiving a GnRH agonist (OR 0.14; 95% CI, 0.02–0.75) (306,307). The proportion of women who were satisfied with their treatment was higher in the *levonorgestrel* intrauterine system treated group than in the control group, but this difference did not reach statistical difference (OR 3.00; 95% CI, 0.79–11.44) (306,307). In another small randomized trial, postsurgical treatment with either *levonorgestrel* intrauterine system or depot *MPA* for 3 years indicated symptom control and recurrence were comparable, but compliance and change in bone mineral density were better in the *levonorgestrel* intrauterine system treated group than in the depot *MPA* group (308).

Based on all this evidence, it can be concluded that there is no strong evidence that short-term postoperative hormonal therapy improves the outcome of conservative surgery for endometriosis, hence it is not recommended in the ESHRE guideline. However, there is a role for postoperative hormonal therapy for secondary prevention

of endometriosis. There is no good evidence to recommend one intervention and the ultimate choice will be influenced by patient preferences, side effects, and costs. **The ESHRE guideline recommends the use of postoperative hormonal therapy in two indications: (1) after cystectomy for an endometrioma in women not immediately seeking conception; and (2) after conservative surgery for endometriosis, for at least 18 to 24 months, for secondary prevention of endometriosis-associated dysmenorrhea.**

Radical Surgery: Oophorectomy and Hysterectomy

Radical procedures such as oophorectomy or total hysterectomy are indicated only in severe situations and can be performed laparoscopically or by laparotomy. Women aged 30 years or younger at the time of hysterectomy for endometriosis-associated pain are more likely than older women to have residual symptoms, to report a sense of loss, and to report more disruption from pain in different aspects of their lives (309). If a hysterectomy is performed, all visible endometriotic tissue should be removed. Although associated with improved pain relief and a reduced chance of future surgery, a bilateral salpingo-oophorectomy (BSO) in young women should be considered in only the most severe or recurrent cases (310,311). Resection is an effective treatment for rectovaginal endometriosis, in combination with hysterectomy (312).

Medical Treatment of Endometriosis-Associated Pain

If the patient desires treatment of pain symptoms that are suggestive of endometriosis in the absence of a definitive diagnosis, empirical treatment is appropriate and includes counseling, analgesia, and progestins or combined OCs. Before starting empirical treatment, other causes of pelvic pain symptoms should be ruled out, as far as possible. **It is unclear whether OCs should be taken in a conventional, continuous, or tricycle regimen. A GnRH agonist may be taken, but is not recommended,** because this class of drug is more expensive and associated with more side effects and concerns about bone density than OCs (1).

Primary Dysmenorrhea

Analgesics

Women suffering from dysmenorrhea are treated with analgesics; many women treat themselves with over-the-counter oral analgesics. Primary dysmenorrhea is defined as menstrual pain without organic pathology, based on physical examination alone, and it can be argued that some women with so-called primary dysmenorrhea probably have endometriosis (313). In a systematic review, it was concluded that **nonsteroidal anti-inflammatories (NSAIDs) were more effective than placebo for relief of primary**

dysmenorrhea, but there was insufficient evidence to suggest whether any individual NSAID was more effective than another (314). In another review, selective cyclooxygenase-2 inhibitors *rofecoxib* and *valdecoxib* were as effective as *naproxen* and more effective than placebo for the treatment of primary dysmenorrhea (315). Concerns were raised about the safety of these medications, and its manufacturers withdrew *rofecoxib* from the market.

According to another systematic review based on two relatively small, RCTs comparing *paracetamol* and *coproxamol* with placebo, *coproxamol* (*paracetamol* 650 mg and *dextropropoxyphene* 65 mg) but not *paracetamol* (500 mg 4 times daily) was more effective than placebo in reducing primary dysmenorrhea (315). This observation may be explained by the suboptimal dosage of *paracetamol* used. A small randomized trial demonstrated that *paracetamol* (*acetaminophen*) 1,000 mg four times daily was superior to placebo for the treatment of primary dysmenorrhea (316).

Oral Contraceptives

There is a paucity of information for the use of modern OCs for primary dysmenorrhea. A Cochrane review suggested that first- and second-generation OCs with 50 µg or more estrogen may be more effective than placebo treatment for dysmenorrhea. It concluded that the studies included for analysis were of poor quality and heterogeneous so that no recommendation could be made regarding the efficacy of modern, lower-dose OCs (evidence level 1a) (317). An RCT comparing a low-dose OC containing 20 µg *ethinyl estradiol* and 100 µg *levonorgestrel* with placebo showed better pain relief in adolescent girls with dysmenorrhea using the OC than placebo (318).

There is some evidence in general populations that OCs can effectively treat dysmenorrhea (319). OCs have the advantage of long-term safety; hence they can be used indefinitely in low-risk women. In clinical practice, when they are used for menstrual pain, they may be taken continuously or with one pill-free week per three cycles to reduce the number of periods or avoid them altogether. There is no direct comparison of these options with the conventional approach.

Other Treatments

Several Cochrane reviews and one clinical evidence review suggest that other treatment modalities that might be helpful in primary dysmenorrhea include supplemental thiamine or vitamin E, high-frequency transcutaneous nerve stimulation, topical heat and herbal remedy *toki-shakuyaku-san.* They suggest that treatment modalities with unknown benefits are vitamin B_{12}, fish oil, magnesium, acupuncture, other herbal remedies, and behavioral interventions, and that spinal manipulation is unlikely to be beneficial (317,319–321).

Treatment of Endometriosis-Associated Pain

Nonsteroidal Anti-Inflammatory Drugs

Considering that endometriosis is a chronic inflammatory disease, anti-inflammatory drugs would appear to be effective for treatment of endometriosis-related dysmenorrhea. Although NSAIDs are used extensively and are often the first-line therapy for reduction of endometriosis-related pain, the analgesic effect of NSAIDs was not studied extensively. Only one small, double-blind, placebo-controlled, four-period, crossover clinical study was published (322). This study claimed complete or substantial pain relief of endometriosis-related dysmenorrhea in 83% of cases treated with *naproxen* compared with 41% in cases treated with placebo. A different analysis of the data from the same study by **the Cochrane Collaborative Network did not confirm a positive effect of *naproxen* on pain relief** (OR 3.27; 95% CI, 0.61–17.69) **in women with endometriosis** (323). There was inconclusive evidence to indicate whether women taking NSAIDs (*naproxen*) were less likely to require additional analgesia (OR 0.12; 95% CI, 0.01–1.29) or to experience side effects (OR 0.46; 95% CI, 0.09–2.47) when compared to placebo (323).

Endometriosis-related pain is nociceptive, but persistent nociceptive input from endometriotic lesions leads to central sensitization manifested by somatic hyperalgesia and increased referred pain (324). The potential effectiveness of NSAIDs in the reduction of endometriosis-related pain may be explained by a local antinociceptive effect and a reduced central sensitization in addition to the anti-inflammatory effect. NSAIDs have significant side effects, including gastric ulceration and possible inhibition of ovulation. PGs are involved in the follicle rupture mechanism at ovulation, which is why women who wish to become pregnant should not take NSAIDs at the time of ovulation (325).

Hormonal Treatment

Effect of Hormonal Treatment on Pain

Because estrogen is known to stimulate the growth of endometriosis, hormonal therapy is designed to suppress estrogen synthesis, thereby inducing atrophy of ectopic endometrial implants or interrupting the cycle of stimulation and bleeding (1). Implants of endometriosis react to gonadal steroid hormones in a manner similar, but not identical, to normally stimulated ectopic endometrium. Ectopic endometrial tissue displays histologic and biochemical differences from normal ectopic endometrium in characteristics such as glandular activity (proliferation, secretion), enzyme activity (17β-hydroxysteroid dehydrogenase), and steroid (estrogen, progestin, and androgen) hormone receptor levels. Withdrawal of estrogen stimulation causes cellular inactivation and degeneration of endometriotic implants but not their disappearance.

There is strong evidence that suppression of ovarian function for 6 months reduces pain associated with endometriosis. **[6]** Combined OCs *danazol, gestrinone, medroxyprogesterone acetate,* and GnRH agonists are all equally effective but their side effects and cost profiles differ (1). **Pain relief may be of short duration,**

presumably because endometriosis and endometriosis-associated pain recur after the cessation of medical treatment. The use of *DES, methyltestosterone,* or other androgens is no longer advocated because they lack efficacy, have significant side effects, and pose risks to the fetus if pregnancy occurs during therapy. A new generation of aromatase inhibitors, oral GnRH antagonists, estrogen receptor modulators, and progesterone antagonists (PRAs) may offer new hormonal treatment options.

Hormonal Treatment for Pain From Rectovaginal Endometriosis

Surgical treatment may reduce the pain associated with rectovaginal endometriosis, but it is associated with a high risk of morbidity and major complications. The effect of medical treatment in terms of pain relief in women with rectovaginal endometriosis appears to be substantial (326). In a systematic review including 217 cases of medically treated rectovaginal endometriosis, the antalgic effect of the considered medical therapies (vaginal danazol, GnRH agonist, progestin, and estrogen–progestin combinations used transvaginally, transdermally, or orally) for the entire treatment period (from 6 to 12 months) was 60% to 90%, with patients reporting considerable reduction or complete relief from pain symptoms, with the exception of when an aromatase inhibitor was used alone (326).

Oral Contraceptives

Although OCs are effective in inducing a decidualized endometrium, the estrogenic component in OCs may stimulate endometrial growth and increase pelvic pain in the first few weeks of treatment. The long-term significance of this effect is undetermined. OCs are less costly than other treatments and may be helpful in the short-term management of endometriosis with potential long-term benefits in some women.

The use of cyclic OCs may provide prophylaxis against the development or recurrence of endometriosis. Estrogens in OCs may stimulate the proliferation of endometriosis. The reduced menstrual bleeding that often occurs in women taking OCs may be beneficial to women with prolonged, frequent menstrual bleeding, which is a known risk factor for endometriosis (48).

Further research is warranted to assess the effect of low-dose OCs in preventing endometriosis and treating associated pain, because the evidence for its efficacy is limited. In a systematic review to assess the effects of OC's in comparison with other treatments for painful symptoms of endometriosis in women of reproductive age, only one study met the inclusion criteria (all truly RCTs of the use of OCs in the treatment of women of reproductive age with symptoms ascribed to the diagnosis of endometriosis and made visually at surgical procedure were included) (327,328). In this study, a total of 57 women were allocated to two groups to compare an OC to a GnRH analog (328). Methods of randomization and allocation concealment were unclear and the analog group became amenorrheic during the treatment period of 6 months, while women in the OC group reported a decrease in dysmenorrhea (327,328). No evidence of a significant

difference between the two groups was observed in terms of dysmenorrhea at 6 months follow-up after stopping treatment (OR 0.48; 95% CI, 0.08–2.90). Some evidence for a decrease in dyspareunia was found at the end of treatment in women in the GnRH analog group; although no evidence of a significant difference in dyspareunia was observed at the end of the 6 months follow-up (OR 4.87; 95% CI, 0.96–24.65). According to these data, there is no evidence of a difference in outcomes between the OC studied and GnRH analog in the treatment of endometriosis-associated painful symptoms (327). The lack of studies with larger sample sizes or studies focusing on other comparable treatments is concerning, and further research is needed to evaluate the role of OCs in managing symptoms associated with management of endometriosis (327).

In a double-blind, randomized, placebo-controlled trial, patients with suspected or surgically proven endometriosis were randomly assigned to receive either monophasic OC (*ethinylestradiol* plus *norethisterone*) or placebo during four cycles (329). Total dysmenorrhea scores assessed by verbal rating scale were significantly decreased at the end of treatment in both groups. From the first cycle through the end of treatment, dysmenorrhea in the OC group was significantly milder than in the placebo group. The volume of ovarian endometrioma was significantly decreased in the OC group but not in the placebo group (329).

Continuous Contraceptives

The treatment of endometriosis with continuous low-dose monophasic OCs (one pill per day for 6 to 12 months) was originally used to induce pseudopregnancy caused by the resultant amenorrhea and decidualization of endometrial tissue (261). The concept was to induce an adynamic endometrium through elimination of the normal cyclic hormonal changes characteristic of the menstrual cycle (330). This induction of a pseudopregnancy state with combination OC pills is effective in reducing dysmenorrhea and pelvic pain. The subsequent amenorrhea induced by OCs could decrease the risk for disease progression by preventing or reducing (retrograde) menstruation. Pathologically, OC use is associated with decidualization of endometrial tissue, necrobiosis, and possibly absorption of the endometrial tissue (331). **There is no convincing evidence that medical therapy with OCs offers definitive therapy. Instead, the endometrial implants survive the induced atrophy and, in most patients, reactivate after termination of treatment.**

Any low-dose OC containing 20 to 35 lg of *ethinyl estradiol* used continuously can be used for the management of endometriosis. The objective of the treatment is the induction of amenorrhea, which should be continued for 6 to 12 months. Continuous or extended cyclic use of OCs is well tolerated when compared to the cyclic use of OCs for contraceptive purposes (332). In an RCT of women with recurrent moderate or severe pelvic pain after unsuccessful conservative surgery for symptomatic rectovaginal endometriosis, continuous treatment with oral *ethinyl E2,* 0.01 mg plus

cyproterone acetate, 3 mg per day, or *norethindrone acetate,* 2.5 mg per day during 12 months resulted in substantially reduced dysmenorrhea, deep dyspareunia, nonmenstrual pelvic pain, and dyschezia scores without major between-group differences in patient satisfaction rates (62% and 73%, respectively) (333).

Table 13-1 Medical Treatment of Endometriosis-Associated Pain: Effective Regimens (Usual Duration: 6 Months)

	Administration	Dose	Frequency
Progestogens			
Medroxyprogesterone acetate	PO	30 mg	Daily
Dienogest	PO	2 mg	Daily
Megestrol acetate	PO	40 mg	Daily
Lynestrenol	PO	10 mg	Daily
Dydrogesterone	PO	20–30 mg	Daily
Antiprogestins			
Gestrinone	PO	1.25 or 2.5 mg	Twice weekly
Danazol	PO	400 mg	Daily
Gonadotropin-Releasing Hormone			
Leuprolide	SC	500 mg	Daily
	IM	3.75 mg	Monthly
Goserelin	SC	3.6 mg	Monthly
Buserelin	IN	300 µg	Daily
	SC	200 µg	Daily
Nafarelin	IN	200 µg	Daily
Triptorelin	IM	3.75 mg	Monthly

PO, oral; SC, subcutaneous; IM, intramuscular; IN, intranasal.

In a patient preference cohort study to evaluate the efficacy and tolerability of a contraceptive vaginal ring (supplying 15 µg of *ethinyl E* and 120 µg per day of *etonogestrel*) and transdermal patch (delivering 20 µg of *ethinyl E* and 150 µg per day *norelgestromin*) in the treatment of women with recurrent moderate or severe pelvic pain after conservative surgery for symptomatic endometriosis and endometriosis-associated pain, patients who preferred the ring were significantly more likely to be satisfied and to comply with treatment than those who chose the patch (264). Both systems were associated with poor bleeding control when used continuously.

Progestins

Progestins may exert an antiendometriotic effect by causing initial decidualization of endometrial tissue followed by atrophy. **Progestins can be considered as the first choice for the treatment of endometriosis** because they are as effective as *danazol* or GnRH analogs and have a lower cost and possibly a lower incidence of side effects than these agents (334).

There is no evidence that any single agent or any particular dose is preferable to another. The effective doses of several progestins are summarized in Table 13-1. In most studies, the effect of treatment was evaluated after 3 to 6 months of therapy. Progestins appear to be an effective therapy for the painful symptoms associated with endometriosis (335).

Medroxyprogesterone Acetate

***MPA* is the most studied agent.** It is effective in relieving pain starting at a dose of 30 mg per day, increasing the dose based on the clinical response and bleeding patterns according to data from nonrandomized trials (336,337). A randomized placebo-controlled study reported a significant reduction in stages and scores of endometriosis in both the placebo group and the group treated with *MPA* 50 mg per day and placebo at laparoscopy within 3 months after cessation of therapy (338). These findings raise questions about the need for medical therapy with *MPA* in this dose.

Evidence suggests a possible role for depot *MPA* in the treatment of endometriosis. In a randomized controlled study, depot *MPA* (150 mg every 3 months) was more effective in the relief of dysmenorrhea than treatment with a cyclic 21-day OC (*ethinyl estradiol* 20 µg plus *desogestrel* 0.15 mg) combined with very low-dose *danazol* (50 mg per day) (339). In another multicenter, randomized, evaluator-blinded, comparator-controlled trial, depot *MPA* (150 mg) or *leuprolide acetate* (11.25 mg), given every 3 months for 6 months were equivalent in reducing endometriosis-associated pain during the study and the 12-month posttreatment follow-up period, with less impact on bone mineral density and fewer hypoestrogenic side effects, but more bleeding being observed in the depot *MPA* treated group (340). Add-back therapy would prevent the negative effects on bone density and hypoestrogenic side effects associated with GnRH-agonist therapy. In a pilot study, pain relief, side effects, and treatment satisfaction were comparable during a 12-month treatment with *etonogestrel* implantate subcutaneous (68 mg) or depot *medroxyprogesterone acetate* 150 mg intramuscular depot *MPA* in 41 patients with dysmenorrhea, nonmenstrual pelvic pain, and dyspareunia associated with histologically proven endometriosis (341). **Although depot *MPA* treatment is effective for the treatment of pain associated with endometriosis, it is not indicated in infertile women because it induces profound amenorrhea and anovulation, and a varying length of time is required for ovulation to resume after discontinuation of therapy.**

Dienogest

In two randomized noninferiority trials, treatment during 6 months with *dienogest* 2 mg per day orally demonstrated equivalent efficacy to depot *leuprolide acetate* (3.75 mg, depot intramuscular injection, every 4 weeks) or intranasal *buserelin acetate* (900 µg per day, intranasally) in relieving the pain associated with endometriosis, offering a different safety and tolerability profile (less bone loss, fewer hot flushes, more irregular genital bleeding) (342,343). *Dienogest* treatment was not compared to the recommended treatment of GnRH agonist combined with add-back in these two trials.

Other Progestins

Megestrol acetate was administered in a dose of 40 mg per day with good results (339). Pain was reduced significantly during luteal phase treatment with 60 mg *dydrogesterone,* and this improvement was still evident at 12-month follow-up (286). Other treatment strategies included *dydrogesterone* (20 to 30 mg per day, either continuously or on days 5 to 21) and *lynestrenol* (10 mg per day).

Side effects of progestins include nausea, weight gain, fluid retention, and breakthrough bleeding caused by hypoestrogenemia. Breakthrough bleeding, although common, is usually corrected by short-term (7-day) administration of *estrogen.* Depression and other mood disorders are a significant problem in about 1% of women taking these medications.

Intrauterine Progesterone

The *levonorgestrel* intrauterine system releasing 20 lg per day of *levonorgestrel* reduces endometriosis-associated pain caused by peritoneal and rectovaginal endometriosis and reduces the risk of recurrence of dysmenorrhea after conservative surgery (344). *Levonorgestrel* induces endometrial glandular atrophy and decidual transformation of the stroma, reduces endometrial cell proliferation, and increases apoptotic activity (344). A systematic review identified two randomized trials and three prospective observational studies, all involving small numbers and a heterogeneous group of patients (345). The evidence suggests that the *levonorgestrel* intrauterine system reduces endometriosis associated pain with symptom control maintained over 3 years (346–349). Twelve months of treatment results in a significant reduction in dysmenorrhea, pelvic pain, and dyspareunia; a high degree of patient satisfaction; and a significant reduction in the volume of rectovaginal endometriotic nodules (346,347). After the first year of use, a 70% to 90% reduction in menstrual blood loss is observed.

Progesterone Antagonists and Selective Progesterone Receptor Modulators

PRAs and selective progesterone receptor modulators (SPRMs) may suppress endometriosis based on their antiproliferative effects on the endometrium, without the risk for hypoestrogenism or bone loss that occurs with GnRH treatment. Four PRA/SPRMs have been approved by the FDA: *mifepristone, ulipristal acetate (UPA),*

gestrinone, and *asoprisnil*. A Cochrane review assessed the available evidence for the use of PRAs/SPRMs in the treatment of endometriosis-associated pain (350). The authors included 10 RCTs with 960 women: two RCTs compared *mifepristone* versus placebo or versus a different dose of *mifepristone,* one RCT compared *asoprisnil* versus placebo, one compared *ulipristal* versus *leuprolide acetate*, and four compared *gestrinone* versus *danazol*, gonadotropin-releasing hormone (GnRH) analogs, or a different dose of *gestrinone.* The quality of evidence ranged from high to very low. The authors conclude that there are insufficient data about the safety and effectiveness of UPA and *asoprisnil.*

Mifepristone

Mifepristone is a potent antiprogestogen with a direct inhibitory effect on human endometrial cells and, in high doses, an antiglucocorticoid action (351). One study compared *mifepristone* with placebo and reported lower rates of dysmenorrhea (OR 0.08, 95% CI, 0.04–0.17) and dyspareunia (OR 0.23, 95% CI 0.11–0.51) in the *mifepristone* group (350). However, the mifepristone group had higher rates of side effects: nearly 90% had amenorrhea and 24% had hot flushes. Two studies compared doses of *mifepristone* and found insufficient evidence to show differences between different doses in terms of effectiveness or safety, if present. However, subgroup analysis of comparisons between *mifepristone* and placebo suggest that the 2.5-mg dose may be less effective than 5 mg or 10 mg for treating dysmenorrhea or dyspareunia.

Gestrinone

Gestrinone is a 19-nortestosterone derivative with androgenic, antiprogestogenic, antiestrogenic, and antigonadotropic properties. It acts centrally and peripherally to increase free testosterone and reduce sex hormone–binding globulin levels (androgenic effect), reduce serum estradiol values to early follicular phase levels (antiestrogenic effect), reduce mean LH levels, and obliterate the LH and follicle-stimulating hormone (FSH) surge (antigonadotropic effect). *Gestrinone* causes cellular inactivation and degeneration of endometriotic implants but not their disappearance (352). Amenorrhea occurs in 50% to 100% of women and is dose dependent.

Resumption of menses generally occurs 33 days after discontinuing the medication (353,354). An advantage of *gestrinone* is its long half-life (28 hours) when given orally. The standard dose is 2.5 mg twice a week. Although 1.25 mg twice weekly is effective, a randomized study demonstrated in women with mild to moderate endometriosis that 2.5 mg *gestrinone* twice weekly for 24 weeks is more effective and has a better effect on bone mass (+7% vs. −7%) when compared with 1.25 mg *gestrinone* twice weekly for 24 weeks (355). The clinical side effects of *gestrinone* are dose dependent and similar to but less intense than those caused by *danazol* (355). They include nausea, muscle cramps, and androgenic effects such as weight gain, acne, seborrhea, and oily hair and skin.

In a multicenter, randomized, double-blind study, *gestrinone* was as effective as GnRH for the treatment of pelvic pain associated with endometriosis, with fewer side effects and the added advantage of twice-weekly administration (356). Pregnancy is contraindicated while taking *gestrinone* because of the risk for masculinization of the fetus.

Danazol

Recognized pharmacologic properties of *danazol* include suppression of GnRH or gonadotropin secretion, direct inhibition of steroidogenesis, increased metabolic clearance of estradiol and progesterone, direct antagonistic and agonistic interaction with endometrial androgen and progesterone receptors, and immunologic attenuation of potentially adverse reproductive effects (99,357). The multiple effects of *danazol* produce a high-androgen, low-estrogen environment (estrogen levels in the early follicular to postmenopausal range) that does not support the growth of endometriosis, and the amenorrhea that is produced prevents new seeding of implants from the uterus into the peritoneal cavity.

The immunologic effects of *danazol* were studied in women with endometriosis and adenomyosis and include a decrease in serum immunoglobulins, a decrease in serum C3, a rise in serum C4 levels, decreased serum levels of autoantibodies against various phospholipid antigens, and decreased serum levels of CA125 during treatment (209,358–364). *Danazol* inhibits peripheral blood lymphocyte proliferation in cultures activated by T-cell mitogens but does not affect macrophage-dependent T-lymphocyte activation of B lymphocytes (365). *Danazol* inhibits IL-1 and TNF production by monocytes in a dose-dependent manner and suppresses macrophage- and monocyte-mediated cytotoxicity of susceptible target cells in women with mild endometriosis (366,367). These immunologic findings may be important in the remission of endometriosis with *danazol* treatment and may offer an explanation of the effect of *danazol* in the treatment of a number of autoimmune diseases, including hereditary angioedema, autoimmune hemolytic anemia, systemic lupus erythematosus, and idiopathic thrombocytopenic purpura (368–372). Doses of 800 mg per day are used frequently in North America, whereas 600 mg per day is prescribed in Europe and Australia. It appears that the absence of menstruation is a better indicator of response than drug dose. A practical strategy for the use of *danazol* is to start treatment with 400 mg daily (200 mg twice a day) and increase the dose, if necessary, to achieve amenorrhea and relieve symptoms (357).

In a systematic review to determine the effectiveness of *danazol* compared to placebo or no treatment for the symptoms and signs, other than infertility, of endometriosis in women of reproductive age, five randomized trials were included in which *danazol* (alone or as adjunctive therapy to surgery) was compared to placebo or no therapy (373). Treatment with *danazol* (including adjunctive to surgical therapy) was

effective in relieving painful symptoms related to endometriosis when compared to placebo (373). Laparoscopic scores improved with *danazol* treatment (including as adjunctive therapy) when compared with either placebo or no treatment (373). Side effects were more commonly reported in those patients receiving *danazol* than for placebo (373).

The significant adverse side effects of *danazol* are related to its androgenic and hypoestrogenic properties. The most common side effects include weight gain, fluid retention, acne, oily skin, hirsutism, hot flashes, atrophic vaginitis, reduced breast size, reduced libido, fatigue, nausea, muscle cramps, and emotional instability. Deepening of the voice is another potential side effect that is nonreversible. *Danazol* can cause increased cholesterol and low-density lipoprotein levels and decreased high-density lipoproteins levels, but it is unlikely that these short-term effects are clinically important. *Danazol* is contraindicated in patients with liver disease because it is largely metabolized in the liver and may cause hepatocellular damage. *Danazol* is contraindicated in patients with hypertension, congestive heart failure, or impaired renal function because it can cause fluid retention. The use of *danazol* is contraindicated in pregnancy because of its androgenic effects on the fetus.

Because of the many side effects of oral *danazol,* alternative routes of administration were studied. In an uncontrolled pilot study, local *danazol* treatment using a vaginal *danazol* ring (1,500 mg) was effective for pain relief in deep endometriosis. This treatment did not cause the classic *danazol* side effects or detectable serum *danazol* levels, and it allowed ovulation and conception to occur (374).

Gonadotropin-Releasing Hormone Agonists

Gonadotropin-releasing hormone agonists bind to pituitary GnRH receptors and stimulate LH and FSH synthesis and release. The agonists have a much longer biologic half-life (3 to 8 hours) than endogenous GnRH (3.5 minutes), resulting in the continuous exposure of GnRH receptors to GnRH-agonist activity. This exposure causes a loss of pituitary receptors and downregulation of GnRH activity, resulting in low FSH and LH levels. Ovarian steroid production is suppressed, providing a medically induced and reversible state of pseudomenopause. A direct effect of GnRH agonists on ectopic endometrium is possible, because expression of the GnRH receptor gene is documented in ectopic endometrium and because direct inhibition of endometriosis cells was shown in vitro (375). In rat models used to study surgical adhesion formation and endometriosis, GnRH-agonist therapy decreased activity of plasminogen activators and matrix MMPs and increased the activity of their inhibitors, suggesting potential GnRH-agonist–regulated mechanisms for reducing adhesion formation (376).

Various GnRH agonists were developed and used for treating endometriosis. These agents include *leuprolide, buserelin, nafarelin, histrelin, goserelin, deslorelin,* and *triptorelin.* These drugs are inactive orally and must be administered intramuscularly,

subcutaneously, or by intranasal absorption. The best therapeutic effect is often associated with an *estradiol* dose of 20 to 40 pg/mL (75 to 150 pmol/L). These so-called depot formulations are attractive because of the reduced frequency of administration and because nasal administration can be complicated by variations in absorption rates and problems with patient compliance (354). The results with GnRH agonists are similar to those with OC *progestin* or *gestrinone* therapy. **Treatment for 3 months with a GnRH agonist is effective in improving pain for 6 months** (295).

Although GnRH agonists do not have an adverse effect on serum lipids and lipoproteins levels, their side effects are caused by hypoestrogenism and include hot flashes, vaginal dryness, reduced libido, and osteoporosis (6% to 8% loss in trabecular bone density after 6 months of therapy). Reversibility of bone loss is equivocal and therefore of concern, because treatment periods of longer than 6 months may be required (377,378). The goal is to suppress endometriosis and maintain serum estrogen levels of 30 to 45 pg/mL. More extreme estradiol suppression will induce bone loss (377). **The dose of daily GnRH agonist can be regulated by monitoring estradiol levels, by the addition of low-dose *progestin* or *estrogen–progestin* in an add-back regimen, or by draw-back therapy.**

The goal of add-back therapy is to treat endometriosis and endometriosis-associated pain effectively while preventing vasomotor symptoms and bone loss related to the hypoestrogenic state induced by GnRH analogs. Add-back therapy can be achieved by administering progestins only, including *norethisterone,* 1.2 mg, and *norethindrone acetate,* 5 mg, but bone loss is not prevented by *medrogestone,* 10 mg per day (378–380). Add-back therapy can be achieved by *tibolone,* 2.5 mg per day, or by an estrogen–progestin combination (i.e., *conjugated estrogens,* 0.625 mg, combined with *medroxyprogesterone acetate,* 2.5 mg, or with *norethindrone acetate,* 5 mg; *estradiol,* 2 mg, combined with *norethisterone acetate,* 1 mg) (374,377,379–383). Treatment for up to 2 years with combined estrogen and progestogen add-back appears to be effective and safe in terms of pain relief and bone density protection; progestogen only add-back is not protective (384).

GnRH agonists should not be prescribed to girls who have not yet attained their maximal bone density, as some concern remains about the long-term effects of GnRH analogs on bone loss. In one report, bone mineral density reduction occurred during long-term GnRH-agonist use and was not fully recovered up to 6 years after treatment (385). Use of add-back therapy (2 mg *estradiol* and 1 mg *norethisterone acetate*) did not affect this process (385). Draw-back therapy was suggested as an alternative in a study showing that 6 months of intake of 400 µg per day of *nafarelin* was as effective as a draw-back regimen consisting of 1 month of intake of 400 µg per day of *nafarelin* followed by 5 months of 200 µg per day of *nafarelin,* with similar estradiol levels (30 pg/mL) but less loss of bone mineral density (386).

Aromatase Inhibitors

Treatment of rats with induced endometriosis using the nonsteroidal aromatase inhibitor *fadrozole hydrochloride* or *YM511* resulted in a dose-dependent volume reduction of endometriosis transplants (387,388). In one case report, treatment of severe postmenopausal endometriosis with an aromatase inhibitor, *anastrozole,* 1 mg per day, and elemental *calcium,* 1.5 g per day for 9 months resulted in hypoestrogenism, pain relief after 2 months, and after 9 months a 10-fold reduction in the 30-mm diameter size of red, polypoid vaginal lesions, along with remodeling to gray tissue (389).

There is concern with the use of aromatase inhibitors such as *anastrozole* or *letrozole* in the treatment of premenopausal women because these drugs are known to stimulate ovulation and continuous administration can result in the development of functional ovarian cysts. This side effect can be prevented by combining aromatase inhibitors with ovarian suppressing drugs such as OCs or *progestins*. A systematic review assessing the effects of aromatase inhibitors in women symptomatic of pain with endometriosis included eight studies including 137 women (390). In case series (seven studies, 40 women), aromatase inhibitors combined with progestins or OCs or GnRH analogs reduced mean pain scores and lesion size and improved quality of life (390). An RCT including 97 women demonstrated that aromatase inhibitors in combination with GnRH analogs significantly improved pain (p <0.0001), compared with GnRH analogs alone, with significant improvement in multidimensional patient scores (p <0.0001), without significant reduction in spine or hipbone densities (391). Aromatase inhibitors appear to have a promising effect on pain associated with endometriosis, but the strength of this inference is limited because of a dearth of evidence and because aromatase inhibitors need to be combined with other hormonal medication (390).

Selective Estrogen Receptor Modulators

The role of selective estrogen receptor modulators (SERMs) in the treatment of endometriosis is unclear. In animal models, *raloxifene* therapy resulted in regression of endometriosis. The effect was seen in a surgically prepared, rat uterine explant model and in *Rhesus* macaques diagnosed with spontaneous endometriosis before exposure (392). In a placebo-controlled randomized trial in women with chronic pelvic pain and surgically treated biopsy-proven endometriosis, postoperative treatment with *raloxifene* for 6 months resulted in a shortened time to return of pain (defined as 2 months of pain equal to or more severe than that at study entry) and to repeat laparoscopy, suggesting that *raloxifene* is not effective in the treatment of endometriosis-associated pain (393). Biopsy-proven endometriosis was not associated with return of pain, suggesting that other factors were implicated in recurrent pelvic pain after surgery in this study (393).

GnRH Antagonists

Gonadotrophin-releasing hormone (GnRH) antagonists inhibit the action of endogenous GnRH through competitively and reversibly binding to GnRH receptors in the pituitary gland (394). Unlike the GnRH agonists, which cause an initial stimulation of the hypothalamic-pituitary-gonadal axis, GnRH antagonists have an immediate onset of action, rapidly reducing sex hormone levels without an initial surge. Gonadotropin-releasing hormone antagonists are available as injectables (*ganirelix, cetrorelix*) and increasingly as oral nonpeptide forms (*elagolix, abarelix, ozarelix*). The use of GnRH antagonists for a variety of reproductive indications, mostly in medically assisted reproduction, has greatly increased over the past decade.

The development of oral GnRH antagonists made these drugs potential candidates for treatment of endometriosis. In contrast to the GnRH agonists and injectable GnRH antagonists, that completely suppress pituitary function, **oral GnRH antagonists can produce a dose-dependent suppression of pituitary function and production of ovarian hormones** (394,395). Similar to the effect of add-back therapy during GnRH agonist treatment, oral GnRH antagonist could be used to suppress the estrogen production to a level that is adequate to control endometriosis-related pain symptoms but minimizes hypoestrogenic effects.

An RCT, including 872 women in total, showed that *elagolix* at low (150 mg once daily) and high dose (200 mg twice daily) was more effective than placebo in improving dysmenorrhea and nonmenstrual pelvic pain during a 6-month period in women with endometriosis-associated pain (395). Women who received *elagolix* had higher rates of hot flushes, higher levels of serum lipids, and greater decreases from baseline in bone mineral density than did those who received placebo. Further studies comparing oral GnRH antagonists with other treatments are required.

Nonhormonal Medical Therapy

Progress in understanding the pathogenesis of endometriosis led to the expectation that new pharmaceutic agents affecting inflammation and angiogenesis activity may prevent or inhibit the development of endometriosis. Most of these compounds were tested only in rodent models, and more research is needed in the baboon model for endometriosis and in women to ensure their safety and efficacy, as they may interfere with normal physiologic processes like ovulation, menstruation, and implantation (57).

Selective Inhibition of Tumor Necrosis Factor α

In rats with experimental endometriosis, recombinant human TNF-α–binding protein can reduce 64% of the size of endometriosis-like peritoneal lesions (396). Several prospective randomized placebo- and drug-controlled studies in baboons showed that TNF-α antagonists effectively prevent and treat induced endometriosis and endometriosis-related adhesions and are effective in the treatment of spontaneous endometriosis in baboons (57). These results were not confirmed in a small placebo-

controlled randomized trial in women with deep endometriosis, who were awaiting surgery, possibly because the endometriosis phenotype in these women (deep and fibrotic disease) was different from the endometriosis phenotype in the baboon studies (inflammatory peritoneal disease with adhesions) (397). TNF-α antagonists are less effective in fibrotic inflammatory bowel disease than in earlier nonfibrotic inflammatory bowel disease.

Pentoxifylline

In a systematic review determining the effectiveness and safety of *pentoxifylline,* which has anti-inflammatory effects in the management of endometriosis in infertile, premenopausal women, four trials involving 334 participants were included (398). *Pentoxifylline* had no significant effect on reduction in pain (one randomized trial, MD −1.60; 95% CI, −3.32–0.12), improvement of fertility (three randomized trials, OR 1.54; 95% CI, 0.89–2.66) or recurrence of endometriosis (one randomized trial, OR 0.88; 95% CI, 0.27–2.84) (398). No trials reported the effects of *pentoxifylline* on the odds of live birth rate per woman, improvement of endometriosis-related symptoms, or adverse events (398).

Peroxisome Proliferator Activated Receptor-γAgonists

Peroxisome proliferator activated receptor-γ (PPAR-γ) agonists prevent and treat endometriosis in rodent and baboon models for endometriosis and show promise for treatment of human endometriosis (399–402).

Other

Many substances potentially capable of modulating immunologic or inflammatory mechanisms involved in the onset or progression of the disease could be the targets for future research in endometriosis (403,404). Preliminary trials with cyclooxygenase-2 (COX-2) inhibitors, leukotriene receptor antagonists, TNF-α inhibitors, antiangiogenic agents and kinase inhibitors show promising results in vitro in rodent and in nonhuman primate models, but their safety is an important issue regarding human use (405).

Treatment of Endometriosis-Associated Infertility

Surgical Treatment

The treatment of endometriosis-related infertility is dependent on the age of the woman, the duration of infertility, the stage of endometriosis, the involvement of ovaries and tubes in the endometriosis process, previous therapy, associated pain symptoms, and the priorities of the patient, taking into account her attitude toward the disease, the cost of treatment, her financial means, and the expected results. If surgery is performed and spontaneous pregnancy does not occur within 2 years of surgery, there is little chance of subsequent natural conception (406).

[7] Surgical management of infertile women with minimal to mild endometriosis is controversial. Based on the results of a meta-analysis of two randomized trials, ablation of endometriotic lesions plus adhesiolysis to improve fertility in minimal to mild endometriosis is effective compared to diagnostic laparoscopy alone (185,186,407). One Canadian study reported that laparoscopic surgery enhanced fecundity in infertile women with minimal or mild endometriosis (185). They studied 341 infertile women, 20 to 39 years of age, with minimal or mild endometriosis. During diagnostic laparoscopy, the women were randomly assigned to undergo resection or ablation of visible endometriosis or diagnostic laparoscopy only. They found that **resection or ablation of minimal and mild endometriosis increased the likelihood of pregnancy in infertile women.** They were followed for 36 weeks after the laparoscopy or, for those who became pregnant during that interval, for up to 20 weeks of pregnancy. The study participants were recruited among infertile women scheduled for diagnostic laparoscopy with strict eligibility criteria. The women in the study had no previous surgical treatment for endometriosis, no medical treatment for endometriosis in the previous 9 months, and no other medical or surgical treatment for infertility in the previous 3 months. They had no history of pelvic inflammatory disease and no severe pelvic pain precluding expectant management. The diagnosis of endometriosis required the presence of one or more typical bluish or black lesions. The stage of endometriosis was determined according to the revised American Society of Reproductive Medicine classification. The MFR and the cumulative pregnancy rate after 36 weeks were significantly higher and twice as high after surgical excision of minimal to mild endometriosis (4.7% and 30.7%, respectively) than after diagnostic laparoscopy (2.4% and 17.7%, respectively). In the treated group, 31% of the patients became pregnant, compared with 18% in the nontreated group (p = 0.006). Limitations of this study include the lack of blinding of the patients, and the fecundity rate after surgery was below that observed in control groups from other studies (1,408).

In a multicenter study in Italy, a similar study design was used to compare the effect of diagnostic laparoscopy with surgical resection and ablation of visible endometriosis (on fertility parameters) in infertile women with minimal to mild endometriosis (186). Eligible patients were less than 36 years old, were trying to conceive, and had a laparoscopically confirmed diagnosis of minimal or mild endometriosis. None of the women had therapy for endometriosis or infertility. Treatment was randomly allocated during laparoscopy. There was a follow-up period of 1 year after the laparoscopy. **The results of this study did not show a beneficial effect of surgery regarding fertility.** During the follow-up period after laparoscopy, no statistically significant differences in conception and live birth rates were observed in the treated group (24% and 20%, respectively) or in the control group (29% and 22%, respectively). The methodologic

quality of the Italian study was inferior to the Canadian study (175,185,186). First, the study was underpowered, including only 91 patients, compared to 341 patients in the Canadian study. Second, it is remarkable and unexplained that the Italian study included after randomization more patients undergoing surgical excision of endometriosis (n = 54) than patients undergoing diagnostic laparoscopy (n = 47). Third, the duration of infertility was longer in the Italian study (4 years) than in the Canadian study (32 months). Duration of infertility is an important factor influencing MFR and cumulative pregnancy rates independently from other causes of infertility. The bias introduced by the long duration of infertility in couples participating in the Italian trial may have reduced the possibility to find any significant effect of surgical treatment, especially in view of the lack of proper power calculation in the Italian study. Fourth, the Italian study did not present any data on MFR or cumulative pregnancy rates using life table analysis, but only published the crude live birth rate per patient, not controlled for number of cycles per patient. Fertility outcome should be measured by more controlled variables such as MFR and the cumulative pregnancy rates or time to pregnancy. Fifth, 41 of 91 patients in the Italian study had received GnRH analog treatment after surgery (18 from the surgical excision group, 23 from the diagnostic laparoscopy group) (186). There was no specification for how long this medical treatment was given and how ovarian function was affected. The lack of this information introduces another bias influencing fertility outcome. Taking into account the relative methodologic weaknesses of the Italian study when compared to the Canadian study, extreme caution is needed before combining these two studies in a meta-analysis, especially because the fertility outcome data are reported so differently. It seems preferable to use the data of the better study demonstrating that **surgical treatment of minimal to mild endometriosis appears to offer a small, but significant, benefit with regard to fertility outcome** (1,175,185,409). The surgical removal of peritoneal endometriosis may be important to prevent progression of endometriosis. Care is needed to prevent adhesion formation that could result as a consequence of overenthusiastic excision of minimal to mild endometriosis.

Surgery for Moderate to Severe Endometriosis

When endometriosis causes mechanical distortion of the pelvis, surgery should be performed to achieve reconstruction of normal pelvic anatomy. No randomized trials or meta-analyses are available to answer the question of whether surgical excision of moderate to severe endometriosis enhances pregnancy rate (1). Most studies present only crude pregnancy rates without detailed information regarding time of follow-up and are therefore not relevant (1).

Based on three studies, there seems to be a negative correlation between the stage of endometriosis and the spontaneous cumulative pregnancy rate after surgical removal of endometriosis, but statistical significance was reached in only one study (410–412).

Other studies reported a significant negative correlation between endometriosis stage and pregnancy rate and decreased pregnancy rates when the revised scores exceeded 15 or 70 (177,410,413). Data from different studies cannot be compared easily because of retrospective design, lack of a control group, significant variability and lack of standardization with respect to inclusion criteria, surgical procedures, extent of surgery, skill of the surgeon, variable duration of follow-up without life table analysis, postoperative hormonal suppression or medically assisted reproduction, and lack of control for other infertility-related factors such as male infertility or ovarian dysfunction. These limitations explain why management differed and was not standardized, and why the cumulative pregnancy rates 9 to 12 months after surgery for moderate to severe endometriosis vary between 24% and 30% (1,414–416).

Surgery for Ovarian Endometriomas in Infertile Patients

In patients with an endometrioma receiving surgery for infertility or pain, cystectomy of the endometrioma increased the postoperative spontaneous pregnancy rate, compared to ablation of the endometrioma (417). Therefore, the **ESHRE guideline recommends cystectomy over ablation of endometriomas in infertile women with an ovarian endometrioma undergoing surgery** (1).

A randomized study demonstrated an increased ovarian follicular response to gonadotrophin stimulation for women who underwent excisional surgery when compared to ablative surgery (weighted mean difference [WMD] 0.6; 95% CI, 0.04–1.16) (418). There is insufficient evidence to favor excisional surgery over ablative surgery with respect to the chance of pregnancy after controlled ovarian stimulation and intrauterine insemination (OR 1.40; 95% CI, 0.47–4.15) or treatment with assisted reproductive technology (272).

Cystectomy and ablation of an endometrioma carry potential risks for the ovarian reserve, either by removal of normal ovarian tissue during excision or by thermal damage to the ovarian cortex during ablation. Although as little as one-tenth of an ovary may be enough to preserve function and fertility, there is concern that ovarian cystectomy with concomitant removal or destruction of normal ovarian tissue may reduce ovarian follicle reserve and reduce fertility (419). In a small prospective randomized clinical trial, 10 patients assigned to undergo laparoscopic cystectomy had a lower antral follicle count and a more pronounced reduction in serum anti-müllerian hormone (AMH) levels (from 3.9 to 2.9 ng/mL) 6 months after surgery when compared to the 10 patients treated with a "three-stage procedure" as described above (reduction in AMH levels from 4.5 to 3.99 ng/mL) (420,421). More randomized trials are needed to assess the effect of ovarian cystectomy on ovarian reserve and on reproductive function, especially with respect to conception after treatment with medically assisted reproduction.

Preoperative and Postoperative Medical Treatment

As described in the section on conservative surgery for endometriosis-associated pain, **there is no evidence of a benefit of preoperative medical therapy (*danazol*, progestins, GnRH agonists) on the outcome of endometriosis surgery.** However, in patients with severe endometriosis, it is common clinical practice that surgical treatment be preceded by a 3-month course of medical treatment because it is believed that this facilitates surgery by reducing inflammation and vascularization of lesions.

Postoperative medical treatment is not indicated because it is ineffective based on randomized trials, prevents pregnancy, and because the highest spontaneous pregnancy rates occur during the first 6 to 12 months after conservative surgery (296,298).

Hormonal Treatment

Conception is either impossible or contraindicated during medical treatment of endometriosis. [8] There is no evidence that medical treatment of minimal to mild endometriosis leads to better chances of pregnancy than expectant management (408). The published evidence does not comment on more severe disease (1).

Medically Assisted Reproduction

Medically assisted reproduction—including controlled ovarian hyperstimulation with intrauterine insemination, IVF, and gamete intrafallopian transfer—may be an option for infertility treatment in addition to surgical reconstruction and expectant management (266). Assisted reproductive technology (ART) is the method of choice when distortion of the tubo-ovarian anatomy contraindicates the use of superovulation with intrauterine insemination or gamete intrafallopian transfer (266).

The role of ART in the treatment of endometriosis-associated infertility may be limited in large tertiary care and referral centers for surgical treatment of endometriosis (422). After conservative surgery for endometriosis, 44% conceived *in vivo* (44%), and 51% of those who failed to conceive *in vivo* did not undergo ART treatment with the cumulative rate of IVF use at 36 months of infertility at 33%. The live birth/ongoing pregnancy rate per started cycle and per patient was 10% and 20%, respectively (422). For a full discussion on the application of ART in infertility, see Chapter 36.

Management of Adolescents

The most common presenting symptom in adolescents with endometriosis is cyclic pain (1). Less commonly acyclic pain, dyspareunia, gastrointestinal symptoms, irregular menses, urinary symptoms, and vaginal discharge are described (1,423–426). Similar presenting symptoms occur in adolescent patients evaluated for pelvic pain with and without endometriosis (426,427). **It is hard to predict the presence of endometriosis in adolescents with pelvic pain merely from the presenting symptoms, because**

similar symptoms occur in patients evaluated laparoscopically for pelvic pain with and without endometriosis (1,426,427). Laparoscopy should be considered for adolescents with chronic pelvic pain who do not respond to medical treatment (NSAIDs, OCs) because endometriosis is very common (up to 70%) under these circumstances (423,426–433). **Minimal and mild endometriosis, according to the revised ASRM classification, are the most common stages of the disease in adolescents.** Gynecologic surgeons should pay special attention to red, clear, or white lesions, which are more prevalent in adolescents than in adults with endometriosis (1,423–435). Mild disease can be treated by laparoscopic surgical removal of implants at the time of diagnosis, followed by continuous administration of low-dose combination OCs to prevent recurrence. More advanced disease can be treated medically for 6 months, followed by continuous OCs to prevent progression of disease. Surgery is indicated if this hormonal treatment is not effective. **GnRH agonists with add-back therapy can be considered for only adolescents older than 17 years of age who have completed pubertal and bone maturation, and then only if symptoms persist during other forms of hormonal suppression** (1,436–438).

Menstrual outflow obstructions such as müllerian anomalies may cause early development of endometriosis in adolescents. Regression of the disease was observed when surgical correction of the anomaly was accomplished (439–441).

Evidence suggests that **absenteeism from school and the incidence and duration of OC use for severe primary dysmenorrhea during adolescence is higher in women who later develop deep endometriosis than in women without deep endometriosis** (160).

Physicians treating adolescents with endometriosis should adopt a multidimensional approach, where surgery, hormonal manipulation, pain medication, mental health support, complementary and alternative therapies, and education in self-management strategies are useful components (1).

Management of Postmenopausal Women

Estrogen dependence is a central pathophysiologic hallmark of endometriosis, supported by a substantial body of molecular studies and clinical observations of symptom regression in hypoestrogenic states. Therefore, **endometriosis is typically regarded as a disease of the reproductive years, resolving after natural or iatrogenic menopause.** There is the concern that hormone replacement therapy (HRT) may reactivate endometriotic lesions, induce development of new lesions, or stimulate malignant transformation. However, a systematic review identified only 17 cases of recurrent endometriosis and 25 cases of malignant transformation in postmenopausal women taking some form of HRT (442). Only one RCT evaluated the potential risk of HRT in women with iatrogenic (bilateral oophorectomy) menopause. In a small RCT,

recurrence of pain was not significantly different in any of 57 patients in the no-treatment arm, or in 4 of 115 women receiving sequential administration of *estrogens* and *progesterone* with two 22-cm patches applied weekly to produce a controlled release of 0.05 mg per day, combined with oral administration of micronized *progesterone* administered orally (200 mg per day) for 14 days with a 16-day interval free of treatment (6,443). In this study, the endometriosis recurrence and reoperation rate were comparable in both groups (2 of 115 of the treatment group; 0 of 57of the no-treatment group) (443). Two observational studies support the findings of this RCT. The first study included 107 women with (n = 90) or without (n = 17) HRT after iatrogenic (hysterectomy and BSO) menopause (444). Recurrence was only identified in four women, 3 women had recurrent pain and one woman had a vaginal nodule. All patients with recurrence were receiving unopposed estrogen therapy. The second observational study reported on 42 women with deep infiltrating endometriosis (445). Nineteen of these 42 patients had a hysterectomy and BSO and 11 were subsequently treated with HRT. During the follow up period (mean = 4.3 years, range 1 to 18) no women were diagnosed with recurrence of endometriosis.

This systematic review shows that **postmenopausal recurrence or malignant transformation of endometriosis is possible but very rare**. The authors conclude that HRT in patients with a history of endometriosis has potential risks, but these risks are likely very small and the substantial benefits of HRT should not be overlooked, especially in women with iatrogenic menopause at a young age. This is in line with the ESHRE guideline, which states that **women should not be denied HRT treatment simply because of a history of endometriosis.** Based on the very limited available data, unopposed estrogen treatment in postmenopausal hysterectomized women with a history of endometriosis is dissuaded. **In young women with endometriosis undergoing iatrogenic (surgical) menopause the ESHRE guideline recommends HRT with combined estrogen/progestogen or *tibolone*, at least up to the age of natural menopause** (1).

Management of Recurrent Endometriosis

Recurrence After Medical Treatment

Because hormonal suppressive treatment does not cure endometriosis (it only suppresses the activity of endometriotic lesions during the treatment), “recurrence,” or rather persistence, of endometriosis can be expected in nearly all patients within 6 months to 2 years after the cessation of medical treatment, and this is positively correlated with the severity of endometriosis.

Recurrence After Conservative Surgery

Conservative surgery for endometriosis is associated with high recurrence rates.

Data regarding recurrence rates after conservative surgical treatment of endometriosis are scarce and systematic reviews identified considerable variation between different studies in the reporting of postoperative recurrence rates of endometriosis or endometriosis-associated symptoms, mostly because of the lack of clear definitions for recurrence. A consensus on precise definitions for suspected recurrence, based on symptoms or imaging, and proven recurrence of endometriosis, based on laparoscopic visualization or histology, was published.

The overall endometriosis recurrence rate is estimated between 2% to 20% per year. Cumulative recurrence rates vary from 4% to 25% at 2 years follow-up to 40% after 5 years (279,446). Recurrence of endometriosis can be the result of incomplete surgery or caused by the development of new lesions. The ASRM classification system has low value to predict pain recurrence and endometriosis relapse after conservative surgical treatment (447).

Recurrence After Hysterectomy

The medium-term outcome of hysterectomy for endometriosis-associated pain is satisfactory; the probability of pain persistence after hysterectomy is 15% and risk of pain worsening is 3% to 5%, with a six times higher risk of further surgery in patients with ovarian preservation as compared to concomitant bilateral ovarian removal (448). **At least one ovary should be preserved in young women, especially in those who cannot or will not receive *estrogen–progestin* therapy** (449). The risk of recurrence of endometriosis during hormonal therapy seems marginal if combined preparations or *tibolone* are used and *estrogen*-only treatments are avoided (449).

Risk Factors for Recurrence

The rate of recurrence increases with the stage of disease, the duration of follow-up, and the occurrence of previous surgery (15,450–453). The likelihood of recurrence appears to be lower when endometriosis is located only on the right side of the pelvis rather than when the left side is involved (453). The risk of endometriosis recurrence is significantly correlated to the age of the patient. The younger the patient is at diagnosis the higher the risk of recurrence.

Prevention of Recurrence

After first-line surgery for endometriosis, women should be invited to seek conception as soon as possible. Alternatively, OC use until pregnancy is desired should be considered because several lines of evidence suggest that ovulation inhibition reduces the risk of endometriosis recurrence (454). A recurrent endometrioma developed in 26 of 250 regular users (10%; 95% CI, 7–15) compared with 46 of 115 never users (40%; 95% CI, 31–50), with a common OR of 0.16 (95% CI, 0.04–0.65) (454).

Medical Treatment of Recurrence

It has been shown that medical treatments may provide a good efficacy for the treatment of pain in women presenting with recurrent endometriosis (455). In a randomized prospective clinical study, continuous treatment for 6 months with *desogestrel* (75 μg per day) (n = 20) versus a combined OC (*ethinyl estradiol* 20 μg plus *desogestrel* 150 μg) resulted in a significant and comparable improvement of pelvic pain and dysmenorrhea with breakthrough bleeding in 20% of the *desogestrel*-treated patients, and a significant body weight increase in 15% of the OC-treated women (455).

Surgical Treatment of Recurrence

The optimal surgical solution in women with recurrent symptoms after previous conservative procedures for endometriosis should be based on the desire for conception and on psychological characteristics (456). Repeat conservative surgery for DE has the same efficacy and limitations as primary surgery. **The long-term probability of pain recurrence after repeat conservative surgery for recurrent endometriosis varies from 20% to 40%, and a further surgical procedure will occur in 15% to 20% of the cases** (448,456). These figures are probably an underestimate related to drawbacks in study design, exclusions of dropouts, and publication bias and should be considered with caution (456). No studies evaluated the association of PSN to the surgical treatment of recurrent endometriosis among patients with recurrent disease (448). When a second surgical approach is intended, **definitive surgery (hysterectomy and bilateral oophorectomy) should be considered, particularly in women over 40 years old and who do not wish to conceive.** The spontaneous conception rate among women undergoing repetitive surgery for recurrent endometriosis associated with infertility is 20% (12- and 24-month cumulative pregnancy rates of 14% and 26%), whereas the overall crude pregnancy rate after a primary surgical procedure is 40% (12- and 24-month cumulative pregnancy rates of 32% and 38%) (448,456). Among infertile patients treated with repetitive surgery for recurrent endometriosis the spontaneous pregnancy rate was 19% (12- and 24-month cumulative pregnancy rates), whereas it was 34% for those untreated (12- and 24-month cumulative pregnancy rates of 25% and 30%). The probability of conception after IVF is not significantly lower after repetitive surgery (20%) when compared to primary surgery (30%) (hazard ratio [HR] 1.51; 95% CI, 0.58–3.91) (456).

COPING WITH DISEASE

Coping with endometriosis as a chronic disease is an important component of management. Patient self-help groups can provide invaluable counseling, support, and advice. ESHRE provides a comprehensive international list of self-help groups on their web site (1). Many women with endometriosis report that nutritional and complementary therapies such as reflexology, traditional Chinese medicine, herbal treatments, and homeopathy improve pain symptoms. Data on the effectiveness of alternative and complementary therapies for endometriosis-associated pain are scarce. The limited available evidence indicates that the effectiveness of transcutaneous electrical nerve stimulation (TENS), dietary supplements, acupuncture, and traditional Chinese medicine is not well established for treatment of endometriosis-associated pain. Hence ESHRE does not recommend the use of alternative and complementary therapies in the management of endometriosis. Although there is no good evidence to support the effectiveness of these treatments in endometriosis, they should not be ruled out if the woman feels they work in conjunction with more traditional therapies or that they could be beneficial to her overall pain management and quality of life.

CHAPTER 14

Family Planning

Wing Kay Fok, Paul D. Blumenthal, Phillip G. Stubblefield

Efficacy
- Medical Eligibility for Contraception
- Cost
- Long-Acting Reversible Contraceptives

Nonhormonal Methods
- Coitus Interruptus
- Breastfeeding
- Fertility Awareness
- Condoms
- Vaginal Spermicides
- Vaginal Barriers
- Intrauterine Contraception

Hormonal Contraception
- Steroid Hormone Action
- Antifertility Effects
- Efficacy of Hormonal Contraception
- Alternative Routes for Hormonal Contraception
- Injectable Hormonal Contraceptives
- Emergency Contraception
- Hormonal Contraception for Men

Sterilization
- Female Sterilization
- Vasectomy

Abortion
- Safety

Techniques for First-Trimester Abortion
Second-Trimester Abortion
Complications of Second-Trimester Abortion

KEY POINTS

1 The most common methods of contraception used in the United States are sterilization, oral contraceptives (OCs), and condoms, in that order.
2 Latex condoms and other barriers reduce the risk of sexually transmitted diseases (STDs) and cervical cancer.
3 The intrauterine devices (IUDs) available in the United States are as effective as tubal sterilization and confer no increased long-term risk of pelvic infection.
4 The combination estrogen–progestin OC, patch, and vaginal ring all provide excellent contraception when used correctly but all can increase the risk of venous thrombosis and thromboembolism.
5 Present low-dose estrogen–progestin combinations do not increase the risk of heart attack among nonsmokers younger than age 35 years who have no other risks for vascular disease.
6 The association between breast cancer and OC use remains controversial, but OCs do not appear to substantially increase the risk of breast cancer. Furthermore, benefits of OC use, particularly protection against pregnancy and other noncontraceptive benefits, outweigh the risks for the majority of women.
7 Use of the progestin-only injectable or implant results in very low pregnancy rates without the estrogen-associated risk of thrombosis.
8 Hormonal contraceptives provide extensive contraceptive and noncontraceptive health benefits, including reduced risk for endometrial and ovarian cancer.
9 *Levonorgestrel 1.5 mg* and *ulipristal acetate 30 mg* are the most effective hormonal means of emergency contraception in the United States. Efficacy is greatest within 24 hours of intercourse but remains high at 5 days. The *copper T380A* IUD within 5 days after unprotected intercourse is even more effective than hormonal methods.
10 Long-acting reversible contraceptive (LARC) methods include subdermal progestin implants, and *copper*- or *levonorgestrel*-releasing IUDs. These offer pregnancy rates comparable to sterilization and are among the safest methods.
11 Safe and permanent contraception is provided with laparoscopy or mini-laparotomy, utilizing bipolar electrocautery, salpingectomy or partial salpingectomy, the Silastic band, or the *Filshie clip*.
12 Hysteroscopic sterilization techniques provide highly effective permanent contraception for women without the use of general anesthesia or abdominal incision. However, reports of adverse patient reactions have prompted the manufacturer to remove the product from the market.
13 Vasectomy provides highly effective, low-cost sterilization for men and is not associated with prostate cancer.
14 Abortion mortality rates fell rapidly with legalization; for safe abortions the overall mortality risk is less than 1 per 100,000.
15 The risk of abortion mortality increases with gestational age. The mortality rate for aspiration procedures was 0.3 per 100,000 at or before 8 weeks and increased to 6.7 per 100,000 at 18 weeks or greater.

The history of contraception is a long one, dating to ancient times. The voluntary control of fertility is especially important in modern society (1). A woman who expects to have no more than one or two children spends most of her reproductive years trying to avoid

pregnancy. Effective control of reproduction is essential to a woman's ability to accomplish her individual goals. From a larger perspective, the rapid growth of the human population in modern times threatens the survival of all. The world population is at 7.3 billion and is expected to reach 10 billion by 2056 (2). For both the individual and the planet, reproductive health requires careful use of effective means to prevent pregnancy and sexually transmitted infections (3).

From puberty until menopause, women are faced with challenges concerning childbearing or its avoidance: the only options are sexual abstinence, contraception, or pregnancy. The contraceptive choices made by couples in the United States in 2013 are shown in **Figure 14-1** (4). **[1]** Oral contraceptives (OCs) were the first choice among women, used by 25.9%. Female sterilization was the second choice, used by 25.1%. With the addition of the 8.2% of couples relying on male sterilization, 33.3% of couples were relying on sterilization, making this the first choice of couples. Condoms were third choice, used by 15.3%. OC use declines with age, and the rate of sterilization increases. Forty-seven percent of women under 25 who use contraceptives use OCs and only 1.6% is sterilized. Of women aged 35 to 44 years using contraception 12.4% uses OCs and 44.2% is sterilized, as is 17.9% of their consorts. About 10% of women use more than one method of contraception. Although contraceptive prevalence is high, a significant proportion of sexually active couples (6.9%) does not use contraception, and each year, 1.46 of every 100 women aged 15 to 44 years have an induced abortion (4,5). Abortion is an obvious indicator of unplanned pregnancy. Abortion ratios by age group indicate that the use of abortion is greatest for the youngest women and least for women in their late 20s and early 30s who are most likely to continue pregnancies **(Fig. 14-2)** (6). The use of abortion increases from the late 30s on. Young women are much more likely to experience unplanned pregnancy because they are more fertile than older women and because they are more likely to have unprotected intercourse.

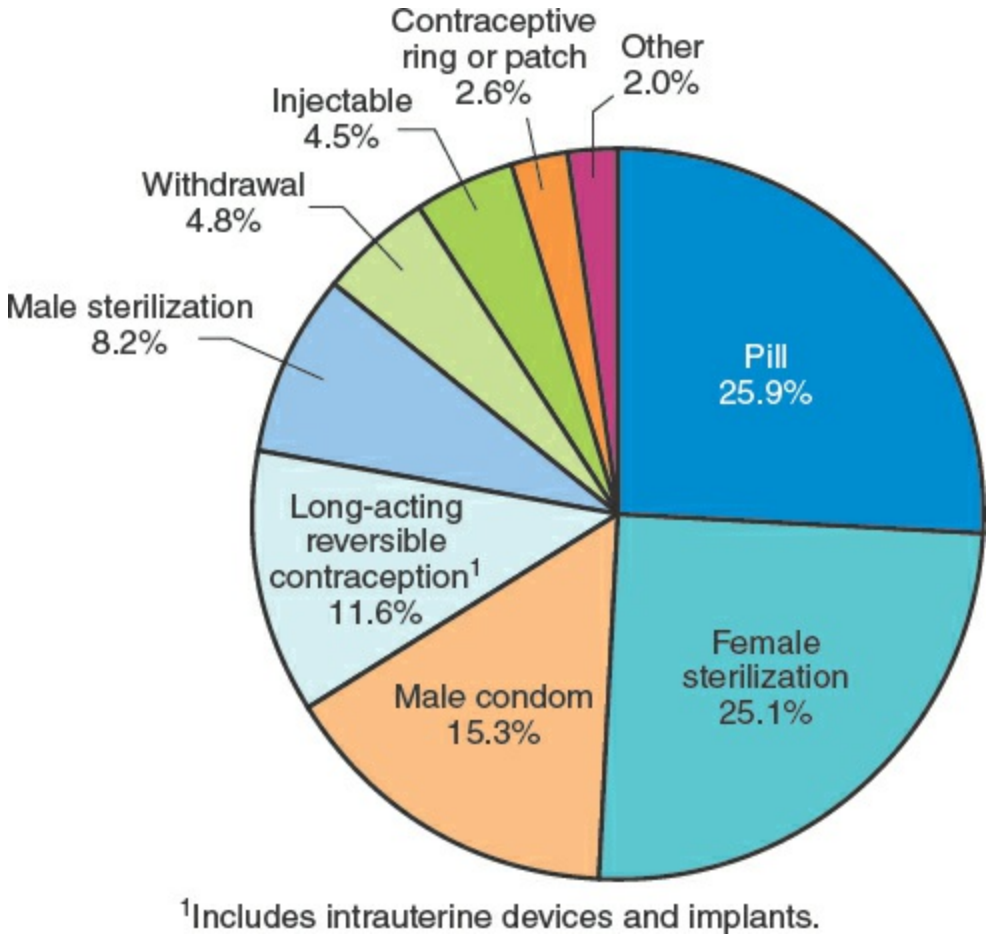

FIGURE 14-1 Percent distribution of women aged 15 to 44 years who are currently using contraception, by the type of contraceptive method used. United States, 2011 to 2013. (From **Daniels K, Daugherty J, Jones J, et al.** Current contraceptive use and variation by selected characteristics among women aged 15–44: United States, 2011–2013. *Natl Health Stat Report* 2015;[86]:1–14; Figure 1.)

EFFICACY

Factors affecting the likelihood of pregnancy include the fecundity of both partners, the timing of intercourse in relation to ovulation, the method of contraception used, the intrinsic effectiveness of the contraceptive method, and the correct use of the method. It is impossible to assess the effectiveness of a contraceptive method in isolation from the other factors. The best way to assess effectiveness is long-term evaluation of a group of sexually active women using a particular method for a specified period to observe how frequently pregnancy occurs. A pregnancy rate per 100 women per year can be calculated using the Pearl formula (dividing the number of pregnancies by the total number of months contributed by all couples, and then multiplying the quotient by 1,200). With most methods, pregnancy rates decrease with time as the more fertile or less careful couples become pregnant and drop out of the calculations. More accurate information is provided by the life-table method. This method calculates the probability of pregnancy in successive months, which are then added over a given interval.

Problems relate to which pregnancies are counted: those occurring among all couples or those in women the investigators deem to have used the method correctly. Because of this complexity, rates of pregnancy with different methods are best calculated by reporting two different rates derived from multiple studies (i.e., the lowest rate and the usual rate), as shown in **Table 14-1**.

Medical Eligibility for Contraception

Since 1996, the World Health Organization (WHO) has regularly published Medical Eligibility Criteria for Contraceptive Use (MEC). These recommendations are based on the best evidence available supplemented by expert opinion. The U.S. Centers for Disease Control undertook a formal process to review and revise the WHO MEC and adapt it to US practice (7). These eligibility criteria have become de facto US national (CDC) and international (WHO) standards for contraceptive practice. All present methods of contraception are assigned to one of four categories of suitability of use by women with more than 60 characteristics or conditions. The categories are:

1. A condition for which there is no restriction for the use of the contraceptive method;
2. A condition for which the advantages of using the method generally outweigh the theoretical or proven risks;
3. A condition for which the theoretical or proven risks usually outweigh the advantages of using the method;
4. A condition that represents an unacceptable health risk if the contraceptive method is used.

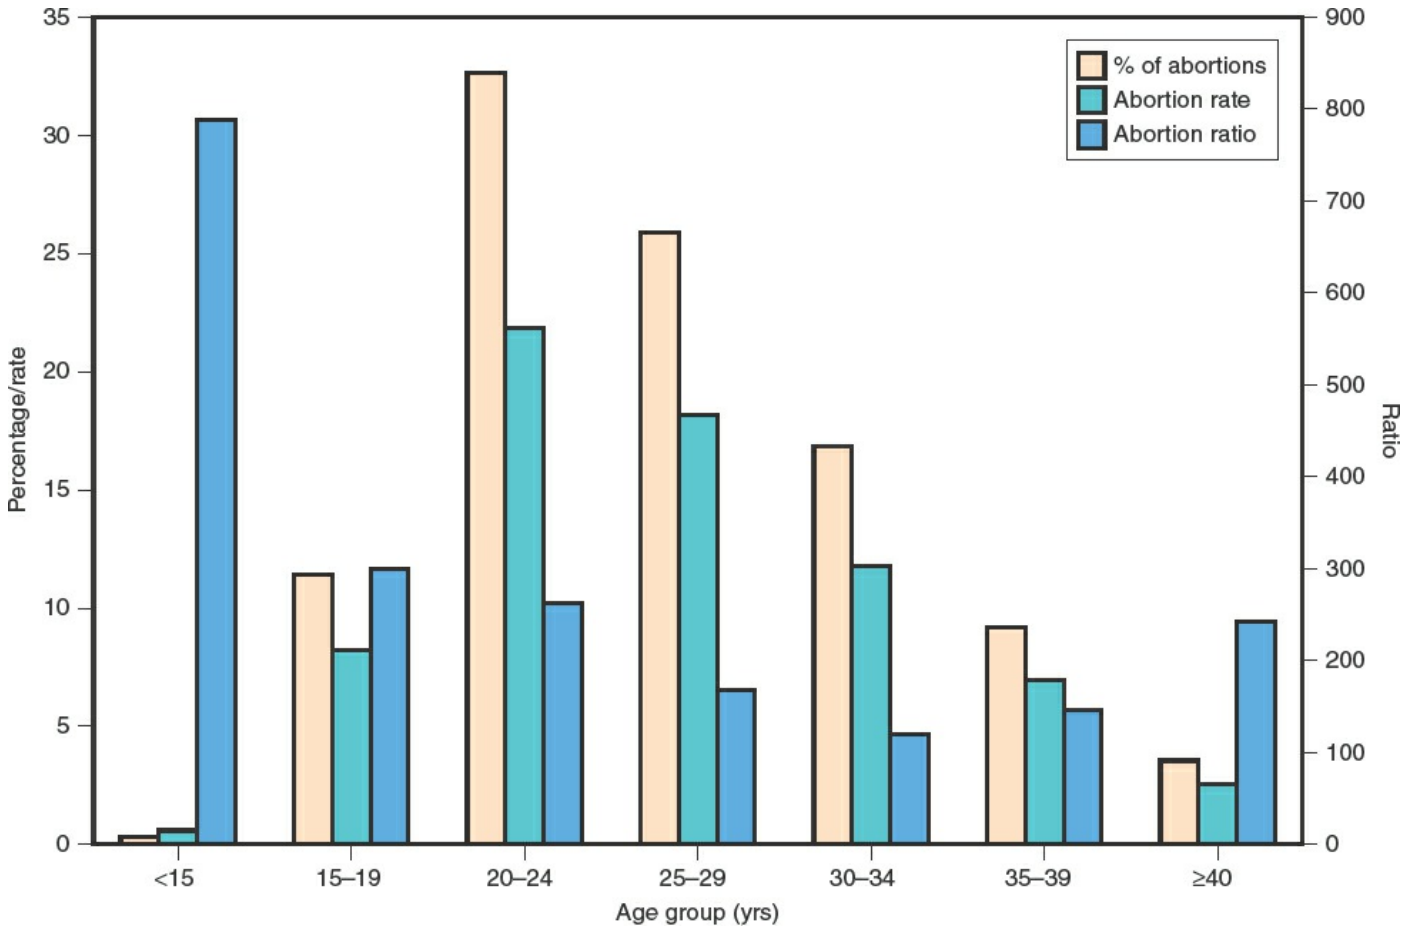

FIGURE 14-2 Percentage of total abortions, abortion rate,* and abortion ratio† by age group of women who obtained a legal abortion—selected reporting areas.§ United States, 2013. *Number of abortions per 1,000 women aged 15–44 years. †Number of abortions per 1,000 live births. §Data are for 47 areas; excludes five areas (California, Florida, Maryland, New Hampshire, and Wyoming) that did not report, did not report by age, or did not meet reporting standards. (From **Jatlaoui TC, Ewing A, Mandel MG, et al.** Abortion surveillance—United States, 2013. *MMWR Surveill Summ* 2016;65[12]:1–44; Figure 2.)

Cost

Some methods, such as intrauterine devices (IUDs) and subdermal implants, require an initial, "up-front" investment, which in some countries can be substantial, but then provide prolonged protection for a low annual cost. A complex cost analysis based on the cost of the method plus the cost of pregnancy if the method fails concludes that sterilization and IUDs are the least expensive over 5 years (Table 14-2) (8).

Long-Acting Reversible Contraceptives

[10] Several contraceptive methods are as effective as sterilization, but are completely reversible. All have the important advantage of being "forgettable," that is, little is required of the user after the method is begun, very much in contrast to methods like the condom that must be used with each act of intercourse, or the OC, which must

be taken daily. **[10]** These "forgettable" methods have typical-use pregnancy rates of less than 1%, are effective for at least several years without attention from the user, and are among the safest methods. They include the *etonogestrel* and *levonorgestrel* subdermal implants, copper-bearing IUDs such as the *copper T380A* and *levonorgestrel*-releasing intrauterine systems (9,10).

NONHORMONAL METHODS

Coitus Interruptus

Coitus interruptus is withdrawal of the penis from the vagina before ejaculation. This method, along with induced abortion and late marriage, is believed to account for most of the decline in fertility of preindustrial Europe (11). Coitus interruptus remains a very important means of fertility control in many countries. Eighty-five million couples are estimated to use the method worldwide, yet it has received little formal study. This method has obvious advantages: immediate availability and no cost. The penis must be completely withdrawn from the vagina and the external genitalia. Pregnancy has occurred from ejaculation on the female external genitalia without penetration. Efficacy is estimated to range from 4 pregnancies per 100 women in the first year with perfect use to 22 per 100 with typical use **(Table 14-1)**. Jones and colleagues offer a modern review of this practice and conclude that it likely is as effective as the condom (12).

Breastfeeding

Breastfeeding can be used as a form of contraception and can be effective depending on individual variables. The use of contraception during lactation should take into consideration the women's needs and the need to maintain lactation. Ovulation is variably suppressed during lactation. The suckling of the infant elevates prolactin levels and reduces gonadotropin-releasing hormone (GnRH) from the hypothalamus, reducing luteinizing hormone (LH) release and thus inhibiting follicular maturation (13). Even with continued nursing, ovulation eventually returns but is unlikely before 6 months, especially if the woman is amenorrheic and is fully breastfeeding with no supplemental foods given to the infant (14). For maximum contraceptive reliability, feeding intervals should not exceed 4 hours during the day and 6 hours at night, and supplemental feeding should not exceed 5% to 10% of the total amount of feeding (15). Six-month pregnancy rates of 0.45% to 2.45% are reported for couples relying solely on this method (16). To prevent pregnancy, another method of contraception should be used from 6 months after birth or sooner if menstruation resumes. Breastfeeding reduces the mother's lifetime risk of breast cancer (17).

Table 14-1 Percentage of Women Experiencing an Unintended Pregnancy During the First Year of Use of Contraception and the Percentage Continuing Use at the End of the First Year

Contraception During Lactation (Lactation Amenorrhea)

Previously, the use of combination estrogen–progestin hormonal methods (OCs, the patch, and the ring) was not advised during lactation because of concern about reduction in the amount and quality of breast milk. However, clinical studies demonstrate conflicting results regarding effects on breastfeeding continuation or exclusivity in women exposed to COCs during lactation and the use of combined estrogen–progestin hormonal methods are category 2 in breastfeeding women beyond 30 days of delivery (7). Progestin-only OCs, implants, and injectable contraception do not affect milk quality or quantity (15). Barrier methods, spermicides, and the *copper T380A* IUD (*ParaGard*) are excellent options for nursing mothers. Few studies have specifically looked at the use of levonorgestrel-IUDs (LNG-IUDs) on breastfeeding. One randomized controlled trial (RCT) raised concerns that immediate insertion of the LNG-

IUD postpartum may be associated with poorer breastfeeding performance when compared with delayed insertion (18). However, while more studies are needed before definitive recommendations can be made, the safety and impact on breastfeeding with the use of other contraceptives such as implants (which produce higher blood levels) have been previously shown (19). Given the comparatively low level of circulating hormone in LNG-IUDs, no adverse effect on breastfeeding is anticipated.

Table 14-2 Cost Effectiveness (C/E) of Contraceptive Methods at 5 Years

Method	Method-related Costs (US$)	Failure Cost (US$)	Cost of Side Effects (US$)	Total Cost (C) (US$)	Effectiveness (E)[a]	C/E (US$)	ICER (US$)
Copper-T IUD	605	42	0	647	99.6	6.50

Fertility Awareness

Periodic abstinence, described as "natural contraception" or "fertility awareness," requires avoiding intercourse during the fertile period around the time of ovulation. A variety of methods are used: the calendar method, the mucous method (Billings or ovulation method), and the symptothermal method, which is a combination of the first two methods. With the mucous method, the woman attempts to predict the fertile period by feeling the cervical mucous with her fingers. Under estrogen influence, the mucous increases in quantity and becomes progressively more slippery and elastic until a peak day is reached. The mucous becomes scant and dry under the influence of progesterone

until the onset of the next menses. Intercourse may be allowed during the "dry days" immediately after menses until mucous is detected. Thereafter, the couple must abstain until the fourth day after the "peak" day.

In the symptothermal method, the first day of abstinence is predicted either from the calendar, by subtracting 21 from the length of the shortest menstrual cycle in the preceding 6 months, or the first day mucous is detected, whichever comes first. The end of the fertile period is predicted by the use of basal body temperature. The woman takes her temperature every morning and resumes intercourse 3 days after the thermal shift, the rise in body temperature that signals that the corpus luteum is producing progesterone and that ovulation occurred. The postovulatory method is a variation in which the couple has intercourse only after ovulation is detected.

A system of hormone monitoring designed to better define the fertile period involves placement of disposable test sticks in a small battery-powered device to detect urinary estrone-3 glucuronide and LH. Changes in these hormones reliably predict the fertile period. These devices (*Persona* and *Clearblue Easy Fertility Monitor [CEFM]*) can serve as aids either to becoming pregnant or avoiding it (20). *Persona* is marketed in Europe for contraception. It is reported to have a correct-use effectiveness of 94% in avoiding pregnancy. CEFM is approved in the United States as an aid to becoming pregnant but is used off label to avoid pregnancy. Exact effectiveness rates are not known. The CEFM is used in the Marquette method, which combines observation of cervical mucous changes with the CEFM results. A correct-use pregnancy rate of 2% and a typical-use pregnancy rate of 12% were reported (21).

Efficacy

The ovulation method was evaluated by the WHO in a five-country study. Women who successfully completed three monthly cycles of teaching were enrolled in a 13-cycle efficacy study. There was a 3.1% probability of pregnancy in 1 year for the small proportion of couples who used the method perfectly and 86.4% probability of pregnancy for the rest (22). A review of 15 national surveys from developing countries estimated a 12-month gross failure rate of 24 pregnancies per 100 (23). One systematic review of RCTs that examined fertility awareness-based methods found that most participants in trials discontinued prematurely and thus comparative efficacy of these methods remains unknown (24).

Risks

Conceptions resulting from intercourse remote from the time of ovulation more often lead to a higher likelihood of spontaneous abortion than conceptions from midcycle intercourse (25). Malformations are not more common.

Condoms

In the 1700s, condoms made of animal intestine were used by the aristocracy of Europe, but condoms were not widely available until the vulcanization of rubber in the 1840s (1). Modern condoms usually are made of latex rubber, although condoms made from animal intestine are still sold and are preferred by some who feel they afford better sensation. New condoms made from nonlatex materials—such as polyurethane or synthetic elastomers that are thin, odorless, transparent, and transmit body heat—are available. Although the nonlatex condoms may break more easily than the latex varieties, substantial numbers of study participants preferred them and would recommend them to others (26).

The risk of condom breakage is about 3% and is related to friction (27). The use of water-based lubricants may reduce the risk of breakage. Petroleum-based products such as mineral oil must be avoided because even brief exposure to them markedly reduces the strength of condoms (28).

Sexually Transmitted Diseases

Gonorrhea, ureaplasma, and pelvic inflammatory disease (PID) and its sequel (tubal infertility) are reduced with consistent use of barrier methods (29–31). **[2]** Tested in vitro, *Chlamydia trachomatis,* herpes virus type 2, HIV, and hepatitis B did not penetrate latex condoms but did cross through condoms made from animal intestine (32). Follow-up of sexual partners of HIV-infected individuals showed that condom use provides considerable protection (33). Consistent condom use provides more protection than inconsistent use (34). In one study, couples who use condoms 0% to 50% of the time had an HIV seroconversion rate of 20.8 per 100 couple years, whereas those who used condoms 100% of the time had a conversion rate of only 2.3 per 100 couple years (35). *Nonoxynol-9 (N-9)* should not be used with condoms for HIV protection because it is associated with genital lesions. *N-9* does not add to the protection afforded by condoms alone (36).

[2] Condoms offer protection from cervical neoplasia (37). **The relative risk (RR) for invasive cervical cancer was 0.4 when those who used condoms or diaphragms were compared with those who never used them** (38). **The presumed mechanism of protection is reduced transmission of human papillomavirus (HPV).**

Risks

Latex allergy could lead to life-threatening anaphylaxis in either partner from latex condoms. Nonlatex condoms of polyurethane and *Tactylon* should be offered to couples who have a history suggestive of latex allergy.

Female Condom

The original female condom introduced in 1992 was a polyurethane vaginal pouch attached to a rim that partly covered the vulva. The FC2 female condom was U.S. Food and Drug Administration (FDA) approved in 2009 and is an improved version made

from softer synthetic latex that does not require hand assembly during manufacture and is therefore less expensive (39). It consists of a loose-fitting nitrile sheath with two flexible rings. It is recommended for prevention of pregnancy and STDs, including HIV. Although breakage may occur less often with the female condom than the male condom, slippage appears to be more common, especially for those new to its use (40). Male condoms should not be used with female condoms as concurrent use increases the risk of breakage. Exposure to seminal fluid is slightly higher than with the male condom (41). Initial US trials showed a pregnancy rate of 15% in 6 months. Subsequent analysis found that with perfect use, the pregnancy rate may be only 2.6%. This rate is comparable to perfect use of the diaphragm and cervical cap, the other female-controlled barrier methods (42). As with the male condom, failure rates fall with increasing experience. Colposcopic studies of women using the female condom demonstrate no signs of trauma or change in the bacterial flora (43).

Vaginal Spermicides

Vaginal spermicides combine a spermicidal chemical, either *N-9* or *octoxynol,* with a base of cream, jelly, aerosol foam, foaming tablet, film, suppository, or a polyurethane sponge. *N-9* is a nonionic surface-active detergent that immobilizes sperm. *N-9* spermicides alone appear considerably less effective in preventing pregnancy than condoms or diaphragms. Women using *N-9* spermicides frequently have higher rates of genital lesions than women not using spermicides. These lesions may increase their risk for STDs and HIV (44). In the same studies of serodiscordant couples in which condoms were proven effective in preventing transmission of HIV, *N-9* spermicides alone were not effective (35).

Concerns were raised about possible teratogenicity of spermicides. *N-9* is not absorbed from the human vagina (45). Several large studies found no greater risk of miscarriage, birth defects, or low birth weight in spermicide users than in other women (46,47).

N-9 is toxic to the lactobacilli that normally colonize the vagina. Women who use spermicides regularly have increased vaginal colonization with the bacterium *Escherichia coli* and may be predisposed to *E. coli* bacteriuria after intercourse (48).

Vaginal Barriers

At the beginning of the 20th century, four types of vaginal barriers were used in Europe: vaginal diaphragm, cervical cap, vault cap, and Vimule. Vaginal diaphragms, new varieties of cervical caps, and the synthetic sponge are used in the United States. When used consistently, vaginal barriers can be reasonably effective. A recent search for alternatives to condoms for HIV prevention in high-prevalence areas has rekindled interest in the other vaginal barriers (49).

Diaphragm

Traditional diaphragms consist of a circular dome covered with fine latex rubber (Fig. 14-3). There are several types of diaphragms, as determined by the spring rim: coil, flat, or arcing. Coil-spring and flat-spring diaphragms become a flat oval when compressed for insertion. Arcing diaphragms form an arc or half-moon when compressed; they are easiest to insert correctly. Traditionally, diaphragms require fitting by practitioners. Spermicide is always prescribed for use with the diaphragm; whether this practice is necessary is not well studied.

Fitting Diaphragms

Fitting a diaphragm should be performed as follows:

1. **A vaginal examination should be performed.** With the first and second fingers in the posterior fornix, the thumb of the examining hand is placed against the first finger to mark where the first finger touches the pubic bone. The distance from the tip of the middle finger to the tip of the thumb is the diameter of the first diaphragm that should be tried.
2. **A set of test diaphragms of various sizes is used, and the test diaphragm is inserted and checked by palpation.** The diaphragm should open easily in the vagina and fill the fornices without pressure. The largest diaphragm that fits comfortably should be selected. A size 65, 70, or 75 diaphragm will fit most women.
3. **The patient should practice insertion and should be reexamined to confirm proper position of the device.** About 1 teaspoon of water-soluble spermicidal jelly or cream is placed in the cavity of the dome. The diaphragm is inserted with the dome downward so that the cervix will sit in a pool of the spermicide.
4. **The diaphragm can be inserted several hours before intercourse. If intercourse is repeated, additional spermicidal jelly should be inserted into the vagina without removing the diaphragm. The diaphragm should be left in place at least 6 hours after intercourse to allow for immobilization of sperm.** When removed, it is washed with soap and water, allowed to dry, and stored away from heat. It should not be dusted with talc because genital exposure to talc may increase the risk of ovarian cancer.

In 2014, the FDA approved the Caya contoured diaphragm for use in the United States. It is a single-size reusable silicone diaphragm. Compared to traditional diaphragms, this contoured diaphragm does not require fitting by a practitioner to determine the size, which in low-resource settings may be especially important for improving access. Caya should be used with a spermicide. It should be kept in place for 6 hours after intercourse to ensure sperm cells are no longer active, but removed within

24 hours to prevent toxic shock syndrome.

Risks

Diaphragm use, especially prolonged use during multiple acts of intercourse, appears to increase the risk of bladder infections. A smaller-sized, wide-seal diaphragm or a cervical cap can be used if recurrent cystitis is a problem, although the problem may relate not only to mechanical obstruction but also to alterations in vaginal flora produced by the spermicide. An epidemiologic study comparing cases of toxic shock with controls found no increased risk from diaphragm use (50).

Other Barriers

FemCap

This version of the cervical cap made of silicone rubber was approved by the FDA in 2003. It looks like a sailor's hat with the dome covering the cervix and the brim fitting into the vaginal fornices. It is made in three sizes—22-, 26-, and 30-mm diameter—and is expected to be reusable for 2 years. It is used with spermicide and should be left in place for at least 6 hours after intercourse, but it may be left in place as long as 48 hours at a time. Additional acts of intercourse require insertion of more spermicide. *FemCap* requires a clinician's fitting and prescription for use. The only available efficacy study compared the *FemCap* to the vaginal diaphragm. The 6-month pregnancy rate for the *FemCap* was 13.5%, substantially higher than the 7.9% rate for the diaphragm. Both groups used *N-9* spermicide with the devices (52).

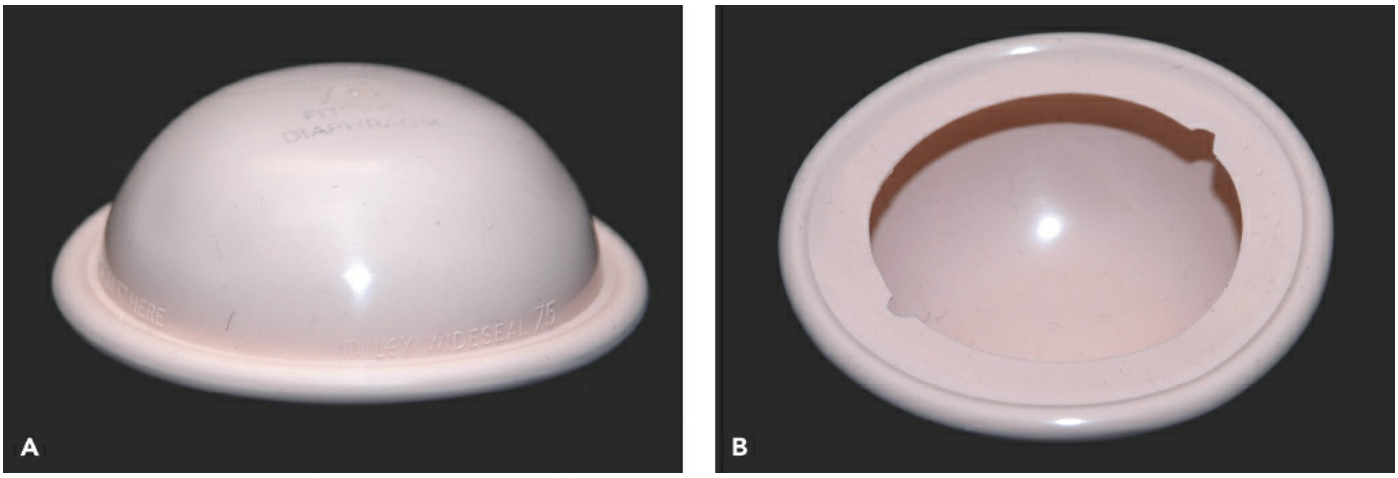

FIGURE 14-3 Wide-seal diaphragm. **A:** Outer caudal side. **B:** Inner cephalad side.

Future Development in Barrier Methods

The *Ovaprene* ring is a nonhormonal "one-size-fits-all" intravaginal organic silicone ring that continuously releases spermiostatic and spermicidal agents over a 4-week period. The phase I trial demonstrated patient acceptability and safety (51). It is expected to undergo a postcoital test clinical trial in 2018.

Sponge

The *Today* sponge is a polyurethane dome-shaped device containing *N-9*. It is moistened with water and then inserted high in the vagina to cover the cervix. It combines the advantages of a disposable barrier with spermicide and provides protection for 24 hours. The contraceptive efficacy appears to differ with parity. Nulliparous women are reported to have a perfect use pregnancy rate of 9% per year, whereas parous women have a pregnancy rate of 20% **(Table 14-1)**. Rates with typical use are estimated as 12% per year in nullipara and 24% in multipara (52). A trial comparing the sponge with a vaginal spermicide preparation used alone without barrier showed the sponge had a slightly lower pregnancy rate (53).

Intrauterine Contraception

Worldwide over 14% of married women use intrauterine contraception (54). In the United States, usage is increasing, but the estimates are that only 6.4% of women use intrauterine contraception (54). Candidacy includes nulliparous women, adolescents, and immunocompromised women. Immediate use postpartum or after a first- or second-trimester abortion broadened usage. Five IUDs are available in the United States: the copper T380A (*ParaGard*), two 52-mg levonorgestrel-releasing *IUDs* (*Mirena and Liletta*), a 19.5-mg levonorgestrel-releasing IUD (*Kyleena*), and a 13.5-mg levonorgestrel-releasing IUD (*Skyla*). The *copper T380A* has bands of copper on the cross arms of the T in addition to the copper wire around the stem, providing a total surface area of 380 mm of copper, almost double the surface area of copper in earlier copper devices **(Fig. 14-4)**. It is approved for up to 10 years of continuous use. The *Mirena* **(Fig. 14-5)** is approved in the United States for 5 years of use, although studies through 7 years of use show no loss of efficacy (55). The *Kyleena* is approved for 5 years of use, while the *Skyla* is approved for 3 years. *Liletta* is manufactured by Medicines360 and is approved for use up to 4 years, with eventual anticipated approval for 7 years, and possibly 10 years (56). **[3] All IUDs provide safe, long-term contraception with effectiveness equivalent to tubal sterilization.**

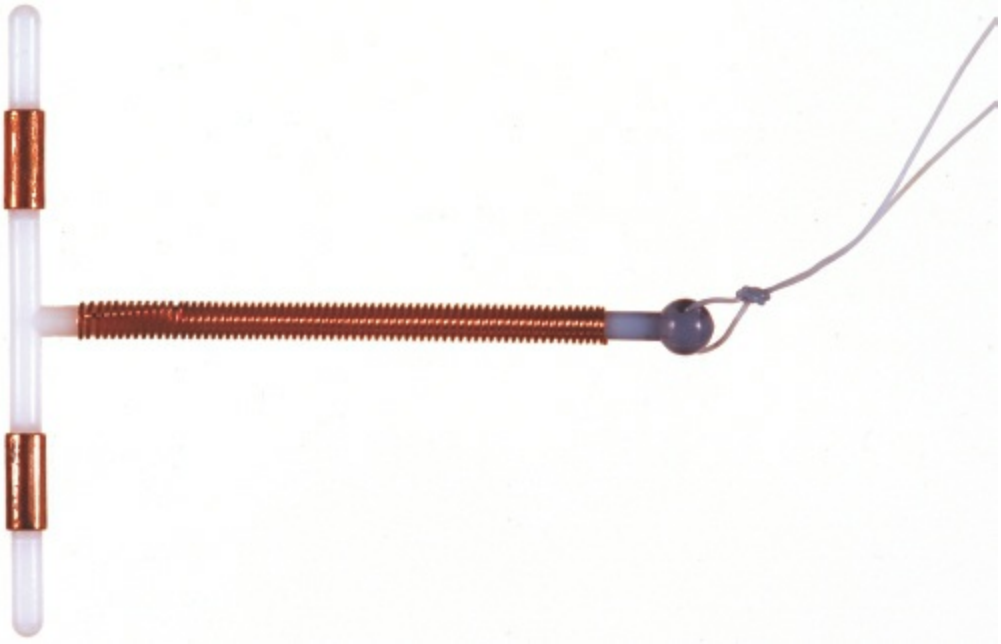

FIGURE 14-4 *Copper T380A* (*ParaGard*) intrauterine device.

Mechanism of Action

IUDs cause the formation of "biologic foam" within the uterine cavity that contains strands of fibrin, phagocytic cells, and proteolytic enzymes. All IUDs stimulate the formation of prostaglandins within the uterus, consistent with both smooth muscle contraction and inflammation. Copper IUDs continuously release a small amount of the metal, producing an even greater inflammatory response. Scanning electron microscopy studies of the endometrium of women wearing nonmedicated IUDs show alterations in the surface morphology of cells, especially of the microvilli of ciliated cells (57). There are major alterations in the composition of proteins within the uterine cavity and new proteins and proteinase inhibitors are found in washings from the uterus (58). **These altered intrauterine environments interfere with sperm passage through the uterus, preventing fertilization.**

The *levonorgestrel* in IUDs is much more potent than natural progesterone and has a profound effect on the endometrium. The hormone is released at an initial rate of 20 μg daily, which declines to half this rate by 5 years. For the 52-mg LNG-IUDs, blood hormone levels are significantly lower than with other progesterone-only contraception and remain stable at approximately 130 to 200 pg/mL (59). About 85% of cycles are ovulatory. The contraceptive effect of the LNG-IUD is a result of thickened and scant cervical mucous, endometrial atrophy, and an intrauterine inflammatory response (56,59).

FIGURE 14-5 *Levonorgestrel T* (*Mirena*) intrauterine device.

The IUD is not an abortifacient. The contraceptive effectiveness does not depend on interference with implantation, although this phenomenon can occur and is, in part, the theoretical basis for using copper IUDs for emergency contraception. Sperm can be obtained by laparoscopy in washings from the fallopian tubes of control women at midcycle; fewer sperm are present in the tubal washings from women wearing IUDs (60). Ova flushed from the tubes at tubal sterilization showed no evidence of fertilization in women wearing IUDs (61). Studies of serum β-human chorionic gonadotropin (β-hCG) levels in women wearing IUDs do not indicate pregnancy (62).

Effectiveness

The *copper T380A* and the 52-mg *LNG-IUDs* have remarkably low pregnancy rates, less than 0.2 per 100 woman-years. Total pregnancies over a 7-year period were only 1.1 per 100 for the *LNG-IUD* and 1.4 for the *copper T380A (*55*)*. Twelve-year data on the *copper T380A* showed a cumulative pregnancy rate of only 1.9 per 100 women and no pregnancies at all after year 8 (63).

Benefits

Modern IUDs provide excellent contraception without continued effort by the user. The *copper T380A* and the *LNG-IUDs* protect against ectopic pregnancy. **The *LNG-IUD,* by releasing *levonorgestrel,* reduces menstrual bleeding and cramping. It is used extensively to treat heavy menstrual bleeding and is used in Europe and the United Kingdom as an alternative to hysterectomy for menorrhagia** (64). The *LNG-IUD* has a beneficial effect on menorrhagia from uterine fibroids; the benefit may be diminished with distorting submucosal fibroids (65,66). **The *LNG-IUD* is an effective way to**

deliver the necessary progestin therapy in postmenopausal women on estrogen therapy (67). Additional noncontraceptive benefits include a reduced risk of endometrial cancer and improvement in symptoms of endometriosis and adenomyosis (68–71).

Risks

Infection

The Women's Health Study found the *Dalkon Shield* device (withdrawn from the market since 1974) to increase the risk of PID eightfold when women hospitalized for PID were compared with control women hospitalized for other illnesses (72). In contrast, risk from the other IUDs was markedly lower. Increased risk was detectable only within 4 months of insertion of the IUD. A prospective WHO study revealed that PID increased only during the first 20 days after insertion. Thereafter, the rate of diagnosis of PID was about 1.6 cases per 1,000 women per year, the same as in the general population (73).

[3] Exposure to sexually transmitted pathogens is the more important determinant of PID risk than IUD use. In the Women's Health Study, women who were married or cohabiting and who said they had only one sexual partner in the past 6 months had no increase in PID (72). In contrast, previously married or single women had marginal increase in risk, even though they had only one partner in the previous 6 months (74). The only pelvic infection that was unequivocally related to IUD use is actinomycosis (75). It appears that PID with actinomycosis was reported only in women wearing an IUD. Rates of colonization with actinomycosis increase with duration of use for plastic devices but appear to be much less for copper-releasing IUDs. Actinomyces may be found in cervical cytology of up to 7% of women with an IUD. Because of the low positive predictive value and a lack of sensitivity and specificity of cervical cytology to diagnose this organism, antibiotic treatment and IUD removal should be reserved for symptomatic women (76).

When PID is suspected in a woman using an IUD, appropriate cultures should be obtained, and antibiotic therapy should be administered. Removal of the IUD is not necessary unless symptoms do not improve after 72 hours of treatment (77). Pelvic abscess, if suspected, should be ruled out by ultrasound examination.

Ectopic Pregnancy

All contraceptive methods protect against ectopic pregnancy by preventing pregnancy. But when the method fails and pregnancy occurs, the risk of ectopic pregnancy is affected by the method of contraception. **IUDs and tubal sterilization increase the probability of the pregnancy being ectopic when pregnancy occurs, but the rate of any pregnancy is so low that women using either of these methods have much lower rates of ectopic pregnancy than women not using contraception** (78). Risk of any pregnancy with a *LNG-IUD* is between 0.1 and 0.2 per 100 woman-years. The rate of

an ectopic in users of this device is reported as 0.02 per 100 woman-years (79). In a large study of the *copper T380A,* the first-year pregnancy rate was 0.5 per 100 woman-years, and the rate of ectopic was 0.1 per 100 woman-years (80). Ectopic is a very rare event with either IUD, but should a woman wearing one present with pelvic pain and a positive β-hCG, an ectopic must be ruled out.

Fertility

Tubal factor infertility is not increased among nulligravid women who used copper IUDs, but exposure to sexually transmitted pathogens such as *C. trachomatis* can increase the risk (81). The contraceptive actions of the LNG-IUD reverse soon after removal of the device. One-year life-table pregnancy rates after removal are 89 per 100 for women less than 30 years of age—rates are similar to women who had not been using any form of birth control (82).

Expulsion and Perforation

The 36-month cumulative expulsion rate is 10.2 per 100 IUD users and did not vary by IUD type (LNG-IUD 10.1 vs. copper IUD 10.7, $p = 0.99$) (83). The cumulative rate of expulsion is lower in nulliparous women compared to parous women and higher in females aged 14 to 19 years compared to older women. The risk of uterine perforation associated with insertion is dependent on the inserter. The risk in experienced hands is on the order of 1 per 1,000 insertions or less (84). The risk of perforation is no different between the copper and the LNG-IUDs (85). Multiparity decreases the risk of perforation (84). Breastfeeding and time since delivery are independently associated with uterine perforation risk. The RR of perforation in lactating compared to nonlactating women at ≤36 weeks since delivery was 4.7 (86).

Clinical Management

Conditions listed as a category 4 (unacceptable health risk) for IUDs by the WHO include pregnancy, puerperal sepsis, PID, active purulent cervicitis, endometrial or cervical cancer, undiagnosed genital bleeding, gestational trophoblastic disease with persistent elevation in β-hCG, uterine anomalies, and fibroid tumors that distort the endometrial cavity (87). **Infection with HIV is not considered a contraindication for IUD use.** There are no differences in genital viral shedding, HIV disease progression or disease transmission among IUD users compared to users of other contraceptives (88). Copper allergy and Wilson disease are contraindications to the use of copper IUDs.

Candidate Selection

IUDs are appropriate for long-term contraception in most women given their ease of use, safety, high efficacy, and favorable side effect profile. Nulliparous women, adolescents, women undergoing a first- or second-trimester surgical abortion, women with a recent medical abortion, and women immediately postpartum should

all be considered candidates for IUDs (89). There is renewed interest in postpartum and postabortal insertion of IUDs. In both circumstances, the woman is clearly no longer pregnant, she may be highly motivated to accept contraception, and the setting is convenient for the woman and the provider (89). **Postpartum and postabortal insertions are safe.** Complications are not increased by comparison to interval insertion. The only disadvantage is that the expulsion rate is higher. Two recent RCTs, involving LNG-IUDs, reported expulsion rates after vaginal postplacental insertion of 24% and 27% (90,91). Postplacental expulsion rates after cesarean sections appear to be lower (92). While comparing postpartum to interval insertion, all the women requesting postpartum IUD received the device, but many women scheduled for interval insertion did not return. When surveyed at 6 months postpartum, more women who had immediate postpartum insertion were wearing IUDs than were those who had scheduled for interval insertion (93,94). Expulsion by 6 months was more likely following immediate insertion (odds ratio [OR], 4.89; 95% confidence interval [CI], 1.47–16.32); however, IUD use at 6 months was more likely with immediate insertion than with delayed insertion (OR, 2.04; 95% CI, 1.01–4.09) (95,96). Thus, in terms of actual continuation, overall, the benefits of IUD insertion immediately postplacental far outweigh the higher expulsion rates associated with such insertions (97). Goodman and colleagues found many fewer repeat abortions among women followed after postabortal IUD insertion compared to a cohort of women choosing non-IUD methods of contraception after an induced abortion (98).

Insertion

At the contraceptive visit, the patient's history is obtained and a physical examination, screening for *Neisseria gonorrhoeae* and chlamydia in high-risk women, and detailed counseling regarding risks and alternatives are provided. Clinicians have traditionally inserted IUDs at the time of menses to ensure the patient is not pregnant, but it can be inserted at any time in the cycle if pregnancy can be excluded (99). The *copper T380A* IUD can be inserted within 5 days of unprotected intercourse for almost 100% effective emergency contraception.

There are limited data on effective treatment of pain during IUD insertion. One randomized double-blind placebo-controlled study demonstrated that self-administered vaginal 2% lidocaine gel did not reduce pain with IUD insertion but did decrease pain with tenaculum placement (100). However, studies utilizing lidocaine–prilocaine creams have demonstrated a reduction in pain during tenaculum placement, sound insertion, and IUD insertion (101,102). Despite some practitioners' preference to premedicate with misoprostol or NSAIDs, these interventions do not reduce pain with insertion (103).

Antibiotic prophylaxis is not beneficial, probably because the risk of pelvic infection with IUD insertion is so low. A large randomized trial of 1,985 patients

receiving either oral *azithromycin* or placebo found no difference in rates of IUD removal during the first 90 days after insertion and no difference in rates of salpingitis (104). A meta-analysis found that antibiotic prophylaxis at the time of IUD insertion did not decrease the risk of PID nor did it reduce the likelihood of removal within the first 3 months (105). For women at high risk of STIs (e.g., aged 25 years or younger or having multiple sex partners), it is reasonable to screen for STIs and place the IUD on the same day. The International Planned Parenthood Federation, in collaboration with WHO and other international organizations, developed guidelines that include the restriction of IUD insertion within 3 months of puerperal sepsis (106).

The technique of insertion is as follows:

1. **The cervix is exposed with a speculum. The vaginal vault and cervix are cleansed with a bactericidal solution, such as an iodine-containing solution.**
2. **Traditionally, the next step is measurement of the uterine cavity with a uterine sound. The depth of the cavity should measure at least 6 cm from the external os.** However, a pilot study assessing a simplified insertion technique without the use of uterine sound or bimanual examination was found to be safe and effective (107).
3. **The use of a tenaculum for insertion is mandatory to prevent perforation. The cervix is grasped with a tenaculum and gently pulled downward to straighten the angle between the cervical canal and the uterine cavity. The IUD, previously loaded into its inserter, is gently introduced through the cervical canal.**
4. **With the *copper T380A,* the outer sheath of the inserter is withdrawn a short distance to release the arms of the T and is gently pushed inward again to elevate the now-opened T against the fundus. The outer sheath and the inner stylet of the inserter are withdrawn, and the strings are cut to project about 2 cm from the external cervical os.**
5. **The *Mirena* 52-mg LNG-IUD is inserted somewhat differently from the *copper T380A.* The inserter tube is introduced into the uterus until the preset sliding flange on the inserter is 1.5 to 2 cm from the external os of the cervix. The arms of the T device are released upward into the uterine cavity, and the inserter is pushed up under them to elevate the IUD up against the uterine fundus.**
6. **The Liletta 52-mg LNG-IUD can be inserted using a one-handed (United States) or a two-handed inserter (international).** In both cases, the deployment mechanism is more similar to that for *Mirena* than for the *copper T380A.*

In nulliparous women, insertion may be more challenging because of a narrower cervical canal than in parous women. Mechanical dilation may be necessary. While

misoprostol was initially proposed to benefit some women during IUD insertion, a systematic review found that routine pretreatment with misoprostol did not lead to improved ease or success of IUD insertion and resulted in more insertional discomfort (108).

Intrauterine Devices in Pregnancy

If an intrauterine pregnancy is diagnosed and the IUD strings are visible, the IUD should be removed as soon as possible to prevent later septic abortion, premature rupture of the membranes, and premature birth (109). When the strings of the IUD are not visible, an ultrasound examination should be performed to localize the IUD and determine whether expulsion has occurred. If the IUD is present, there are three options for management:

1. Elective abortion
2. Ultrasound-guided intrauterine removal of the IUD
3. Continuation of the pregnancy with the device left in place

If the patient wishes to continue the pregnancy, ultrasound evaluation of the location of the IUD should be considered (110). If the IUD is not in a fundal location, ultrasound-guided removal using small alligator forceps may be successful. If the location is fundal, the IUD should be left in place. When pregnancy continues with an IUD in place, the patient must be warned of the symptoms of intrauterine infection and should be cautioned to seek care promptly for fever or flulike symptoms, abdominal cramping, or bleeding. At the earliest sign of infection, high-dose intravenous antibiotic therapy should be given and the pregnancy evacuated promptly.

Duration of Use

Annual rates of pregnancy, expulsions, and medical removals decrease with each year of use (111). Therefore, a woman who has no problem by year 5, for example, is very unlikely to experience problems in the subsequent years. The *copper T380A* is FDA approved for 10 years and the *LNG-IUD* for 5 years, although good data support use of the *copper T380A* through 12 years and of the *LNG-IUD* through 7 years (63,85). Newer data from a prospective cohort study support the use of 52-mg LNG-IUD into year 6 and 7 (112,113).

Choice of Devices

All IUDs available in the United States, provide protection for many years, have remarkably low pregnancy rates, and substantially reduce the risk of ectopic pregnancy. The *LNG-IUDs* reduce the amount of menstrual bleeding and dysmenorrhea. Amenorrhea rates are 19% to 20%, 12%, and 6% for the 52-, 19.5-, and 13.5-mg LNG-IUDs at 1 year of insertion, respectively (56,59,114,115). The *copper T380A* can be

expected to initially increase menstrual bleeding. It is the most effective means for emergency contraception.

Management of Bleeding and Cramping With Intrauterine Devices

The most important medical reason that women give for requesting removal of an IUD is bleeding and pelvic pain. These symptoms are common in the first few months, but diminish over time, in most cases in months. Nonsteroidal anti-inflammatory drugs are usually helpful. When pain and bleeding occur later, the patient should be examined for signs of PID, partial expulsion of the device, or an intracavitary fibroid. Two ultrasonographic studies comparing women with these symptoms after 6 months to women with no bleeding complaints show downward displacement of the IUDs into the cervical canal in many symptomatic women and in some cases, intracavitary fibroids (116,117). When the patient wishes to continue with an IUD, removal of the displaced device and insertion of a new one is advisable. In situations where IUDs are inexpensive and ultrasound is expensive or not available, the best course is to offer immediate removal and replacement of the IUD without ultrasound proof of displacement.

Future of Intrauterine Devices

VeraCept

A novel nitinol-frame low-dose copper IUD, VeraCept (ContraMed, Campbell, California), is under investigation in a phase II multicenter study in the United States. Because of its thinner nitinol frame, the insertion tube has a small diameter. In a randomized comparison against copper T380S, VeraCept was associated with less pain with insertion, higher continuation rate at 12 months, lower expulsion rate at 12 months, and fewer removals for pain/bleeding (118). Despite containing less than half as much copper surface area (175 mm^2) as the T380S (380 mm^2), the contraceptive efficacy is similar. However, long-term efficacy has yet to be studied.

Intrauterine Ball With Copper Pearls

IUB (OCON Medical, Modiin, Israel) copper pearls are strung on a memory alloy nitinol wire, and when inserted into the uterine cavity, take the shape of the uterus. This device comes in three sizes, ranging from 12 to 18 mm in diameter with copper ranging from 300 to 380 mm^2. Preliminary results from a pilot study, however, are concerning for high expulsion rates and low user satisfaction (119).

FibroPlant

The FibroPlant 14 LNG-IUS (Contrel Research, Ghent, Belgium) is a frameless levonorgestrel-releasing IUD which contains a nonresorbable thread with a knot that is implanted into the myometrium of the uterine fundus. The attached implant delivers either 14 or 20 mcg of levonorgestrel each day and is approved for 5 years of use. The

reported pregnancy rate at 5 years is 0.4%, with similarly low expulsion and perforation rates (120).

HORMONAL CONTRACEPTION

Hormonal contraceptives are female sex steroids, synthetic estrogen and synthetic progesterone (progestin), or progestin-only without estrogen. They can be administered in the form of OCs, patches, implants, and injectables. The most widely used hormonal contraceptive is the combination OC containing estrogen and progestin. Combination OCs can be monophasic, with the same dose of estrogen and progestin administered each day, or multiphasic, in which varying doses of steroids are given through a 21-day or 24-day cycle. Combination OCs are packaged with 21 active tablets and 7 placebos, or 24 active tablets and 4 placebo tablets. The inclusion of placebos allows the user to take one pill every day without having to count. The medication-free interval while the user takes the placebo tablets allows withdrawal bleeding that mimics a 28-day menstrual cycle. To begin OC use, the user takes the first pill any time from the first day of menses through the Sunday after menstruation begins and thereafter starts a new pack as soon as the first pack is completed. The 7-day medication-free interval was standard for years, but studies showed that a shorter medication-free interval is adequate to trigger cyclic withdrawal bleeding and maintains better suppression of ovulation. Ovarian follicles mature more during the 7-day medication-free interval than during the 4-day interval. Hence the new 24/4 combination theoretically could be more effective in preventing pregnancy than the 21/7 combination, but this has not been demonstrated. Other variations of OC administration are the extended-cycle and the continuous-cycle methods. Users take active pills containing an estrogen–progestin combination for 3 months at a time (extended cycle) or indefinitely for a year or more (continuous cycle). Users on these regimens have more unscheduled days of spotting or bleeding than those on 28-day cycles in the beginning, but become amenorrheic. As a result, they experience fewer cycle-triggered symptoms such as headache and menstrual pain. Continuous combined regimens are preferred for women with chronic pelvic pain or when dysmenorrhea is not relieved by OCs taken in 28-day cycles (121).

Progestin-only OCs are taken every day without interruption. Other forms of hormonal contraception include transdermal administration with the patch, injectable progestins, injectable estrogen–progestin combinations, subdermal implants that release progestin, and vaginal rings that release either estrogen–progestin or progestin alone (122).

Where modern hormonal contraception is concerned, it is important to note that: (i) ALL hormonal contraceptives, even those containing estrogen are progestin-dominant, meaning that progestin effects are the dominant ones and (ii) the progestin is doing the

real contraceptive "work" by either suppressing ovulation or thickening the cervical mucous. The presence of the estrogen component assists with cycle control and adds to the ovarian suppressive effect, but overall the progestin component dominates.

Steroid Hormone Action

Sex steroids are characterized by their affinity for specific estrogen, progesterone, or androgen receptors, and by their biologic effects in different systems (123). Steroids are rapidly absorbed in the gut but go directly into the liver through the portal circulation, where they are rapidly metabolized and inactivated. Therefore, large doses of steroids are required when they are administered orally. The addition of the ethynyl group to carbon-17 of the steroid molecule hinders degradation by the liver enzyme 17-hydroxysteroid dehydrogenase and allows potent biologic activity after oral doses of only micrograms.

Progestins

Progestins are synthetic compounds that mimic the effect of natural progesterone but differ from it structurally. The progestins differ from one another in their affinities for estrogen, androgen, and progesterone receptors; their ability to inhibit ovulation; and their ability to substitute for progesterone and to antagonize estrogen. Some are directly bound to the receptor (*levonorgestrel, norethindrone*), whereas others require bioactivation as, for example, desogestrel, which is converted in the body to its active metabolite, etonogestrel. The 17-acetoxy progestins (e.g., *medroxyprogesterone acetate*) are bound by the progesterone receptor. *Norgestrel* exists as two stereoisomers, identified as dextronorgestrel and levonorgestrel. Only levonorgestrel is biologically active. Three newer progestins (*norgestimate, desogestrel,* and *gestodene*) are viewed as more "selective" than the other 19-nor progestins, in that they have little or no androgenic effect at doses that inhibit ovulation (124). The FDA-approved *norgestimate*- and *desogestrel*-containing OCs, and *gestodene* are available in Europe. *Gestodene* is a derivative of levonorgestrel that is more potent than the other preparations (i.e., very little of it is required for antifertility effects). Similarly, *norelgestromin* is an active metabolite of *norgestimate* and more potent than the parent compound. It is used in the transdermal patch. *Drospirenone,* a progestin introduced in the United States, is a derivative of the diuretic spironolactone. It has a high affinity for progesterone receptors, mineralocorticoid receptors, and androgen receptors. It acts as a progesterone agonist but is a mineralocorticoid antagonist and androgen antagonist (125). Comparative studies suggest a small decrease in body weight and in blood pressure, with equivalent cycle control and contraceptive efficacy, in women taking an OC containing 3 mg of *drospirenone*/30-µg *ethinylestradiol (EE)* versus women taking a 150-µg *levonorgestrel*/30-µg *EE* preparation (126). Pilot studies among women with polycystic ovary syndrome showed good cycle control and reduction in androgen levels

with no change in weight, blood pressure, or glucose metabolism (127). The FDA approved the 20-µg *EE*/3-mg *drospirenone* OC for premenstrual dysphoric disorder (PMDD) in women who chose OCs for contraception. When compared to an OC with 30-µg *EE*/150-µg *levonorgestrel,* women taking the *drospirenone* OC had better relief of menstrual symptoms, better improvement in acne, reduction in negative affect during the menstrual phase, and a greater feeling of well-being (128). *Dienogest,* another progestin introduced in the United States, is combined with *estradiol valerate,* not *EE.* Whether it offers any advantage over already marketed OC combinations is not yet evident. The *dienogest/estradiol valerate* combination is as effective as *levonorgestrel/EE* as a contraceptive, and in treating abnormal uterine bleeding (129).

Estrogens

In the United States, most OCs contain *EE.* An older formulation OC contains *mestranol,* which is *EE* with an extra methyl group. It requires bioactivation in the liver, where the methyl group is cleaved, releasing the active agent, *EE.* OCs with 35 µg of *EE* provide the same blood levels of hormone as do OCs containing 50 µg of *mestranol* (130). Other contraceptives contain 17 β-estradiol (Zoely) or its ester, *estradiol valerate* (Qlaira) or *estradiol cypionate* (Cyclofem), an injectable.

Antifertility Effects

Combination Estrogen–Progestin Contraceptives

Ovulation can be inhibited by estrogen or by progestin alone. Pharmacologic synergism is exhibited when the two hormones are combined and ovulation is suppressed at a much lower dose of each agent. Combination OCs, patches, and the *NuvaRing* suppress basal follicle-stimulating hormone (FSH) and LH. They diminish the ability of the pituitary gland to synthesize gonadotropins when it is stimulated by hypothalamic GnRH (131). Ovarian follicles do not mature, little estradiol is produced, and there is no midcycle LH surge. Ovulation does not occur, the corpus luteum does not form, and progesterone is not produced. This blockade of ovulation is dose related. Newer low-dose OCs do not provide as dense a block and allow somewhat higher baseline FSH and LH levels than higher-dose formulations (132). This makes ovulation somewhat more likely to occur if pills are missed or if the patient takes another medication that reduces blood levels of the contraceptive steroids.

Progestin-Only Preparations

Highly effective contraception can be provided by progestin alone, thus avoiding the risks of estrogen. The mode of action of progestin-only contraceptives is highly dependent on the dose of the compound (133). With low levels of progestin in the blood, ovulation will occur part of the time. At moderate levels of progestin in the

blood, normal basal levels of FSH and LH are present, and some follicle maturation may occur. At higher blood levels as seen with *DepoProvera,* the basal FSH is reduced, and there is less follicular activity, less estradiol production, and no LH surge.

Transdermal Hormonal Contraception

The patch (*Ortho Evra*), which adheres to the user's skin, and the vaginal *NuvaRing* contain combinations of *EE* and a potent progestin. Both provide sustained release of the steroids and result in relatively constant serum levels that are less than the peak levels seen with OCs but sufficient to prevent ovulation.

Hormonal Implants

With the *levonorgestrel* subdermal implants there is some follicular maturation and estrogen production, but LH peak levels are low and ovulation is often inhibited. In the first year of use, ovulation is believed to occur in about 20% of cycles. The proportion of ovulatory cycles increases with time, probably as a result of the decline in hormone release. By the fourth year of use, 41% of cycles are ovulatory. The more potent progestin released by the *etonogestrel* implant is even more effective at preventing ovulation (134). The mechanisms of action of low-dose progestins include effects on the cervical mucous, endometrium, and tubal motility. The scant, dry cervical mucous that occurs in women using implants inhibits sperm migration into the upper tract. Progestins decrease nuclear estrogen receptor levels, decrease progesterone receptors, and induce activity of the enzyme 17-hydroxysteroid dehydrogenase, which metabolizes natural 17 β-estradiol (133).

The sustained release offered by contraceptive implants allows for highly effective contraception at relatively low steroid blood levels. **Figure 14-6** depicts expected steroid blood levels with implants, injectables, and OCs. An additional mechanism for contraception was discovered with the antiprogesterone *mifepristone* (*RU486*). In the normal cycle, there is a small amount of progesterone production from the follicle just before ovulation. This progesterone appears essential to ovulation, because if *mifepristone* is given before ovulation this can be delayed for several days (135,136).

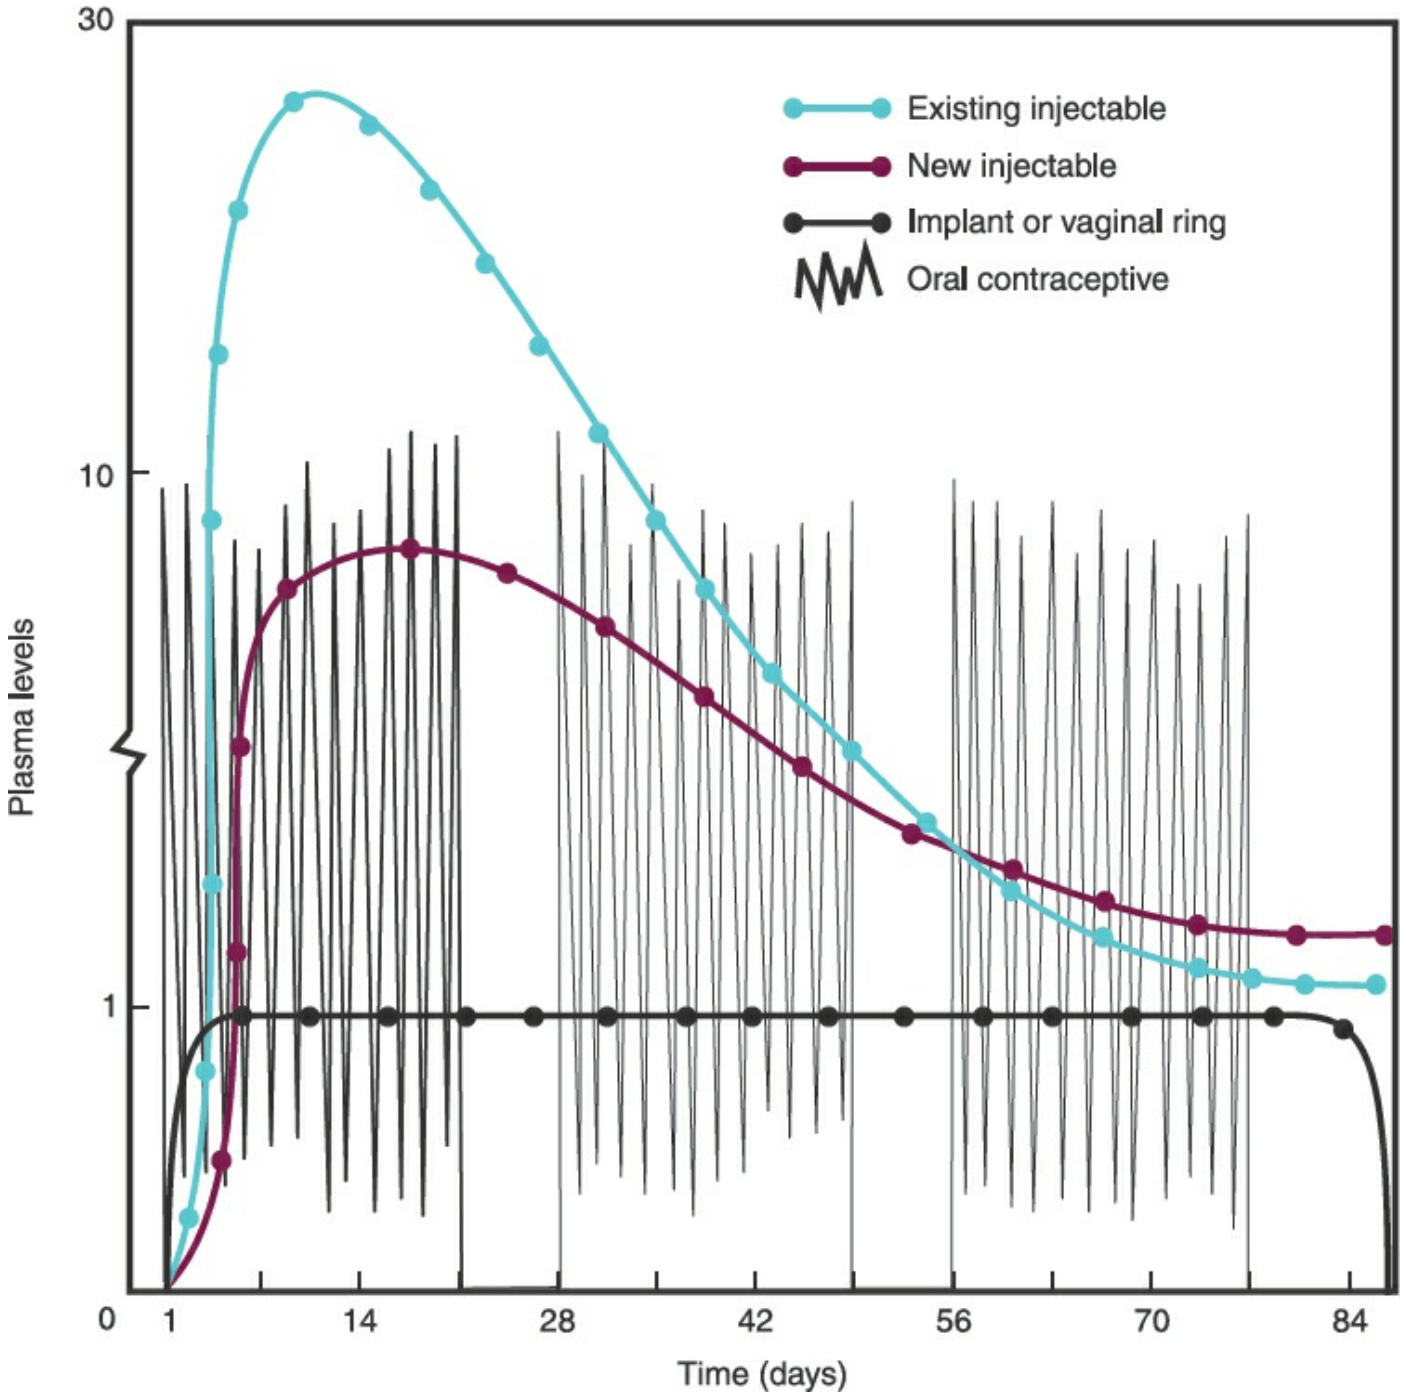

FIGURE 14-6 Schematic representation of the expected pharmacokinetic profiles of progestogens administered in different formulations. (From **Landgren BM**. Mechanism of action of gestagens. *Int J Gynaecol Obstet* 1990;32:95–110, with permission.)

Efficacy of Hormonal Contraception

[4] When used consistently, combination OCs have pregnancy rates as low as 2 to 3 per 100 women per year. Progestin-only OCs are less effective than combination estrogen–progestin preparations, with best results of 3 to 4 pregnancies per 100 woman-years. All methods have the potential for user error; therefore, there may be a

10-fold difference between the best results and results in typical users of OCs. Injectable progestins and implants are much less subject to user error than OCs. The difference between the best results and results in typical users is small and is comparable to pregnancy rates after tubal sterilization (Table 14-1). Pregnancy rates with the *Ortho Evra* patch and the *NuvaRing* were equivalent to those of OCs; however, because it is easier to use these methods consistently, larger studies may well demonstrate better typical user results than with OCs (137,138). Typical use pregnancy rates with *depomedroxyprogesterone acetate (DMPA)* are lower. The subdermal implants have the lowest failure rates of any hormonal contraceptive method.

Hormonal Contraception for Obese Women

The rate of obesity worldwide is increasing. Across the United States, more than one in three adults are obese (139). Most studies of contraceptive efficacy intentionally excluded obese women, so the available information is limited. Obese women are no less likely than other women to become pregnant, but they have an increased risk of pregnancy complications (140). A systematic review of hormonal contraception for overweight and obese women focused on 12 relevant studies (141). The data on the risk of pregnancy in overweight and obese women using OCs was mixed, with one study showing increased risk while another showing decreased risk. Analysis of data from other contraceptive methods indicated no association of pregnancy with overweight or obesity. These included depot medroxyprogesterone acetate (subcutaneous), LNG-IUD, the two-rod levonorgestrel implant, and the etonogestrel implant. One study evaluated a contraceptive patch containing EE and levonorgestrel, and found that obese women in the "treatment-compliant" subgroup had a higher reported Pearl Index than nonobese women.

Metabolic Effects and Safety

Venous Thrombosis

[4] Women who use estrogen-containing hormonal contraceptives are at increased risk for venous thrombosis and thromboembolism. Normally the coagulation system maintains a dynamic balance of procoagulant and anticoagulant systems. Estrogens affect both systems in a dose-related fashion. For most women, fibrinolysis (anticoagulation) is increased as much as coagulation, maintaining the dynamic balance at increased levels of production and destruction of fibrinogen (Fig. 14-7) (142). Older studies included women with what are now considered contraindications to the use of estrogen-containing hormonal contraceptives: previous thrombosis, preexisting vascular disease, coronary artery disease, cancers, and serious trauma (142,143). Low-dose OCs have a less measurable effect on the coagulation system, and fibrinolytic factors increase at the same rate as procoagulant factors. **Lower estrogen–dose (30- to 35-lg *EE*) OCs reduce the risk of a thromboembolic event when compared with higher-**

dose (50-lg estrogen) OCs (144). A very large Danish study showed for the first time that combination OCs with 20 µg of *EE* have an 18% further reduction in thrombosis risk compared with 30- to 40-µg OCs after adjustment for duration of use (145). The progesterone-only OCs and the *levonorgestrel*-releasing IUD were not associated with venous thrombosis.

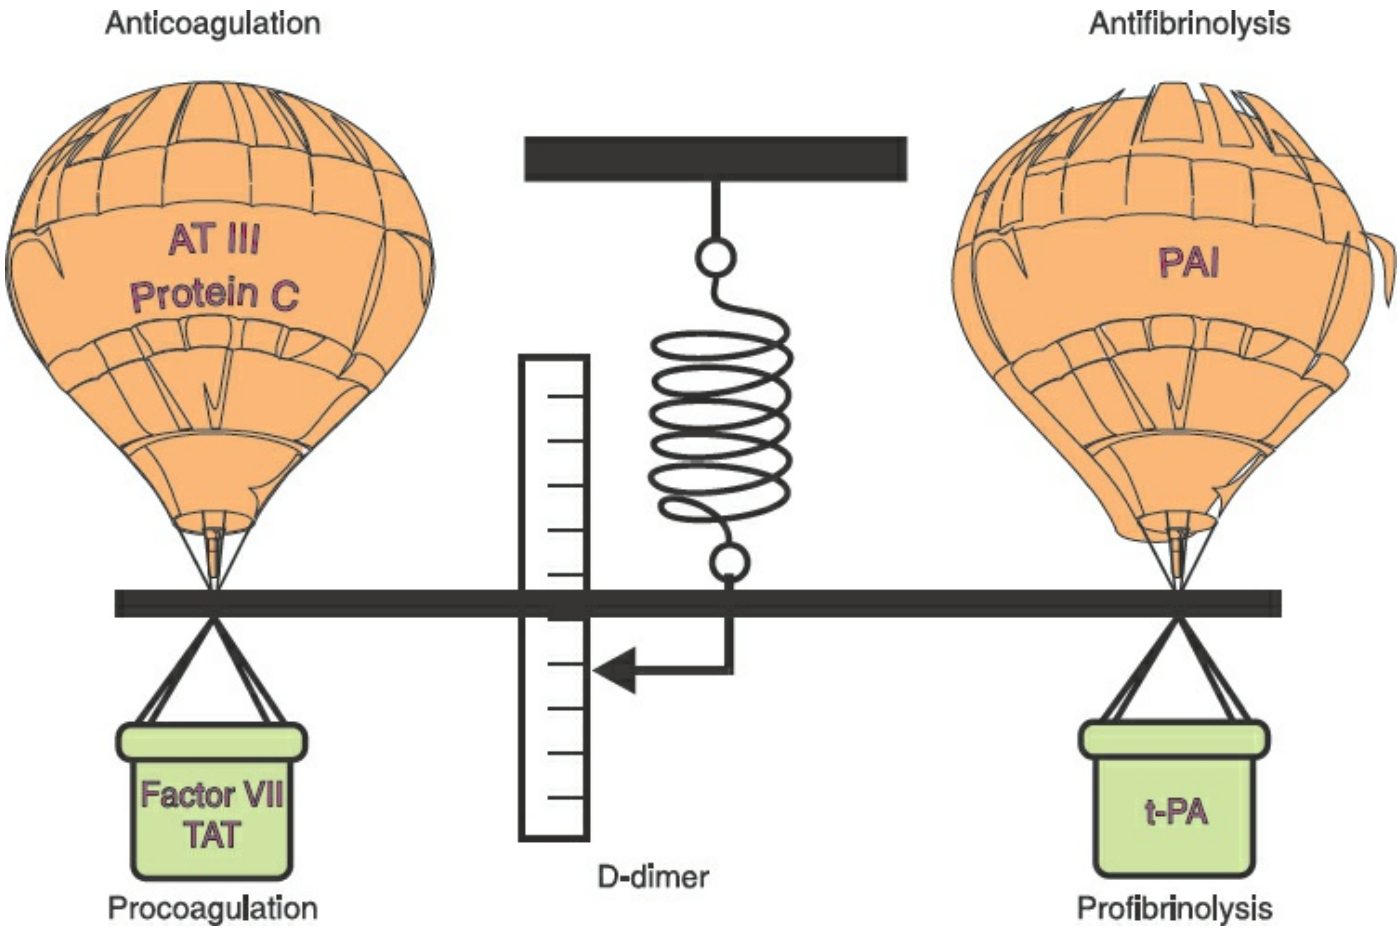

FIGURE 14-7 Dynamic balance of hemostasis. (From **Winkler UH, Buhler K, Schlinder AE**. The dynamic balance of hemostasis: implications for the risk of oral contraceptive use. In: Runnebaum B, Rabe T, Kissel L, eds. *Female Contraception and Male Fertility Regulation. Advances in Gynecological and Obstetric Research Series*. Oxfordshire, UK: CRC Press, 1991:85–92. Reproduced by permission of Taylor and Francis Group, LLC, a division of Informa plc.)

The absolute risk of deep vein thrombosis was strongly influenced by age, increasing from 1.84 per 10,000 women aged 15 to 19 years to 6.59 per 10,000 for women aged 45 to 49 years with current users, former users, and never users combined. With all types of OCs combined, the overall absolute rate of deep vein thrombosis was 6.29 per 10,000 woman-years for current OC users compared to 3.01 among nonusers, giving an adjusted rate ratio of 2.83 (95% CI, 2.65–3.01). This is a higher absolute risk than the 3 per 10,000 woman-years previously estimated and may reflect, among other things, the use of better means for diagnosis of deep vein thrombosis (145). This population-based study includes all Danish women aged 15 to 49 years, excluding only women with a

diagnosis of cancer or of cardiovascular disease diagnosed before the study interval. Thrombosis risk was highest during the first year of use and decreased thereafter.

Thrombophilia

Changes in the coagulation system are detectable in all women, including those taking lower-dose OCs; some women are genetically predisposed to thrombosis when challenged by pregnancy or administration of exogenous estrogen**. Women with inherited deficiencies of antithrombin III (ATIII), protein C, or protein S are at very high risk for thrombosis with pregnancy or estrogen therapy, but they make up a very small proportion of potential OC users.** A much more common variation, factor V Leiden exists in 3% to 5% of the Caucasian population. It codes for a one amino acid mutation in the factor V protein, inhibiting cleavage of the protein by activated protein C (APC), which is an essential step in maintaining the balance between coagulation and fibrinolysis (146). Risk for a first thromboembolic episode among women using OCs was 2.2 per 10,000 woman-years for women without the factor V mutation and 27.7 per 10,000 woman-years for women with the mutation (147). There are pronounced ethnic differences in the presence of this mutation. The Leiden allele is found in 3% to 5% of Caucasians but is rare in Africans, Asians, Amerindians, Eskimos, and Polynesians (148). A similar mutation is found in the prothrombin gene at position 20,210 and is described as prothrombin G20210A. This mutation occurs in 3% of the European population and is strongly associated with venous thrombosis in women taking OCs (149). Many more genetic conditions predisposing to thrombosis were described. Pregnancy is an even greater challenge for women with inherited defects of anticoagulation (150). A woman who sustains a venous event while using OCs should be evaluated thoroughly after she has recovered. Assessment should include at minimum the measurement of ATIII, protein C, and protein S levels, resistance to APC, serum homocysteine, factor V Leiden mutation, the prothrombin G20210A mutation and testing for antiphospholipid syndrome. It should not be assumed that hormonal contraception was the unique cause of the thrombotic episode.

Routine screening for all women before prescribing hormonal contraception is not justified because effective contraception would be denied to 5% of Caucasian women, and only a small number of fatal pulmonary emboli would be prevented (151,152). Screening women with a personal or family history of deep vein thrombosis before starting estrogen-containing hormonal contraception or pregnancy is strongly recommended. Women already diagnosed as having factor V Leiden should not receive estrogen-containing contraceptives, that is, the pill, patch, or ring.

Thrombosis and the New Progestins

Several studies found increased risk of venous thrombosis when users of OCs containing the newer progestins *desogestrel* or *gestodene* combined with 20 to 30 μg of *EE* were compared with users of *levonorgestrel* combined with the same doses of

estrogen (153,154). Subsequent studies showed mixed results. One study found no difference in thrombosis risk in users of OCs containing desogestrel or gestodene compared to users of OCs with other progestins in a large study of cases occurring between 2002 and 2006 in Austria (155). In 2013, a systematic review combining data from 26 studies (including the aforementioned ones) demonstrated that the RR of venous thrombosis for OCs containing 30 to 35 µg of EE and gestodene, desogestrel, cyproterone acetate or drospirenone were 50% to 80% higher than formulations containing levonorgestrel **(Fig. 14-8)**. However, this risk increase corresponds to approximately a difference of 3 cases per 10,000 women-years comparing second and third generation progestin users (in contrast to a VTE incidence of 20 cases per 10,000 in pregnancy) (156).

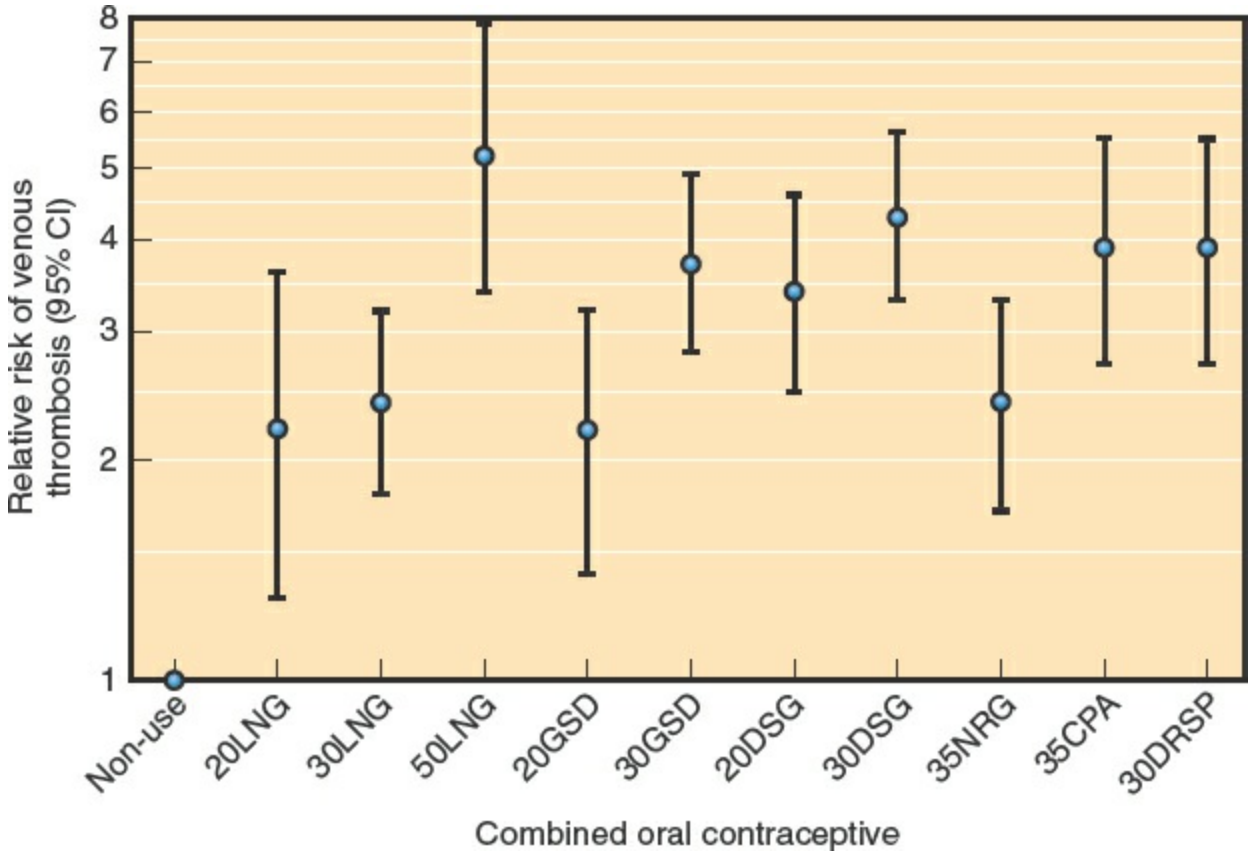

FIGURE 14-8 Network meta-analysis, per contraceptive plotted on a logarithmic scale. 20LNG, 20-µg ethinylestradiol with levonorgestrel; 30LNG, 30-µg ethinylestradiol with levonorgestrel; 50LNG, 50-µg ethinylestradiol with levonorgestrel; 20GSD, 20-µg ethinylestradiol with gestodene; 30GSD, 30-µg ethinylestradiol with gestodene; 20DSG, 20-µg ethinylestradiol with desogestrel; 30DSG, 30-µg ethinylestradiol with desogestrel; 35NRG, 35-µg ethinylestradiol with norgestimate; 35CPA, 35-µg ethinylestradiol with cyproterone acetate; 30DRSP, 30-µg ethinylestradiol with drospirenone; overall relative risk (95% confidence interval) of venous thrombosis (*dots* [*lines*]); non-use, reference group.

Ischemic Heart Disease

Ischemic heart disease and stroke were the major causes of death attributed to OC use in the past. It is known that the principal determinants of risk are advancing age and

cigarette smoking (157). **With higher-dose OCs used in the 1980s, smoking had a profound effect on risk. Women smoking 25 or more cigarettes per day had a 30-fold increased risk for myocardial infarction if they used OCs, compared with nonsmokers not using OCs** (158). **The use of OCs became safer because most women are taking low-dose pills and because physicians prescribe selectively, excluding women with major cardiovascular risk factors.** A very large study in the United States confirmed the safety of OCs as currently prescribed. A total of 187 women aged 15 to 44 years with confirmed myocardial infarction were identified during 3.6 million woman-years of observation in the Kaiser Permanente Medical Care Program in California from 1991 to 1994. This is a rate of 3.2 per 100,000 woman-years (159). Nearly all of the users took OCs with less than 50 µg of *EE.* After adjusting for age, illness, smoking, ethnicity, and body mass index, risk for myocardial infarction was not increased by OC use (OR, 1.14; 95% CI, 0.27–4.72). Of heart attack victims, 61% smoked; only 7.7% were current users of OCs. In a later study, the same investigators pooled results from the California study with a similar study from the Washington State. The results were the same. **[5] Current users of low-dose OCs had no increased risk for myocardial infarction after adjustment for major risk factors and sociodemographic factors** (160). Past use of OCs does not increase risk for subsequent myocardial infarction (161). These observations are supported by another population-based prospective study. OC use and myocardial infarction were studied prospectively among 48,321 randomly selected women aged 30 to 49 years in the Uppsala Health Care Region of Sweden (162). There was no association between current or past OC use and myocardial infarction. Most current users were taking low-dose estrogen pills (defined as less than 50 µg of EE or less than 75 µg of *mestranol*) with second or third generation progestins, more than half were aged 35 or older, and 26% were current cigarette smokers.

Oral Contraceptives and Stroke

In the 1970s, OC use appeared to be linked to the risk of hemorrhagic and thrombotic stroke, but these studies failed to take into consideration preexisting risk factors (163). A rare form of cerebrovascular insufficiency, the moyamoya disease, is linked to OC use, especially among cigarette smokers (164). **The evidence shows no risk of stroke among women who are otherwise healthy and who use low-dose pills.** One study identified all Kaiser Permanente Medical Care Program patients aged 15 to 44 years who sustained fatal or nonfatal stroke in California from 1991 to 1994 (165). Hypertension, diabetes, obesity, current cigarette smoking, and black ethnicity were strongly associated with stroke risk, but neither current nor past OC use was associated with stroke. A WHO study of cases from 1989 to 1993 from 17 countries in Europe and the developing world included women taking higher-dose OCs and low-dose OCs. European women using low-dose OCs had no increased risk for either type of stroke,

thrombotic or hemorrhagic. Those taking higher-dose OCs did have measurable risk (166,167). Women in developing countries had an apparent modest increase in risk, but this finding was attributed to undetected existing risk factors. Another study from Europe found less stroke risk from low-dose pills than from older, higher-dose pills, and that the risk was less if the patient's blood pressure was checked before starting OCs.

Women who smoke and those who have hypertension and diabetes are at increased risk for cardiovascular disease regardless of whether they use OCs. The important question is whether the risk is further increased if they use low-dose OCs, and if so, by how much. The WHO study provides some insight: smokers taking OCs had seven times the risk of ischemic (thrombotic) stroke when compared with smokers who did not use OCs, and hypertensive women had 10-fold increased risk if they took OCs, but a fivefold risk if they did not (166). Similarly, a study from Denmark found that women with diabetes had a fivefold increase risk for stroke, which increased to 10-fold if they took OCs (168). These data were not limited to low-estrogen OCs. The data suggest that although the risk is primarily determined by the predisposing condition—hypertension, diabetes, or cigarette smoking—the risk can be magnified by OC use, even when the OCs are low dose. These observations were confirmed in a systematic review (169). Hypertensive women using combination estrogen– progestin oral contraceptives (COCs) had higher risk for ischemic stroke and acute myocardial infarction than hypertensive women not using COCs. The US practice of limiting hormonal contraceptives containing estrogen by women older than 35 years of age to nonsmokers without other vascular disease risk factors is prudent (7).

Blood Pressure

OCs have a dose-related effect on blood pressure. With the older high-dose pills, as many as 5% of patients could be expected to have blood pressure levels greater than 140/90 mm Hg. The mechanism is believed to be an estrogen-induced increase in renin substrate in susceptible individuals. **Low-dose pills have minimal blood pressure effects,** but surveillance of blood pressure is advised to detect the occasional idiosyncratic response.

Glucose Metabolism

Oral estrogen alone has no adverse effect on glucose metabolism, but progestins exhibit insulin antagonism (170). Older OC formulations with higher doses of progestins produced abnormal glucose tolerance tests with elevated insulin levels in the average patient. The effect on glucose metabolism, similar to the effect on lipids, is related to androgenic potency of the progestin and to its dose.

Lipid Metabolism

Androgens and estrogens have competing effects on hepatic lipase, a liver enzyme

critical to lipid metabolism. **Estrogens depress low-density lipoproteins (LDL) and elevate high-density lipoproteins (HDL), changes that can be expected to reduce the risk of atherosclerosis** (171). Androgens and androgenic progestins can antagonize these beneficial changes, reducing HDL and elevating LDL levels. Estrogens elevate triglyceride levels. Low-dose formulations have minimal adverse effect on lipids, and the newer formulations (with *desogestrel* and *norgestimate* as the progestin) produce potentially beneficial changes by elevating HDL and lowering LDL (172,173). Although average values of a large group show only small lipid changes with the use of current OCs, an occasional patient may have exaggerated effects. Women whose lipid values are higher than the mean before treatment are more likely to experience abnormalities during treatment (172).

Other Metabolic Effects

OCs can produce changes in a broad variety of proteins synthesized by the liver. The estrogen in OCs increases circulating thyroid-binding globulin, thereby affecting tests of thyroid function that are based on binding, increasing total thyroxine (T_4) levels, and decreasing triiodothyronine (T_3) resin uptake. The results of actual thyroid function tests, as measured by free T_4 and radioiodine tests, are normal (174).

Oral Contraceptives and Neoplasia

Endometrial and Ovarian Cancers

Combination OCs reduce the risk of subsequent endometrial cancer and ovarian cancer (175,176). **[8] Two-year use of OCs reduces the risk of endometrial cancer by 40%, and 4 or more years of use reduces the risk by 60%. The evidence for this benefit continues to accumulate** (177). **[8] A 50% reduction in ovarian cancer risk for women who took OCs for 3 to 4 years and an 80% reduction with 10 or more years of use were reported** (178). There was some benefit from as little as 3 to 11 months of use. **A review of all available studies in the world published in English through 2008 concluded that ovarian cancer risk decreased by 20% for each 4 years of use and was seen for carriers of the BRCA1 and BRCA2 mutations as well. The benefit persisted for at least 30 years after last use** (179). A similar reduction of risk of ovarian epithelial cancer was found in a prospective study from Norway and Sweden, with borderline tumor risk equally reduced. Combination OCs with less than 50 µg of *EE,* or less than 100 µg of mestranol and reduced doses of progestin, provided as much protection as higher-dose pills (180). Today's lower-dose 20-µg *EE* pills were not separately studied. Whether or not they provide the same benefit remains unproven; however, progestin-only contraceptives are reported to provide risk reduction equivalent to that of combined OCs (181).

Colorectal Cancer

There is evidence that OC use is protective against colon cancer. A case-control study in Italy comparing women with colon cancer with controls found a 37% reduction in colon cancer and a 34% reduction in rectal cancer (colon cancer OR, 0.63; 95% CI, 0.45–0.87 and rectal cancer OR, 0.66; 95% CI, 0.43–1.01). Longer use produced more protection against colon cancer (182). Results of the US Nurses' Health Study disclosed some degree of protection. Women who used OCs for 96 months or more had a 40% lower risk of colorectal cancer (RR, 0.60; 95% CI, 1.15–2.14) (183). A large case-control study from Wisconsin found most of the benefit limited to women who were less than 14 years since discontinuing OCs (184). The mechanism of protection has not been identified. A long-term study that prospectively evaluated women for up to 44 years detected ever use of OCs was associated with reduced colorectal cancer (IRR, 0.81; 99% CI, 0.66–0.99) (185).

Cervical Cancer

There may be a weak association between OC use and cancer of the cervix. A systematic review of 28 epidemiologic studies of cervical cancer in OC users compared with those who never used OCs reported summary RRs of 1.1 (95% CI, 1.1–1.2) at less than 5 years of pill use, 1.6 (1.4–1.7) at 5 to 9 years, and 2.2 (1.9–2.4) at 10 or more years (186). A 2007 update by these same authors reported a pooled RR for all studies of 1.9 (95% CI, 1.69–2.13) for invasive cervical cancer or CIN3/carcinoma in situ (CIS) with 5 or more years of OC use. The risk declined after use ceased and by 10 years returned to that of never users (187). In a study that observed women for up to 44 years, an increased risk of cervical cancer that was seen in current and recent users appeared to be lost within 5 years of stopping oral contraception with no evidence of increased risk in ever users with time (185). Critics of these studies argued that causation is not proven because few adequately control for the key behavioral factors of partners, use of barrier contraception, and adequacy of cervical cancer screening (188). Important risk factors for cervical cancer are early sexual intercourse and exposure to HPV. Women who used OCs typically started sexual relations at younger ages than women who have not used OCs and, in some studies, report having had more partners. These factors increase one's chance of acquiring HPV, the most important risk factor for cervical cancer. Because barrier contraceptives reduce the risk of cervical cancer, the use of alternative choices for contraception compounds the difficulty in establishing an association with OC use alone (189). The presence of HPV types 16 or 18 is associated with a 50-fold increase in risk for precancerous lesions of the cervix (190). Adenocarcinomas of the cervix are rare, they are not as easily detected as other lesions by screening cervical cytology, and the incidence appears to be increasing. One study found a doubling of risk for adenocarcinoma with OC use that increased with the duration of use, reaching an RR of 4.4 if the total use of OCs exceeded 12 years (191). The results of this study were adjusted for history of genital warts, number of sexual

partners, and age at first intercourse. Another summary of case-control studies includes testing for HPV. HPV types 16 or 18 were present in 82% of the patients, yielding an RR of 81.3 (95% CI, 42.0–157.1) for the disease. Cofactors identified with adenocarcinoma included longer-term use of hormonal contraception. The use of hormonal contraception by women aged 20 to 30 years is estimated to increase the incidence of cervical cancer (any cervical cancer, or CIN3/CIS) diagnosed by age 50 from 7.3 to 8.3 per 1,000 women in lesser-developed countries and from 3.8 to 4.5 in developed countries (192). The use of OCs is, at most, a minor factor in causation of cervical cancer; these findings emphasize the need to immunize against HPV and to provide cervical cancer screening worldwide. To reduce the risk, women who are not in mutually monogamous relationships should be advised to use barrier methods in addition to hormonal contraception. A meta-analysis demonstrated that invasive cervical cancer may be approximately one-third less frequent in women who have used an IUD (193).

Breast Cancer

There is a large volume of conflicting literature on the relationship between OC use and breast cancer (194). No increase in overall risk is found from OC use, but some studies found that risk may increase in women who used OCs before their first term pregnancy, used OCs for many years, are nulligravid, are young at the time of diagnosis, or continue using OCs in their 40s. **[6]** A meta-analysis of 54 studies of breast cancer and hormonal contraceptive use reanalyzed data on 53,297 women with breast cancer and 100,239 controls from 25 countries, representing about 90% of the epidemiologic data available worldwide (195). Current use of OCs was associated with a very small, but statistically stable 24% increased RR (1.24; 95% CI, 1.15–1.33). The risk fell rapidly after discontinuation, to 16% 1 to 4 years after stopping and to 7% 5 to 9 years after stopping. Risk disappeared 10 years after cessation (RR, 1.01; 95% CI, 0.96–1.05). Results did not differ in any important way by ethnic group, reproductive history, or family history. Since the meta-analysis was published, subsequent studies found no increased risk. A case-control study of 4,575 women with breast cancer and 4,682 controls aged 35 to 64 years living in five cities in the United States concluded that breast cancer risk was not increased for current or past users of OCs and did not increase with prolonged or with higher-estrogen OC use (196). Neither family history of breast cancer nor beginning use at a young age was associated with increased risk. A similar study in Sweden compared 3,016 women aged 50 to 74 years who had invasive breast cancer with 3,263 controls of the same age. **[6]** No relation was found between the past use of OCs and breast cancer (197). Effect of hormone dose was explored in a 2008 US study of 1,469 women with breast cancer who were matched by race, age, and neighborhood to community controls. The investigators administered questionnaires and performed BRCA1 and BRCA2 testing. Subjects who

began OC use during or after 1975 were considered to have used low-dose pills. "Low dose" was not further defined. Neither OC use overall or "low-dose" OC use was associated with breast cancer risk, among the total group, or within any subset. Women with BRCA1 or BRCA2 did not have higher rates of cancer whether they were OC users or nonusers (198). **[6]** A prospective cohort study evaluating very–long-term risks or benefits associated with the use of combined OCs found an increased breast cancer risk in current and recent users that appeared to be lost within 5 years of stopping (185). **The controversy over the association between breast cancer and OC use is likely to continue. While concerns about a connection continue to circulate, the benefits of OC use, particularly protection against pregnancy and the other noncontraceptive benefits, outweigh the risks for the vast majority of women.**

Liver Tumors

OCs were implicated as a cause of benign adenomas of the liver. These hormonally responsive tumors can cause fatal hemorrhage. They usually regress when OC use is discontinued; the risk is related to prolonged use (199). The tumors are rare; about 30 cases per 1 million users per year were predicted with older formulations. Presumably, newer low-dose products pose less risk. A link to hepatic carcinoma was proposed. This cancer is closely associated with chronic hepatitis B and C infections and is usually seen in cirrhotic livers. There are case reports of hepatocellular carcinoma in young women with no risk factors other than long-term OC use (200). A large study from six countries in Europe found no association between the use of OCs and subsequent liver cancer (201). A systematic review looked for evidence of harm associated with hormonal contraceptive use among women already at risk because of liver disease (202). The authors concluded from the limited data available that OCs do not affect the course of acute hepatitis or chronic hepatitis, and do not affect the rate of progression or the severity of cirrhotic fibrosis, the risk of hepatocellular carcinoma in women with chronic hepatitis, or the risk of liver dysfunction in hepatitis B virus carriers.

Oral Contraceptives and Sexually Transmitted Infections

Chlamydial colonization of the cervix appears more likely in OC users than in nonusers but, despite this finding, several case-control studies found a reduced risk of acute PID among OC users (203,204). In contrast, a subsequent study found no protection with OC use (205). Whether hormonal contraceptives influence acquisition of HIV remains under debate. A recent systematic review increased concern about a potential causal association between DMPA use and HIV acquisition with hazard ratio (HR) estimated at 1.5 or less (206). In response to these findings, the WHO convened and updated recommendations for the use of progestogen-only injectables from category 1 to category 2. Women should not be denied the use of progestogen-only injectables but should be advised about the uncertainty over a causal relationship. There remains no

suspected increased risk of HIV acquisition with use of OCs or contraceptive implants.

Health Benefits of Oral Contraceptives

OCs have important health benefits (Table 14-3). These include contraceptive and noncontraceptive benefits.

Contraceptive Benefits

OCs provide highly effective contraception and prevent unwanted pregnancy, an important public health problem. Combination and progestin-only contraceptives decrease the risk of pregnancy and therefore, decrease the risk of ectopic pregnancy. Studies have reported an increased proportion of pregnancies that are ectopic, in women who became pregnant while using progestin-only implants, IUDs, and OCs (207). A systematic review of progestin-only injectables and implants reported higher proportions of ectopic pregnancies in the event that pregnancy occurs; however, the review confirmed that the absolute risk of ectopic pregnancy is lower for women using these methods compared with noncontraceptive users (208). Furthermore, the clinical and epidemiologic evidence indicated that LNG-containing implants are more likely to result in an ectopic pregnancy (or any pregnancy) than the etonogestrel implant or progestin-only injectables.

Noncontraceptive Benefits

OC use produces strong and lasting reduced risk for endometrial and ovarian cancer. In addition, protection was found for women with known hereditary ovarian cancer. The use of OCs in BRCA mutation carriers was associated with a significantly reduced risk of ovarian cancer (SRR, 0.50; 95% CI, 0.33–0.75) (209). Protection increased with longer duration of use. The exact mechanisms of action of OCs in the prevention of ovarian cancer is unknown, but one leading mechanism stems from the "incessant ovulation" theory, according to which chronic ovulation contributes to ovarian cancer by causing repeated trauma of the ovarian surface epithelium (210). Therefore, OCs may decrease the risk of ovarian cancer by suppressing ovulation.

Table 14-3 Established and Emerging Noncontraceptive Benefits of Oral Contraceptives

Established Benefits
Menses-related
Increased menstrual cycle regularity
Reduced blood loss
Reduced iron-deficiency anemia
Reduced dysmenorrhea

Reduced symptoms of premenstrual dysphoric disorder[a]
Inhibition of Ovulation
Fewer ovarian cysts
Fewer ectopic pregnancies
Other
Reduced fibroadenomas/fibrocystic breast changes
Reduced acute pelvic inflammatory disease
Reduced endometrial cancer
Reduced ovarian cancer
Emerging Benefits
Increased bone mass
Reduced acne
Reduced colorectal cancer
Reduced uterine leiomyomata
Reduced rheumatoid arthritis
Treatment of bleeding disorders
Treatment of hyperandrogenic anovulation
Treatment of endometriosis
Treatment of perimenopausal changes

[a]Only the low-dose *EE/droperidol* oral contraceptive has U.S. Food and Drug Administration approval for premenstrual dysphoric disorder treatment.

From **Burkman R, Schlesselman JJ, Zieman M.** Safety concerns and health benefits associated with oral contraception. *Am J Obstet Gynecol* 2004;190(Suppl):S12, with permission.

Other documented benefits of OC use include reduction of benign breast disease (211). The use of OCs helps relieve dysmenorrhea (212). OCs offer effective therapy for women with menorrhagia and dysfunctional uterine bleeding.

All combination OCs offer some protection from functional ovarian cysts, but this is dose related (213). Although OCs may prevent cyst formation, they are not helpful in treating large functional ovarian cysts and should not be used for this purpose (214).

All combination OCs reduce circulating androgen levels and usually improve acne. Three OCs were specifically FDA approved for acne treatment: the *norgestimate/EE triphasic* (*Ortho Tri-Cyclen*), the *norethindrone/EE multiphasic*

(*Estrostep*), and the 20-µg *EE*/3-mg drospirenone OC.

Fertility After Oral Contraceptive Use

After discontinuing OCs, the return of ovulatory cycles may be delayed for a few months. Women who have amenorrhea more than 6 months after discontinuation of OCs should undergo a full evaluation because of the risk for prolactin-producing pituitary tumors. This risk is not related to OC use but rather to the probability that the slow-growing tumor was already present and produced menstrual irregularity, prompting the patient to take OCs (215).

Sexuality

There is limited literature focusing on the topic of sexual function among OC users. A 2003 Spanish study demonstrated that in a comparative cohort of women using OCs and a cohort using IUDs, sexual desire decreased over time, but was not affected by the contraceptive method (216). OCs containing the new progestin *drospirenone* are reported to improve sexual functioning and feelings of well-being (217,218).

Teratogenicity

A meta-analysis of 12 prospective studies, including 6,102 women who used OCs and 85,167 women who did not, revealed no increase in the overall risk for malformation, congenital heart defects, or limb reduction defects with the use of OCs (219). Progestins were used to prevent miscarriage. A large study compared women showing signs of threatened abortion who were treated with progestins (primarily oral *medroxyprogesterone acetate*) with women who were not treated. The rate of malformation was the same among the 1,146 exposed infants as among the 1,608 unexposed infants (220). Conversely, exposure *in utero* to diethylstilbestrol, a nonsteroidal estrogen, can induce clear cell vaginal cancer and congenital anomalies of the reproductive tract in the female offspring (221). A literature search revealed no recent reports linking teratogenicity to hormonal contraception.

Interaction of Oral Contraceptives With Other Drugs

Some drugs (e.g., *rifampin*) reduce the effectiveness of OCs; conversely, OCs can augment or reduce the effectiveness of other drugs (e.g., *benzodiazepines*) (222,223). **Perhaps of greatest clinical significance are six antiepileptic drugs: *phenytoin, phenobarbital, carbamazepine, oxcarbazepine, felbamate,* and *topiramate*** (224). These drugs and the antibiotic *rifampin* all induce synthesis of liver cytochrome P450 enzymes and reduce plasma levels of *EE* in women taking OCs, increasing the likelihood of contraceptive failure. Some antiseizure agents have no effect on the levels of contraceptive steroids in the blood. These include *valproic acid, vigabatrin, lamotrigine, gabapentin, tiagabine, levetiracetam, zonisamide, ethosuximide,* and *benzodiazepines* (224). *St. John's wort* induces cytochrome P450

and is reported to increase clearance of *EE* and *norethindrone* (225). The antifungal agents *griseofulvin, ketoconazole,* and *itraconazole* induce these hepatic enzymes and may reduce OC efficacy (225). *Ampicillin* and *tetracycline* were implicated in numerous case reports of OC failure. They kill gut bacteria (primarily clostridia) that are responsible for hydrolysis of steroid glucuronides in the intestine, which allows reabsorption of the steroid through enterohepatic circulation. It was not possible to demonstrate reduced plasma levels of *EE* overall or differences in pregnancy rates (226). Certain drugs, such as protease inhibitor *atazanavir*, appear to increase plasma levels of contraceptive steroids but the clinical significance of such an interaction is unclear (227).

An example of OCs affecting the metabolism of other drugs is seen with *diazepam* and related compounds. OC use reduces the metabolic clearance and increases the half-life of those *benzodiazepines* that are metabolized primarily by oxidation: *chlordiazepoxide, alprazolam, diazepam,* and *nitrazepam. Caffeine* and *theophylline* are metabolized in the liver by two of the P450 isozymes, and their clearance is reduced in OC users. *Cyclosporine* is hydroxylated by another of the P450 isozymes, and its plasma concentrations are increased by OCs. Plasma levels of some analgesic drugs are decreased in OC users. *Salicylic acid* and *morphine* clearances are enhanced by OC use; therefore, higher doses could be needed for adequate therapeutic effect. Clearance of *ethanol* may be reduced in OC users.

The interactions of antiretroviral drugs with contraceptive steroids are complex. Some of the drugs increase plasma steroid levels and some reduce them. A complete list of interactions is available in the Centers for Disease Control and Prevention's "U.S. Medical Eligibility for Contraception" (7).

Oral Contraceptives and Clinical Chemistry Alterations

OCs have the potential to alter a number of clinical laboratory tests as a result of estrogen-induced changes in hepatic synthesis; however, a large study comparing OC users with pregnant and nonpregnant controls found minimal changes (228). Hormone users took a variety of OCs containing 50 to 100 µg of estrogen, higher doses than are used today. Compared with nonpregnant women who were not using OCs, the OC users had an increase in T_4 that is explained by increased circulating thyroid-binding protein, no change in creatinine and globulin levels, slight reduction in mean fasting glucose values and serum glutamic oxaloacetic transaminase, and a decrease in total bilirubin and alkaline phosphatase.

Choice of Oral Contraceptives

More recently introduced OCs include those containing *drospirenone,* more preparations with only 20 µg of *EE,* new multiphasic preparations, cyclic OCs with 24 days of active medication and 4 days of either placebo or 10 µg of *EE,* and extended-

cycle and continuous-cycle preparations plus branded generic versions of most OCs. A combination OC containing *estradiol valerate* with a new progestin, *dienogest,* was approved in 2010. There is new evidence that 20-µg *EE* pills offer reduced risk for venous thrombosis (145). An approach to OC selection for new patients is to begin with a 20-µg *EE* combination and then adjust depending on the patient's symptoms after the first 2 to 3 months. As reported in a large systematic review of 20-µg *EE* OCs compared to 30- to 35-µg *EE* pills, women taking the lower-dose OCs more often report changes in vaginal bleeding, episodes of irregular bleeding and heavy bleeding, and more amenorrhea (229). If a 20-µg pill is offered, the patient should understand that bleeding may be a problem and that she should return if this persists and try a different OC rather than stop the pill. The progestin component may become more important in determining cycle control when 20-µg *EE* is used. A comparison of 20-µg *EE* OCs, one containing 100 µg of *levonorgestrel,* the other with 1 mg of *norethindrone acetate* (*NEA*) found the *NEA* to have about twice as many days of unscheduled vaginal bleeding during the first 3 months, a critical time period for new users, which might be expected to lead to discontinuation (230). In a three-way trial, the 35-µg *EE*/*norgestimate* triphasic OC (*Tri-Cyclen*) was compared with two 20-µg *EE* pills, one containing 100 µg of *levonorgestrel* (*Alesse*), the other containing 150-µg *desogestrel,* followed by 2 hormone-free days and 5 days of 10-µg *EE* per day (*Mircette*) (231). Contraceptive efficacy was not significantly different. In the first two-pill cycles, more women taking *Alesse* had breakthrough bleeding and bleeding in the second half of the cycle than those taking the other two OCs in the first two cycles, but thereafter there was little difference. Women taking the higher-estrogen *Tri-Cyclen* consistently experienced more frequent estrogenic side effects—bloating, breast tenderness, and nausea—than did women taking either 20-µg *EE* OC. These authors concluded that for the specific OCs evaluated, changing to either one of the 20-µg preparations would be beneficial.

For the average patient, the first choice of preparation for contraceptive purposes is a very low estrogen OC (20-lg *EE*) unless there are other considerations, for example, previous pregnancy while taking the pill. Patients with persistent breakthrough spotting or bleeding could be offered a pill with the same low estrogen dose, but a more potent progestin, for example *levonorgestrel.* Patients with apparent weight gain from fluid retention while taking OCs, or with hirsutism or acne that did not respond to other OCs, may benefit from a change to the *drospirenone/EE* pill. The lower-*estrogen drospirenone* combination is FDA approved for treatment of PMDD and should be considered for women with these symptoms who want hormonal contraception. **Women with acne often benefit from the reduction in circulating testosterone that occurs with all combination OCs. Women who experience continuing pelvic pain, dysmenorrhea, or other menstrual-triggered symptoms or who simply prefer fewer menstruations may be offered an extended-**

cycle or continuous-cycle OC regimen.

Alternative Routes for Hormonal Contraception

The *Ortho Evra* patch and the *NuvaRing* provide combinations of ultrapotent progestins with *EE.* Both patch and ring provide almost constant low levels of the contraceptive steroids that are less than the peak levels seen with OCs. Both offer greater convenience to the user, which improves compliance. The patch has a surface area of 20 cm^2. It delivers a daily dose of 150-µg *norelgestromin,* the active metabolite of norgestimate, and 20 µg of *EE.* The patch is worn for 1 week then replaced with a new patch for 7 days, continuing for 3 consecutive weeks followed by a week with no patch. The patch was compared with a multiphasic OC containing *levonorgestrel* 50 to 125 µg, and 30- to 40-µg *EE* (*Triphasil*) in a randomized trial of 1,417 women (137). The overall and method failure Pearl indices were 1.24 and 0.99 pregnancies per 100 woman-years in the patch group and 2.18 and 1.23 in the OC group, respectively, numerically less in the patch group but not statistically significant. Patch users had more breakthrough bleeding or spotting in the first two cycles, but thereafter this did not differ from OC users. Patch users reported more breast discomfort, dysmenorrhea, and abdominal pain than the OC users, but other adverse events were uncommon and did not differ. Perfect compliance was reported for 88.2% of patch users' cycles versus 77.7% of the pill users' cycles (p <0.001). Pregnancy risk with the patch appears to be higher for women weighing more than 90 kg.

The *NuvaRing* is 54 mm in the outer diameter and has a cross section of 4 mm. It delivers daily doses of 120 µg of *etonogestrel,* the active metabolite of *desogestrel,* with 15 µg of *EE,* and thus is the lowest estrogen combination hormonal method available in the United States. The soft, flexible ring is worn in the vagina for 3 weeks, and then removed for 1 week, after which time a new ring is inserted. Alternatively, similar to OCs, women trying to avoid menstrual bleeding can simply use the ring for an entire month and then change immediately to a new ring. In a pharmacokinetic study comparing the ring with a combination OC containing 150 µg of *desogestrel* and 30 µg of *EE,* maximum blood levels of *EE* with the ring were about one-third of those seen with the OC, and the *etonogestrel* level was about 40% of that produced by the OC. Despite these findings, ovulation was inhibited in all women studied (232). Women wearing the ring are reported to have fewer days of irregular bleeding or spotting than women taking an OC with 150 µg of *levonorgestrel* and 30 µg of *EE* (233). A large study found a Pearl Index of 1.18 (95% CI, 0.73–1.80) for the vaginal ring (233). Some women prefer to remove the ring for intercourse, although this is not necessary. It should be reinserted within 3 hours to avoid loss of efficacy. If the ring is out of the vagina for more than 3 consecutive hours, contraceptive efficacy may be reduced and a barrier method should be used for 7 days.

Patch and Ring and Thrombosis

Since both methods provide constant low blood levels of *EE,* it was hoped that this might reduce the risk for thrombosis. The FDA took the unusual step of issuing a "black box warning" for the *EE/norelgestromin* patch after several thrombosis cases were reported, and a small study of pharmacodynamics was interpreted as showing higher mean *EE* blood levels for the patch than with the oral route of administration. A small crossover study found increased APC resistance when women were changed from a 30-µg *EE*/150-µg *desogestrel* pill to either the patch or the *EE/etonogestrel* ring. This was interpreted as prothrombotic (234). In another study, women on a variety of OCs had baseline measurement of APC resistance, and protein S. Then the patients were switched to either the patch or the ring. Those moving to the patch had changes in laboratory parameters that could be interpreted as prothrombotic, while those moved to the ring showed an improvement in the same studies, theoretically reducing the risk of clotting (235). Three data-based epidemiologic studies looked at thrombosis in patch users compared to oral contraception. The first found no difference, but two subsequent studies did find increased risk. One study found an overall doubling of the risk of deep vein thrombosis when patch users were compared to users of an OC containing 30-µg *EE*/150-µg *levonorgestrel,* but the risk estimate was of borderline statistical significance and disappeared when the analysis was restricted to women aged 39 years or less (236). Following the publication of these studies, the FDA convened in December 2011 to discuss the possibly increased risk of blood clots in users of Ortho Evra compared to women who use certain birth control pills. The Joint Advisory Committee recommended that Ortho Evra remain in the market as an option for contraception but that the label be revised to more clearly describe the risks and benefits associated with *Ortho Evra* (237).

No similar FDA warnings were issued about the ring. There are two case reports in the world literature of venous thrombosis with the ring. Both were women in their 30s who sustained cerebral venous thrombosis (238,239). It is best to assume that the ring has the same risk for thrombosis as the other combination hormonal contraceptives and to counsel women about risk in the same way.

Future of the Vaginal Ring

The Population Council has developed a one-year contraceptive vaginal ring that releases 150-mcg *Nestorone*, a nonandrogenic progestin that is inactive orally, and 15-mcg *EE* daily. It can be worn for 3 weeks, removed for 1 week, and then reinserted for up to 13 cycles (240). Refrigeration is unnecessary, and this method may be especially advantageous for women in low resource settings where access to a pharmacy and electricity are unreliable. The Population Council will submit a New Drug Application (NDA) to the U.S. FDA and pursue regulatory approval in low- and middle-income countries.

Injectable Hormonal Contraceptives

Depot Medroxyprogesterone Acetate

DMPA, a suspension of microcrystals of a synthetic progestin, was approved for contraception in 1992. A single 150-mg intramuscular dose will suppress ovulation in most women for 14 weeks or longer (241). **[7]** The regimen of 150 mg every 3 months is highly effective, producing pregnancy rates of about 0.3 per 100 women per year. Probably because of the high blood levels of the progestin, efficacy appears not to be reduced by administration of other drugs and is not dependent on the patient's weight. Women treated with *DMPA* experience disruption of the menstrual cycle and have initial spotting and bleeding at irregular intervals. Eventually, total amenorrhea develops in most women who take *DMPA;* with continued administration, amenorrhea develops in 50% of women by 1 year and in 80% by 3 years **(Fig. 14-9)**.

The most important medical reason women discontinue the use of *DMPA* and other progestin-only methods is persistent irregular vaginal bleeding. A variety of medications are used to stop this bleeding. Many are effective in terminating individual bleeding episodes, but a systematic review concluded that none improved continuation rates long term (242). New approaches include *mifepristone* and low-dose *doxycycline. Mifepristone* is of interest because irregular bleeding with *DMPA* was related to the downregulation of endometrial estrogen receptors. Treatment with 50 mg of *mifepristone* every 2 weeks increases endometrial estrogen receptors and reduces breakthrough bleeding in new users of both *DMPA* and the *levonorgestrel* progestin implant (243). Another line of investigation concerns endometrial matrix metalloproteinase, which appears to play a regulatory role in the breakdown of the endometrium to produce normal menstruation. Treatment with *doxycycline* inhibits matrix metalloproteinase production in the endometrium in women after insertion of *levonorgestrel* subdermal implants (244). Five-day courses of either *mifepristone* 25 mg twice a day for 1 day, followed by *EE* 20 μg per day for 4 days, or *doxycycline* 20 mg twice a day for 5 days, reduced bleeding days by about 50% when compared to placebos during a 6-month randomized trial in women treated for prolonged or frequent bleeding occurring with etonogestrel subdermal implants (245). Capsules of 20-mg *doxycycline* are sold in the United States for treatment of periodontal disease.

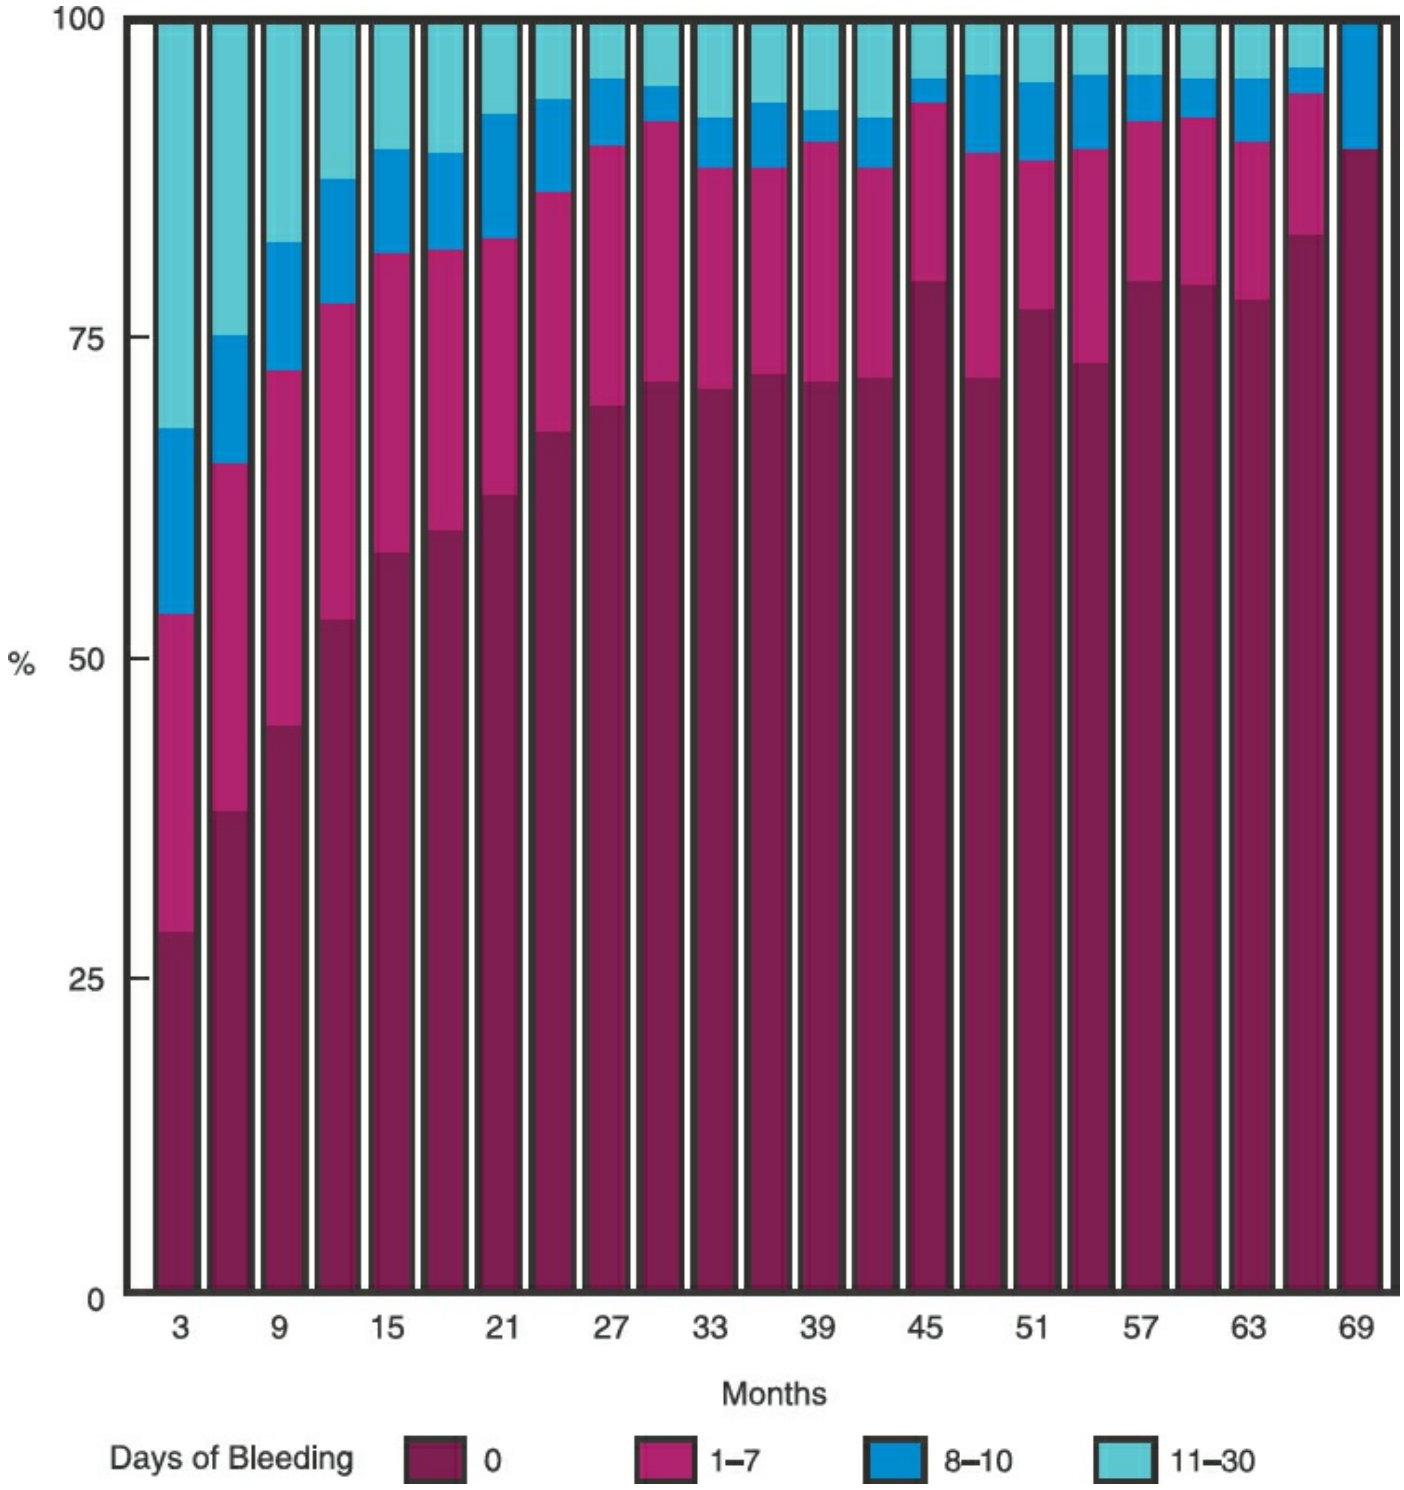

FIGURE 14-9 Bleeding pattern and duration of use of *depomedroxyprogesterone acetate (DMPA)*: percentage of women who have bleeding, spotting, or amenorrhea while taking *DMPA* 150 mg every 3 months. (From **Schwallie PC, Assenzo JR**. Contraceptive use-efficacy study utilizing *medroxyprogesterone acetate* administered as an intramuscular injection once every 90 days. *Fertil Steril* 1973;24:331–339, with permission.)

DMPA use is commonly associated with weight gain, and that is another principal reason women discontinue use. A large study is representative of the literature. Three cohorts of women who chose their method of contraception were followed for 36

months with measurements of weight and body fat. *DMPA* users gained an average of 5.1 kg. The cohort using OCs over the same interval gained only 1.47 kg, slightly less than the 2.05 kg gained by the cohort not using any hormonal contraception. Total body fat increased 4.14 kg in the *DMPA* cohort, while the increase in the OC users was 1.9 kg, only slightly more than the 1.17 kg in the nonhormonal contraceptive cohort. Many women were followed for 2 years after discontinuing *DMPA*. Those who chose nonhormonal methods after discontinuing *DMPA* lost a mean of 0.42 kg each 6 months. Those who chose to use OCs gained a mean of 0.43 kg each 6 months during the follow-up interval (246).

Weight gain during the first 6 months and self-reporting of increased appetite are strongly predictive of continued weight gain. Women who gained less than or equal to 5% of body weight in the first 6 months gained a mean of 2.49 kg by 36 months, while those who gained more than 5% by 6 months gained a total mean of 11.08 kg by 36 months (247). Studies are needed of interventions to prevent the weight gain. At minimum, women considering *DMPA* need to know the possibility of significant weight gain and be advised to avoid calorie-dense foods and weigh themselves regularly. Ideally they should be weighed when they return for subsequent injections so they can be counseled about the need for avoiding further gain. Women who gain 5% of body weight by 6 months should consider other contraceptive options.

DMPA persists in the body for several months in women who used it for long-term contraception, and return to fertility may be delayed. Studies of return to ovulation indicated a wide variation in time to ovulation post injection with the majority ranging from 15 to 49 weeks from the last injection for DMPA (248). In a cohort of Thai women, 70% of former users desiring pregnancy conceive within 12 months, and 90% conceive within 24 months after terminating *DMPA* use (249).

Safety

DMPA suppresses ovarian estrogen production. Prospective studies demonstrated bone loss during *DMPA* therapy, with recovery of bone mass after *DMPA* use is discontinued (250). Although bone loss was observed, it did not approach the fracture threshold. Similar bone loss and then recovery occurs with lactation. Adolescents are of special concern because they normally gain bone mass; most of adult bone mass is attained by age 20. Estrogen injections prevent the bone loss and allow adolescent women to gain bone density despite the use of *DMPA* (251). A long-term study in adolescents documented bone density loss and confirmed recovery of lumbosacral bone mineral density to baseline by 60 weeks after discontinuation of *DMPA* and significant gain above baseline by 180 weeks. Recovery of density at the hip was slower, 240 weeks to significant gain (252). A systematic review of *DMPA* clinical trials could find no studies where fracture was an outcome, so whether long-term use leads to fractures is still not known (253). The FDA black box warning added to *DMPA* labeling proposes

that *DMPA* treatment be limited to 2 years at a time, unless the patient has no other good options for contraception. For many women, especially in developing countries, *DMPA* is often the only option for highly effective contraception because it is inexpensive and easy to administer. The issue should be discussed with women who are considering *DMPA,* but *DMPA* should not be routinely discontinued after 2 years unless the patient wants to conceive or wants to change to another contraceptive method for other reasons.

The effect of *DMPA* on plasma lipids is inconsistent; *DMPA* users appear to have reduced total cholesterol and triglyceride levels, slight reduction in HDL cholesterol, and no change or slight increase in LDL cholesterol, all of which are consistent with a reduction in circulating estrogen levels. In some studies, the decrease in HDL and increase in LDL are statistically significant, although the values remain within normal ranges (254). *DMPA* is not associated with myocardial infarction. Glucose tolerance tests disclose a small elevation of glucose in *DMPA* users.

There is no change in hemostatic parameters, with the exception that ATIII levels are sometimes reduced with chronic therapy (254). As noted earlier, large epidemiologic studies have not found *DMPA* to be associated with thrombosis (145). *DMPA* is not associated with teratogenicity (255). Nor is it associated with affective disorders or mood changes (256).

DMPA and Lactation

There is widespread support for the use of *DMPA* during lactation when the *DMPA* is initiated at or after 6 weeks postpartum. There is good evidence that neither infant growth nor lactation is impaired by *DMPA* or progestin-only OCs (257). There is continued controversy as to how early *DMPA* should be given after delivery. Because lactation occurs in response to falling maternal estrogen and progesterone levels after birth, administration of *DMPA* in the first few days theoretically might interfere with the initiation of lactation. There is concern about the possible neonatal effects of the progestin, but investigators were unable to demonstrate the presence of *DMPA* or its metabolites in the urine of infants whose mothers received *DMPA* or any other suppression of reproductive hormones (257). In the United States, *DMPA* is commonly started at the time of hospital discharge, 48 to 72 hours after delivery. In a systematic review, including 11 nonrandomized clinical trials and observational studies, progestogen-only injectables were initiated in the first 6 weeks postpartum and most found either no effect on breastfeeding outcomes or improved outcomes among DMPA users (19). The "U.S. Medical Eligibility Criteria for Contraceptive Use 2016" considers *DMPA* use prior to 1 month postpartum as category 2: the benefit is thought to exceed the theoretical risk (7).

DMPA and Neoplasia

The use of *DMPA* is not associated with cervical cancer (258). Neither is it associated with ovarian cancer (259). The risk of endometrial cancer is substantially reduced by

past use of *DMPA* (260). A large study found no increase in breast cancer risk among *DMPA* users (261).

Benefits

DMPA has many of the noncontraceptive benefits of combination OCs (262). Decreases in anemia, PID, ectopic pregnancy, and endometrial cancer are reported. *DMPA* is reported to benefit women with sickle cell disease (263).

Subcutaneous DMPA

Depo-subQ Provera 104, a lower-dose *DMPA* preparation for subcutaneous administration, received FDA approval in 2005. The total dose is 30% less than that of the *DMPA* intramuscular preparation. Because the dose is administered subcutaneously, blood levels are adequate to completely suppress ovulation for more than 13 weeks in all subjects tested, with a mean time of 30 weeks for return to ovulatory function (264). Contraception efficacy is superb, with no pregnancies in a total of 16,023 woman-cycles in the phase III studies done in the United States (265). Blood levels were lower in very obese women but still sufficient to completely suppress ovulation. The weight gain reported with the 150-mg *DMPA* remains a problem with the lower-dose *DMPA.* Mean weight gain was 1.59 kg in the first year of use. Loss of bone density was observed with this dosage of *DMPA,* as with the larger intramuscular dose. In select countries, DMPA-SQ is available in a single-use Uniject device and is sold under the name Sayana Press (266). The Uniject is a small, prefilled, single-use injection device that any trained person, including community health workers, pharmacists, and even women themselves can administer. In an open-label observational study, current users of DMPA IM found Sayana Press to be acceptable, with most users preferring Sayana Press over DMPA IM, indicating promising uptake (267).

Once-a-Month Injectable

A once-a-month injectable contraception containing only 25 mg of *DMPA* in combination with 5 mg of the long-acting estrogen *estradiol cypionate* was briefly available in the United States, but was withdrawn by the manufacturer because of a packaging problem (268). Originally developed by the WHO, it is described as *Cyclofem* or *CycloProvera* in the literature and was marketed in the United States as *Lunelle* (269). Given once a month, this combination produces excellent contraceptive effects. Monthly withdrawal bleeding is similar to a normal menses, leading to high continuation rates despite the need for a monthly injection. Monthly injectable combinations continue to be widely used outside the United States.

Subdermal Implants

Three progestin-releasing subdermal implants systems are in use worldwide: *Jadelle* (Bayer, Leverkusen, Germany), *Sino-Implant* II (Dahua, Shanghai, China), and

Nexplanon (Merck, Kenilworth, USA). All three offer long-acting contraception that requires no continuing action by the user and are, hence, forgettable. All are very highly effective and have no serious risk. Each can produce irregular bleeding, which is the principal reason for discontinuation. The mechanism of action is suppression of ovulation in the initial years of use, plus thickening of the cervical mucous that prevents sperm penetration.

The original *levonorgestrel* implant (*Norplant*) six-rod system was replaced with a two-rod version (*Jadelle*), which is identical in its release rate and clinical activity to *Norplant* and is easier to insert and remove (270). *Jadelle* is widely used around the world. It is approved by the FDA but not marketed in the United States. It is approved for 5 years. The *Sino-Implant II* (*Levoplant*) is a less expensive two-rod *levonorgestrel* system manufactured in China and available in several countries. It is labeled for 3 years of use, with trials ongoing for a fourth year (271). In June 2017, the product received WHO prequalification, which recognizes that the product meets international quality standards for manufacturing and clinical performance. This allows additional donors to purchase the product for country programs. Thus, the availability of the *Sino-Implant II* (*Levoplant*) is likely to increase. *Nexplanon* (or *Implanon-NXT*) is a single-rod system containing *etonogestrel,* the active metabolite of *desogestrel.* It was first approved in 2006 as *Implanon*. In 2011, Merck replaced *Implanon* with Nexplanon, which contains 15 mg of barium sulfate to create a radiopaque quality and utilizes a simpler applicator for easier, and potentially safer insertion. All studies regarding safety and effectiveness of *Implanon* apply to Nexplanon.

A systematic review of 29,972 women and 28,108 woman-months of follow-up with *Norplant*, *Jadelle*, or *Implanon* found no differences in pregnancies or continuation rate over 4 years. No pregnancies occurred in any of the trials. There were no differences in side effects or adverse events. The most common side effect was unpredictable vaginal bleeding (272).

In 923 women followed for 20,648 treatment cycles in 11 studies, there were no pregnancies with the etonogestrel implant in place. Six pregnancies occurred within 14 days of removal of the devices. **[7]** When these are included, as required by the FDA, the cumulative Pearl Index was 0.38 pregnancies per 100 woman-years at 3 years (273). Irregular bleeding was a problem, but occurred most frequently in the first 90 days of use and decreased over time. In a randomized comparison with the six-rod *Norplant*, etonogestrel implant users had less frequent vaginal bleeding, but more became amenorrheic (274). Other commonly reported side effects are headache, weight gain, acne, breast tenderness, and emotional lability (273). Only 2.3% of subjects discontinued because of weight gain. Most women can use *Nexplanon*. The US MEC lists only a small number of conditions as category 3, and these are based on theoretical concerns without actual evidence of harm (7). Insertion in the postpartum period appears to have no adverse effects on the mother or infant. Among women who initiated

the ETG implant or LNG-IUD 6 weeks postpartum, there was no difference in the weight or height of their infants through 6 months (275). An RCT found no difference in growth at 12 months among breastfed infants whose mothers had etonogestrel implant inserted within 48 hours postpartum versus at 6 weeks postpartum (276). A study of etonogestrel implants compared with the copper IUD placed 4 to 8 weeks postpartum found no differences in infant growth, adverse events, respiratory or skin disorders, or developmental scores (277). One population in which special considerations should be taken when using progestin implants is HIV-positive women concurrently taking efavirenz-based antiretroviral therapy (ART), because efavirenz may reduce the effectiveness of contraceptive implants. Pharmacokinetic studies have reported reduced etonogestrel and levonorgestrel concentrations in implant users concurrently using efavirenz-based ART, which raises concerns about potential decreased contraceptive efficacy (278,279). In a retrospective cohort study of HIV-positive women with contraceptive implants, the adjusted pregnancy rates in efavirenz users were *triple* that of nevirapine users (280). Nevertheless, these findings should not preclude women taking efavirenz from using implants because even in this population, the implant remains more effective than non-LARC contraceptive methods.

Bone density is not affected by the etonogestrel implant, probably because ovarian follicular activity is not totally suppressed and estradiol synthesis continues (281). Enlarged follicular ovarian cysts are common during the first year of use of *Jadelle* or etonogestrel implant and usually resolve spontaneously (282).

[7] A comparative study of coagulation and fibrinolytic factors in users of *etonogestrel* and *levonorgestrel* implants showed no significant changes from the baseline, with the exception of a modest increase in ATIII and a small decrease in factor VII activity, changes that might reduce coagulability. Lipid levels and liver function studies were not changed, with the exception of small elevations of bilirubin, with somewhat more observed in *levonorgestrel* users than *etonogestrel* users (283). Another study of hemostatic factors found modest decreases in many measurements, within the range of normal, and a modest reduction in the generation of thrombin in users of the *etonogestrel* implant (284). Taken together these studies provide considerable reassurance that the progestin implants do not increase thrombosis risk. With several million women now using the implants, there are no published studies linking either implant to venous thrombosis or myocardial infarction.

Emergency Contraception

Postcoital use of sex steroids to prevent pregnancy began in the 1960s with high-dose estrogen taken daily for 5 days (285). This was replaced with the combination OC containing *EE* and *levonorgestrel* for greater convenience (286). **[9]** In the late 1990s, *levonorgestrel* alone became the method of choice after the WHO showed its

superiority in a large randomized trial with 1,998 women. The pregnancy rate was 3.2% with the *EE/levonorgestrel* method and only 1.1% with *levonorgestrel* alone (RR for pregnancy, 0.32; 95% CI, 0.18–0.70) for women treated within 72 hours of intercourse. Nausea and vomiting occurred much less frequently with *levonorgestrel* alone (23.1% vs. 50.5%, and 5.6% vs. 18.8%, respectively) (287). The efficacy of both methods declined as the time after intercourse increased. But even after 72 hours, the pregnancy rate with the *levonorgestrel* treatment was only 2.7% (288). A single dose of 1.5-mg *levonorgestrel* is just as effective as two doses of 0.75 mg, has no more side effects, and is more convenient for the patient. Both dosing regimens are FDA approved. While recognizing that *levonorgestrel* is more effective the sooner it is taken, the WHO allows for the use of 1.5 mg of *levonorgestrel* as a single dose, given up to 120 hours after intercourse (289). Research suggests that the main mechanism of action is delay of ovulation. Noe et al. established that *levonorgestrel* works only if it is administered prior to the day of ovulation (290). No pregnancies occurred to 87 women who received *levonorgestrel* from 1 to 5 days prior to the day of ovulation. Seven pregnancies occurred to 35 women treated on the day of ovulation or later. **Postcoital *levonorgestrel* is not an abortifacient because it is effective only when taken before ovulation.** *Levonorgestrel* alone is safer than the estrogen-containing preparations. There were several case reports of thrombotic events after use of the estrogen/levonorgestrel combination emergency contraception (291). No such complications with *levonorgestrel* alone were published.

Antiprogestins

The antiprogesterone *mifepristone* (*RU486*) is highly effective for postcoital contraception. The usual abortifacient dose is 200 mg, but a dose of only 10 mg is effective for emergency contraception. In one study, 2,065 women were randomized to *mifepristone,* 10 mg, or *levonorgestrel,* two doses of 0.75 mg, including women up to 120 hours after intercourse (292). The crude pregnancy rate was 1.3% for *mifepristone* and 2.0% for *levonorgestrel* ($p = 0.46$). Side effects were the same, and both methods were judged highly acceptable by the patients. *Mifepristone* is not being developed for this use and is not available at the appropriate dose.

[9] *Ulipristal acetate,* sold by the trade name of Ella, is a progesterone-receptor modulator that was approved by the FDA and the European Union for emergency contraception up to 120 hours after intercourse. It is a single 30-mg tablet, available by prescription only, whereas *levonorgestrel* 1.5 mg has been available without a prescription since 2013. When ovulation is imminent, ulipristal is more effective than levonorgestrel in delaying ovulation. The odds of pregnancy for ulipristal were 42% lower by 72 hours after intercourse and 65% lower in the first 24 hours (293). When *ulipristal* is administered prior to the LH peak, it delays the rupture of the preovulatory follicle for 5 days or more, which may be its primary mechanism of action (294). In

women with BMI >30, the risk of pregnancy is greater for those taking levonorgestrel (OR, 4.41) than for those taking ulipristal (OR, 2.62) (295). Thus, for obese women, ulipristal is preferred over levonorgestrel. Subsequent studies on EC and obesity have shown that the total concentration of levonorgestrel for obese women with one dose of levonorgestrel was significantly lower than the level observed in normal BMI women (296). However, the concentration of ulipristal was similar between obese and normal BMI women (297). *Ulipristal* is primarily metabolized by the CYP3A4 enzyme system; hence, patients on drugs such as barbiturates, *rifampin*, and several of the anticonvulsants may have reduced protection from pregnancy with it. With regards to starting hormonal contraception following the use of emergency contraceptive pills, hormonal contraception can be started immediately after administration of levonorgestrel. However, in one study where women were given either a placebo or a progestin-only pill, desogestrel, the day after ulipristal, ovulation occurred in 45% of cycles in women receiving desogestrel compared to 3% in the placebo group (298). Therefore, in 2015, the *Ella* label was updated to recommend that patients who use ulipristal wait 5 days before starting a hormonal contraceptive method (299).

The Copper Intrauterine Device for Emergency Contraception

Postcoital insertion of a copper IUD was first reported by Lippes et al. in 1976 (300). In initial trials, the copper IUD was inserted within 7 days of intercourse and was more effective than steroids for emergency contraception. Subsequent studies included women only within 5 days from intercourse. The multicenter trial by Wu and colleagues is an example of the superb efficacy offered by the *copper T380A* (301). Of 1,893 women who returned for a follow-up visit, there were no pregnancies within 1 month of IUD insertion. **[9] Efficacy for emergency contraception is 100% when the device is inserted up to 5 days after intercourse, and almost 100% up to 7 days after intercourse** (301). An added benefit was that 94% of the patients were continuing with the IUD at the 12-month follow-up. There were no uterine perforations. Zhou and colleagues reported similar excellent results in a large study with a different copper device, the *Multiload Cu-375* IUD (302). In much of the world, copper IUDs are very inexpensive. Even in the United States where IUDs are costly, the benefit to the patient of extremely effective emergency contraception, and long-term contraception with one intervention, makes emergency IUDs cost effective. Whether the *LNG-IUD* would work for emergency contraception is being studied.

Hormonal Contraception for Men

The same negative feedback of sex steroids that blocks ovulation in women suppresses spermatogenesis in men, but it will produce loss of libido and potentially extinguish sexual performance. The principle was first demonstrated in 1974 using oral estrogen and methyl testosterone (303). Testosterone given alone can suppress sperm production

to very low levels while maintaining normal libido and sexual performance. Over many years investigators have studied long-acting testosterone salts for male contraception (304). Ethnicity is an important predictor of efficacy of sperm suppression with testosterone therapy. Asian men virtually always achieve azoospermia or oligospermia when treated with *testosterone undecanoate* (*TU*) monthly injections, whereas only 86% of Caucasian men achieved azoospermia or oligospermia or with similar testosterone regimens (305). In a Chinese trial, 1,045 men were treated with monthly *TU* 500 mg. Only 4.8% failed to suppress to a sperm count less than 1×10^6 per mL. The cumulative pregnancy rate was only 1.1 per 100 men at 30 months (306). In Caucasian populations, testosterone was combined with progestins to further suppress gonadotropin and improve efficacy. In an important trial with Caucasian men, *etonogestrel* subdermal implants and *TU* injections were compared to placebo implants and injections. Only 3% failed to suppress to a sperm count of less than 1×10^6 (307). Side effects that were more common in the medicated group than placebo included acne, night sweats, libido changes (usually increased), and weight gain. In a study using Nestorone (progestin) and testosterone transdermal gels, 89% of men achieved suppression of their sperm concentrations to $\leq 1 \times 10^6$ per mL, with minimal side effects (308).

Nonhormonal male methods are being investigated. One product called reversible inhibition of sperm under guidance (RISUG) has been studied in both preclinical and human research in India (309). It consists of styrene maleic anhydride which when injected into the vasa differentia creates an incompatible pH level for sperm and blocks transport. *Vasalgel* involves a similar approach but uses a different formulation and is being developed in the United States. It is a high–molecular-weight polymer consisting of styrene-alt-maleic acid dissolved in dimethyl sulfoxide, which is injected into the vasa deferentia, where it remains as a soft gel-like state that allows water-soluble substances to pass but not sperm. It is meant to be reversible and in rabbit studies shows rapid restoration of sperm flow after an injection of sodium bicarbonate (310). Thus far, *Vasalgel* has been studied only in animal models (311). *Vasalgel* is expected to begin enrollment of men in clinical trials in the United States.

STERILIZATION

Surgical sterilization is the most common method of fertility control used by couples worldwide, with more than 250 million women and men relying on female sterilization or vasectomy for contraception (312). Laparoscopic and hysteroscopic techniques for women and vasectomy for men are safe and readily available throughout the United States. The mean age at sterilization is 30 years. Age younger than 30 years when sterilized, conflict within the marriage, and divorce and remarriage are predictors of sterilization regret, which may lead to a request for reversal of sterilization (313).

Female Sterilization

Hysterectomy is no longer considered for sterilization because morbidity and mortality are too high in comparison with tubal sterilization. Vaginal tubal sterilization, which was associated with occasional pelvic abscess, is rarely performed in the United States. **[11] Five procedures are used in the United States.**

1. **Tubal sterilization at the time of laparotomy for a cesarean delivery or other abdominal operation**
2. **Postpartum minilaparotomy soon after vaginal delivery**
3. **Interval minilaparotomy**
4. **Laparoscopy**
5. **Hysteroscopy**

Postpartum tubal sterilization at the time of cesarean delivery adds no risk other than a slight prolongation of operating time; cesarean birth poses more risk than vaginal birth, and planned sterilization should not influence the decision to perform a cesarean delivery. **Minilaparotomy can be performed in the immediate postpartum state. The uterus is enlarged, and the fallopian tubes lie in the midabdomen, easily accessible through a small, 3- to 4-cm subumbilical incision.**

Interval minilaparotomy, first described by Uchida, was rediscovered and popularized in the early 1970s in response to an increased demand for sterilization procedures and a simpler alternative to laparoscopy (314). Still widely practiced in lower resource settings, it is uncommon in the United States because of widespread availability of the endoscopic techniques.

Surgical Technique

The procedure usually elected for tubal sterilization by laparotomy is the Pomeroy or modified Pomeroy technique **(Fig. 14-10)**. In the classic Pomeroy procedure, a loop of tube is excised after ligating the base of the loop with a single absorbable suture. A modification of the procedure is excision of the midportion of the tube after ligation of the segment with two separate absorbable sutures. This modified procedure has several names: *partial salpingectomy, Parkland Hospital technique, separate sutures technique,* and *modified Pomeroy.* In the Madlener technique, now abandoned because of too many failures, a loop of tube is crushed by cross-clamping its base, ligated with permanent suture, and excised. Pomeroy and partial salpingectomy procedures have failure rates of 1 to 4 per 1,000 cases (313). In contrast, pregnancy is exceedingly rare after tubal sterilization by the Irving or Uchida methods. In the Irving method, the midportion of the tube is excised, and the proximal stump of each tube is turned back and led into a small stab wound in the wall of the uterus and sutured in place, creating a blind loop. With the Uchida method, a *saline–epinephrine* solution (1:1,000) is injected

beneath the mucosa of the midportion of the tube, separating the mucosa from the underlying tube. The mucosa is incised along the antimesenteric border of the tube, and a tubal segment is excised under traction so that the ligated proximal stump will retract beneath the mucosa when released. The mucosa is closed with sutures, burying the proximal stump and separating it from the distal stump. In Uchida's personal series of more than 20,000 cases, there were no pregnancies (314).

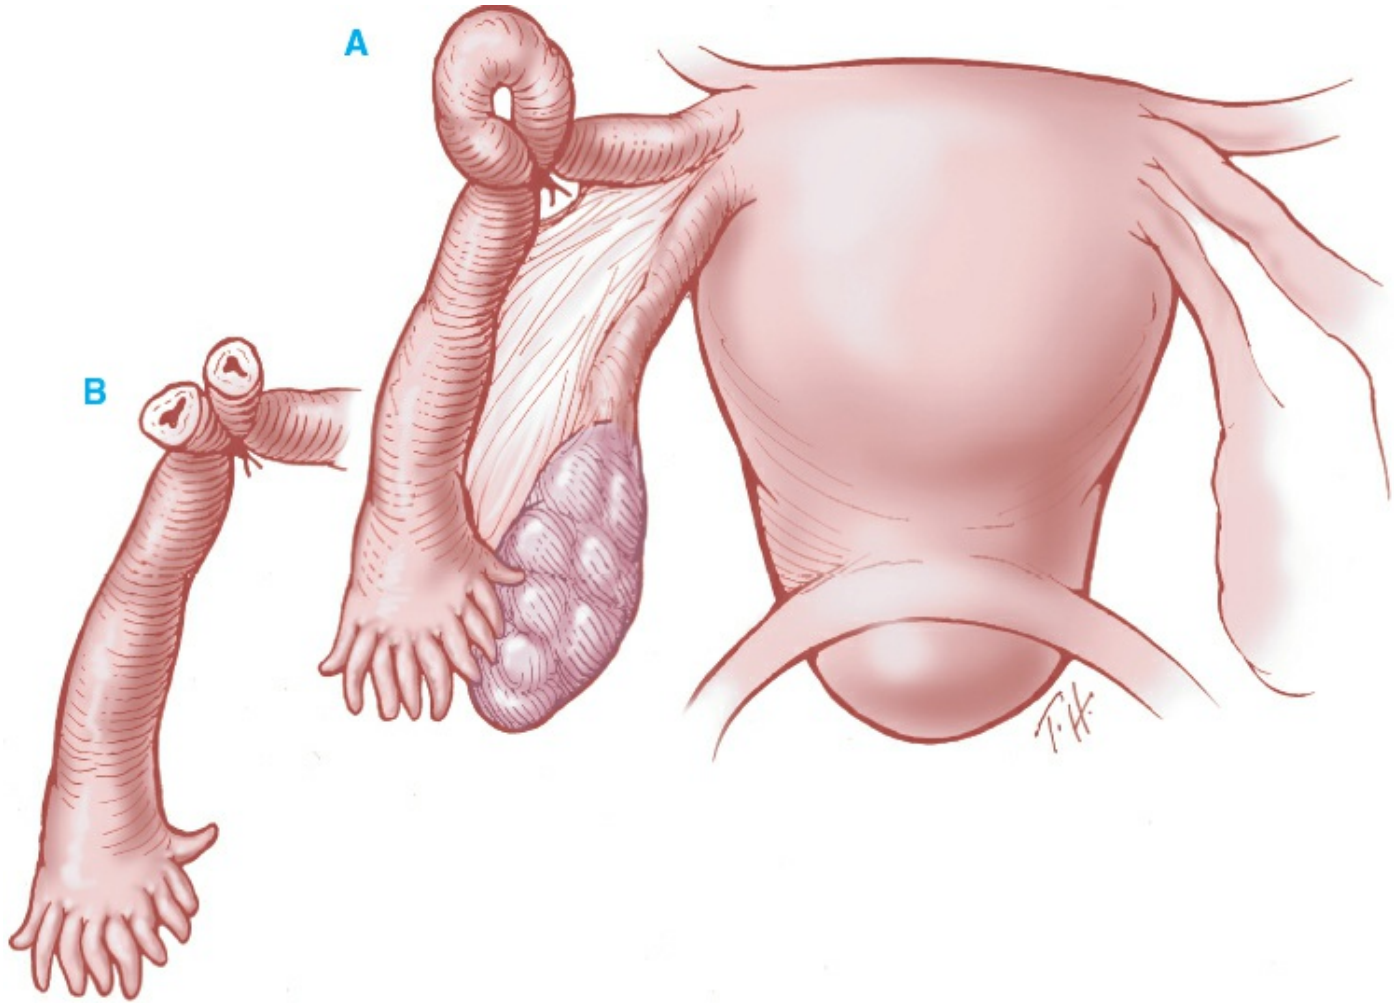

FIGURE 14-10 Pomeroy technique for tubal sterilization. **A:** Ligation of loop of fallopian tube. **B:** Subsequent excision of loop.

Laparoscopy

Laparoscopy is the most common method of interval sterilization in the United States. In the standard laparoscopy technique, after the abdomen is inflated with a gas, the laparoscope is inserted into the abdominal cavity through a trocar, usually at the lower margin of the umbilicus. Although single puncture laparoscopic sterilization procedures can be performed with an "operating laparoscope," it is increasingly common for a second, and sometimes third, trocar to be inserted in the suprapubic region or lateral lower quadrants to allow the insertion of special grasping forceps.

Laparoscopic sterilization is usually performed in the hospital under general anesthesia but can be performed under local anesthesia with conscious sedation. Overnight hospitalization for laparoscopy is rarely needed.

Techniques for Tubal Occlusion at Laparoscopy

Laparoscopic tubal occlusion is accomplished by any of four techniques: bipolar electrical coagulation, application of a small Silastic rubber band (Falope ring), the spring clip (Hulka clip), or the titanium clip (Filshie clip). The Filshie clip, first introduced in the United States in 1996, is used extensively in the United Kingdom and Canada (315). It is a hinged device made of titanium with a liner of silicone rubber tubing. Because of its lower pregnancy rate, the Filshie clip has largely supplanted the Hulka clip (316).

In the bipolar electrocoagulation technique, the midisthmic portion of the tube and adjacent mesosalpinx are grasped with special bipolar forceps, and radiofrequency electric current is applied to three adjacent areas, coagulating 3 cm of tube **(Fig. 14-11)**. The tube alone is recoagulated in the same places. The radiofrequency generator must deliver at least 25 W into a 100-Ω resistance at the probe tips to ensure coagulation of the complete thickness of the fallopian tube and not just the outer layer; otherwise, the sterilization will fail (317).

To apply the Falope ring, the midisthmic portion of the tube is grasped, with tongs advanced through a cylindrical sleeve that has the ring stretched around it **(Fig. 14-12A)**. A loop of tube is pulled back into the sleeve, and the outer cylinder is advanced **(Fig. 14-12B)**, releasing the Silastic ring around the base of the loop of the tube, producing ischemic necrosis over time **(Fig. 14-12C)**. If the tube cannot be pulled easily into the applicator, the operator should stop and change to electrical coagulation rather than persist and risk lacerating the tube with the Falope ring applicator. The banded tube must be inspected at close range through the laparoscope to demonstrate that the full thickness of the tube was pulled through the Falope ring.

The Hulka clip is placed across the midisthmus, ensuring that the applicator is at right angles to the tube and that the tube is completely contained within the clip before the clip is closed. The Filshie clip is placed at right angles across the midisthmus, taking care that the anvil of the posterior jaw can be visualized through the mesosalpinx beyond the tube to ensure that the complete thickness of the tube is completely within the jaws of the clip before it is closed **(Fig. 14-13)**.

The cautery band or clip techniques each have advantages and disadvantages. Bipolar coagulation can be used with any fallopian tube. The Falope ring and Hulka and Filshie clips cannot be applied if the tube is thickened from previous salpingitis. There is more pain during the first several hours after Falope ring application. This can be prevented by bathing the tubes with a few milliliters of 0.5% *bupivacaine* just before ring placement (318). Failure of the Falope ring or the clips generally results from

misapplication, and pregnancy, if it occurs, is usually intrauterine. After bipolar sterilization, pregnancy may result from tuboperitoneal fistula and is ectopic in more than 50% of cases. If inadequate electrical energy is used, a thin band of fallopian tube remains that contains the intact lumen and allows intrauterine pregnancy to occur. Thermocoagulation, the use of heat probes rather than electrical current, is employed extensively in Germany for laparoscopic tubal sterilization but is little used in the United States.

FIGURE 14-12 Placement of the Falope ring for tubal sterilization.

Laparoscopic Salpingectomy

Salpingectomy, either partial or complete, has not been traditionally used for sterilization because of perceived comparative ease and safety of occlusion methods. However, a large observational study compared salpingectomy with other methods and found no increase in complication rates but an increase in operative time of approximately 10 minutes (319). A recent study including salpingectomies and tubal occlusion cases showed comparable immediate and short-term complications rates across sterilization methods and an average increase of 6 minutes of operative time for salpingectomy (320). **Prophylactic salpingectomy may reduce the risk of ovarian/fallopian tube cancer because most epithelial ovarian cancers arise in the distal fallopian tube, and is now recommended when women are undergoing gynecologic surgeries for other benign indications.**

Noncontraceptive Benefits of Tubal Sterilization

In addition to providing excellent contraception, tubal ligation is associated with reduced risk for ovarian cancer. Among the largest studies to illustrate the relationship between tubal ligation and ovarian cancer were the Nurses' Health Study and Nurses' Health Study II. These two prospective cohort studies included 29,340 women who had tubal ligation and found that tubal ligation overall was associated with a decreased risk of ovarian cancer (HR, 0.76; 95% CI, 0.64–0.90) (321). In a large prospective cohort study in the United Kingdom, the association of tubal ligation with decreased risk varied by histology, with a significant decrease in the risk of high-grade serous carcinomas (RR, 0.77; 95% CI, 0.67–0.89), endometrioid (RR, 0.54; 95% CI, 0.43–0.69), and clear cell tumors (RR, 0.55; 95% CI, 0.39–0.77) (322).

FIGURE 14-13 Filshie clip for tubal sterilization. (Courtesy of Femcare Ltd, Romsey, UK.)

Furthermore, studies have explored the risks and benefits of opportunistic salpingectomy compared to tubal ligation with regards to ovarian cancer risk reduction. One study concluded that opportunistic salpingectomy at the time of sterilization is cost effective with an incremental cost effectiveness ratio of $31,432 per quality-adjusted life year (323). Another study comparing partial salpingectomy (modified Pomeroy method) to complete salpingectomy (use of LigaSure) at the time of cesarean delivery found no significant differences in short-term complications (postpartum fever, wound infection, relaparotomy, estimated blood loss) (324). In addition, one trial which aimed to evaluate short-term ovarian reserve by measuring antimüllerian hormone levels,

detected no significant difference between the groups, with an average increase of 0.58 ± 0.98 versus 0.39 ± 0.41 ng/mL in the salpingectomy and tubal ligation groups, respectively ($p = 0.45$). Surgeries including salpingectomy were longer by an average 13 minutes (66.0 ± 20.5 vs. 52.3 ± 15.8 minutes, $p = 0.01$) (325). A trend may develop that favors salpingectomy over tubal occlusion or ligation for sterilization.

Risks of Tubal Sterilization

Tubal sterilization is remarkably safe. The Collaborative Review of Sterilization (CREST) study, a 1983 review of 9,475 interval sterilizations from multiple centers in the United States, reported a total complication rate of 1.7 per 100 procedures (313). Complications were increased by the use of general anesthesia, previous pelvic or abdominal surgery, history of PID, obesity, and diabetes mellitus. The most common significant complication was unintended laparotomy for sterilization after intra-abdominal adhesions were found. In another series, 2,827 laparoscopic sterilizations were performed with the Silastic band using local anesthesia and intravenous sedation (326). Only four cases could not be completed (a technical failure rate of 0.14%), and laparotomy was never needed. Rarely, salpingitis can occur as a complication of the surgery. This occurs more often with electric coagulation than nonelectric techniques. The risk of death with female sterilization was 1 to 2 per 100,000 sterilizations in a national study based on data from 1979 to 1980 (313). Almost half of the deaths were from complications of general anesthesia, usually related to the use of mask ventilation. When general anesthesia is used for laparoscopy, endotracheal intubation is mandatory because the pneumoperitoneum increases the risk of aspiration. International data from the Association for Voluntary Surgical Contraception show a similar record of safety from third-world programs: 4.7 deaths per 100,000 female sterilizations and 0.5 deaths per 100,000 vasectomies (327).

Sterilization Failure

Many "failures" occur during the first month after surgery and are the result of a pregnancy already begun when the sterilization was performed. Contraception should be continued until the day of surgery, and a sensitive pregnancy test should be routinely performed on the day of surgery. Because implantation does not occur until 6 days after conception, a woman could conceive just before the procedure and there would be no way to detect it. Scheduling sterilization early in the menstrual cycle obviates the problem but adds to the logistic difficulty. Another cause of failure is the presence of anatomic abnormalities, usually adhesions surrounding and obscuring one or both tubes. An experienced laparoscopic surgeon with appropriate instruments usually can lyse the adhesions, restore normal anatomic relations, and positively identify the tube. In some circumstances, successful sterilization will not be possible by laparoscopy, and the surgeon must know before surgery whether the patient is prepared

to undergo laparotomy, if necessary, to accomplish sterilization. The CREST study reported on a cohort of 10,685 women sterilized from 1978 to 1986 at any of 16 participating centers in the United States who were followed from 8 to 14 years (313). The true failure rates for 10 years obtained by the life-table method are given in Table 14-4. Pregnancies resulting from sterilization during the luteal phase of the cycle in which the surgery was performed were excluded. Of all remaining pregnancies, 33% were ectopic. The most effective methods at 10 years were unipolar coagulation at laparoscopy and postpartum partial salpingectomy, generally a modified Pomeroy procedure. Bipolar tubal coagulation and the Hulka-Clemens clip were least effective. The Filshie clip was not evaluated because it was not in use in the United States. Younger women had higher risk for failure, as would be expected because of their greater fecundity.

Table 14-4 Ten-Year Life-Table Cumulative Probability of Pregnancy per 1,000 Procedures With Different Methods of Tubal Sterilization, United States, 1978–1986

Unipolar coagulation	7.5
Postpartum partial salpingectomy	7.5
Silastic band (Falope or Yoon)	17.7
Interval partial salpingectomy	20.1
Bipolar coagulation	24.8
Hulka-Clemens clip	36.5
Total: all methods	18.5

From **Peterson HB, Xia Z, Hughes JM, et al.** The risk of pregnancy after tubal sterilization: findings from the U.S. Collaborative Review of Sterilization. *Am J Obstet Gynecol* 1996;174:1164; Table 2, with permission.

Since the CREST study began, sterilization by unipolar electrosurgery was abandoned because of the risk of bowel burns and was replaced with bipolar electrosurgery or the nonelectric methods (tubal ring, Hulka-Clemens clip, and the Filshie clip). **An analysis of the CREST data found that bipolar sterilization can have a very low long-term failure rate if an adequate portion of the tube is coagulated.** CREST study participants who were sterilized with bipolar electrosurgery from 1985 to 1987 had lower failure rates than those sterilized earlier (1978–1985). The important difference was in the application technique of the electric energy to the tubes. Women whose bipolar procedure involved coagulation at three sites or more had low 5-year failure rates (3.2 per 1,000 procedures), whereas women who had fewer than three sites of tubal coagulation had a 5-year failure rate of 12.9 per 1,000 (p = 0.01) (328).

Family Health International reported large randomized multicenter trials of the different means of tubal sterilization. The Filshie and Hulka clips were compared in two trials. A total of 2,126 women were studied, of which 878 had either clip placed by minilaparotomy and 1,248 had either clip placed by laparoscopy. The women were evaluated at up to 24 months (329). Pregnancy rates were 1.1 per 1,000 women with the Filshie clip and 6.9 per 1,000 with the Hulka clip at 12 months, a difference in rates that approached statistical significance ($p = 0.06$). This same group compared the Filshie clip with the Silastic tubal ring in a similar study with a total of 2,746 women, of which 915 had the devices placed at minilaparotomy and 1,831 at laparoscopy (330). Pregnancy rates at 12 months were the same for the Filshie clip and the tubal ring: 1.7 per 1,000 women. The ring was judged more difficult to apply. The Filshie clip was expelled spontaneously from the vagina by three women during the 12 months of follow-up.

Hysteroscopy

In 2002, the FDA approved *Essure*, a hysteroscopic method of permanent birth control. It can be provided in an office setting, with only local anesthesia or conscious sedation and both offer the prospect of greater safety, lower cost, and greater long-term effectiveness than the best laparoscopy **[12]** methods. ***Essure* is a microinsert consisting of a soft stainless steel inner coil and a dynamic nickel titanium alloy outer coil (Fig. 14-14)**. Soft fibers of polyethylene terephthalate run along and through the inner coil. To insert the device, a hysteroscope is introduced into the uterine cavity, which is distended with saline. The tubal ostia are visualized. The *Essure* device is inserted through the operating channel of the hysteroscope on the end of a slender delivery wire, guided into the tubal opening and advanced into the tube under direct vision **(Fig. 14-15)**. Once in place, an outer sheath is retracted, releasing the outer coils, which expand to anchor the device in the interstitial portion of the tube. The delivery wire is detached and removed and the procedure repeated for the other tube. When properly placed, three to eight of the end coils of the microinsert are visible inside the uterine cavity. The rest are inside the fallopian tube (331,332).

[12] ***Essure* can be installed under local anesthesia in an outpatient setting.** No incision is needed. Over time fibrous tissue grows, occluding the tubes permanently. The Essure Confirmation Test using either a transvaginal ultrasound (TVUS) or modified hysterosalpingogram (HSG) is required. The FDA approved the TVUS as an alternative confirmation test in July 2015. Patients must meet all criteria at the time of placement to be eligible for TVUS. Otherwise, they must undergo confirmation with modified HSG. A few notable criteria include certainty about bilateral placement, procedure time ≤15 minutes, and one to eight trailing coils bilaterally (333). Patients who are on active immunosuppressive therapy (systemic corticosteroids or chemotherapy) are not eligible for TVUS as a result of concern for failure of tissue

ingrowth. The modified HSG for *Essure* should document bilateral placement of the devices at the uterotubal junction and a lack of peritoneal spillage of dye. The patient with transcervical sterilization should continue to use a reliable method of contraception until successful occlusion is documented.

FIGURE 14-14 *Essure* device for hysteroscopic sterilization. (Courtesy of Conceptus, Inc.)

FIGURE 14-15 *Essure* device with guide wire and handle. (Courtesy of Conceptus, Inc.)

Risks of Hysteroscopy

Adverse events or side effects were reported on the day of procedure in 3% of the initial *Essure* patients. These consisted of vasovagal responses, cramping, nausea, and vaginal spotting (334). Possible but uncommon risks of the hysteroscopic tubal sterilization methods include perforation by the device at insertion and expulsion of the device. Tubal and uterine perforation was reported to range from 0% to 1.8% (335). Other potential combinations with transcervical sterilization are related to the hysteroscopy procedure, not the tubal occlusion process. These include hypervolemia, injury to surrounding organs, bleeding, and infection and occur in less than 1% of cases. **[12]** Between November 2002 and May 2015, the FDA received a total of 5,093 reports related to Essure, prompting it to convene a panel to review the safety and effectiveness

of Essure sterilization. In 2016, the FDA ordered the manufacturer to conduct a postmarket surveillance study to determine heightened risks for particular women, and issue a black box warning about risk of perforation, persistent pain and suspected allergic or hypersensitivity reactions (336). Subsequently, in July 2018, due to a decline in sales, the manufacturer removed the device from the market.

Sterilization Failure With Essure

A meta-analysis of 31 studies including more than 12,000 procedures reported bilateral placement rates of 81% to 98% with higher success rates reported from studies published since 2007 (337). Reasons for failure of insertion were tubal obstruction, stenosis, or difficulty in accessing the tubal ostia. In a review of over 66,000 Essure placements, there were 102 pregnancies (1.5 per 1,000). Seventy-six percent occurred in women who did not have postprocedure imaging to confirm tubal occlusion, did not have reliable contraception prior to confirmation imaging or had misread imaging (338). Other studies report similar rates of pregnancy, ranging from 1.2 to 1.5 per 1,000 (339).

Reversal of Sterilization

Reversal of sterilization is more successful after mechanical occlusion than after electrocoagulation, because the latter method destroys much more of the tube. With modern microsurgical techniques and an isthmus-to-isthmus anastomosis, the first-year pregnancy rate is about 44% (340). A retrospective review comparing microsurgical reanastomosis to in vitro fertilization (IVF) found similar total pregnancy rates, but a higher live birthrate with IVF because 10% of the pregnancies after microsurgery were ectopic (340). Hysteroscopic sterilization by *Essure* should be considered irreversible. However, reversal following hysteroscopic sterilization has been reported using tubouterine implantation. Thirty-six percent of those undergoing surgery subsequently conceived naturally (341).

Late Sequelae of Tubal Sterilization

Increased menstrual irregularity and pain are attributed to previous tubal sterilization. Study of the problem is complicated by the fact that many women develop these symptoms as they age, even though they did not have tubal surgery, and are treated with OCs that reduce pain and create an artificially normal menstrual cycle. Women who discontinue OC use after tubal sterilization will experience more dysmenorrhea and menstrual irregularity, which is unrelated to the sterilization. The best answer available comes from the CREST study (342). A total of 9,514 women who underwent tubal sterilization were compared with 573 women whose partners had undergone vasectomy. Both groups were followed up to 5 years with annual standardized telephone interviews. Women who underwent tubal sterilization were no more likely to report persistent changes in intermenstrual bleeding or length of the menstrual cycle than

women whose partners had vasectomy. The sterilized women reported decreases in the days of bleeding, amount of bleeding, and menstrual pain but were slightly more likely to report cycle irregularity (OR, 1.6; 95% CI, 1.1–2.3). In summary, the CREST study provided good evidence that there is no "posttubal ligation syndrome."

Vasectomy

About 500,000 vasectomies are performed each year in the United States (313). Vasectomy is a highly effective method. The literature on efficacy is often difficult to interpret because most studies report failure as failure to achieve azoospermia, rather than long-term pregnancy rates among the relevant women. **Vasectomy is not effective until all sperm are cleared by the reproductive tract, which can take up to 20 ejaculations or 3 months. It is estimated that up to half of pregnancies after vasectomy occur during the interval between the surgery and the clearance of all sperm** (343). Not all pregnancies after vasectomy can be attributed to the men who had the operation. **[13]** The best long-term information comes from the CREST study. The cumulative probability of failure was 7.4 per 1,000 procedures at 1 year and 11.3 at year 5, and comparable to the failure rate of tubal sterilization (313).

[13] Vasectomy is usually performed under local anesthesia. The basic technique is to palpate the vas through the scrotum, grasp it with fingers or atraumatic forceps, make a small incision over the vas, and pull a loop of the vas into the incision. A small segment is removed, and a needle electrode is used to coagulate the lumen of both ends. Improved techniques include the no-scalpel vasectomy, in which the pointed end of the forceps is used to puncture the skin over the vas. This technique reduces the risk of hematoma (344). Another variation is the open-ended vasectomy, in which only the abdominal end of the severed vas is coagulated while the testicular end is left open. This is believed to prevent congestive epididymitis and sperm granuloma (345). Fascial interposition creates a tissue barrier between the vasal ends and reduces vasectomy failure (346).

Reversibility

Vasectomy must be regarded as a permanent means of sterilization. However, among men undergoing surgical reanastomosis (vasovasostomy), subsequent patency has been reported in over 90% of cases when current microsurgical techniques are employed (347). Nevertheless, the longer the interval since vasectomy, the poorer is the chance of reversal (348).

Safety

Operative complications include scrotal hematomas, wound infection, and epididymitis, but serious sequelae are rare. There were no reports of deaths from vasectomy in the United States in many years, and the death rate in a large third-world series was only

0.5 per 100,000. Concerns about long-term safety recurred with the report of a possible association between prostate cancer and vasectomy (349). **[13] Large studies present the very clear conclusion that vasectomy is not associated with prostate cancer** (350–352).

ABORTION

It is extremely likely that couples will experience at least one unwanted pregnancy at some time during their reproductive years. In developing countries, desired family size is larger (although decreasing), but access to effective contraception is limited. As a result, abortion, often unsafe, is common. Because of population growth, the absolute number of abortions increased by 5.9 million, from 50.4 million per year from 1990 to 1994 to 56.3 million per year from 2010 to 2014 (353). Globally, 25% of pregnancies ended in abortion from 2010 to 2014. In the developed world, the percent of pregnancies ending in abortion declined by 11 points from 39% to 28%, whereas in the developing world, it increased significantly by 3 points from 21% to 24% (353). It is estimated that 25 million, or nearly half of all abortions are "unsafe" where either the persons terminating the pregnancy lack the necessary skills or the environment in which it is performed does not conform to minimal medical standards, or both (354).

As shown in **Figure 14-16**, there are large discrepancies in the rate of safe abortions compared with unsafe abortions worldwide. In the developed countries where there is access to legal abortion, unsafe abortions are rare. In developing countries, where abortion is often highly restricted or completely illegal, they are very common. The highest proportion of unsafe abortions are found in Middle and Western Africa, where mortality rates from abortion are highest. The subregions with the highest proportions of safe abortions (northern Europe and northern America) include countries with less restrictive laws on abortion, high contraceptive use, high economic development, high levels of gender equality, and well-developed health infrastructures (354). **[14]** **Where abortion is legal, it is generally safe; where it is illegal, complications are common.** Forty-seven thousand women die every year from complications of unsafe abortion (355). Societies cannot prevent abortion, but they can determine whether it will be illegal and dangerous or legal and safe. **[14]** Death from illegal abortion was once common in the United States. In the 1940s, more than 1,000 women died each year of complications from abortion (356). In 1972, 24 women died of complications of legal abortion and 39 died from known illegal abortions. In 2012, the most recent year for which complete data are available, there were four deaths from legally induced abortion and no deaths from illegal abortion (abortion induced by a nonprofessional) in the entire United States (6). The American Medical Association's Council on Scientific Affairs reviewed the impact of legal abortion and attributes the decline in deaths during this century to the introduction of antibiotics to treat sepsis; the widespread use of effective contraception beginning in the 1960s, which reduced the number of unwanted pregnancies; and the shift from illegal to legal abortion (357).

The number of abortions reported each year in the United States—926,000 in 2014—has been declining since the peak level of 1.61 million in 1990 (5). In 2014, the national

abortion ratio was 18.8 abortions for every 100 pregnancies, and the national abortion rate was 14.6 per 1,000 women aged 15 to 44 years (5). While abortion rates for all racial and ethnic groups have declined, they are significantly higher for non-Hispanic black women. Non-Hispanic white women have 37.5% of all abortions, non-Hispanic black women have 35.6%, and Hispanic women 19%. Most women who obtain abortions are unmarried, 85.2% in 2013 (6). The use of abortion varies markedly with age. In 2013, 11.3% of women obtaining abortions were between 15 and 19 years of age, and 44.7% were 24 years of age or younger. In 2013, the abortion ratio for women younger than 15 years of age was 789 per 1,000 live births **(Fig. 14-2)** (6). The lowest abortion ratio, 121 per 1,000 live births, is for women aged 30 to 34 years.

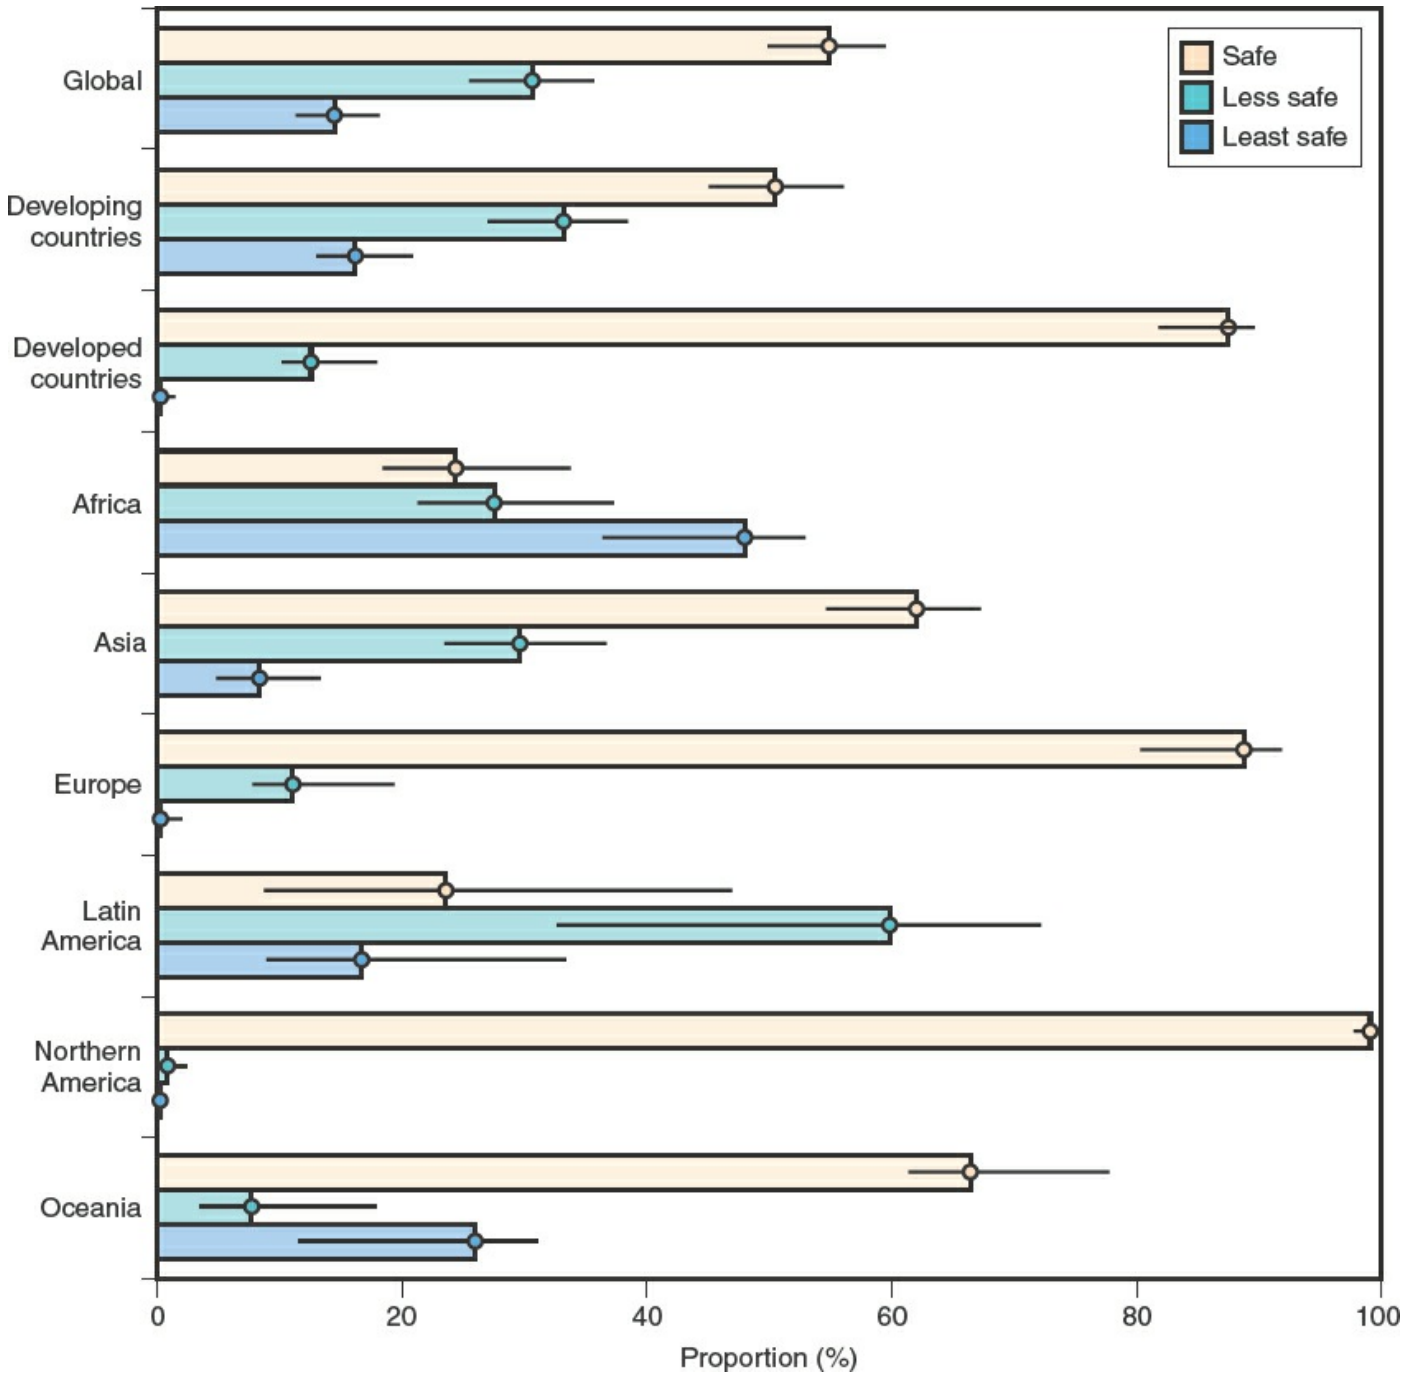

FIGURE 14-16 Distribution of abortion safety categories worldwide and by region. Bars and dots show the point estimates of the proportion of abortions in each category and horizontal lines are 90% uncertainty intervals. (From **Ganatra B, Gerdts C, Rossier C, et al.** Global, regional, and subregional classification of abortions by safety, 2010–14: estimates from a Bayesian hierarchical model. *Lancet* 2017;390[10110]:2372–2381.)

Regardless of personal feelings about the ethics of interrupting pregnancy, health professionals have a duty to know the medical facts about abortion and to share them with their patients (358). Providers are not required to perform abortions against their ethical principles, but they have a duty to help patients assess pregnancy risks and to make appropriate referrals.

Safety

[15] The overall annual risk of death with legal abortion decreased markedly, from 4.1 per 100,000 in 1972 to 1.8 in 1976, and remained less than 1 per 100,000 since 1987. Today, legal abortion remains an extremely safe procedure, with a mortality rate of 0.7 per 100,000 procedures (359). **[15]** Risk increases exponentially with gestational age. Pregnancy-associated mortality rate with aspiration procedures was 0.3 per 100,000 at or before 8 weeks and increased to 6.7 per 100,000 at 18 weeks or greater (359). Nevertheless, in comparison to a maternal mortality rate of 8.8 deaths per 100,000 live births, abortion by dilation and evacuation (D&E) beyond 18 weeks' gestation is safer than continuing pregnancy (360). It was estimated that 87% of the legal abortion deaths occurring after 8 weeks would have been prevented had the woman been able get abortion services by 8 weeks (361).

For individual women with high-risk conditions (e.g., cyanotic heart disease), even late abortion is a safer alternative to birth. Because of the availability of low-cost, out-of-hospital, first-trimester abortion, 88% of legal abortions are performed during the first trimester (before 13 weeks of amenorrhea), when abortion is the safest.

Techniques for First-Trimester Abortion

Vacuum Curettage

Most first-trimester abortions are performed by vacuum curettage. Most are performed with local anesthesia with or without moderate sedation, and usually on an outpatient basis in a freestanding specialty clinic or doctor's office (362). Cervical dilation is accomplished with metal or plastic dilators, or by osmotic cervical dilators or *misoprostol* 400 μg, given vaginally or by the buccal route 3 to 4 hours before the procedure (363). A plastic vacuum cannula of 5- to 12-mm diameter is used with a manual vacuum source or an electric vacuum pump. Manual vacuum provided by a modified 50-mL syringe is as effective as the electric pump through 10 menstrual weeks (364). The Society of Family Planning recommends a short course of antibiotics preoperatively to lower the risk of infection following surgical abortion (365). A single dose of doxycycline is a safe and effective prophylactic antibiotic and can be taken with dinner the night preceding a procedure. A large retrospective study of women's health care visits within 6 weeks after an abortion using California Medicaid data estimated abortion-related complication rates (366). Complications following first-trimester aspiration procedures are presented in Table 14-5. Major complications, defined as requiring hospital admission, surgery or blood transfusion, occurred in 0.16% of first-trimester aspiration abortions. The most common complications were other or undetermined diagnoses, most of which led to repeat abortions. More extensive descriptions of the management of complications are published elsewhere (367).

Table 14-5 Distribution of Abortion-Related Complication Diagnoses Among 34,755 First-Trimester Aspiration Procedures

Complication Diagnosis	
Incomplete abortion	116 (0.33)
Failed abortion	14 (0.04)
Hemorrhage	44 (0.13)
Infection	94 (0.27)
Uterine perforation	2 (0.01)
Anesthesia-related	2 (0.01)
Other or undetermined[a]	166 (0.48)
Total	438 (1.26)

[a]For major complications, this diagnosis includes undetermined diagnoses that required blood transfusions and surgery. For minor complications, the majority of this diagnosis consisted of cases treated with repeat abortion, but the exact diagnosis could not be determined. This category also includes diagnoses such as nonanesthesia-related allergic reactions and seizures.

Data are *n* (%).

Medical Abortion in the First Trimester

Mifepristone (RU486), an analog of the progestin *norethindrone,* has a strong affinity for the progesterone receptor but acts as an antagonist, blocking the effect of natural progesterone. Given alone, the drug was moderately effective in causing abortion of early pregnancy; the combination of *mifepristone* with a low dose of *prostaglandin* proved very effective, producing complete abortion in 96% to 99% of cases (368). In 2016, the FDA approved updated labeling for *mifepristone.* Changes included expansion of its use to 70 days from the start of the last menstrual period and a decrease in dose from 600 to 200 mg. Furthermore, misoprostol dose was increased from 400 mcg orally to 800 mcg buccally and home administration was allowed. Lastly, a posttreatment examination visit to the clinic was no longer required. These label changes were adopted because 200 mg of *mifepristone* was as effective as 600 mg, 800-mcg misoprostol by vaginal or buccal routes provide higher efficacy than 400-mcg oral dose, misoprostol can be taken at 24, 48, or 72 hours after mifepristone with equal efficacy, and women may safely self-administer misoprostol at home (369–373). Misoprostol can be taken by buccal or vaginal routes with similar blood levels and similar areas under the plasma concentration curve (AUC) (374,375). After case reports of death from *Clostridium sordellii,* a large cohort study was published by Planned

Parenthood describing the use of prophylactic *doxycycline* 100 mg twice a day for 1 week, and buccal rather than vaginal administration of *misoprostol* (376). No additional cases of *C. sordellii* have been recently reported. While individuals practitioners may decide to use antibiotics, the Society of Family Planning does not believe universal antibiotics are required for all women having a medical abortion.

Contraindications to medical abortion with *mifepristone/ misoprostol* include ectopic pregnancy; an IUD in place (remove IUD first); chronic adrenal failure; concurrent long-term corticosteroid therapy; history of allergy to *mifepristone, misoprostol,* or other *prostaglandins;* hemorrhagic disorder; and inherited porphyrias (377).

Methotrexate/Misoprostol and Misoprostol Alone

Alternatives to medical abortion when *mifepristone* is not available include regimens with *methotrexate/misoprostol* and *misoprostol* alone. The antifolate *methotrexate* provides another medical approach to pregnancy termination, but takes longer than the technique using *mifepristone/misoprostol* (378). Medical abortion can be induced with *misoprostol* alone, although it is less effective than the *mifepristone/misoprostol* combination. Vaginal *misoprostol,* 800 µg, repeated in 24 hours if fetal expulsion has not occurred, produces a complete abortion in 91% of pregnancies up to 56 days of amenorrhea (379).

Complications of Medical Abortion

Heavy or prolonged bleeding is the principal complication, with up to 8% of women experiencing some bleeding for as long as 30 days. Need for surgical curettage is predicted by the gestational age when the *mifepristone* is administered. Two percent of women treated at 49 days or less, 3% of those treated at 50 to 56 days, and 5% of those treated at 57 to 63 days needed curettage for bleeding or failed abortion in a large study with 200 mg of *mifepristone* and 800 µg of vaginal *misoprostol* (380). Late bleeding, at 3 to 5 weeks after expulsion of the pregnancy, accounted for more than half of the curettages. Under the updated protocol, serious complications requiring hospitalization for infection treatment or transfusion occur in fewer than 0.4% of patients (381). The updated regimen has been shown to cause fewer gastrointestinal side effects, such as nausea, vomiting, and diarrhea (382).

Medication Abortion and Telemedicine

With the 2016 mifepristone FDA label update excluding the requirement of in-clinic follow-up, telemedicine can facilitate the provision of medication abortions. Removing barriers to clinic access for rural women or mitigating the need for travel could reduce delays in receiving care and enable women to obtain an abortion at the earliest stages of pregnancy when it is safest (383). In one study, there were no differences in adverse events between in-person and telemedicine patients seeking medication abortion, and

telemedicine patients were more likely to recommend the service to a friend (384).

Second-Trimester Abortion

Abortions performed after 13 weeks include those done for fetal anomalies, medical illness, or delays resulting from pregnancy denial or difficulties making arrangements. Young maternal age is the single greatest factor determining the need for late abortion (6).

Dilation and Evacuation

D&E is the most commonly used method of midtrimester abortion in the United States. Prior to surgery, it is essential to prepare the cervix (to make it soft and pliable). There are a number of approaches to cervical ripening in this setting:

1. The cervix can be prepared by insertion of hygroscopic dilators, stems of the seaweed *Laminaria japonica* (laminaria), or Dilapan-S hydrophilic polymer rods. Placed in the cervical canal as small rods, these devices take up water from the cervix and swell, producing mechanical dilation, and induce endogenous prostaglandin synthesis, which aids in cervical softening. When the dilators are removed the following day, sufficient cervical dilation is accomplished to allow insertion of specialized forceps and a large-bore vacuum cannula to extract the fetus and placenta (385,386). Ultrasound guidance during the procedure is helpful (387). At the end of the midtrimester, procedures that combine serial insertion of two or more sets of laminaria or Dilapan-S for increased cervical dilation with a feticidal injection, or a combination of dilators with misoprostol to induce labor, followed by assisted expulsion of the fetus are possible (388).
2. Misoprostol can also be used for cervical preparation prior to midtrimester abortion. Osmotic dilator placement more effectively dilates and prepares the cervix before D&E than misoprostol alone (389,390). However, misoprostol in lieu of osmotic dilators has not been shown to increase the rate of serious complications. A large case series of D&Es between 17 and 23 weeks performed by highly experienced providers in women who received multidose misoprostol regimen as an alternative to overnight dilation reported a major complication rate less than 2% (391). However, the average dose of misoprostol used was 1,200 mcg.
3. Mifepristone is another option. A recent study comparing mifepristone as an adjunct or replacement for osmotic dilators in women undergoing D&E between 19 and 23 weeks found that, while median total procedure time was slightly longer for the mifepristone group compared to women who received mifepristone and osmotic dilators or only osmotic dilators, there were no differences in complications between the three groups (392). While some providers insert osmotic dilators sequentially over the course of 2 days, an RCT of D&Es from 19 to 23 weeks

showed that there were no differences in procedure times, initial cervical dilation, ease of procedure, or complications in women who received overnight synthetic osmotic dilators with mifepristone and misoprostol compared to women who received 2 days of dilators and misoprostol (393).

Intact D&E is another modification useful for procedures at the end of the midtrimester. After wide cervical dilation is achieved with serial placement of cervical dilators, the membranes are ruptured and an assisted breech delivery is performed, with decompression of the after-coming fetal head to allow delivery of the fetus intact (394). In response to the federal abortion ban of 2003, an increasing number of providers are using feticidal agents prior to late second-trimester terminations (395). Intra-amniotic or intrafetal *digoxin* and intracardiac *potassium chloride* are the two most common agents used for this purpose. Both are efficacious with little maternal adverse effects (396,397). The clinical utility of these agents is unproven. The only randomized controlled study looking at clinical outcomes found no change in procedure time or blood loss with the use of *digoxin* (398). Varying doses of *digoxin* were reported. In one study, 1.5-mg intra-amniotic *digoxin* was always successful in inducing fetal demise within 24 hours (399).

Labor-Induction Methods

In Europe and the United Kingdom, labor induction is much more common than D&E for midtrimester abortion (400). Induction abortion with hypertonic saline or urea was widely employed for labor induction abortion in the 1970s. These were supplanted by the use of synthetic prostaglandins, and by regimens that combine *mifepristone* and *misoprostol*.

Prostaglandins

Prostaglandins of the E and F series can cause uterine contraction at any stage of gestation. The 15 methyl analogs of prostaglandin $F_2\alpha$ (*carboprost*) and prostaglandin E_2 (*dinoprostone*) are highly effective for midtrimester abortion but frequently produce side effects of vomiting, diarrhea, and with *dinoprostone,* fever. *Misoprostol*, a 15 methyl analog of PGE_1, is much less expensive than other prostaglandins, stable at room temperature, and at doses effective for abortion, produces fewer side effects (401). Transient fetal survival is not infrequent after prostaglandin inductions. In the United States, it is common to induce fetal demise before induction with regimens similar to those used in late second-trimester D&E: intra-amniotic or intrafetal *digoxin,* 1 to 1.5 mg, or fetal intracardiac *potassium chloride* (3 mL of a 2-mmol solution).

Midtrimester Mifepristone/Misoprostol

Mifepristone pretreatment markedly increases the abortifacient efficacy of *gemeprost* and *misoprostol*. *Mifepristone,* 200 mg, is just as effective for this purpose as 600 mg

(402). A common protocol was developed using *mifepristone* and *misoprostol* that is now recommended by the Royal College of Obstetricians and Gynecologists (RCOG) and the WHO (403,404). Most women are cared for as hospital day-patients without need for overnight admission, a marked improvement over the labor induction methods of the past that often required 2 to 3 days of hospitalization. In the United States, ACOG recommends administering mifepristone, 200 mg orally, followed in 24 to 48 hours by either 800-mcg misoprostol vaginally followed by 400 mcg vaginally every 3 hours, or 400-mcg misoprostol buccally every 3 hours (405). Earlier studies evaluated intervals of 24 to 48 hours between dosing mifepristone and misoprostol. A systematic review including studies of 24- to 48-hour intervals calculated weighted median induction times of 7.6 hours for 1-day interval and 6.8 hours for 2-day interval (406). When comparing mifepristone–misoprostol intervals of 36 to 48 hours to intervals of 24 hours or less, shorter intervals on average had only minimally longer induction times (1 to 2 hours) but consistently much shorter overall total procedure times (mifepristone to pregnancy expulsion).

Combination of Induction and Assisted Delivery

Hern developed a procedure that combines a feticidal injection of *digoxin* with serial insertion of multiple laminaria tents over 2 to 3 days, followed by amniotomy, placement of *misoprostol* in the lower uterine segment, and intravenous *oxytocin* to induce labor, and then an assisted delivery (407). The procedure was successful in a large case series at 18 to 34 weeks with very few complications.

Complications of Second-Trimester Abortion

Surgical Abortion Complications

Complications of second-trimester surgical abortion are uncommon, but risk increases with gestational age. Complications and their frequency encountered in almost 3,000 midtrimester abortions performed by laminaria followed by D&E on a referral service are listed in Table 14-6. The gestational ages were 14 to 27 weeks and mean gestational age was 20.2 weeks. The most common complication was a cervical laceration that required suturing. A major complication, defined as one necessitating transfusion, disseminated intravascular coagulation, reoperations with uterine artery embolization, laparoscopy, or laparotomy, was encountered in 1.3% of patients. History of two or more cesareans, gestational period of 20 weeks or more, and insufficient initial cervical dilation by laminaria were independent risk factors for a major complication in a multivariate analysis (408). The rates of complication in Table 14-6 cannot be directly compared to the rates of complications with labor-induction abortion described below because half of the D&E group were 20 weeks or more gestation, while only a few of the induction patients were more than 20 weeks.

Table 14-6 Complications of 2,935 Midtrimester Dilation and Evacuation Abortion and Intervention Rates on a Referral Service

	Number (%)	95% Confidence Interval (%)
Complication		
Cervical laceration	99 (3.3)	2.7–4.0
Atony	78 (2.6)	2.1–3.3
Hemorrhage	30 (1.0)	0.6–1.4
Other	15 (0.5)	0.3–0.8
Disseminated intravascular coagulation	7 (0.2)	0.1–0.4
Retained products	6 (0.2)	0.04–0.4
Perforation	6 (0.2)	0.04–0.4
Treatment of Complications		
Reaspiration	46 (1.5)	1.1–2.0
Hospitalization	42 (1.4)	1.0–1.8
Transfusion	30 (1.0)	0.7–1.4
Uterine artery embolization	21 (0.7)	0.4–1.0
Laparoscopy or laparotomy	13 (0.4)	0.2–0.7

From **Frick AC, Drey EA, Diedrich JT, et al.** Effect of prior cesarean delivery on risk of second-trimester surgical abortion complications. *Obstet Gynecol* 2010;115:762; Table 2, with permission.

Induction Abortion Complications

The labor-induction methods share common hazards: failure of the primary procedure to produce abortion within a reasonable time, incomplete abortion, retained placenta, hemorrhage, infection, and embolic phenomena. With modern protocols, these are rare. In a series of 1,002 women treated with *mifepristone* and *misoprostol* at 13 to 21 weeks, 0.7% required a blood transfusion, 0.3% required ergot treatment for hemorrhage, and one required laparotomy for otherwise uncontrollable hemorrhage; 2.6% of patients received antibiotics for presumed pelvic infection after hospital discharge and 7.9% complained of prolonged bleeding (409). Uterine rupture has been reported in women with previous cesarean delivery treated with *misoprostol* in the midtrimester. In a case series of 101 women with one or more previous cesarean births and three smaller case series totaling 87 patients, no ruptures occurred (410). In another retrospective study of women 14 to 26 weeks undergoing induction, there were 3

ruptures, all in women who had 2 or more cesarean sections. These women had received 200 mcg vaginal misoprostol every 4 hours. The uterine rupture rate in these women alone was 11.5% (411). The Society of Family Planning recommends consideration of a 200 mcg or lower dose for women with a prior uterine scar, but concludes that data are insufficient to advise a change in dosing interval (412).

KEY POINTS

1 Vulvovaginitis is diagnosed by office-based testing.
2 More prolonged antifungal therapy is indicated for women with complicated vulvovaginal candidiasis (VVC) than for those with uncomplicated disease.
3 Women with normal physical examination findings and no evidence of fungal infection disclosed by microscopy are unlikely to have VVC and should not be treated empirically unless results of a vaginal yeast culture are positive.
4 Cervicitis is commonly associated with bacterial vaginosis (BV), which, if not treated concurrently, leads to significant persistence of the symptoms and signs of cervicitis.
5 Women with mild-to-moderate pelvic inflammatory disease (PID) can be treated as outpatients.
6 Trocar drainage, with or without placement of a drain, is successful in as many as 90% of patients with PID complicated by tubo-ovarian abscess that fails to respond to antimicrobial therapy within 72 hours.
7 Because false-negative results are common with herpes simplex virus (HSV) cultures, especially in patients with recurrent infections, type-specific glycoprotein G-based (IgG) antibody assay tests are useful in confirming a clinical diagnosis of genital herpes.
8 Suppressive treatment partially decreases symptomatic and asymptomatic viral shedding and the potential for transmission.

Genitourinary tract infections are among the most frequent disorders for which patients seek care from gynecologists. By understanding the pathophysiology of these diseases, and having an effective approach to their diagnosis, physicians can institute appropriate antimicrobial therapy to treat these conditions and reduce long-term sequelae.

THE NORMAL VAGINA

Normal vaginal secretions are composed of vulvar secretions from sebaceous, sweat, Bartholin, and Skene glands; transudate from the vaginal wall; exfoliated vaginal and cervical cells; cervical mucus; endometrial and oviductal fluids; and micro-organisms and their metabolic products. The type and amount of exfoliated cells, cervical mucus, and upper genital tract fluids are determined by biochemical processes that are influenced by hormone levels (1). Vaginal secretions may increase in the middle of the

menstrual cycle because of an increase in the amount of cervical mucus.

The vaginal desquamative tissue is made up of vaginal epithelial cells that are responsive to varying amounts of estrogen and progesterone. Superficial cells, the main cell type in women of reproductive age, predominate when estrogen stimulation is present. Intermediate cells predominate during the luteal phase because of stimulation by progesterone. Parabasal cells predominate in the absence of either hormone, a condition that may be found in postmenopausal women who are not receiving hormonal therapy.

The normal vaginal flora is mostly aerobic, with an average of six different species of bacteria, the most common of which is hydrogen peroxide–producing lactobacilli. The microbiology of the vagina is determined by factors that affect the ability of bacteria to survive (2). These factors include vaginal pH and the availability of glucose for bacterial metabolism. **The pH level of the normal vagina is lower than 4.5, which is maintained by the production of lactic acid.** Estrogen-stimulated vaginal epithelial cells are rich in glycogen. Vaginal epithelial cells break down glycogen to monosaccharides, which can be converted by the cells themselves, and lactobacilli to lactic acid.

[1] Normal vaginal secretions are floccular in consistency, white in color, and usually located in the dependent portion of the vagina (posterior fornix). Vaginal secretions can be analyzed by a wet-mount preparation. A sample of vaginal secretions is suspended in 0.5 mL of normal saline in a tube, transferred to a slide, covered with a slip, and assessed by microscopy. Some clinicians prefer to prepare slides by suspending secretions in saline placed directly on the slide. Secretions should not be placed on the slide without saline because this method causes drying of the vaginal secretions and does not result in a well-suspended preparation. Microscopy of normal vaginal secretions reveals many superficial epithelial cells, few white blood cells (less than one per epithelial cell), and few, if any, clue cells. **Clue cells are superficial vaginal epithelial cells with adherent bacteria, usually *Gardnerella vaginalis*, which obliterates the crisp cell border when visualized microscopically.** Potassium hydroxide 10% (KOH) may be added to the slide, or a separate preparation can be made, to examine the secretions for evidence of fungal elements. The results are negative in women with normal vaginal microbiology. Gram stain reveals normal superficial epithelial cells and a predominance of gram-positive rods (lactobacilli).

VAGINAL INFECTIONS

Bacterial Vaginosis

Bacterial vaginosis (BV) is a polymicrobial clinical syndrome resulting in alteration of normal vaginal bacterial flora that results in the loss of hydrogen peroxide–

producing lactobacilli and an overgrowth of predominantly anaerobic bacteria (3,4). **The most common form of vaginitis in the United States is BV** (5). Anaerobic bacteria can be found in less than 1% of the flora of normal women. In women with BV, however, the concentration of anaerobes, and *G. vaginalis* and *Mycoplasma hominis*, is 100 to 1,000 times higher than in normal women. Lactobacilli are usually absent.

It is not known what triggers the disturbance of normal vaginal flora. It is postulated that repeated alkalinization of the vagina, which can occur with frequent sexual intercourse or use of douches, plays a role. After normal hydrogen peroxide– producing lactobacilli disappear, it is difficult to reestablish normal vaginal flora, and recurrence of BV is common.

Numerous studies show an association of BV with significant adverse sequelae. Women with BV are at increased risk for pelvic inflammatory disease (PID), postabortal PID, postoperative cuff infections after hysterectomy, and abnormal cervical cytology (6–10). **Pregnant women with BV are at risk for premature rupture of the membranes, preterm labor and delivery, chorioamnionitis, and postcesarean endometritis** (8–9). In women with BV who are undergoing surgical abortion or hysterectomy, perioperative treatment with *metronidazole* eliminates this increased risk (10).

Diagnosis

Office-based testing is required to diagnose BV. It is diagnosed on the basis of the following findings (11): clinical criteria require three of the following signs or symptoms (Amsel Diagnostic Criteria):

1. **A fishy vaginal odor, which is particularly noticeable following coitus, and vaginal discharge are present.**
2. **Vaginal secretions are gray and thinly coat the vaginal walls.**
3. **The pH of these secretions is higher than 4.5 (usually 4.7 to 5.7).**
4. **Microscopy of the vaginal secretions reveals an increased number of clue cells, and leukocytes are conspicuously absent. In advanced cases of BV, more than 20% of the epithelial cells are clue cells.**
5. **The addition of KOH to the vaginal secretions (the "whiff" test) releases a fishy, amine-like odor.**

Clinicians who are unable to perform microscopy should use alternative diagnostic tests such as a pH and amines test card, detection of *G. vaginalis* ribosomal RNA, or Gram stain (12). Culture of *G. vaginalis* is not recommended as a diagnostic tool because of its lack of specificity.

Treatment

Ideally, treatment of BV should inhibit anaerobes but not vaginal lactobacilli. **The following treatments are effective:**

1. ***Metronidazole*, an antibiotic with excellent activity against anaerobes but poor activity against lactobacilli, is the drug of choice for the treatment of BV.** A dose of 500 mg administered orally twice a day for 7 days should be used. Patients should be advised to avoid using alcohol during treatment with oral *metronidazole* and for 24 hours thereafter.
2. ***Metronidazole* gel, 0.75%, one applicator (5 g) intravaginally once daily for 5 days, may alternatively be prescribed.**

The overall cure rates range from 75% to 84% with the aforementioned regimens (5). ***Clindamycin* in the following regimens is effective in treating BV:**

1. ***Clindamycin* ovules, 100 mg, intravaginally once at bedtime for 3 days**
2. ***Clindamycin* bioadhesive cream, 2%, 100 mg intravaginally in a single dose**
3. ***Clindamycin* cream, 2%, one applicator full (5 g) intravaginally at bedtime for 7 days**
4. ***Clindamycin*, 300 mg, orally twice daily for 7 days**

Many clinicians prefer intravaginal treatment to avoid systemic side effects such as mild to moderate gastrointestinal upset and unpleasant taste. Treatment of the male sexual partner does not improve therapeutic response and therefore is not recommended (5).

Trichomonas Vaginitis

Trichomonas vaginitis*, the most prevalent nonviral sexually transmitted infection in the United States is caused by the sexually transmitted, flagellated parasite, *Trichomonas vaginalis (5,13). The transmission rate is high; 70% of men contract the disease after a single exposure to an infected woman, which suggests that the rate of male-to-female transmission is even higher. The parasite, which exists only in trophozoite form, is an anaerobe that has the ability to generate hydrogen to combine with oxygen to create an anaerobic environment. It often accompanies BV, which can be diagnosed in as many as 60% of patients with trichomonas vaginitis (13–15). *T. vaginalis* infection is associated with a two to threefold increased risk for HIV acquisition (15).

Diagnosis

Local immune factors and inoculum size influence the appearance of symptoms.

Symptoms and signs may be much milder in patients with small inocula of trichomonads, and trichomonas vaginitis often is asymptomatic (13–15).

1. **Trichomonas vaginitis is associated with a profuse, purulent, malodorous vaginal discharge that may be accompanied by vulvar pruritus.**
2. **A purulent vaginal discharge may exude from the vagina.**
3. **In patients with high concentrations of organisms, a patchy vaginal erythema and colpitis macularis ("strawberry" cervix) may be observed.**
4. **The pH of the vaginal secretions could be variable or higher than 5.0.**
5. **Microscopy of the secretions reveals motile trichomonads and increased numbers of leukocytes.**
6. **Clue cells may be present because of the common association with BV.**
7. **The whiff test may be positive.**

Morbidity associated with trichomonas vaginitis may be related to BV. Patients with trichomonas vaginitis are at increased risk for postoperative cuff cellulitis following hysterectomy (7). **Pregnant women with trichomonas vaginitis are at increased risk for premature rupture of the membranes and preterm delivery**. Because of the sexually transmitted nature of trichomonas vaginitis, women with this infection should be tested for other sexually transmitted diseases (STDs).

Treatment

The treatment of trichomonas vaginitis can be summarized as follows:

1. ***Metronidazole* is the drug of choice for treatment of vaginal trichomoniasis.** Both a single-dose (2 g orally) and a multidose (500 mg twice daily for 7 days) regimen are highly effective and have cure rates of about 95%.
2. ***Tinidazole* 2 g orally in a single dose is another recommended regimen.**
3. **The sexual partner should be treated.**
4. **Women who do not respond to initial therapy should be treated again with *metronidazole*, 500 mg, twice daily for 7 days.** If repeated treatment is not effective, the patient should be treated with a single 2-g dose of *metronidazole* once daily for 5 days or *tinidazole*, 2 g, in a single dose for 5 days.
5. **Patients who do not respond to repeated treatment with *metronidazole* or *tinidazole* and for whom the possibility of reinfection is excluded should be referred for expert consultation.** In these uncommon refractory cases, an important part of management is to obtain cultures of the parasite to determine its susceptibility to *metronidazole* and *tinidazole.*
6. **Retesting for *T. vaginalis* is recommended within 3 months following initial**

treatment due to high rate of reinfection.

7. ***Metronidazole* gel should not be used for the treatment of vaginal trichomoniasis.**

Vulvovaginal Candidiasis

An estimated 75% of women experience at least one episode of vulvovaginal candidiasis (VVC) during their lifetimes (5,16). Nearly 45% of women will experience two or more episodes (16). Few are plagued with a chronic, recurrent infection. *Candida albicans* is responsible for 85% to 90% of vaginal yeast infections. Other species of *Candida*, such as *Candida glabrata* and *Candida tropicalis*, can cause vulvovaginal symptoms and tend to be resistant to therapy. Candida are dimorphic fungi existing as blastospores, which are responsible for transmission and asymptomatic colonization, and as mycelia, which result from blastospore germination and enhance colonization and facilitate tissue invasion. The extensive areas of pruritus and inflammation often associated with minimal invasion of the lower genital tract epithelial cells suggest that an extracellular toxin or enzyme may play a role in the pathogenesis of this disease. A hypersensitivity phenomenon may be responsible for the irritative symptoms associated with VVC, especially for patients with chronic, recurrent disease. Patients with symptomatic disease usually have an increased concentration of these micro-organisms ($>10^4$ per mL) compared with asymptomatic patients ($<10^3$ per mL) (17).

Factors that predispose women to the development of symptomatic VVC include antibiotic use, pregnancy, immunosuppressive states, and diabetes (18–20). Pregnancy and diabetes are associated with a qualitative decrease in cell-mediated immunity, leading to a higher incidence of candidiasis.

It is helpful to categorize women with VVC as having either uncomplicated or complicated disease (Table 15-1).

Table 15-1 Classification of Vulvovaginal Candidiasis

Uncomplicated	Complicated
Sporadic or infrequent in occurrence	Recurrent symptoms
Mild to moderate symptoms	Severe symptoms
Likely to be *Candida albicans*	Non-albicans Candida
Immunocompetent women	Immunocompromised, e.g., diabetic women, HIV, immunosuppressive therapy

From **Sobel JD, Faro S, Force RW, et al.** Vulvovaginal candidiasis: Epidemiologic, diagnostic, and

therapeutic considerations. *Am J Obstet Gynecol* 1998;178:203–211.

Diagnosis

The main symptom of VVC is vulvar pruritus associated with a vaginal discharge that typically resembles cottage cheese. A few patients may have minimal vaginal discharge.

1. **The discharge can vary from watery to homogeneously thick.** Vaginal soreness, dyspareunia, vulvar burning, and irritation may be present. External dysuria ("splash" dysuria) may occur when micturition leads to exposure of the inflamed vulvar and vestibular epithelium to urine. Examination reveals erythema and edema of the labia and vulvar skin. Discrete pustulopapular peripheral lesions may be present. The vagina may be erythematous with an adherent, whitish discharge. The cervix appears normal.
2. **The pH of the vagina in patients with VVC is usually normal (<4.5).**
3. **Fungal elements, either budding yeast forms or mycelia, appear in as many as 80% of cases.** The results of saline preparation of the vaginal secretions usually are normal, although there may be a slight increase in the number of inflammatory cells in severe cases.
4. **The whiff test is negative.**
5. **A presumptive diagnosis can be made in the absence of fungal elements confirmed by microscopy if the pH and the results of the saline preparation evaluations are normal *and* the patient has increased erythema based on examination of the vagina or vulva. A fungal culture is recommended to confirm the diagnosis. Conversely, women with normal physical examination findings and no evidence of fungal elements disclosed by microscopy are unlikely to have VVC and should not be empirically treated unless a vaginal yeast culture is positive.**

Treatment

The treatment of VVC is summarized as follows:

1. **Topically applied azole drugs are the most commonly available treatment for VVC and are more effective than *nystatin*** (Table 15-2) (5). Treatment with azoles results in relief of symptoms and negative cultures in 80% to 90% of patients who have completed therapy. Symptoms usually resolve in 2 to 3 days. Short-course regimens up to 3 days are recommended. The short-course formulations have higher concentrations of the antifungal agent, causing an inhibitory concentration in the vagina that persists for several days.
2. **The oral antifungal agent, *fluconazole*, used in a single 150-mg dose, is**

recommended for the treatment of VVC. It appears to have equal efficacy when compared with topical azoles in the treatment of mild to moderate VVC (26). Patients should be advised that their symptoms will persist for 2 to 3 days so they will not expect additional treatment.

3. **[2] Women with complicated VVC (Table 15-1) benefit from an additional 150-mg dose of *fluconazole* given 72 hours after the first dose. Patients with complications can be treated with a more prolonged topical regimen lasting 10 to 14 days. Adjunctive treatment with a weak topical steroid, such as 1% *hydrocortisone* cream, may help relieve some of the external irritative symptoms.**

Table 15-2 Vulvovaginal Candidiasis—Topical Treatment Regimens

Butoconazole
2% cream (single dose bioadhesive product), 5 g intravaginally in a single application[a,b]
Clotrimazole
1% cream, 5 g intravaginally for 7–14 days[a,b]
2% cream 5 g intravaginally for 3 days
Miconazole
2% cream, 5 g intravaginally for 7 days[a,b]
200-mg vaginal suppository, one suppository for 3 days[a]
100-mg vaginal suppository, one suppository daily for 7 days[a,b]
4% cream 5 g intravaginally daily for 3 days
1,200-mg vaginal suppository, one suppository for 1 day
Nystatin
100,000-U vaginal tablet, one tablet for 14 days
Tioconazole
6.5% ointment, 5 g intravaginally, single dose[a,b]
Terconazole
0.4% cream, 5 g intravaginally daily for 7 days[a,b]
0.8% cream, 5 g intravaginally daily for 3 days[a,b]

80-mg suppository, one suppository daily for 3 days

[a]Oil-based, may weaken latex condoms.

[b]Available as over-the-counter preparation.

Recurrent Vulvovaginal Candidiasis

A small number of women develop recurrent VVC (RVVC), defined as four or more episodes in a year. Non-albicans candida species are observed in 10% to 20% of RVVC. These women experience persistent irritative symptoms of the vestibule and vulva. **Burning replaces itching as the prominent symptom in patients with RVVC**. The diagnosis should be confirmed by direct microscopy of the vaginal secretions and by fungal culture. **[3] Many women with RVVC presume incorrectly they have a chronic yeast infection. Many of these patients have chronic atopic dermatitis or atrophic vulvovaginitis.**

The treatment of patients with RVVC consists of inducing a remission of chronic symptoms with *fluconazole* (150 mg every 3 days for three doses). Patients should be maintained on a suppressive dose of this agent (*fluconazole*, 150 mg weekly) for 6 months (21). On this regimen, 90% of women with RVVC will remain in remission. After suppressive therapy, approximately half will remain asymptomatic. Recurrence will occur in the other half and should prompt reinstitution of suppressive therapy (21). Patients with RVVC should have a fungal culture performed to look for non-albicans candida, and potential resistance to fluconazole. If recurrence persists or in patients with non-albicans candida, Boric acid 600-mg vaginal suppository is recommended for 2 weeks (22,23).

Inflammatory Vaginitis

Desquamative inflammatory vaginitis **is a clinical syndrome characterized by diffuse exudative vaginitis, epithelial cell exfoliation, and a profuse purulent vaginal discharge** (24). The cause of inflammatory vaginitis is unknown, but Gram stain findings reveal a relative absence of normal long gram-positive bacilli (lactobacilli) and their replacement with gram-positive cocci, usually streptococci. Women with this disorder have a purulent vaginal discharge, vulvovaginal burning or irritation, and dyspareunia. A less frequent symptom is vulvar pruritus. Vaginal erythema is present, and there may be an associated vulvar erythema, vulvovaginal ecchymotic spots, and colpitis macularis. The pH of the vaginal secretions is uniformly higher than 4.5 in these patients. Microscopy of the vaginal secretions, shows an increase in inflammatory cells and parabasal epithelial cells (immature squamous cells). Vaginal flora is abnormal and pH is always elevated above 4.5.

Topical vaginal clindamycin and local vaginal corticosteroids are used as treatment. Initial therapy is the use of 2% *clindamycin* cream, one applicator full (5 g) intravaginally once daily for 4 weeks. Relapse occurs in about 30% of patients, who should be retreated with intravaginal 2% *clindamycin* cream or vaginal hydrocortisone 10% cream 3 to 5 g daily for 6 weeks. When relapse occurs in postmenopausal patients, supplementary hormonal therapy should be considered (28). Some women with relapse may benefit from maintenance therapy.

Atrophic Vaginitis

Estrogen plays an important role in the maintenance of normal vaginal ecology. **Women undergoing menopause, either naturally or secondary to surgical removal of the ovaries, may develop inflammatory vaginitis, which may be accompanied by an increased, purulent vaginal discharge. In addition, they may have dyspareunia and postcoital bleeding resulting from atrophy of the vaginal and vulvar epithelium.** Examination reveals atrophy of the external genitalia, along with a loss of the vaginal rugae. The vaginal mucosa may be somewhat friable. Microscopy of the vaginal secretions shows a predominance of parabasal epithelial cells and an increased number of leukocytes.

Atrophic vaginitis is treated with topical *estrogen* vaginal cream. Use of 1 g of *conjugated estrogen* cream intravaginally each day for 1 to 2 weeks generally provides relief. Maintenance *estrogen* therapy, either topical or systemic, should be considered to prevent recurrence of this disorder.

Cervicitis

The cervix is made up of two different types of epithelial cells: squamous epithelium and glandular epithelium. The cause of cervical inflammation depends on the epithelium affected. The ectocervical epithelium can become inflamed by the same micro-organisms that are responsible for vaginitis. The ectocervical squamous epithelium is an extension of and is continuous with the vaginal epithelium. Trichomonas, candida, and herpes simplex virus (HSV) can cause inflammation of the ectocervix. Conversely, *Neisseria gonorrhoeae* and *Chlamydia trachomatis* infect only the glandular epithelium (25,26).

Diagnosis

The diagnosis of cervicitis is based on the finding of a purulent endocervical discharge, generally yellow or green in color and referred to as "mucopus" (26).

1. **After removal of ectocervical secretions with a large swab, a small cotton swab**

is placed into the endocervical canal and the cervical mucus is extracted. The cotton swab is inspected against a white or black background to detect the green or yellow color of the mucopus. The zone of ectopy (glandular epithelium) is friable or easily induced to bleed. This characteristic can be assessed by touching the ectropion with a cotton swab or spatula.

2. **Placement of the mucopus on a slide that can be Gram stained will reveal the presence of an increased number of neutrophils (>30 per high-power field).** The presence of intracellular gram-negative diplococci, leading to the presumptive diagnosis of gonococcal endocervicitis, may be detected. If the Gram stain results are negative for gonococci, the presumptive diagnosis is chlamydial cervicitis.
3. **Tests for gonorrhea and chlamydia, preferably using nucleic acid amplification tests (NAAT), should be performed.** The microbial etiology of endocervicitis is unknown in about 50% of cases in which neither gonococci nor chlamydia is detected. *Mycoplasma genitalium,* an emerging sexually transmitted disease, can be detected in 10% to 30% of women with clinical cervicitis (5).

Treatment

Treatment of cervicitis consists of an antibiotic regimen recommended for the treatment of uncomplicated lower genital tract infection with both chlamydia and gonorrhea (5). Dual therapy is recommended for the treatment of gonorrhea, and cefixime is no longer a first-line regimen (Table 15-3) (5). Fluoroquinolone resistance is common in *N. gonorrhoeae* isolates, and, therefore, these agents are no longer recommended for the treatment of women with gonococcal cervicitis. It is imperative that all sexual partners be treated with a similar antibiotic regimen. **[4]** Cervicitis is commonly associated with BV, which, if not treated concurrently, leads to significant persistence of the symptoms and signs of cervicitis.

Table 15-3 Treatment Regimens for Gonococcal and Chlamydial Infections

Neisseria gonorrhoeae endocervicitis
Ceftriaxone, 250 mg IM in a single dose, PLUS
Azithromycin 1g orally in single dose
If ceftriaxone is not available:
Cefexime, 400 mg in a single dose, PLUS
Azithromycin 1 g orally in single dose
Chlamydia trachomatis endocervicitis
Azithromycin, 1 g orally (single dose), or

Doxycycline, 100 mg orally twice daily for 7 days

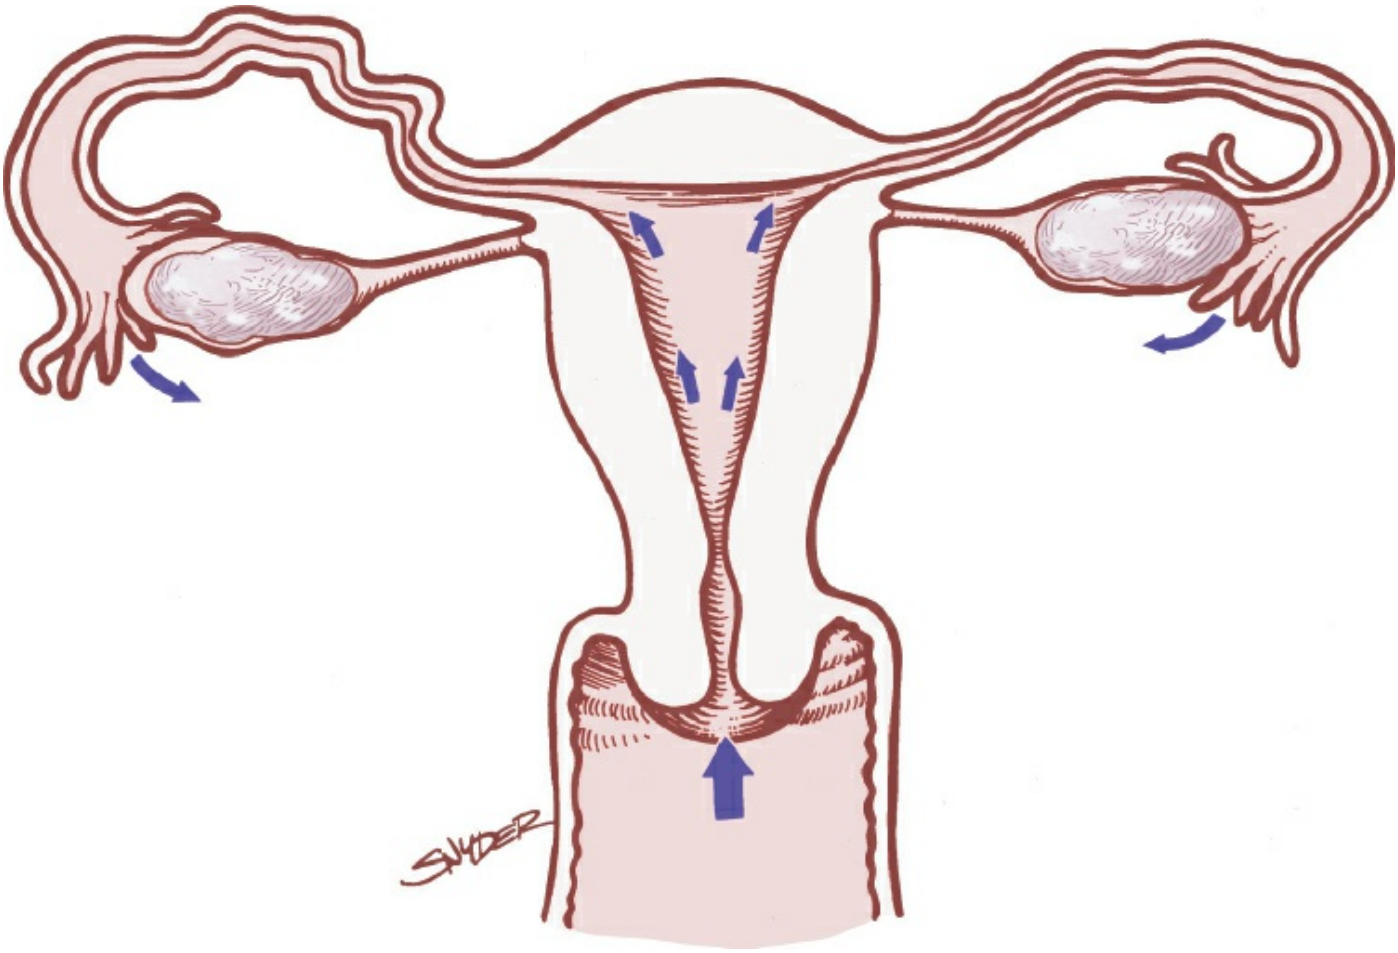

FIGURE 15-1 Micro-organisms originating in the endocervix ascend into the endometrium, fallopian tubes, and peritoneum, causing pelvic inflammatory disease (endometritis, salpingitis, peritonitis). (From **Soper DE**. Upper genital tract infections. In: Copeland LJ, ed. *Textbook of Gynecology*. Philadelphia, PA: Saunders, 1993:521, with permission.)

Pelvic Inflammatory Disease

PID is caused by microorganisms colonizing the endocervix and ascending to the endometrium and fallopian tubes. It is a clinical diagnosis implying that the patient has upper genital tract infection and inflammation. The inflammation may be present at any point along a continuum that includes endometritis, salpingitis, and peritonitis (Fig. 15-1).

PID is commonly caused by the sexually transmitted microorganisms *N.*

gonorrhoeae* and *C. trachomatis (27–29). Recent evidence suggests that *M. genitalium* can cause PID and presents with mild clinical symptoms similar to chlamydial PID (30). Endogenous microorganisms found in the vagina, particularly the BV microorganisms, are often isolated from the upper genital tract of women with PID. The BV microorganisms include anaerobic bacteria such as *Prevotella*, *Peptostreptococci,* and *G. vaginalis*. BV often occurs in women with PID, and the resultant complex alteration of vaginal flora may facilitate the ascending spread of pathogenic bacteria by enzymatically altering the cervical mucus barrier (31). Less frequently, respiratory pathogens such as *Haemophilus influenzae*, group A streptococci, and pneumococci can colonize the lower genital tract and cause PID.

Diagnosis

Traditionally, the diagnosis of PID is based on a triad of symptoms and signs, including pelvic pain, cervical motion and adnexal tenderness, and the presence of fever. It is recognized that there is wide variation in many symptoms and signs among women with this condition, which makes the diagnosis of acute PID difficult. Many women with PID exhibit subtle or mild symptoms that are not readily recognized as PID. Consequently, delay in diagnosis and therapy probably contributes to the inflammatory sequelae in the upper reproductive tract (32).

In the diagnosis of PID, the goal is to establish guidelines that are sufficiently sensitive to avoid missing mild cases but sufficiently specific to avoid giving antibiotic therapy to women who are not infected. Genitourinary tract symptoms may indicate PID; therefore, the diagnosis of PID should be considered in women with any genitourinary symptoms, including, but not limited to, lower abdominal pain, excessive vaginal discharge, menorrhagia, metrorrhagia, fever, chills, and urinary symptoms (33). **Some women may develop PID without having overt symptoms**.

Pelvic organ tenderness, either uterine tenderness alone or uterine tenderness with adnexal tenderness, is present in patients with PID. Cervical motion tenderness suggests the presence of peritoneal inflammation, which causes pain when the peritoneum is stretched by moving the cervix and causing traction of the adnexa on the pelvic peritoneum. Direct or rebound abdominal tenderness may be present.

Evaluation of both vaginal and endocervical secretions is a crucial part of the workup of a patient with PID (34). **In women with PID, an increased number of polymorphonuclear leukocytes may be detected in a wet mount of the vaginal secretions or in the mucopurulent discharge.**

More elaborate tests may be used in women with severe symptoms because an incorrect diagnosis may cause unnecessary morbidity **(Table 15-4)** (34). These tests include endometrial biopsy to confirm the presence of endometritis, ultrasound or radiologic tests to characterize a tubo-ovarian abscess, and laparoscopy to visually confirm salpingitis.

Treatment

Therapy regimens for PID must provide empirical, broad-spectrum coverage of likely pathogens, including *N. gonorrhoeae*, *C. trachomatis*, *M. genitalium*, gram-negative facultative bacteria, anaerobes, and streptococci (5,35). Recommended regimens for the treatment of PID are listed in Table 15-5. **[5] An outpatient regimen of *cefoxitin* and *doxycycline* is as effective as an inpatient parenteral regimen of the same antimicrobials** (36). **Therefore, hospitalization is recommended only when the diagnosis is uncertain, pelvic abscess is suspected, clinical disease is severe, or compliance with an outpatient regimen is in question. Hospitalized patients can be considered for discharge when their fever has lysed (<99.5çF for more than 24 hours), the white blood cell count has become normal, rebound tenderness is absent, and repeat examination shows marked amelioration of pelvic organ tenderness** (37).

Table 15-4 Clinical Criteria for the Diagnosis of Pelvic Inflammatory Disease

Symptoms
None necessary
Signs
Pelvic organ tenderness
Leukorrhea and/or mucopurulent endocervicitis
Additional Criteria to Increase the Specificity of the Diagnosis
Endometrial biopsy showing endometritis
Elevated C-reactive protein or erythrocyte sedimentation rate
Temperature higher than 38°C (100.4°F)
Leukocytosis
Positive test for gonorrhea or chlamydia
Elaborate Criteria
Ultrasound documenting tubo-ovarian abscess
Laparoscopy visually confirming salpingitis

Sexual partners of women with PID should be evaluated and treated for urethral infection with chlamydia or gonorrhea (Table 15-3). One of these STDs usually is found in the male sexual partners of women with PID not associated with chlamydia or gonorrhea (38).

Tubo-Ovarian Abscess

An end-stage process of acute PID, tubo-ovarian abscess is diagnosed when a patient with PID has a pelvic mass that is palpable during bimanual examination. The condition usually reflects an agglutination of pelvic organs (tube, ovary, bowel) forming a palpable complex. Occasionally, an ovarian abscess can result from the entrance of microorganisms through an ovulatory site. **[6] Tubo-ovarian abscess is treated with an antibiotic regimen administered in a hospital (Table 15-5). About 75% of women with tubo-ovarian abscess respond to antimicrobial therapy alone. Failure of medical therapy suggests the need for drainage of the abscess** (39). Although drainage may require surgical exploration, percutaneous drainage guided by imaging studies (ultrasound or computed tomography) should be used as an initial option if possible. Trocar drainage, with or without placement of a drain, is successful in up to 90% of cases in which the patient failed to respond to antimicrobial therapy after 72 hours (40).

Table 15-5 Guidelines for Treatment of Pelvic Inflammatory Disease

Outpatient Treatment
Cefoxitin, 2 g intramuscularly, plus probenecid, 1 g orally concurrently, *or*
Ceftriaxone, 250 mg intramuscularly, *or*
Equivalent cephalosporin
Plus:
Doxycycline, 100 mg orally 2 times daily for 14 days, *or*
Azithromycin, 500 mg initially and then 250 mg daily for a total of 7 days
Inpatient Treatment
Regimen A
Cefoxitin, 2 g intravenously every 6 hrs, *or*
Cefotetan, 2 g intravenously every 12 hrs
Plus:
Doxycycline, 100 mg orally or intravenously every 12 hrs
Regimen B
Clindamycin, 900 mg intravenously every 8 hrs
Plus:

Ceftriaxone, 1–2 g intravenously every 12 hrs, *or*
Gentamicin, intravenously (5 mg/kg of body weight) daily

[a]Outpatient treatment only, that is, women treated for PID as an outpatient should also receive *metronidazole* gel for BV if they have BV.

Adapted from **Soper DE.** Pelvic inflammatory disease. *Obstet Gynecol* 2010;116:419–428.

OTHER MAJOR INFECTIONS

Genital Ulcer Disease

In the United States, most patients with genital ulcers have genital HSV or syphilis (5,41–44). Others causes of sexually transmitted ulcers include **chancroid, followed by the rare occurrence of lymphogranuloma venereum (LGV) and granuloma inguinale (donovanosis). These diseases are associated with an increased risk for HIV infection.** Other infrequent and noninfectious causes of genital ulcers include abrasions, fixed drug eruptions, carcinoma, and Behçet disease.

Diagnosis

A diagnosis based on history and physical examination alone is often inaccurate. **Therefore, all women with genital ulcers should undergo a serologic test for syphilis** (42). Because of the consequences of inappropriate therapy, such as tertiary disease and congenital syphilis in pregnant women, diagnostic efforts are directed at excluding syphilis. Optimally, the evaluation of a patient with a genital ulcer should include: dark-field examination; direct immunofluorescence testing for *Treponema pallidum*, or PCR; culture or PCR testing for HSV; and culture for *Haemophilus ducreyi*. Dark-field or fluorescent microscopes and selective media to culture for *H. ducreyi* often are not available in most offices and clinics. Even after complete testing, the diagnosis remains unconfirmed in one-fourth of patients with genital ulcers. For this reason, most clinicians base their initial diagnosis and treatment recommendations on their clinical impression of the appearance of the genital ulcer **(Fig. 15-2)** and knowledge of the most likely cause in their patient population (41).

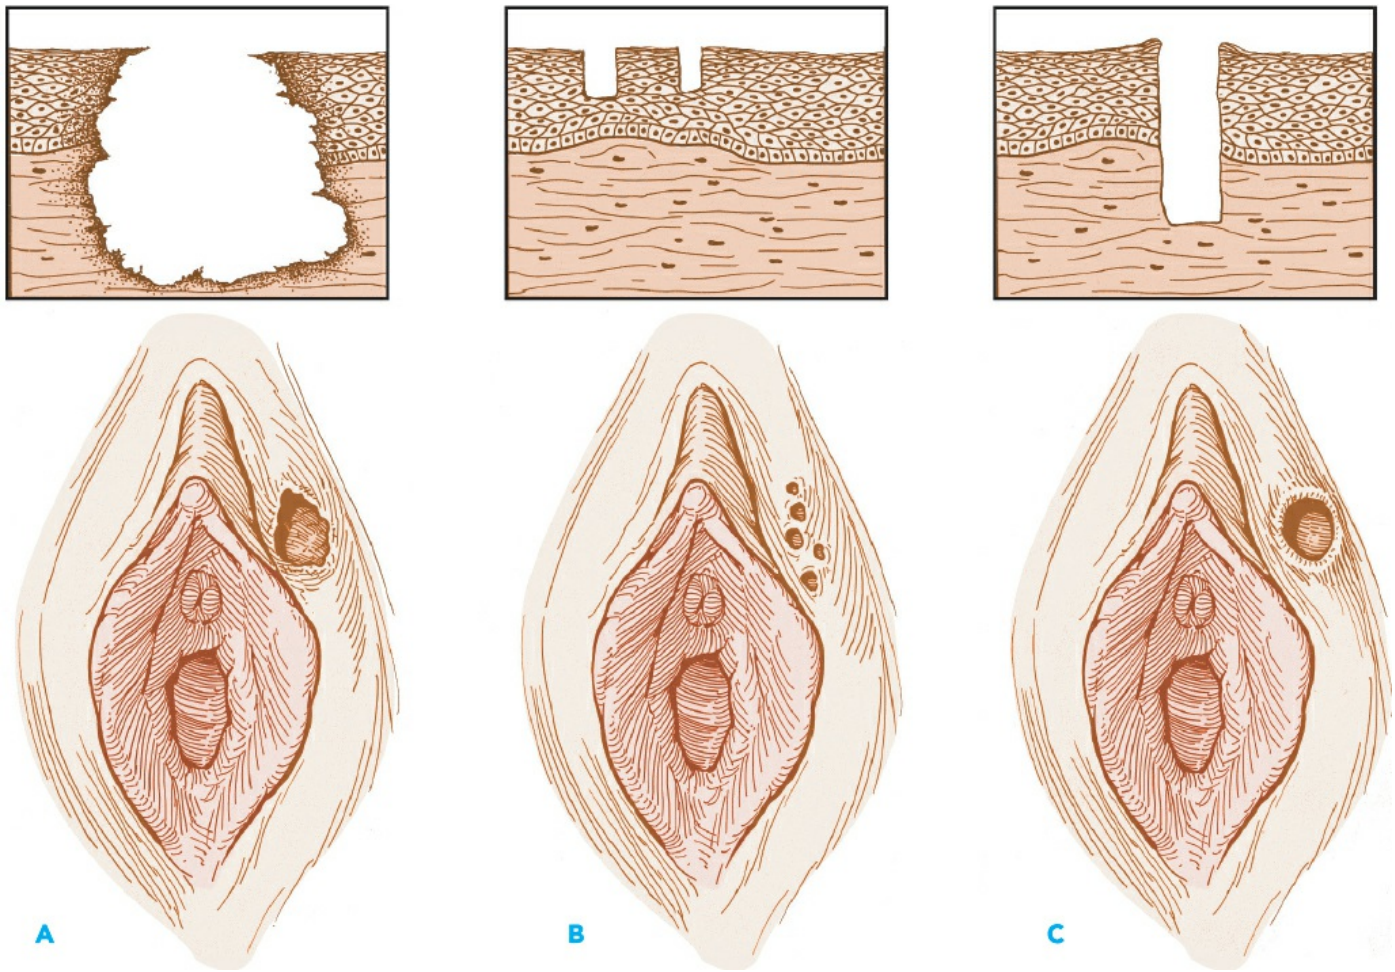

FIGURE 15-2 Showing the appearance of the ulcers of chancroid **(A)**, herpes **(B)**, and syphilis **(C)**. The ulcer of chancroid has irregular margins and is deep with undermined edges. The syphilis ulcer has a smooth, indurated border and a smooth base. The genital herpes ulcer is superficial and inflamed. (Modified from **Schmid GP, Shcalla WO, DeWitt WE**. Chancroid. In: Morse SA, Moreland AA, Thompson SE, eds. *Atlas of Sexually Transmitted Diseases*. Philadelphia, PA: Lippincott; 1990.)

Several clinical presentations are highly suggestive of specific diagnoses:

1. **A painless and minimally tender ulcer, not accompanied by inguinal lymphadenopathy, is likely to be syphilis, especially if the ulcer is indurated.** A nontreponemal rapid plasma reagin (RPR) test, or venereal disease research laboratory (VDRL) test, and a confirmatory treponemal test—fluorescent treponemal antibody absorption (FTA ABS) or microhemagglutinin–*T. pallidum* (MHA TP)—should be used to diagnose syphilis presumptively. Some laboratories screen samples with treponemal enzyme immunoassay (EIA) tests, the results of which should be confirmed with nontreponemal tests. The results of nontreponemal tests usually correlate with disease activity and should be reported quantitatively.
2. [7] **Grouped vesicles mixed with small ulcers, particularly with a history of such lesions, are almost always pathognomonic of genital herpes.** Nevertheless, laboratory confirmation of the findings is recommended because the **diagnosis of**

genital herpes is traumatic for many women, alters their self-image, and affects their perceived ability to enter new sexual relationships and bear children. Cell culture and PCR are preferred testing. HSV culture's sensitivity approaches 100% in the vesicle stage and 89% in the pustular stage and drops to as low as 33% in patients with ulcers. NAAT, including PCR assays for HSV DNA are more sensitive (5,43). Because false-negative results are common with HSV cultures, especially in patients with recurrent infections, type-specific glycoprotein G-based antibody assays are useful in confirming a clinical diagnosis of genital herpes.

3. **One to three extremely painful ulcers, accompanied by tender inguinal lymphadenopathy, are unlikely to be anything except chancroid.** This is especially true if the adenopathy is fluctuant.
4. **An inguinal bubo accompanied by one or several ulcers is most likely chancroid. If no ulcer is present, the most likely diagnosis is LGV.**

Treatment

Chancroid

Recommended regimens for the treatment of chancroid include *azithromycin,* 1 g orally in a single dose; *ceftriaxone*, 250 mg intramuscularly in a single dose; *ciprofloxacin*, 500 mg orally twice a day for 3 days; or *erythromycin* base, 500 mg orally four times daily for 7 days. Patients should be reexamined 3 to 7 days after initiation of therapy to ensure the gradual resolution of the genital ulcer, which can be expected to heal within 2 weeks unless it is unusually large.

Herpes

A first episode of genital herpes should be treated with *acyclovir*, 400 mg orally three times a day; or *famciclovir*, 250 mg orally three times a day; or *valacyclovir*, 1 g orally twice a day for 7 to 10 days or until clinical resolution is attained. Although these agents provide partial control of the symptoms and signs of clinical herpes, it neither eradicates latent virus nor affects subsequent risk, frequency, or severity of recurrences after the drug is discontinued. Daily suppressive therapy (*acyclovir*, 400 mg orally twice daily; or *famciclovir*, 250 mg twice daily; or *valacyclovir*, 1 g orally once a day) reduces the frequency of HSV recurrences by at least 75% among patients with six or more recurrences of HSV per year. **[8]** Suppressive treatment partially, but not totally, decreases symptomatic and asymptomatic viral shedding and the potential for transmission (5).

Syphilis

Parenteral administration of *penicillin G* is the preferred treatment of all stages of syphilis. *Benzathine penicillin G*, 2.4 million units intramuscularly in a single dose, is the recommended treatment for adults with primary, secondary, or early latent syphilis.

The Jarisch–Herxheimer reaction—an acute febrile response accompanied by headache, myalgia, and other symptoms—may occur within the first 24 hours after any therapy for syphilis; patients should be advised of this possible adverse reaction.

Latent syphilis is defined as those periods after infection with *T. pallidum* when patients are seroreactive but show no other evidence of disease. Patients with latent syphilis of longer than 1 year's duration or of unknown duration should be treated with *benzathine penicillin G*, 7.2 million units total, administered as three doses of 2.4 million units intramuscularly each, at 1-week intervals. All patients with latent syphilis should be evaluated clinically for evidence of tertiary disease (e.g., aortitis, neurosyphilis, gumma, and iritis). Quantitative nontreponemal VDRL or RPR serologic tests should be repeated at 6 months and again at 12 months. An initially high antibody titer (1:32) should decline at least fourfold (two dilutions) within 12 to 24 months.

Genital Warts

External genital warts are a manifestation of human papillomavirus (HPV) infection (5,45). The nononcogenic HPV types 6 and 11 are usually responsible for external genital warts. HPV types 16, 18, 31, 33, and 35 are occasionally found in anogenital warts. The warts tend to occur in areas most directly affected by coitus, namely the posterior fourchette and lateral areas on the vulva. Less frequently, warts can be found throughout the vulva, in the vagina, and on the cervix. Minor trauma associated with coitus can cause breaks in the vulvar skin, allowing direct contact between the viral particles from an infected man and the basal layer of the epidermis of his susceptible sexual partner. Infection may be latent or may cause viral particles to replicate and produce a wart. External genital warts are highly contagious; more than 75% of sexual partners develop this manifestation of HPV infection when exposed.

Table 15-6 Treatment Options for External Genital and Perianal Warts

Modality	Efficacy (%)	Recurrence Risk
Cryotherapy	63–88	21–39
Imiquimod 5% cream[a]	33–72	13–19
Podophyllin 10–25%	32–79	27–65
Podofilox 0.5%[a]	45–88	33–60

Trichloroacetic acid 80–90%	81	36
Electrodesiccation or cautery	94	22
Laser[b]	43–93	29–95
Interferon	44–61	0–67
Sinecatechin 15% ointment	60	ND

[a]May be self-applied by patients at home.

[b]Expensive; reserve for patients who have not responded to other regimens.

ND, no data.

The goal of treatment is removal of the warts; it is not possible to eradicate the viral infection. Treatment is most successful in patients with small warts that were present for less than 1 year. It is not determined whether treatment of genital warts reduces transmission of HPV. Selection of a specific treatment regimen depends on the anatomic site, size, and number of warts, and expense, efficacy, convenience, and potential adverse effects (Table 15-6). **Recurrences more often result from reactivation of subclinical infection than reinfection by a sex partner; therefore, examination of sex partners is not absolutely necessary.** However, many of these sex partners may have external genital warts and may benefit from therapy and counseling concerning transmission of warts. **HPV infection with types 6, 11, 16, 18, 31, 33, 45, 52, and 58 can be prevented by vaccination** (5).

Human Immunodeficiency Virus

It is estimated that almost 40% to 50% of individuals with human immunodeficiency virus (HIV) are women. Intravenous drug use and heterosexual transmission are responsible for most of the cases of AIDS in women in the United States (46,47). Infection with HIV produces a spectrum of disease that progresses from an asymptomatic state to full-blown AIDS. The pace of disease progression in untreated adults is variable. The median time between infection with HIV and the development of AIDS is 10 years, with a range from a few months to more than 12 years. In a study of adults infected with HIV, symptoms developed in 70% to 85% of infected adults, and AIDS developed in 55% to 60% within 12 years after infection. The natural history of the disease can be significantly altered by antiretroviral therapy (ART). **Early diagnosis**

and linkage to care are essential for a patient's health, and to reduce the risk of transmitting HIV to others. U.S. guidelines recommend all persons with HIV infection diagnoses be offered effective ART (47). Women with HIV-induced altered immune function are at increased risk for infections such as tuberculosis (TB), bacterial pneumonia, and *Pneumocystis jiroveci* pneumonia (PCP). Because of its impact on the immune system, HIV affects the diagnosis, evaluation, treatment, and follow-up of many other diseases and may decrease the efficacy of antimicrobial therapy for some STDs.

Diagnosis

Infection is most often diagnosed by HIV antibody tests. However, tests for HIV antibodies are often negative during the acute HIV phase (5). Antibody testing begins with a sensitive screening test such as enzyme-linked immunosorbent assay (ELISA) or a rapid assay. If confirmed by Western blot, a positive antibody test result confirms that a person is infected with HIV and is capable of transmitting the virus to others. HIV antibody is detectable in more than 95% of patients within 6 months of infection. Women diagnosed with any STI, particularly genital ulcer disease, should be offered HIV testing (5,15). **Routine HIV screening is recommended for women aged 19 to 64 years and targeted screening for women with risk factors outside of that age range** (46).

The initial evaluation of an HIV-positive woman includes screening for diseases associated with HIV, such as TB and STIs, administration of recommended vaccinations (hepatitis B, pneumococcal, meningococcal and influenza), and behavioral and psychosocial counseling. Intraepithelial neoplasia is strongly associated with HPV infection and occurs in high frequency in women with both HPV and HIV.

Treatment

ART is recommended for all HIV-infected individuals, regardless of CD4 T-lymphocyte cell count, to reduce the morbidity and mortality associated with HIV infection. ART is recommended for HIV-infected individuals to prevent HIV transmission (47). **When initiating ART, it is important to educate patients regarding the benefits and considerations regarding ART, and to address strategies to optimize adherence. Patients must be willing to accept therapy to avoid the emergence of resistance caused by poor compliance.** Dual nucleoside regimens used in addition to a protease inhibitor or nonnucleoside reverse transcriptase inhibitor provide a more durable clinical benefit, monotherapy is not recommended.

Patients with less than 200 CD4+ T cells per lL should receive prophylaxis against opportunistic infections, such as *trimethoprim/sulfamethoxazole* or aerosol *pentamidine* for the prevention of PCP pneumonia. Those with less than 50 CD4+ T cells per μL should receive *azithromycin* prophylaxis for mycobacterial infections (47).

URINARY TRACT INFECTION

Acute Cystitis

Women with acute cystitis generally have an abrupt onset of multiple, severe urinary tract symptoms including dysuria, frequency, and urgency associated with suprapubic or low-back pain. Suprapubic tenderness may be noted on physical examination. Urinalysis reveals pyuria and sometimes hematuria. Several factors increase the risk for cystitis, including sexual intercourse, the use of a diaphragm and a spermicide, delayed postcoital micturition, and a history of a recent urinary tract infection (48–50).

Diagnosis

***Escherichia coli* is the most common pathogen isolated from the urine of young women with acute cystitis, and it is present in 80% of cases** (51). *Staphylococcus saprophyticus* is present in an additional 5% to 15% of patients with cystitis. The pathophysiology of cystitis in women involves the colonization of the vagina and urethra with coliform bacteria from the rectum. For this reason, the effects of an antimicrobial agent on the vaginal flora play a role in the eradication of bacteriuria.

Treatment

High concentrations of *trimethoprim* and *fluoroquinolone* in vaginal secretions can eradicate *E. coli* while minimally altering normal anaerobic and microaerophilic vaginal flora. An increasing linear trend in the prevalence of resistance of *E. coli* (>10%) to the fluoroquinolones (e.g., *ciprofloxacin*) was noted (52). Despite a similar increase in *E. coli* resistance (9% to 18%) to *trimethoprim/ sulfamethoxazole*, therapeutic efficacy remains stable. In contrast, no such increase in resistance was noted with *nitrofurantoin*. *Nitrofurantoin* (macrocrystals, 100 mg orally twice daily for 5 days) or *trimethoprim/sulfamethoxazole* (160/800 mg orally twice daily for 3 days) are the optimal choices for empirical therapy for uncomplicated cystitis (52).

In patients with typical symptoms, an abbreviated laboratory workup followed by empirical therapy is suggested. The diagnosis can be presumed if pyuria is detected by microscopy or leukocyte esterase testing. Urine culture is not necessary, and a short course of antimicrobial therapy should be given. No follow-up visit or culture is necessary unless symptoms persist or recur.

Recurrent Cystitis

About 20% of premenopausal women with an initial episode of cystitis have recurrent infections. More than 90% of these recurrences are caused by exogenous reinfection. Recurrent cystitis should be documented by culture to rule out resistant microorganisms. **Patients may be treated by one of three strategies: (1) continuous prophylaxis; (2) postcoital prophylaxis; or (3) therapy initiated by the**

patient when symptoms are first noted.

Postmenopausal women may have frequent reinfections. **Hormonal therapy or topically applied estrogen cream, along with antimicrobial prophylaxis, is helpful in treating these patients.**

Urethritis

Women with dysuria caused by urethritis have a more gradual onset of mild symptoms, which may be associated with abnormal vaginal discharge or bleeding related to concurrent cervicitis. Patients may have a new sex partner or experience lower abdominal pain. Physical examination may reveal the presence of mucopurulent cervicitis or vulvovaginal herpetic lesions. *C. trachomatis*, *N. gonorrhoeae*, or genital herpes may cause acute urethritis. Nongonococcal, nonchlamydial urethritis could be caused by *M. genitalium* (5). Pyuria is present on urinalysis, but hematuria is rarely seen. Treatment regimens for chlamydia and gonococcal infections are presented in Table 15-3.

Occasionally, vaginitis caused by *C. albicans* or trichomonas is associated with dysuria. On careful questioning, patients generally describe external dysuria, sometimes associated with vaginal discharge, and pruritus and dyspareunia. They usually do not experience urgency or frequency. Pyuria and hematuria are absent.

Acute Pyelonephritis

The clinical spectrum of acute, uncomplicated pyelonephritis in young women ranges from gram-negative septicemia to a cystitis-like illness with mild flank pain. *E. coli* accounts for more than 80% of these cases (51). Microscopy of unspun urine reveals pyuria and gram-negative bacteria. A urine culture should be obtained in all women with suspected pyelonephritis; blood cultures should be performed in those who are hospitalized because results are positive in 15% to 20% of cases. In the absence of nausea and vomiting and severe illness, outpatient oral therapy can be given safely. Patients who have nausea and vomiting, are moderately to severely ill, or are pregnant should be hospitalized. Outpatient treatment regimens include *trimethoprim/sulfamethoxazole* (160/800 mg every 12 hours for 14 days) or a quinolone (e.g., *levofloxacin*, 750 mg daily for 7 days). Inpatient treatment regimens include the use of parenteral *levofloxacin* (750 mg daily), *ceftriaxone* (1 to 2 g daily), *ampicillin* (1 g every 6 hours), and *gentamicin* (especially if *Enterococcus* species are suspected) or *aztreonam* (1 g every 8 to 12 hours). Symptoms should resolve after 48 to 72 hours. If fever and flank pain persist after 72 hours of therapy, ultrasound or computed tomography should be considered to rule out a perinephric or intrarenal abscess or ureteral obstruction. A follow-up culture should be obtained 2 weeks after

the completion of therapy (53).

KEY POINTS

1 The criteria for the diagnosis of intraepithelial neoplasia may vary according to the pathologist, but the significant features are cellular immaturity, cellular disorganization, nuclear abnormality, and increased mitotic activity.

2 Metaplasia advances from the original squamocolumnar junction (SCJ) inward, toward the external os and over the columnar villi to establish the *transformation zone*. Cervical intraepithelial neoplasia (CIN) typically originates in the transformation zone at the advancing SCJ.

3 Infection with human papillomavirus (HPV) is the primary cause of cancer of the cervix and its precursor lesions. Persistent high-risk oncogenic HPV infection is the principal risk factor for the development of CIN. In the vast majority of cases, HPV infection will clear in 9 to 15 months.

4 Specific high-risk HPV types account for about 90% of high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, -59, and -68). HPV-16 is the most common HPV found in invasive cancer and in CIN 2 and CIN 3. Malignant transformation requires the expression of E6 and E7 HPV oncoproteins.

5 High-risk HPV testing is a critical component of the triage for equivocal (ASC-US) cytology, as a component of co-testing with simultaneous cytology, and as a stand-alone primary screening modality.

6 Evidence-based guidelines recommend that cervical cancer screening not begin until age 21 years, regardless of sexual history. For women 21 to 29 years, the recommendation is screening with cytology every 3 years. From 30 to 65 years co-testing with conventional cytology and high-risk HPV testing every 5 years or cytology alone every 3 years are appropriate alternatives. After the age of 65 it is appropriate to discontinue screening in women with a negative screening history as documented by either 3 negative cytology results or 2 negative co-tests in the previous 10 years.

7 The usefulness of high-risk HPV testing in the assessment of atypical squamous cells of unknown significance (ASC-US) Pap test results is well established, and aids in the identification of 90% of the patients with CIN 2 or 3 lesions.

8 Women with atypical squamous cells-high grade (ASC-H) should be referred to colposcopy because of the underlying risk of CIN 2 and/or 3, and should not be triaged with high-risk HPV testing.

9 Colposcopy is required for the evaluation of a low-grade squamous intraepithelial lesion (LSIL) cytology. Any woman with a cytology consistent with high-grade squamous intraepithelial lesion (HSIL) must undergo colposcopy and directed biopsy.

10 The minimum elements of a comprehensive colposcopic examination include visualization of squamocolumnar junction, identification of acetowhitening or other lesion(s), and an overall colposcopic impression (normal/benign, low grade, high grade, cancer).

11 It is a best practice for pathologists and colposcopists to review jointly the colposcopic examination findings, cytology, molecular testing, cervical biopsy, and endocervical sampling in order to develop a therapeutic and surveillance plan.

12 The evidence-based guidelines for the management of cervical cytologic and histologic entities lend

themselves to structured clinical algorithms that are available for download from the Web (www.asccp.org), on various mobile phone applications, and may be incorporated into a variety of electronic health record platforms.

13 CIN 1 is a histopathologic manifestation of HPV infection, not a cancer precursor. For CIN 1 that persists for 24 months or more, a patient with an adequate colposcopic examination may be given the choice of continued surveillance or destruction of the transformation zone with ablation or excision.

14 CIN 2 and CIN 3 lesions are neoplastic precursors and grouped for the purposes of diagnostic reporting and treatment. Women, 25 years of age and older, with adequate colposcopy and histologic documentation of CIN 2 and/or CIN 3 require destruction or excision of the transformation zone.

15 Although CIN 2 and CIN 3 can be treated with a variety of outpatient techniques, the preferred treatment is LEEP. Ablative therapy using cryotherapy, laser ablation, or any other technique is not appropriate if there is evidence of microinvasive or invasive cancer on cytology, colposcopy, endocervical curettage (ECC), or biopsy.

16 Adenocarcinoma *in situ* (AIS) is a cancer precursor, and the preferred management for women who have completed childbearing and have a histologic diagnosis of AIS on a specimen from a diagnostic excisional procedure is hysterectomy.

17 Loop excision should not typically be used before a high-grade intraepithelial lesion is identified with histopathology. However, treatment after an HSIL cytology may be appropriate among populations for whom colposcopic follow-up is not possible.

18 Conization is indicated for diagnosis in women with CIN 3 or atypical glandular cell (AGC)-adenocarcinoma *in situ*, but hysterectomy is the treatment of last resort for recurrent high-grade CIN.

19 Women with persistent abnormal cytology without evident cervical pathology and those with abnormal cytology after treatment of CIN should be examined carefully for vaginal intraepithelial neoplasia (VAIN). VAIN 1/HPV or VAIN 2 does not require treatment and may be managed with surveillance. VAIN 3 lesions that are adequately sampled to rule out invasive disease can be treated with laser therapy or excisional therapy.

20 Vulvar intraepithelial neoplasia (VIN) 3 is a neoplastic precursor and can be unifocal or multifocal. The therapeutic alternatives for VIN 3 are simple excision, laser ablation, and superficial vulvectomy.

CERVICAL INTRAEPITHELIAL NEOPLASIA

The concept of *preinvasive disease* of the cervix was introduced in 1947, when pathologists identified features suggestive of invasive cancer but confined to epithelium (1). Subsequent studies showed that these lesions left untreated could progress to cervical cancer (2). Improvements in cytologic assessment led to the identification of early precursor lesions known as *dysplasia,* a term that connotes the malignant potential of these lesions. Historically, carcinoma *in situ* (CIS) was treated very aggressively (most often with hysterectomy), whereas dysplasias were believed to be less significant and were not treated or were treated by colposcopic biopsy and cryosurgery. The concept of *cervical intraepithelial neoplasia* (CIN) was introduced in 1968, when Richart suggested that dysplasias have the potential for progression (3). **[1] The criteria for the diagnosis of intraepithelial neoplasia may vary according to the pathologist, but the significant features are cellular immaturity, cellular disorganization, nuclear abnormality, and increased mitotic activity.** The extent of the mitotic activity, immature cellular proliferation, and nuclear atypia identifies the

degree of neoplasia. If the presence of mitoses and immature cells is limited to the lower third of the epithelium, the lesion usually is designated as CIN 1. Involvement of the middle and upper thirds is diagnosed as CIN 2 and CIN 3, respectively **(Fig. 16-1)**.

Cervical Anatomy

The cervix is composed of *columnar epithelium,* which lines the endocervical canal, and *squamous epithelium,* which covers the exocervix (4). The point at which they meet is called the *squamocolumnar junction* (SCJ) (**Figs. 16-2** and **16-3**).

The Squamocolumnar Junction

The SCJ is not restricted to the external os. Instead, it is a dynamic point that changes in response to puberty, pregnancy, menopause, and hormonal stimulation **(Fig. 16-4)**. In neonates, the SCJ is located on the exocervix. At menarche, the production of estrogen causes the vaginal epithelium to fill with glycogen. Lactobacilli act on the glycogen to lower the pH, stimulating the subcolumnar reserve cells to undergo *metaplasia* (4).

[2] Metaplasia advances from the original SCJ inward, toward the external os and over the columnar villi to establish the *transformation zone.* The transformation zone extends from the original SCJ to the physiologically active SCJ, as demarcated by the SCJ. As the metaplastic epithelium in the transformation zone matures, it begins to produce glycogen and eventually resembles the original squamous epithelium, both colposcopically and histologically **(Fig. 16-5A,B)**.

CIN typically originates in the transformation zone at the advancing SCJ. The anterior lip of the cervix is twice as likely to develop CIN as the posterior lip, and CIN rarely originates in the lateral angles. Once CIN occurs, it can progress horizontally to involve the entire transformation zone, but it usually does not replace the original squamous epithelium. This progression usually results in CIN with a sharp external border. Proximally, CIN involves the cervical clefts, and this area tends to have the most severe CIN lesions. The extent of involvement of these cervical glands has significant therapeutic implications since the entire gland must be destroyed to ensure elimination of the CIN (4). The only way to determine where the original SCJ was located is to look for nabothian cysts or cervical cleft openings, which indicate the presence of columnar epithelium. After the metaplastic epithelium matures and forms glycogen, it is called the *healed* transformation zone and is relatively resistant to oncogenic stimuli.

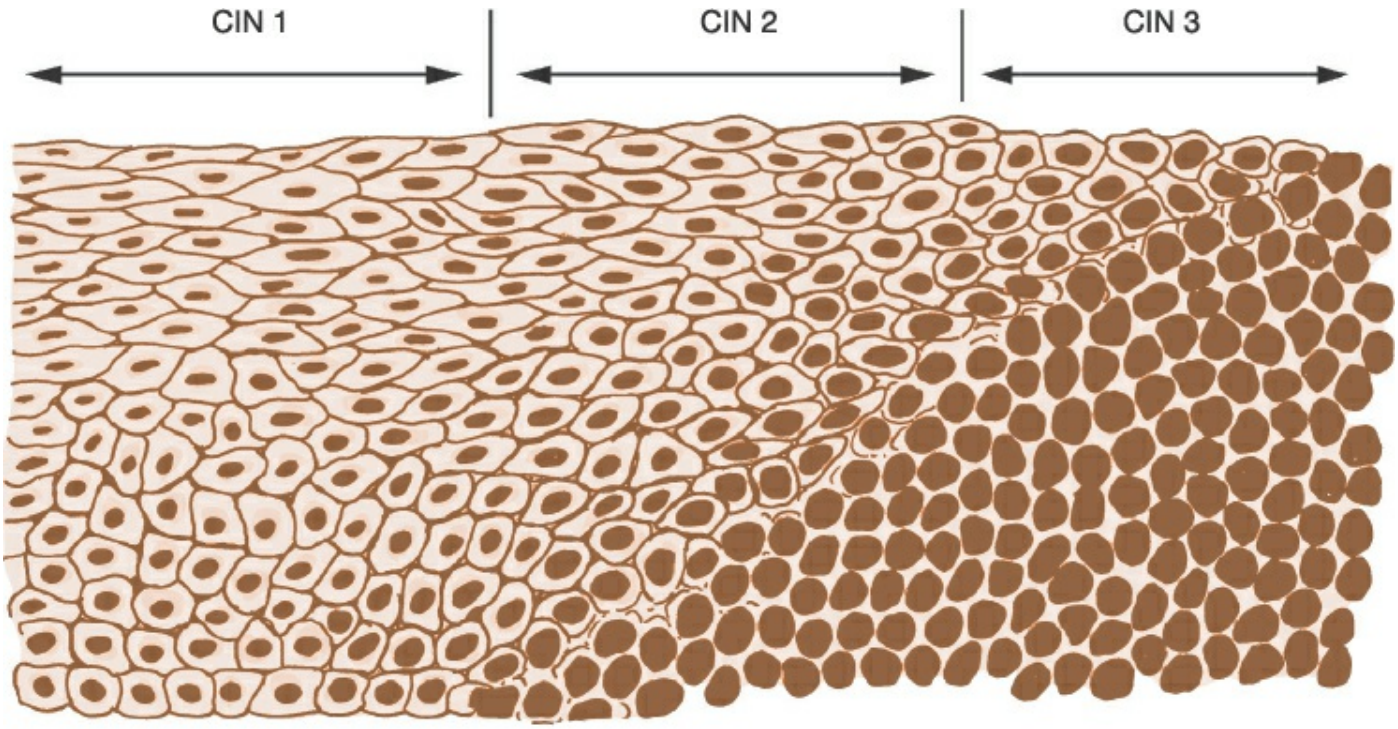

FIGURE 16-1 Diagram of cervical intraepithelial neoplasia compared with normal epithelium.

The entire SCJ with early metaplastic cells is susceptible to oncogenic factors, which may cause these cells to transform into CIN. Changes associated with CIN are most likely to begin either during menarche or after pregnancy, when metaplasia is most active. Conversely, after menopause a woman undergoes little metaplasia and is at a lower risk of developing CIN from de novo human papillomavirus (HPV) infection. HPV infection occurs through sexual contact in general and intercourse in particular. Although several agents, including sperm, seminal fluid histones, trichomonas, chlamydia, and herpes simplex virus, were studied, it is well established that **persistent high-risk oncogenic HPV infection is the overwhelming risk factor for the development of CIN.**

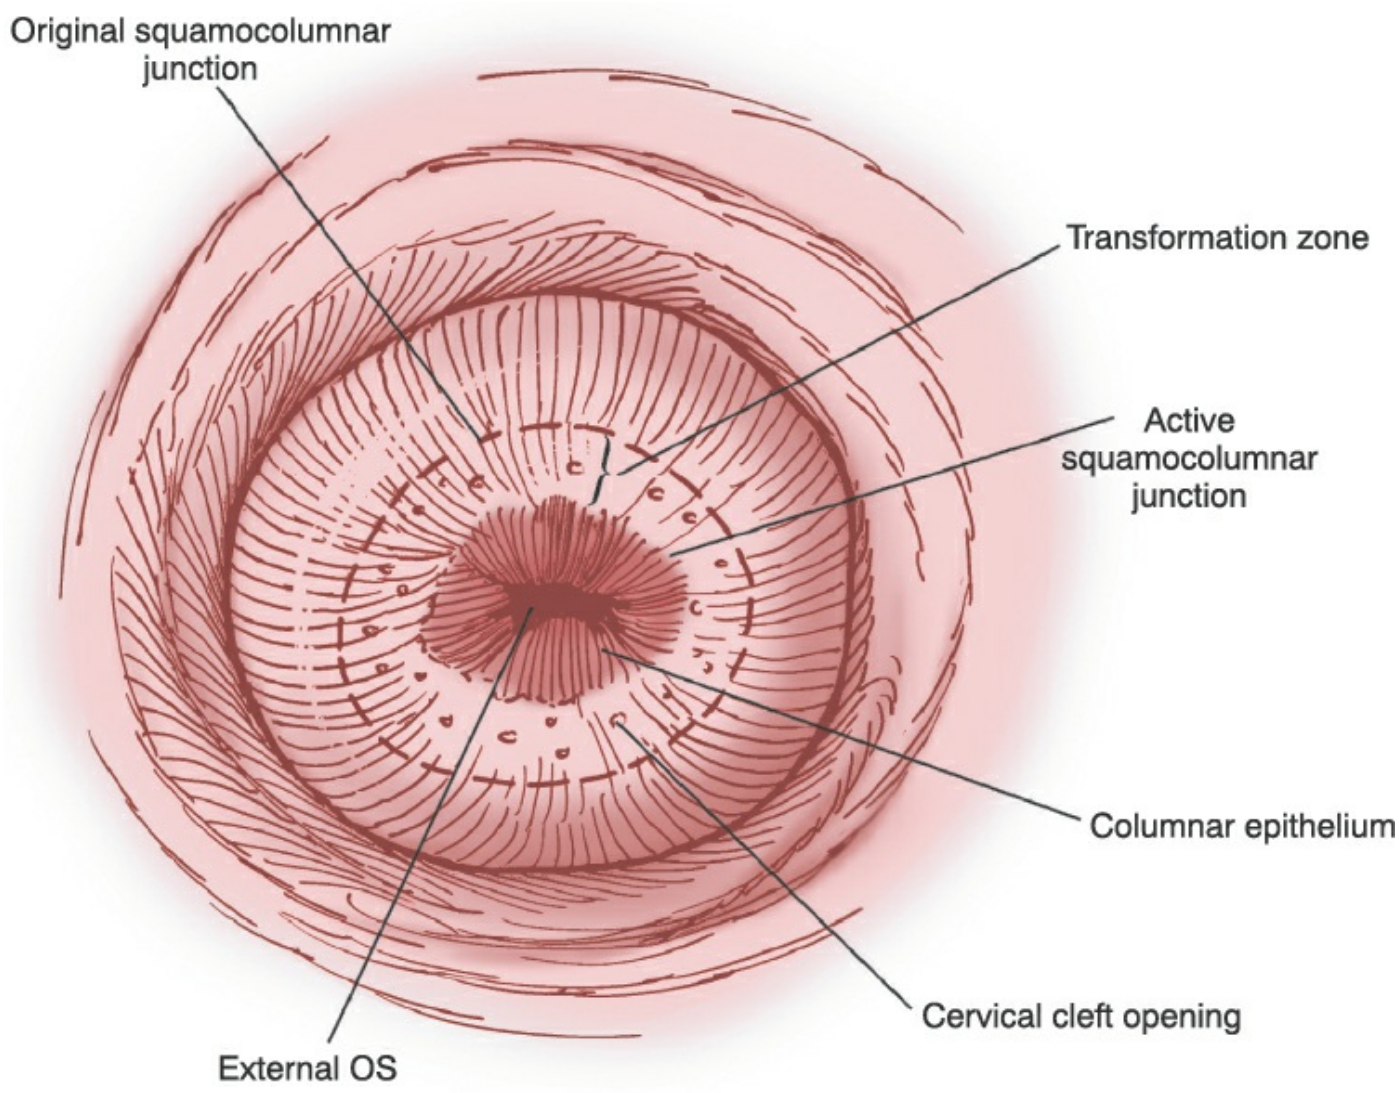

FIGURE 16-2 The cervix and the transformation zone.

Normal Transformation Zone

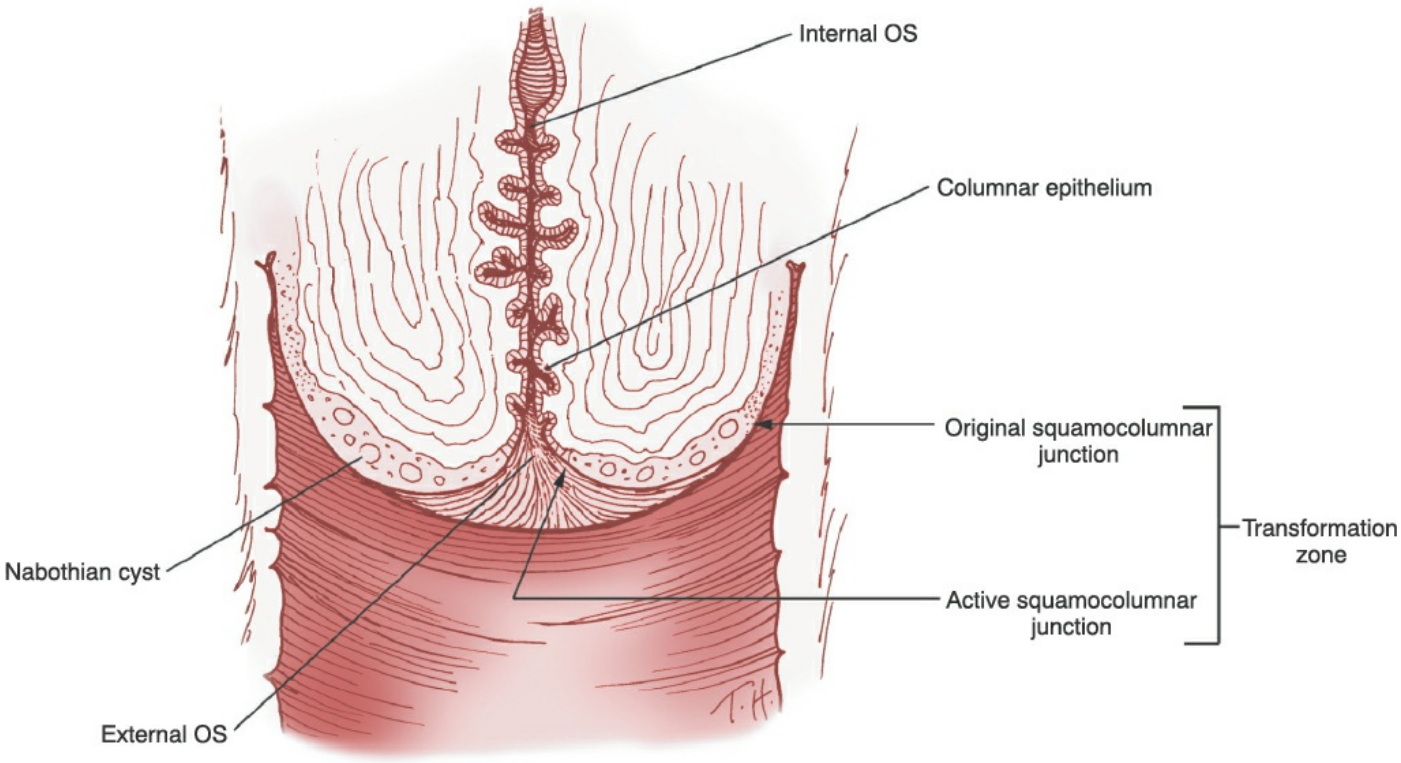

FIGURE 16-3 Diagram of the cervix and the endocervix.

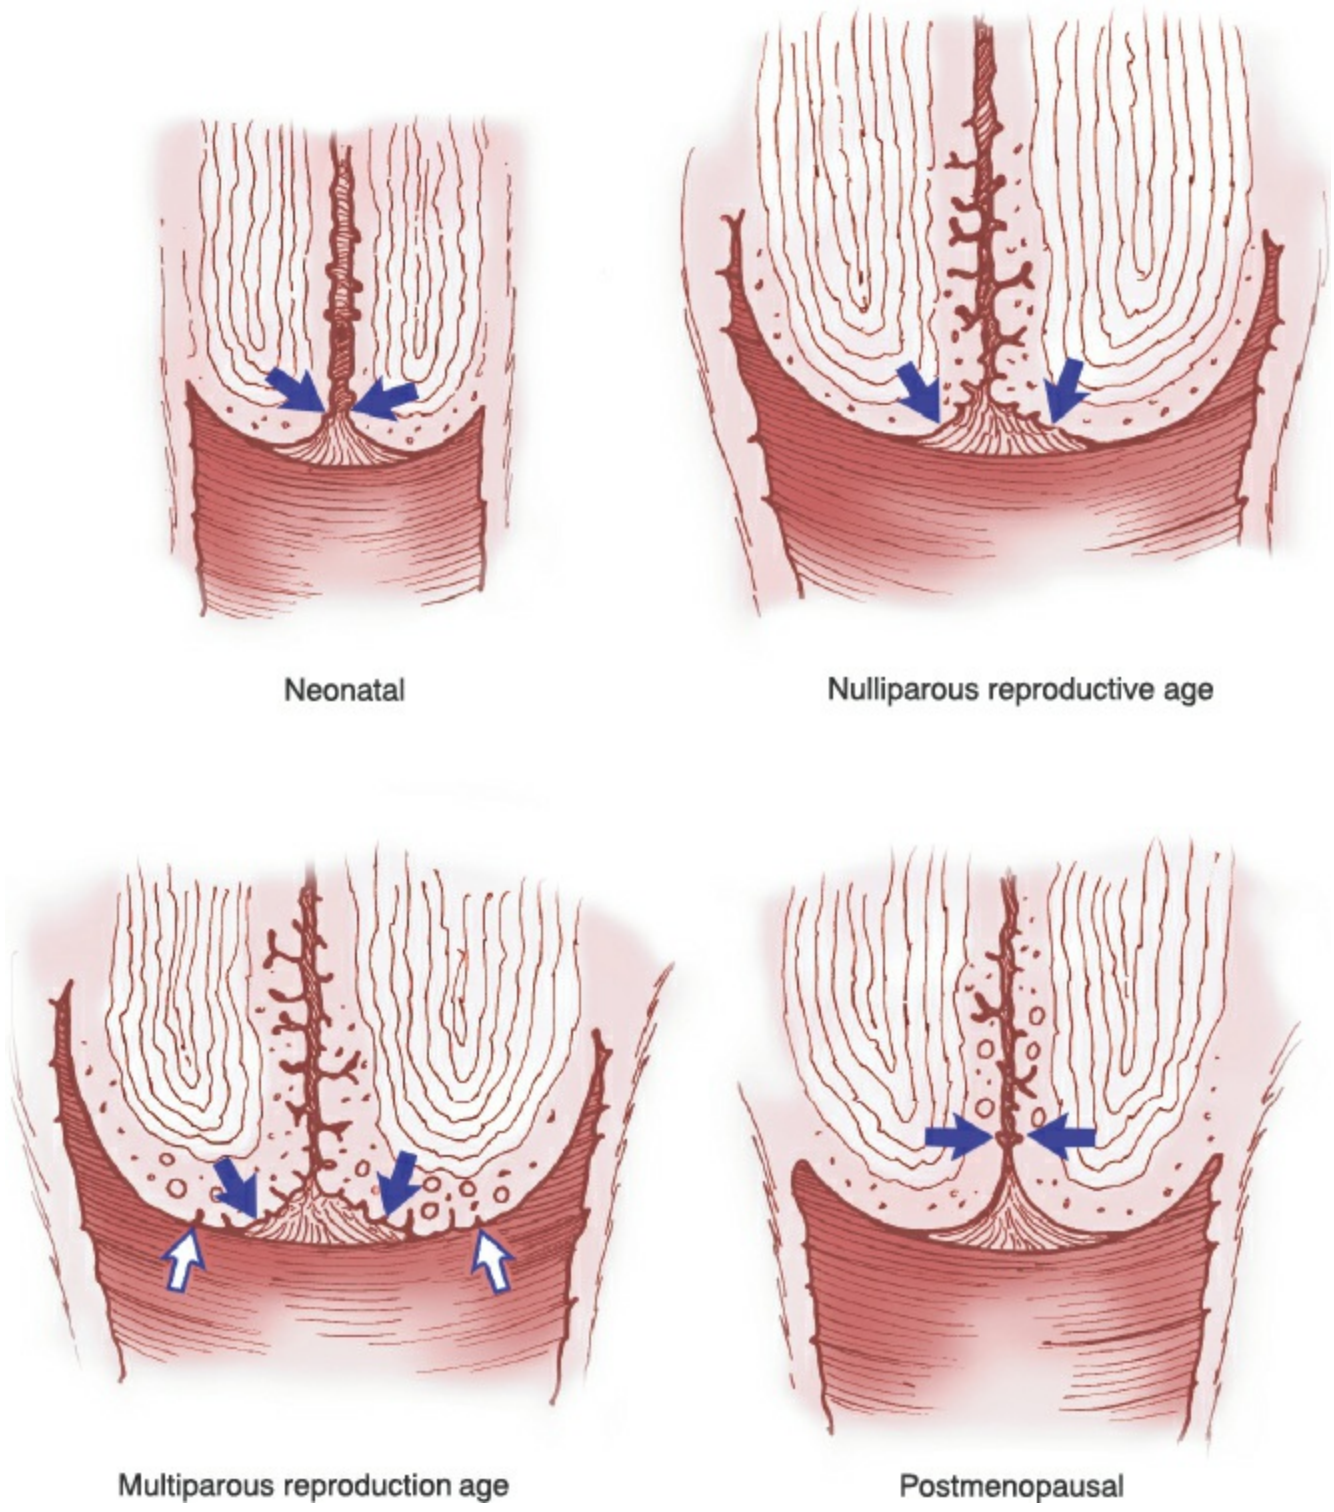
The original squamous epithelium of the vagina and exocervix has four layers (4):

1. The *basal layer* is a single row of immature cells with large nuclei and a small amount of cytoplasm.
2. The *parabasal layer* includes two to four rows of immature cells that have normal mitotic figures and provide the replacement cells for the overlying epithelium.
3. The *intermediate layer* includes four to six rows of cells with larger amounts of cytoplasm in a polyhedral shape separated by an intercellular space. Intercellular bridges, where differentiation of glycogen production occurs, can be identified with light microscopy.
4. The *superficial layer* includes five to eight rows of flattened cells with small uniform nuclei and a cytoplasm filled with glycogen. The nucleus becomes pyknotic, and the cells detach from the surface (exfoliation). These cells form the basis for Papanicolaou (Pap) testing more accurately known as cervical cytology.



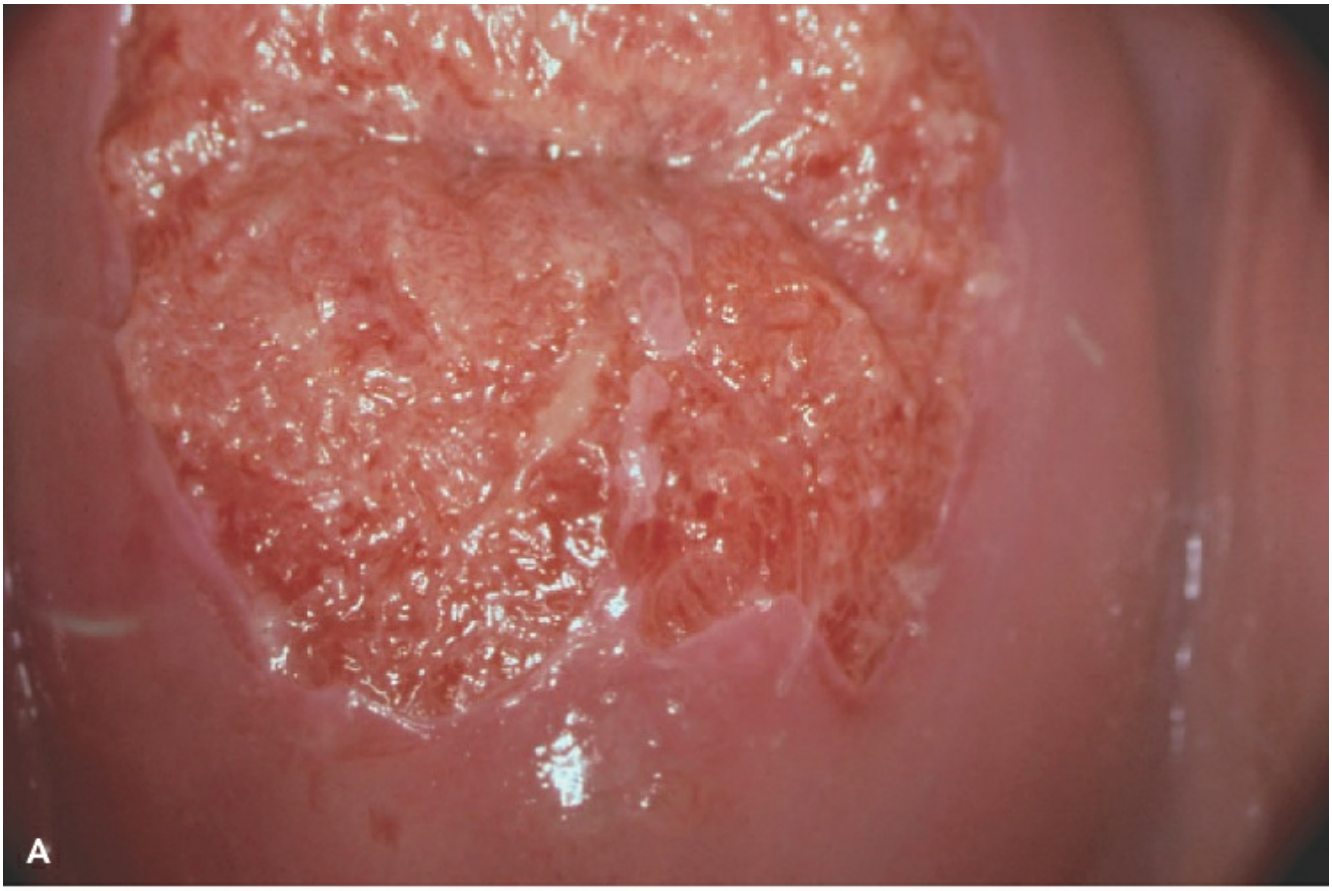


FIGURE 16-4 Different locations of the transformation zone and the squamocolumnar junction during a woman's lifetime. The *arrows* mark the active transformation zone. The *blue arrows* indicate internal boundaries of SCJ. The *white arrows* indicate external boundaries of the SCJ.

FIGURE 16-5 **A:** Active metaplasia in the transformation zone. **B:** Maturing metaplasia in the transformation zone.

Columnar Epithelium

Columnar epithelium has a single layer of columnar cells with mucus at the top and a round nucleus at the base. The glandular epithelium is composed of numerous ridges, clefts, and infoldings and, when covered by squamous metaplasia, leads to the appearance of gland openings. Technically, the endocervix is not a gland, but often the term *gland openings* is used.

Metaplastic Epithelium

Metaplastic epithelium, found at the SCJ, begins in the subcolumnar reserve cells. Under stimulation of lower vaginal acidity, the reserve cells proliferate, lifting the columnar epithelium. The immature metaplastic cells have large nuclei and a small amount of cytoplasm without glycogen. As the cells mature normally, they produce glycogen, eventually forming the four layers of epithelium. The metaplastic process begins at the tips of the columnar villi, which are exposed first to the acid vaginal environment. As the metaplasia replaces the columnar epithelium, the central capillary of the villus regresses, and the epithelium flattens out, leaving the epithelium with its typical vascular network. As metaplasia proceeds into the cervical clefts, it replaces columnar epithelium and similarly flattens the epithelium. The deeper clefts may not be completely replaced by the metaplastic epithelium, leaving mucus-secreting columnar epithelium trapped under the squamous epithelium. Some of these glands open onto the surface; others are completely encased, with mucus collecting in nabothian cysts. Gland openings and nabothian cysts mark the original SCJ and the outer edge of the original transformation zone **(Fig. 16-5A,B)** (4).

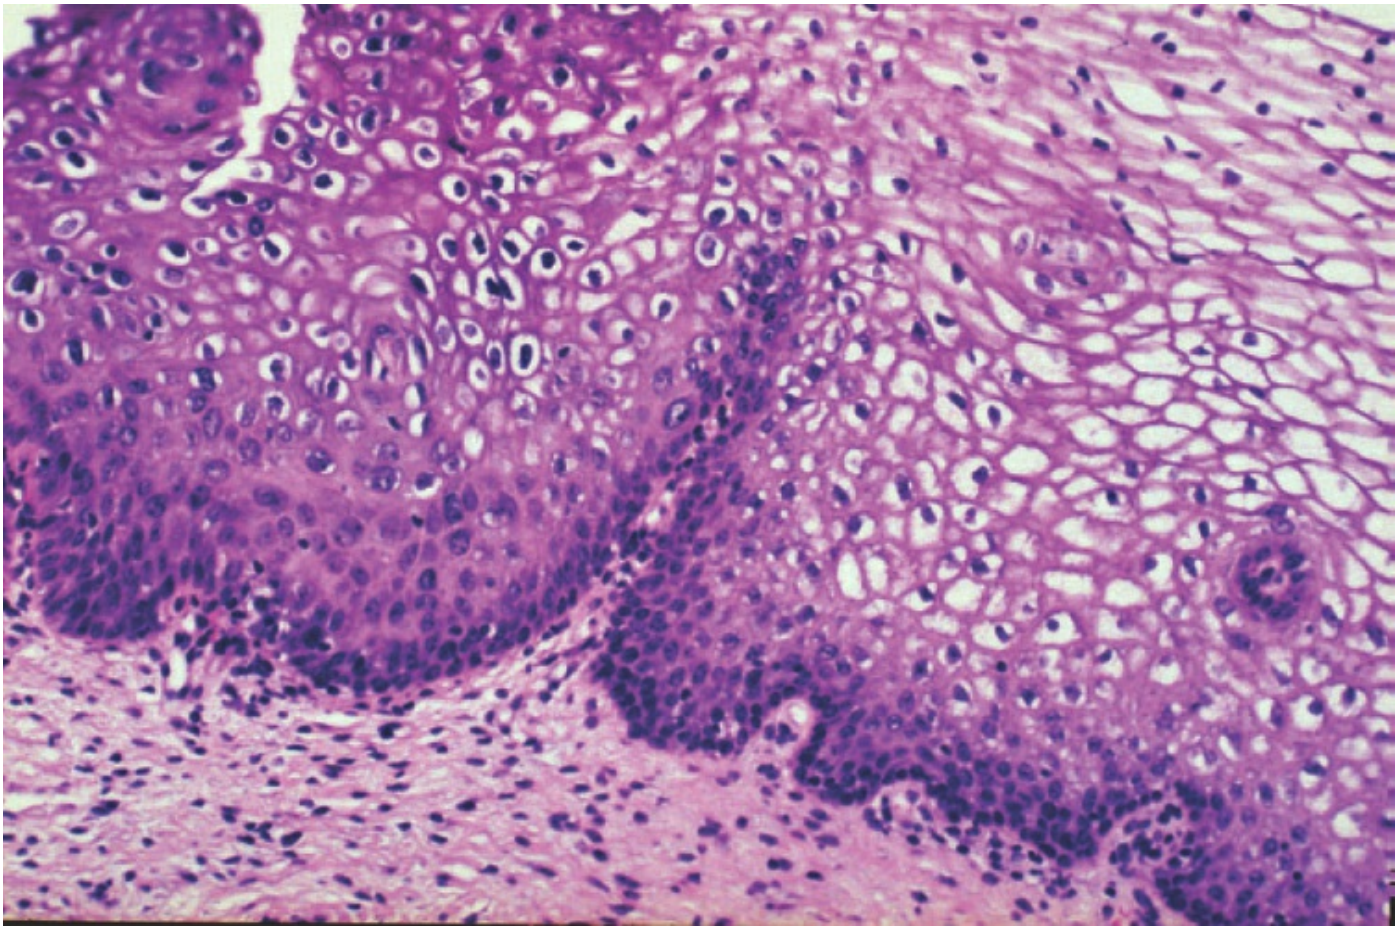

FIGURE 16-6 Cervical intraepithelial neoplasia grade 1 (CIN 1) with koilocytosis. The normal maturation process and differentiation from the basal and parabasal layers to the intermediate and superficial layers are maintained. In the upper layers, koilocytes are characterized by perinuclear halos, well-defined cell borders, and nuclear hyperchromasia, irregularity, and enlargement.

Human Papillomavirus

The cytologic changes of HPV were first recognized by Koss and Durfee in 1956 and given the term *koilocytosis* (5). Their significance was not recognized until 20 years later, when Meisels et al. reported these changes in mild dysplasia **(Fig. 16-6)** (6). Molecular biologic studies showed high levels of HPV DNA and capsid antigen, indicating productive viral infection in these koilocytic cells (7). HPV-related changes are found in all grades of cervical neoplasia (8). **[3] Infection with HPV is the primary cause of cancer of the cervix and its precursor lesions** (9). As the CIN lesions become more severe **(Fig. 16-7)**, the koilocytes disappear, the HPV copy numbers decrease, and the capsid antigen disappears, indicating that the virus is not capable of reproducing in less differentiated cells (10). Instead, portions of the HPV DNA become integrated into the host cell. Integration of the transcriptionally active DNA into the host cell appears to be essential for malignant transformation (11). **Malignant transformation requires the expression of E6 and E7 HPV oncoproteins**

(12). Because HPV will not grow in cell culture, there is no direct evidence of the carcinogenesis of HPV. However, a cell culture system for growing keratinocytes was described that allows for stratification and differentiation of specific keratinase types (13). When normal cells are transfected with the plasmid-containing HPV-16, the transfected cells produce cytologic abnormalities identical to those seen in intraepithelial neoplasia. The E6 and E7 oncoproteins are identifiable in the transfected cell lines, providing strong laboratory evidence of a cause-and-effect relationship (14). Cervical cancer cell lines that contain active copies of HPV-16 or -18 (SiHa, HeLa, C 4–11, Ca Ski) express HPV-16 E6 and E7 oncoproteins (15).

HPV DNA can be detected in the overwhelming majority of women with cervical neoplasia (16,17). There are more than 120 types of HPV identified, with 30 of these HPV types primarily infecting the squamous epithelium of the lower anogenital tract of men and women (18,19). Detection of HPV is associated with a 250-fold increase in risk of high-grade CIN (20). The percentage of intraepithelial neoplasia attributed to HPV infection approaches 90% (17).

Specific high-risk HPV types account for about 90% of high-grade intraepithelial lesions and cancer (HPV-16, -18, -31, -33, -35, -39, -45, -51, -52, -56, -58, -59, and -68) (17). **[4] HPV-16 is the most common HPV found in invasive cancer and in CIN 2 and CIN 3** (21). It is the most common HPV type found in women with normal cytology.

HPV-16 infection is not a very specific finding and can be found in 16% of women with low-grade lesions and in up to 14% of women with normal cytology. HPV type-18 is found in 23% of women with invasive cancers, 5% of women with CIN 2 and CIN 3, 5% of women with HPV and CIN 1, and fewer than 2% of patients with negative findings (17). Therefore, HPV-18 is more specific than HPV-16 for invasive tumors.

Usually, HPV infections are typically transient and those that do persist may remain latent for many years. Most women who are exposed have no clinical evidence of disease, and the infection is eventually suppressed or eliminated (16). Other women exhibit low-grade cervical lesions that mostly regress spontaneously. **[3] In the vast majority of cases, HPV infection will clear in 9 to 15 months** (22). A small minority of women exposed to HPV develops persistent infection that may progress to CIN (16,23). Persistent high-risk HPV infection increases the risk of high-grade disease 300-fold and is required for the development and maintenance of CIN 3 (24,25). Factors that may have a role in persistence and progression include smoking, contraceptive use, infection with other sexually transmitted diseases, or nutrition (16,21). Any factor that influences the integration of HPV DNA into the human genome may contribute to progression to invasive disease (26).

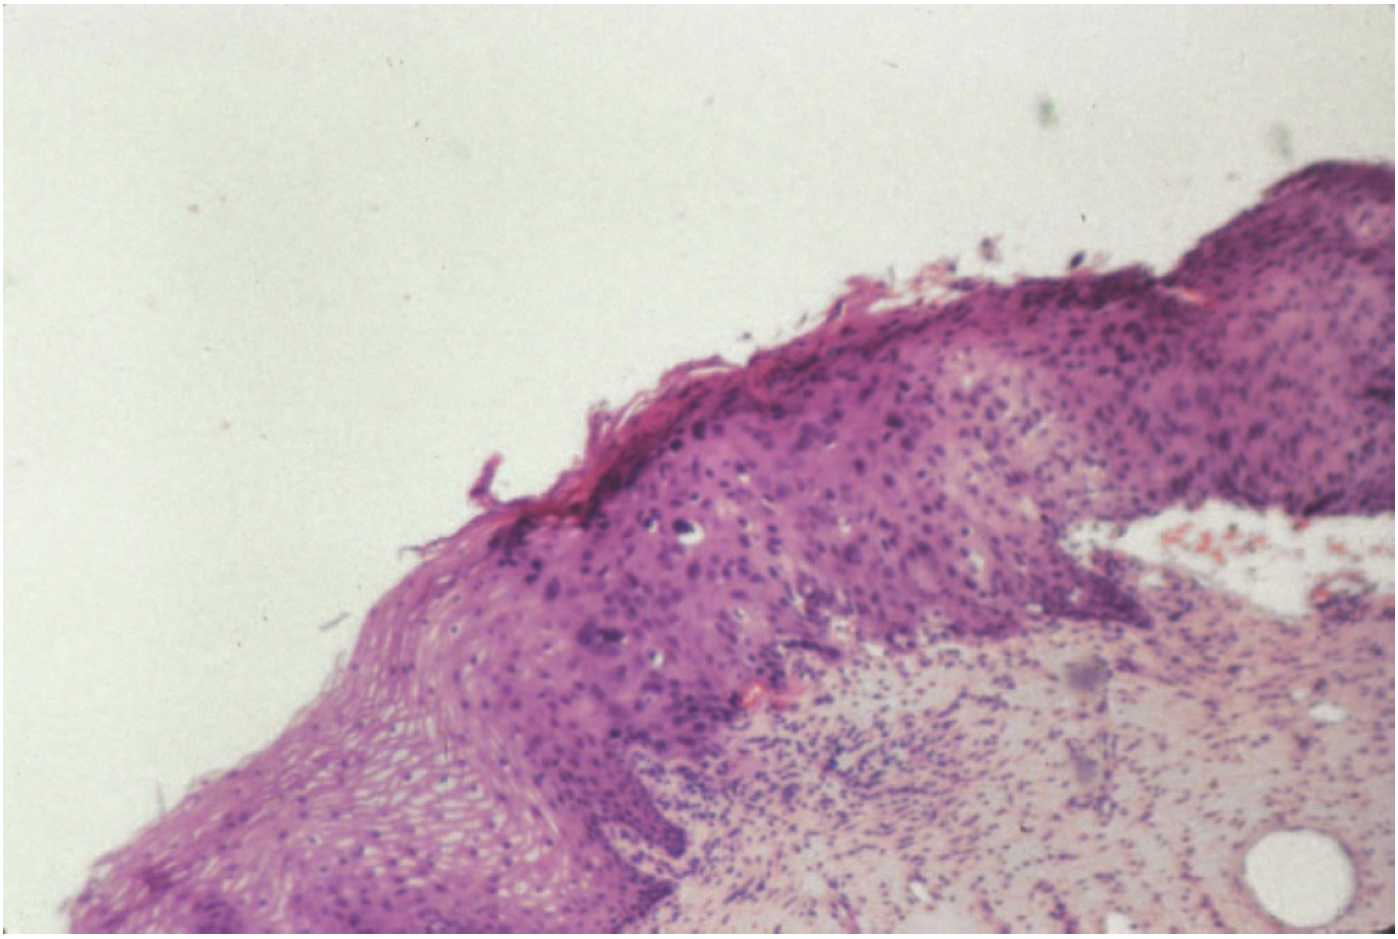

FIGURE 16-7 Cervical biopsy showing normal cells, cervical intraepithelial neoplasia 2 and 3 (CIN 2, CIN 3). In CIN 3, the normal maturation is lost.

Screening

Cervical Cytology

Cervical cytology has been the mainstay of cervical cancer screening since the mid-20th century. Its terminology has evolved to reflect an evolving and improved understanding of the pathogenesis of HPV-related disease in the lower genital tract. In 1988, the first National Cancer Institute (NCI) workshop held in Bethesda, Maryland, resulted in the development of the Bethesda System for cytologic reporting. That standardized method of reporting cytology findings facilitated peer review and quality assurance and was updated and refined in the Bethesda III System (2001) **(Table 16-1)**.

According to this system, potentially premalignant squamous lesions fall into specific categories: (i) *atypical squamous cells* (ASC), (ii) *low-grade squamous intraepithelial lesions* (LSILs), and (iii) *high-grade squamous intraepithelial lesions* (HSILs) (27). The ASC category is subdivided into two categories: those of unknown significance (ASC-US) and those in which high-grade lesions must be excluded (ASC-H). LSILs include CIN 1 (mild dysplasia) and the changes of HPV, termed *koilocytotic*

atypia. The HSIL category includes CIN 2 and CIN 3 (moderate dysplasia, severe dysplasia, and CIS). The terminology, AGUS, or atypical glandular cells of undetermined significance, was developed to characterize evidence of nonsquamous glandular neoplasia originating in the cervix.

Cellular changes associated with HPV (i.e., koilocytosis and CIN 1) are included within the category of LSIL because the natural history, distribution of various HPV types, and cytologic features are the same (26). Histopathologic and molecular virologic correlation showed a similar heterogeneous distribution of low- and high-risk HPV types in both koilocytosis and CIN 1 (28,29). On the basis of clinical behavior, molecular biologic findings, and morphologic features, HPV changes and CIN 1 are the same disease. The rationale for combining CIN 2 and CIN 3 into the category of HSIL is similar. The biologic studies reveal a comparable mix of high-risk HPV types in the two lesions, and the separation of the lesions is not reproducible (29,30). The management of CIN 2 and CIN 3 is similar.

Cervical Cytologic Screening Test Accuracy

Screening for cervical cancer precursors using exfoliative cervicovaginal cytology, the Pap test, was successful in reducing the incidence of cervical cancer by 79% and the mortality by 70% since 1950 (31). The annual incidence rate dropped from 8 to 5 cases per 100,000 women, so approximately 8,200 women per year are diagnosed with cervical cancer (31–33). A literature review of cervical cytology testing techniques was conducted by the Agency for Healthcare Research and Quality (34). The conclusion was that the sensitivity of conventional cytologic testing in detecting cervical cancer precursor lesions was 51%, with an estimated false-negative rate of 49%. In three reviews of the accuracy of cervical cytology assessment, **the sensitivity of the cervical cytology for the detection of CIN 2 or 3 ranged from 47% to 62% and the specificity ranged from 60% to 95%** (35–37). More than half of all cases of invasive cancer occur in women who were never screened or who were underscreened. The causes of missed cases of cervical cancer in women who have been screened are errors of sampling, fixation, interpretation or lack of follow-up (38).

Conventional cytology has improved in order to reduce false-negative errors. Sampling errors occur because a lesion is too small to exfoliate cells or the device did not pick up the cells and transfer them to the fixation media. Historically, preparation errors occurred because of poor fixation on the glass slide, leading to air drying and its consequences for interpretation. The slide preparations could be too thick and obscured by vaginal discharge, blood, or mucus. These problems were obviated with the widespread utilization of liquid-based media. Interpretive errors have been reduced by the large scale implementation of automated detection devices that assist the cytotechnologist in identifying significant cellular abnormalities. The ubiquitous use of liquid-based medium to collect the cytologic sample and preserve the collected cervical

cells significantly decreased specimen sampling and preparation errors. With this technique, liquid samples are processed to provide a uniform, thin layer of cervical cells without debris on a glass slide. The cell sample is collected with an endocervical brush used in combination with a plastic spatula or with a plastic broom. The sample is rinsed in a vial containing liquid alcohol-based preservative. With this technique, 80% to 90% of the cells are transferred to the liquid media, as compared with the 10% to 20% transferred to the glass slide with conventional cytologic testing. Use of liquid-based media eliminates air drying. The cells are retrieved from the vial by passing the liquid through a filter, which traps the larger epithelial cells, separating them from the small blood and inflammatory cells. This process yields a thin layer of diagnostic cells properly preserved and more easily interpreted by the cytologist. This technique reduces by 70% to 90% the rate of unsatisfactory samples encountered with conventional cytologic testing (39). Liquid-based cytology is commonly performed by most of the laboratories in the United States.

Another technology approved by the Food and Drug Administration (FDA) for primary screening and rescreening samples of cervical cytology initially interpreted as normal is the automated image-guided slide screening system. This technique uses an automated microscope coupled to a special digital camera. The system scans the slide and uses computer imaging techniques to analyze each field of view on the slide. Computer algorithms rank each slide on the probability that the sample may contain an abnormality. The selected slides are reviewed by a cytotechnologist or cytopathologist. This technique reduced the false-negative rate by 32% (40).

Human Papillomavirus Testing in Screening

An improved understanding of the critical role of high-risk human papillomavirus infection in the development of cervical cancer and its precursors has generated the proliferation of molecular tools that have come into clinical practice. Such methods have undergone extensive clinical trials, have been submitted to the rigorous approval process of the FDA, and have resulted in their licensure for specific roles in the screening process. **[5] High-risk HPV testing is a critical component of the triage for equivocal (ASC-US) cytology, as a component of co-testing with simultaneous cytology, and as a stand-alone primary screening modality** (Table 16-2).

Cervical Cancer Screening Recommendations

Guidelines based on the literature were developed to guide cervical cancer screening, follow-up, and treatment. The evolving state of the science and our improved understanding of HPV and cervical carcinogenesis, and clinical practice and liability considerations, occasionally lead to subtle differences in the interpretation of these guidelines. Ultimately, guidelines cannot substitute for an informed discussion of risks and benefits between a patient and health care provider in order to make decisions

about treatment.

The American College of Obstetricians and Gynecologists (ACOG) updated its guidelines (41). **[6]** The ACOG recommends that women not initiate cervical cancer screening until they are 21, regardless of the onset of sexual activity. This acknowledges the very low prevalence of invasive cancer in very young women, the long multiyear process of cervical carcinogenesis, and the very low but real risks for preterm birth associated with outpatient excisional procedures. Likewise, screening frequency was revised to every 2 years from ages 21 to 29 (with either conventional slide or liquid-based cytology), and every 3 years for women after age 30 years if 3 consecutive negative, that is, negative for intraepithelial lesion or malignancy (NILM) Pap tests can be documented. More frequent screening continues to be recommended for HIV-positive women (twice first year and annually after), those who are immune suppressed, *diethylstilbestrol* (DES) daughters, and for those with a history of CIN 2 or greater (screen annually for 20 years). Discontinuation of screening is reasonable between 65 and 70 years, with reassessment of risk factors annually to determine if reinitiating screening is appropriate. Likewise, in the setting of posthysterectomy for benign indications it is reasonable to discontinue screening in the absence of a history of high-grade CIN or cancer (Table 16-3).

Table 16-2 Commercially Available High-Risk HPV Assays and Their FDA-Approved Clinical Indications

Molecular Target *Technique*	Commercial Product	Typing	ASC-US Triage	Co-Test	Primary
DNA—genomic *DNA:RNA Hybridization*	*Hybrid Capture 2*	No	X	X	
DNA *Invader Technology*	*Cervista*	16/18 Reflex	X	X	
L1 DNA *PCR TaqMan*	*Cobas HPV*	16/18	X	X	X
E6/E7 mRNA *TMA*	*APTIMA*	16/18, 45 reflex	X	X	

Table 16-3 Comparison of Screening Guidelines From the American Cancer Society, American Society of Colposcopy and Cervical Pathology and American Society Clinical Pathology, the American College of Obstetricians and Gynecologists, and the U.S. Preventive Services Task Force

	ACS-ASCCP-ASCP 2012	ACOG 2009	USPSTF 2012	USPSTF 2017
Start Age	21	21	21	21
Ages 21–29	Cytology every 3 years (liquid or conventional) AGAINST annual Pap	Cytology every 2 years (liquid or conventional)	Cytology every 3 years (liquid or conventional)	Cytology every 3 years (liquid or conventional)
Ages 30–65	Co-test every 5 years (preferred) OR Every 3 years with cytology alone (acceptable) AGAINST more frequent screening	Co-test every 3 years OR Every 3 years with cytology alone	Co-test every 5 years OR Every 3 years with cytology alone	Cytology every 3 years (liquid or conventional) OR High-risk HPV testing every 5 years OR Co-test every 5 years
After 65	Discontinue after age 65 if 3 negative Pap tests or 2 negative HPV tests in last 10 years with most recent test in last 5 years	Discontinue at age 65–70 after 3 negative tests in last 10 years	Discontinue after age 65 if adequate prior screening	Recommend against screening if adequate prior screening and not at increased risk

The 2011 American Society for Colposcopy and Cervical Pathology (ASCCP), American Cancer Society (ACS), and the American Society for Clinical Pathology (ASCP) co-convened a guidelines development process in collaboration with more than 21 partner organizations. The goal of this process was to develop a set of updated evidence-based screening guidelines that reflected our best understanding of the science (42). Contemporaneously and independent of this effort the U.S. Preventive Services Task Force (USPSTF) is using an entirely different methodology and on the basis of an independent systematic evidence review in the process of updating that entity's cervical cancer screening recommendations (43). These near-parallel processes produced a set of remarkably concordant recommendations whose uniformity has been beneficial to patients and clinicians.

[6] These **evidence-based guidelines recommend that cervical cancer screening not begin until age 21 years, regardless of sexual history. For women 21 to 29 years, the recommendation is screening with cytology every 3 years. From 30 to 65 years co-testing with conventional cytology and high-risk HPV testing every 5 years or cytology alone every 3 years are appropriate alternatives. After the age of 65 it is appropriate to discontinue screening in women with a negative screening history as documented by either 3 negative cytology results or 2 negative co-tests in the previous 10 years** (42,43).

The USPSTF published its updated draft guidelines and made them available for stakeholder input **(Table 16-3)**. The major and historic innovation is the unprecedented incorporation of primary screening using molecular high-risk HPV testing (as an alternative to cytology every 3 years) in women between 30 and 65 years.

Atypical Squamous Cells

The ASC category does not include benign, reactive, and reparative changes, classified as normal in the Bethesda system. This cytologic diagnosis is relatively common, ranging from 3% to 25% in some centers (44). When standardized diagnostic criteria are used, the rate of ASC results should be 3% to 5% (45). The ASC category is subdivided into ASC-US and ASC-H.

The cytologic diagnosis of ASC-US is associated with a 10% to 20% incidence of CIN 1 and a 3% to 5% risk for CIN 2 or 3 (46–49). CIN 1 is most often a benign HPV infection and will regress spontaneously in more than 60% of cases; therefore, the goal of triage of an ASC-US Pap test result is to identify more advanced CIN 2 and CIN 3 lesions (50).

Immediate colposcopy is assumed to be the most sensitive method of detecting CIN 2 or 3 (46,49). Because 80% of patients will not have significant lesions, it is important to avoid overinterpretation of the colposcopic findings. **[7] The usefulness of high-risk HPV testing in the assessment of ASC-US Pap test results** (51–53) **is well established, and aids in the identification of 90% of the patients with CIN 2 or 3 lesions.** To compare the aforementioned triage method in a prospective, randomized fashion, the NCI funded an ASC-US/LSIL Triage Study (ALTS) (54). Patients with ASC-US or LSIL were randomized to three triage arms: (i) immediate colposcopy, (ii) HPV test, and (iii) conservative management by repeat Pap test. There were 1,163 women in the immediate colposcopy group, and 14 refused the examination. The results of colposcopy are assumed to reflect the prevalent disease rates, which were as follows: CIN 1, 14.3%; CIN 2, 16.1%; and CIN 3, 5%. Thus, 75% of the women with ASC-US had negative colposcopy results and either did not have a biopsy (25%) or had a biopsy with negative results. The HPV test results were positive in 56.1% of the patients, and 6.1% of the patients did not return for colposcopy. Of the 494 who underwent colposcopy, the results were as follows: CIN 1, 22.5%; CIN 2, 11.9%; and CIN 3, 15.6%. The sensitivity of HPV test was 95.9% for the detection of CIN 2 and 96.3% for the detection of CIN 3.

In the conservatively managed group, only one follow-up cytology was reported. The results of the single follow-up Pap test were included. Using a cutoff that includes any positive finding of ASC-US or greater, the sensitivity is 85% for CIN 2 and 85.3% for CIN 3, with 58.6% of patients referred for colposcopy. If LSIL is used as a cutoff, 26.2% of the patients are referred, with sensitivity of 64.0% for both CIN 2 and CIN 3. Using HSIL as the cutoff, 6.9% are referred, and the sensitivity falls to 44%. The conclusion of the ALTS trial is that HPV triage is highly sensitive in identifying CIN 2 and CIN 3 lesions and that it cuts the rate of referral for colposcopy by approximately one-half (55). When mathematical models are used to simulate the natural history of HPV and cervical cancer in a cohort of US women, a 2- to 3-year screening strategy using cytology with reflex high-risk HPV triages is more effective and less costly in reducing the rate of cancer than annual conventional cytology (56).

[8] Women with ASC-H should be referred to colposcopy because of the underlying risk of CIN 2 and/or 3, and should not be triaged with high-risk HPV testing.

Low-Grade Squamous Intraepithelial Lesions

The cytologic diagnosis of LSIL is reproducible and accounts for 1.6% of cytologic diagnoses (45). About 75% of the patients have CIN, with 20% being CIN 2 or 3 (46–48). These patients require additional evaluation. The ALTS trial closed the HPV test arm early because the HPV positivity rate was 82% and was not a valid discriminator in determining the presence of disease. The ALTS trial found that a cytology interpretation of LSIL is associated with a 25% risk of histologic CIN 2 or 3 within 2 years. No effective triage strategy was identified to spare many women from colposcopic referral without increasing their risk of CIN 3 and invasive carcinoma (57). **[9] Guidelines reaffirm the appropriateness of colposcopy to evaluate after an LSIL cytology** (52).

High-Grade Squamous Intraepithelial Lesions

[9] Any woman with a cytologic specimen suggesting the presence of HSIL must undergo colposcopy and directed biopsy (52). Two-thirds of patients with this cytologic finding will have CIN 2 or greater. After colposcopically directed biopsy and determination of the distribution of the lesion, excisional or ablative therapy that addresses the entire transformation zone should be performed. For populations who have completed childbearing and who are likely to be lost to follow-up, outpatient excision of the transformation may be considered after this cytologic diagnosis.

Colposcopic Diagnosis

The ASCCP convened a process to develop evidence-based and expert consensus recommendations for the practice of colposcopy in the United States (58). An outcome of this process was the development of standardized terminology for findings at colposcopic examination (59). It described **[10] the minimum elements of a comprehensive colposcopic examination, which include visualization of SCJ, the identification of acetowhitening or other lesion(s), and an overall colposcopic impression (normal/benign, low grade, high grade, cancer)** (Table 16-4) (59,60).

Table 16-4 Essential Elements of a Colposcopic Examination (Adapted from ASCCP)

Component	Content
Precolposcopic assessment	Evaluate/document the following: Indication; history of prior screening tests, colposcopy, and treatment; parity, contraception, pregnancy, menopause, hysterectomy, smoking, HIV, HPV vaccination.

	Informed consent.
Examination	Gross assessment of the vulva, vagina, perianal area, and cervix. Examination of the cervix and upper vagina with magnification after application of 3–5% acetic acid using white light and green/blue filter.
Documentation	Document cervix visibility, and visualization of squamocolumnar junction. Document (using diagram or photography) findings including presence, location, size, appearance, and characteristic of the lesion. Colposcopic impression.
Tissue sampling	Perform/document biopsy type, location of lesions. Perform/document endocervical sampling.
Postprocedure	Document modality and timing of how patient will be notified.

The guidelines formalize the practice of risk-based colposcopy. In general, colposcopists are asked to consider at least two and up to four biopsies of all suspected lesions (61). For women at the lowest risk of high-grade disease (those with less than HSIL cytology, no evidence for HPV16/18, and a normal colposcopic impression), random non-targeted biopsies are not recommended. Conversely, nonpregnant women at the greatest risk of disease may merit a more aggressive diagnostic workup.

The p16 protein is a cell cycle regulator, and under physiologic conditions, p16 acts as an inhibitor of cyclin-dependent kinases CDK4 and CDK6; this leads to cell cycle arrest in epithelial cells undergoing cellular differentiation. However, in response to a transforming infection by high-risk human papillomavirus (hrHPV) with overexpression of oncogenic protein E7, p16 levels rise. **The excess p16 is thus a surrogate marker of the transforming HPV infection. p16 is recommended for use as an adjudication tool for cases in which there is a professional disagreement in histologic specimen interpretation, with the caveat that the differential diagnosis includes a precancerous lesion (CIN 2/-IN2 or CIN 3/-IN3)** (62,63).

The 2012 ASCCP consensus guidelines recommended grouping CIN 2 and CIN 3 together as high-grade histology. However, it was recognized that there was a subset of CIN 2 patients that would not progress and thus did not need treatment. In 2012, the College of American Pathologists and ASCCP cosponsored the Lower Anogenital Squamous Terminology (LAST) standardization project and published the LAST recommendations for histopathology reporting of HPV-related squamous lesions of the lower anogenital tract. Specifically LAST calls for the use of a 2-tier nomenclature (low-grade squamous intraepithelial lesion/high-grade squamous intraepithelial lesion [LSIL/HSIL]) and expanded use of the biomarker p16 to classify equivocal lesions as either precancer (HSIL) or low-grade lesions (LSIL)/non-HPV changes. In one study, among 166 patients with subsequent pathology (including 131 excisions), 26.2% of p16-positive cases of grade 2 intraepithelial neoplasia versus 4.4% of p16-negative cases were associated with a subsequent

diagnosis of HSIL (-IN 3) or worse ($P = 0.002$) (64). **The results indicate that using the LAST recommendations would result in approximately one-third of equivocal (-IN 2) diagnoses being downgraded to LSIL over 1 year. The significant association of p16 expression with a higher risk for HSIL on a subsequent specimen suggests that the use of p16 to adjudicate equivocal (-IN 2) diagnoses in lower anogenital tract specimens as either LSIL or HSIL would likely predict lesion grade more accurately and avoid unnecessary excisional procedures. Therefore, strong and diffuse block-positive p16 results support a categorization of precancerous disease. Negative or non–block-positive staining strongly favors an interpretation of low-grade disease or a non–HPV-associated pathology such as immature squamous metaplasia, atrophy, or reparative changes.** Subsequent publications have confirmed the accuracy of p16 IHC (62,63).

Therefore, women with histologic diagnosis of CIN 2 with negative p16 staining have a very low risk of advancing to CIN 3 and no patient has developed invasive cancer in these studies. These women can avoid treatment, especially if they want further childbearing. Postmenopausal women often have atrophy or reparative changes and they may benefit from p16 testing as well.

Colposcopy Findings

Colposcopic assessment is a critical component of the follow-up of the abnormal cervical screening. Specialty providers in a variety of clinical settings have historically performed this procedure. In an effort to improve the quality and consistency of this procedure the American Society of Colposcopy and Cervical Pathology has developed and disseminated a new set of standards for services in this arena (59). This process developed standard terminology and definitions of findings. Table 16-4 summarizes the essential elements of a colposcopic evaluation.

Acetowhite Epithelium

Epithelium that turns white after application of acetic acid (3% to 5%) is called *acetowhite epithelium* (34). The application of acetic acid coagulates the proteins of the nucleus and cytoplasm and makes the proteins opaque and white (4).

The acetic acid does not affect mature, glycogen-producing epithelium because the acid does not penetrate below the outer one-third of the epithelium. The cells in this region have very small nuclei and a large amount of glycogen (not protein). These areas appear pink during colposcopy. Dysplastic cells are those most affected. They contain large nuclei with abnormally large amounts of chromatin (protein). The columnar villi become “plumper” after acetic acid is applied, making these cells easier to see. They appear slightly white, particularly in the presence of metaplasia. The immature metaplastic cells have larger nuclei and show some effects of the acetic acid. Because the metaplastic epithelium is very thin, it is not as white or opaque as CIN but instead

appears gray and filmy (4).

Leukoplakia

Translated literally, *leukoplakia* is white plaque (4). This plaque is white epithelium, visible before application of acetic acid. Leukoplakia represents a layer of keratin on the surface of the epithelium. Immature squamous epithelial cells have the potential to develop into keratin- or glycogen-producing cells. In the vagina and on the cervix, the normal differentiation is toward glycogen. Leukoplakia should not be confused with the white plaque of a monilial infection, which can be completely wiped off with a cotton-tipped applicator.

Keratin production is abnormal in the cervicovaginal mucosa. Leukoplakia results from this process and is commonly associated with HPV infection **(Fig. 16-8)** and related keratinizing intraepithelial or invasive lesions and should be biopsied. Other etiologies for this lesion include chronic trauma from diaphragm, pessary, or tampon use and radiotherapy.

Punctation

Dilated capillaries terminating on the surface appear from the ends as a collection of dots and are referred to as punctation **(Fig. 16-9)**. When these vessels occur in a well-demarcated area of acetowhite epithelium, they indicate an abnormal epithelium—most often high-grade CIN **(Fig. 16-10)** (4). The punctate vessels are formed as the metaplastic epithelium migrates over the columnar villi. Normally, the capillary regresses; however, when CIN occurs, the capillary persists and appears more prominent.

Mosaic

Terminal capillaries surrounding roughly circular or polygonal-shaped blocks of acetowhite epithelium crowded together are called mosaic because of their appearance **(Fig. 16-11)**. These vessels form a "basket" around the blocks of abnormal epithelium. They may arise from a coalescence of many terminal punctate vessels or from the vessels that surround the cervical gland openings (4). Mosaicism tends to be associated with high-grade lesions (CIN 2 and CIN 3) (**Figs. 16-12** and **16-13**).

FIGURE 16-8 Colposcopy of cervical intraepithelial neoplasia 2 (CIN 2) associated with human papillomavirus (HPV) infection of the cervix.

The International Federation for Cervical Pathology and Colposcopy published additional colposcopic criteria for CIN 3. They are ridge sign—dense acetowhite extending along the cervical ridges, and inner border sign—thick acetowhite with distinct border existing inside a finer, lacy acetowhite lesion **(Fig. 16-14)**. These are added to the previously described cuffed gland—dense acetowhite around the gland openings, and rag sign—peeling of the epithelium in an area of acetowhite **(Fig. 16-15)** (65).

Atypical Vascular Pattern

Atypical vascular patterns are characteristic of invasive cervical cancer and include looped vessels, branching vessels, and reticular vessels.

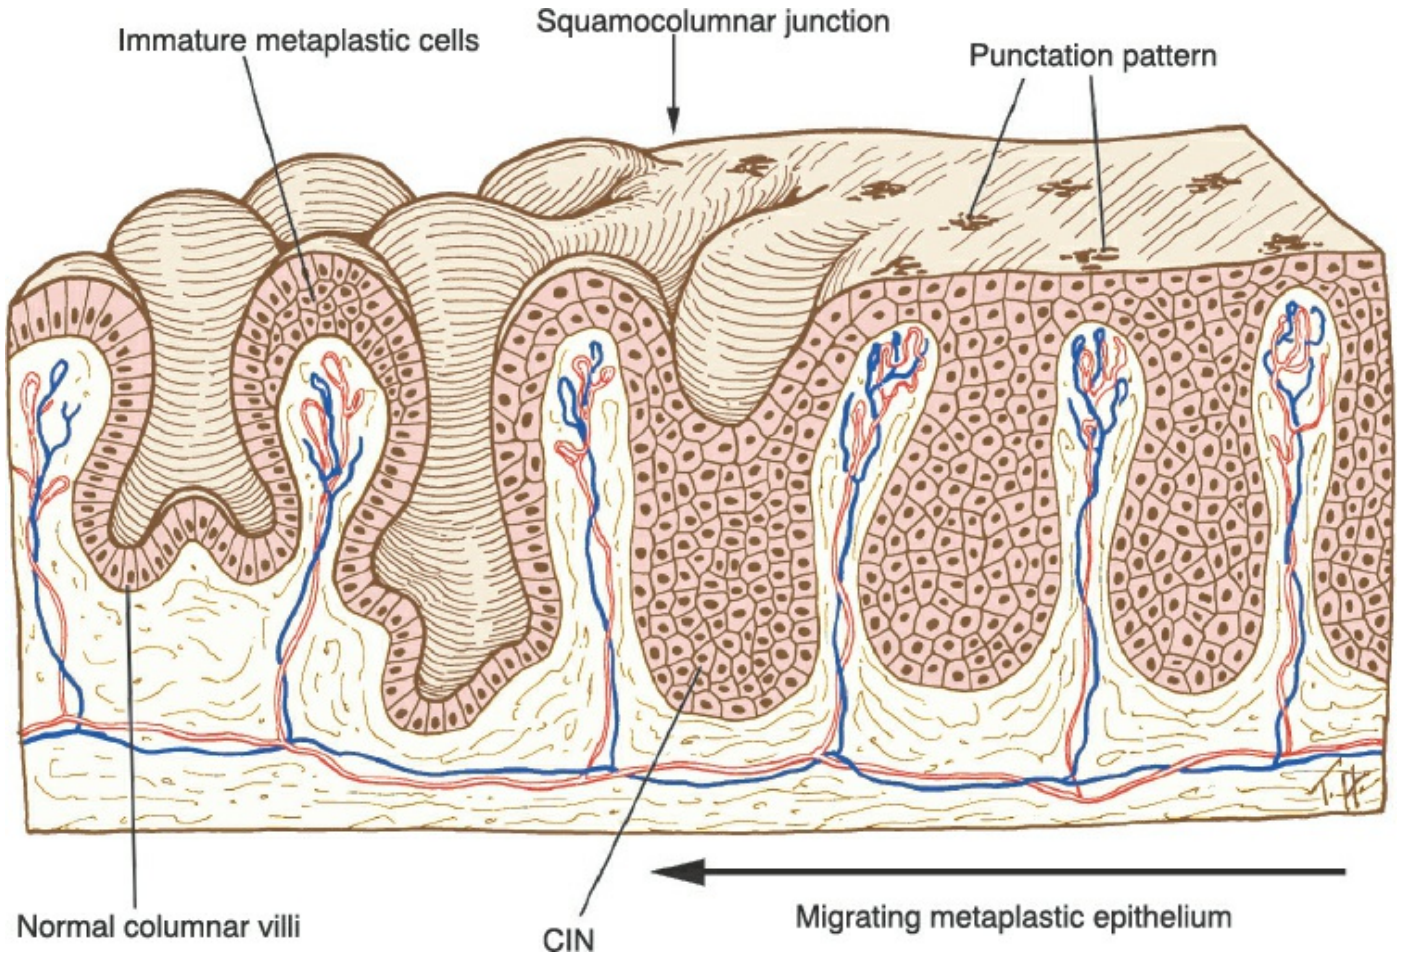

FIGURE 16-9 Diagram of punctation. The central capillaries of the columnar villi are preserved and produce the punctate vessels on the surface.

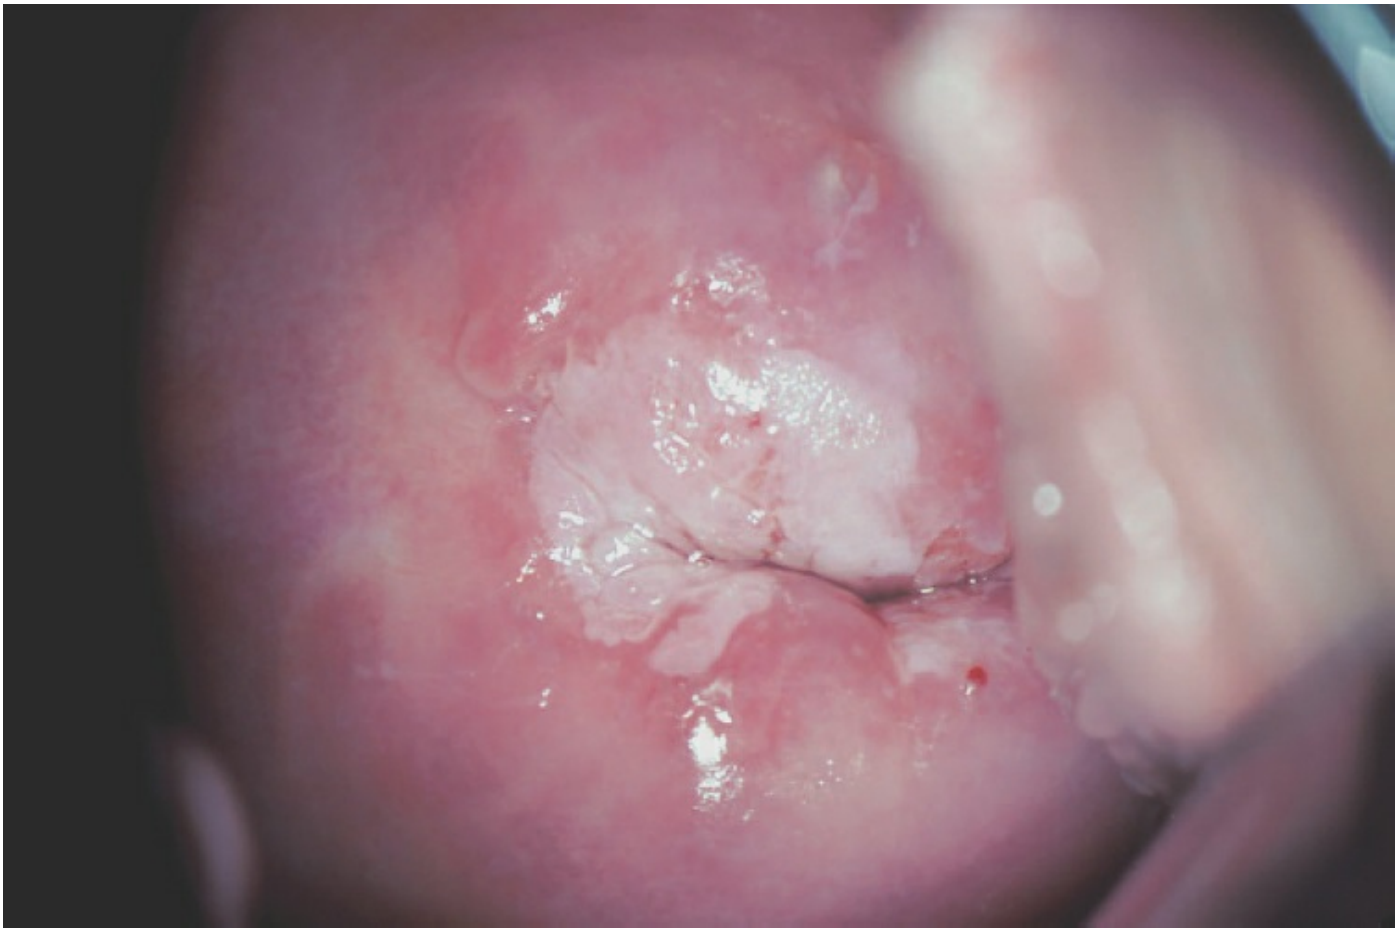

FIGURE 16-10 Human papillomavirus (HPV)/cervical intraepithelial neoplasia 2 (CIN 2) presents as a white lesion with surface spicules.

Clinical Pathologic Correlation

[11] It is a best practice for pathologist and colposcopist to jointly review the colposcopic examination findings, cytology, molecular testing, cervical biopsy, and endocervical sampling in order to develop a therapeutic plan. Cytology results should not be sent to one laboratory and the histology results to another. When the cytology, biopsy, and molecular testing results correlate, the colposcopist can be reasonably certain that the most clinically significant lesion was identified. If cytology indicates a more significant lesion than the histology, the patient may require further evaluation, including repeat colposcopy, additional biopsies, and excisional diagnostic procedures under certain circumstances.

Management

Clinical Disease Management Guidelines

In 2012, the ASCCP and the NCI sponsored a consensus conference to update evidence-based guidelines for abnormal cervical cancer screening. This gathering brought

together 47 experts and 23 professional societies, national and international health organizations, and federal agencies to review the latest natural history and clinical data, and consider how the newly updated cervical cancer screening impacted the clinical follow-up of abnormal screens (66). **[12] The new comprehensive evidence-based guidelines for the management of cervical cytologic and histologic entities lend themselves to structured clinical algorithms that are available for download from the Web (www.asccp.org), on various mobile phone applications, and can be incorporated into a variety of electronic health record platforms.**

CIN 1

[13] Although CIN 1 is a histopathologic manifestation of HPV infection, it is not a cancer precursor. The spontaneous regression rate of biopsy-proven CIN 1 is conservatively estimated to be 60% to 85% in prospective studies and regression typically occurs within a 2-year follow-up (4,52,67–70). Patients who have biopsy-proven CIN 1 (after a cytologic finding of ASC, LSIL) with satisfactory colposcopy are followed with cytology and high-risk HPV testing (co-testing) at 12 months. With a negative cytology and high-risk HPV test at the 12-month follow-up these women can be returned to age-appropriate screening. The patient is returned to colposcopy for appropriate reevaluation in the event of abnormality on surveillance testing (66). Young women of ages 21 to 24 years in this clinical scenario may undergo surveillance with repeat cytology only at 12 and 24 months, with referral to colposcopy for ASC-US or greater (66).

[14] For CIN 1 that persists 24 months or more, a patient with an adequate colposcopic examination may be given the choice of continued surveillance or destruction of the transformation zone with ablation or excision (66). However, if colposcopy is inadequate, ablative therapy should be avoided. Expectant management may not be appropriate for patients with chronic systemic immunosuppression, such as those requiring steroids, chemotherapy, or antirejection drugs, and others who may have persistent low-grade abnormalities (52).

Clinical situations where biopsy histopathology is CIN 1 preceded by ASC-H or HSIL cytology carry a higher risk. In these settings, follow-up with co-testing (with cytology and high-risk HPV) at 12 and 24 months or loop excision procedure may be more appropriate (66).

CIN 2 and CIN 3

Typically, **CIN 2 and CIN 3 lesions are neoplastic precursors and grouped for the purposes of diagnostic reporting and treatment. [14] Women, 25 years of age and older, with adequate colposcopy and histologic documentation of CIN 2 and CIN 3 require destruction or excision of the transformation zone** (66). Ablation should not be considered in cases where colposcopy is inadequate, CIN 2 and/or 3 is recurrent, or

endocervical sampling is positive. This recommendation is based on a meta-analysis showing that CIN 2 progresses to CIS in 20% of cases and to invasion in 5%. Progression of CIS to invasion is 5% (71). Surveillance with co-testing at 12 and 24 months is necessary prior to returning a patient to routine age-appropriate screening (66).

Mosaic pattern
B

FIGURE 16-11 A: Mosaic pattern and punctation. This pattern develops as islands of dysplastic epithelium proliferate and push the ends of the superficial blood vessels away, creating a pattern that looks like mosaic tiles. **B:** Diagram of mosaic pattern.

There are exceptions to this therapeutic recommendation. The first is among pregnant women, who in the absence of invasive disease, are followed with cytology and colposcopy, until reevaluation at 6 weeks postpartum. Additionally, in recognition of the small but real risk for preterm birth, in young women less than 25 years of age with CIN 2–3, a program of intensive observation with colposcopy and cytology is performed at 6 and 12 months, and if normal, followed by co-testing in another year (66).

FIGURE 16-12 Human papillomavirus (HPV)/cervical intraepithelial neoplasia 3 (CIN 3). Cribriform pattern of HPV at periphery with mosaicism and punctation near the squamocolumnar junction.

[15] Although CIN 2–3 can be treated with a variety of outpatient techniques, the preferred treatment is LEEP. This allows pathologic evaluation to identify occult microinvasive cancer or adenomatous involvement. In the latter case, margin status has important prognostic implications. The persistent and recurrent disease rate post treatment is estimated at 4% to 10% (72,73).

Ablative therapy using cryotherapy, laser ablation, or any other technique is not

appropriate when there is CIN 2–3 in the endocervix based on colposcopy and endocervical curettage (ECC), or **evidence of microinvasive or invasive cancer on cytology, colposcopy, ECC, or biopsy.**

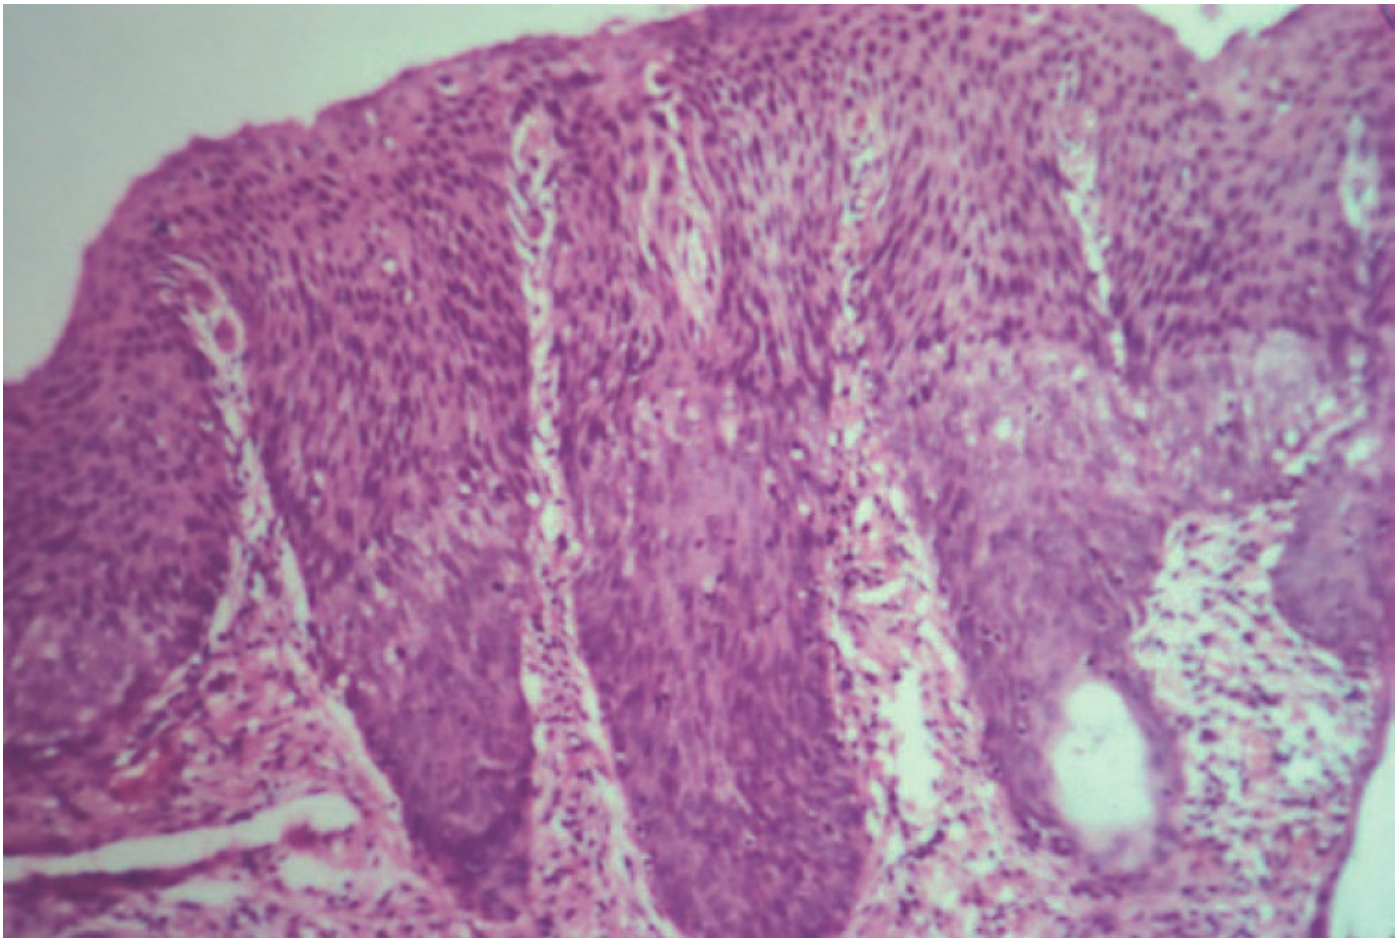

FIGURE 16-13 Cervical intraepithelial neoplasia grade 3 (CIN 3).

Cervical Adenocarcinoma In Situ

In adenocarcinoma *in situ* (AIS), the endocervical glandular cells are replaced by tall columnar cells with nuclear stratification, hyperchromasia, irregularity, and increased atypical mitotic activity (74). Cellular proliferation results in crowded, cribriform glands. The normal branching pattern of the endocervical glands is preserved. About 50% of women with cervical AIS have squamous CIN 2–3, and AIS lesions represent incidental findings in specimens removed for treatment of squamous neoplasia. Usually AIS is located near or above the transformation zone and conventional cervical specimens may not be effective for detecting glandular disease. Obtaining good endocervical specimens by Cytobrush may improve the detection of AIS during the screening process.

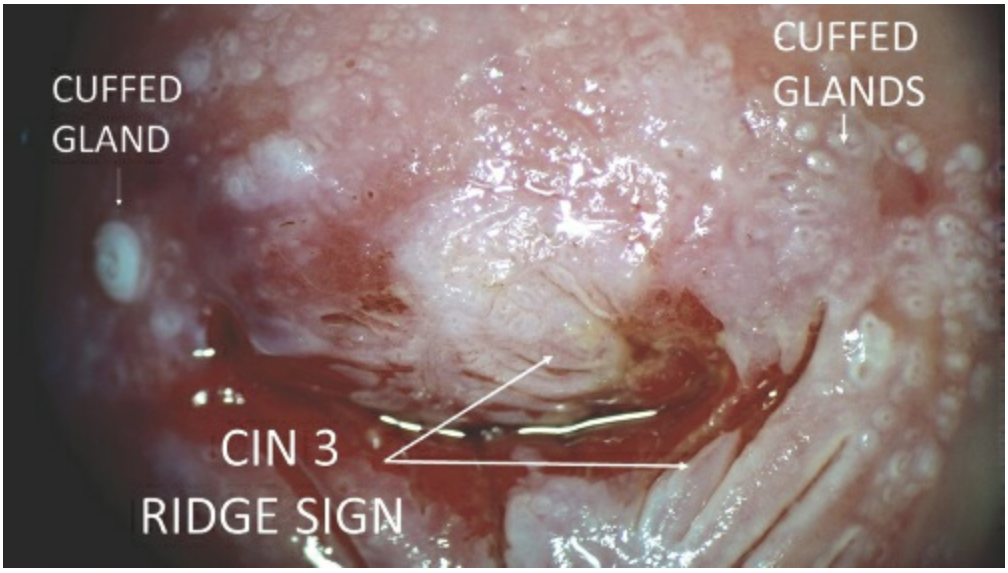

FIGURE 16-14 Colposcopic findings of CIN 3: cuffed gland openings and ridge sign.

[16] AIS is a cancer precursor, and the preferred management for women who have completed childbearing and have a histologic diagnosis of AIS on a specimen from a diagnostic excisional procedure is hysterectomy (66). A histologic diagnosis of AIS from a punch biopsy or a cytologic diagnosis of AIS is insufficient to justify hysterectomy in the absence of a diagnostic excisional procedure.

Conservative management with conization can be considered for women desiring future fertility (66). In such a setting, the status of surgical conization margins and endocervical sampling at the time of surgery are critical. If either is positive, reexcision is recommended because of the risk of cancer.

The limits of AIS lesions are difficult to establish by colposcopy or pathology because of frequent extension of disease within the endocervical canal and the presence of multifocal, "skip lesions" (i.e., lesions that are not contiguous). For this reason, negative margins on an excisional specimen may not be entirely reassuring.

There is good evidence that AIS may progress to invasive cancer (75). In a study of 40 patients with AIS who had cervical conization, 23 of 40 patients (58%) had coexisting squamous intraepithelial lesions and 2 had invasive squamous cell carcinoma (76). Of the 22 patients who underwent hysterectomy, the margins on the cone specimen were positive in 10 patients, and 70% had residual AIS, including 2 patients with foci of invasive adenocarcinoma. One of the 12 patients with negative margins had focal residual adenocarcinoma in the hysterectomy specimen, and 18 women had conization only with negative margins and no relapse of disease after a medium interval of 3 years. Thus, positive margins on the conization specimen are significant findings in these patients (77). In a more alarming study of 28 patients with AIS, of the 8 patients with positive margins who underwent repeat conization or hysterectomy, 3 had residual AIS and 1 patient had invasive adenocarcinoma (78). Of 10 patients with negative margins

who underwent hysterectomy or repeat conization, 4 had residual AIS. One patient in whom the cone margin could not be evaluated had invasive adenocarcinoma. Of the 15 patients treated conservatively with repeat conization of the cervix and close follow-up, 7 (47%) had a recurrent glandular lesion detected after the conization, including invasive adenocarcinoma in 2 women. A glandular lesion was not suspected in 48% of the patients, based on Pap test and ECC results obtained before conization of the cervix.

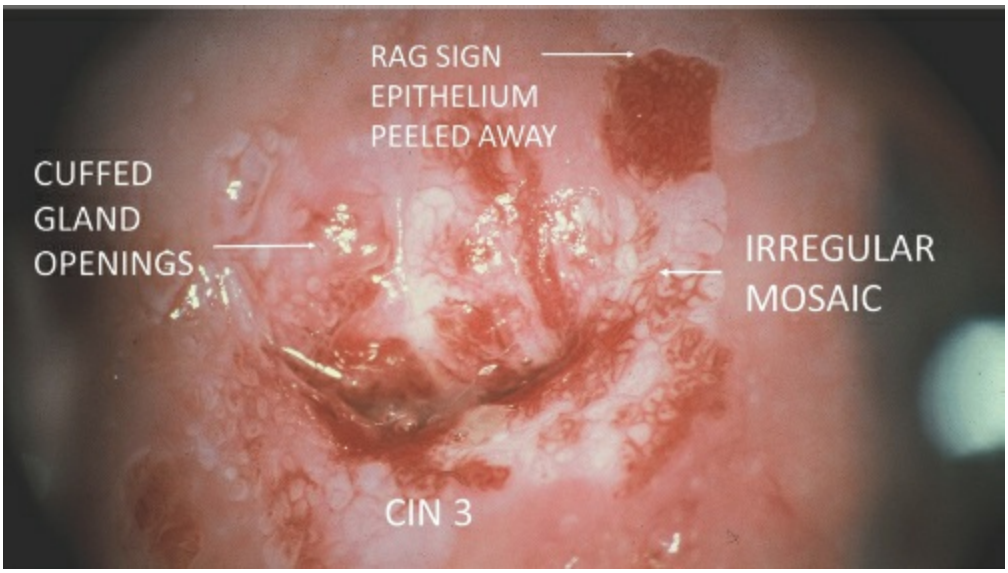

FIGURE 16-15 Colposcopy findings of CIN 3: rag sign and cuffed gland openings.

In all cases post conization for AIS, recommended surveillance requires reassessment at 6 months using a combination of cytology, colposcopy, HPV DNA testing, and endocervical sampling for women who do not undergo hysterectomy.

Treatment Modalities

Cryotherapy

Cryotherapy destroys the surface epithelium of the cervix by crystallizing the intracellular water, resulting in the eventual destruction of the cell. The temperature needed for effective destruction must be in the range of −20° to −30°C. Nitrous oxide (−89°C) and carbon dioxide (−65°C) produce temperatures below this range and, therefore, are the most commonly used gases for this procedure.

The technique believed to be most effective is a freeze-thaw-freeze method in which an ice ball is achieved 5 mm beyond the edge of the probe. The time required for this process is related to the pressure of the gas; the higher the pressure, the faster the ice ball is achieved. Cryotherapy is an effective treatment for CIN with very acceptable failure rates under certain conditions (79–82). It is a relatively safe procedure with few complications. Cervical stenosis is rare but can occur. Posttreatment bleeding is

uncommon and is usually related to infection.

Cure rates are related to the grade of the lesion; CIN 3 has a greater chance of treatment failure (Table 16-5). Townsend showed that cures are related to the size of the lesion; those covering most of the ectocervix have failure rates as high as 42%, compared with a 7% failure rate for lesions less than 1 cm in diameter (83). Positive findings on ECC can reduce the cure rate significantly. Endocervical gland involvement is important because the failure rate in women with gland involvement was 27%, compared with 9% in those who did not have such involvement (84).

Cryotherapy is acceptable when the following criteria are met:

1. CIN 1 that has persisted for 24 months, or CIN 2
2. Small lesion
3. Ectocervical location only
4. Negative endocervical sample
5. No endocervical gland involvement on biopsy

Loop Electrosurgical Excision

Loop electrosurgical excision is a valuable tool for the diagnosis and treatment of CIN (75,85–94). It offers the advantage of performing an operation that is simultaneously diagnostic and therapeutic during one outpatient visit (95–105).

The tissue effect of electricity depends on the concentration of electrons (size of the wire), the power (watts), and the water content of the tissue. If low power or a large-diameter wire is used, the effect will be electrocautery, and the thermal damage to tissue will be extensive. If the power is high (35 to 55 W) and the wire loop is small (0.5 mm), the effect will be electrosurgical, and the tissue will have little thermal damage. The actual cutting is a result of a steam envelope developing at the interface between the wire loop and the water-laden tissue. This envelope is pushed through the tissue, and the combination of electron flow and acoustical events separates the tissue. After the excision, a 5-mm diameter ball electrode is used, and the power is set at 50 W. The ball is placed near the surface so that a spark occurs between the ball and the tissue. This

process is called *electrofulguration,* and it results in some thermal damage that leads to hemostasis. If too much fulguration occurs, the patient will develop an eschar with more discharge, and the risk for infection and late bleeding will be higher.

Loop excision should not typically be used before a high-grade intraepithelial lesion is identified with histopathology. [17] However, treatment after an HSIL cytology may be appropriate in certain settings and among populations for whom colposcopic follow-up is not possible.

LEEP may be associated with an increased risk of overall preterm delivery, preterm delivery after premature rupture of membranes, and low–birth-weight infants in subsequent pregnancies at greater than 20 weeks' gestation (106). The excision of the entire transformation zone along with varying amounts of the cervical canal, may compromise birth outcomes (92,94). This is particularly true for young women, who may have large, immature transformation zones with extensive acetowhite areas. Complications following loop electrosurgical excision are relatively minor and compare favorably with those following laser ablation and conization. Intraoperative hemorrhage, postoperative hemorrhage, and cervical stenosis can occur but at low rates. The SCJ is visible in more than 90% of patients after this procedure. Effectiveness of LEEP and comparison of LEEP to other excision procedures are shown in **Tables 16-9** and **16-10**.

Conization

Conization of the cervix plays an important role in the management of CIN. It can be accomplished with a scalpel, electrosurgical needle, or laser. Before the availability of colposcopy, conization was the standard method of evaluating an abnormal Pap test result. Conization is a diagnostic and therapeutic procedure and has the advantage over ablative therapies of providing tissue for further evaluation to rule out invasive cancer and accurately assess surgical margins (100,101,103,107).

[18] Conization is indicated for diagnosis in women with CIN 3 or AGC-AIS and may be considered under the following conditions:

1. Limits of the lesion cannot be visualized with colposcopy.
2. The SCJ is not evaluable at colposcopy.
3. ECC histologic findings are positive for CIN 2 or CIN 3.
4. Substantial lack of correlation between cytology, biopsy, and colposcopy results.
5. Microinvasion is suspected based on biopsy, colposcopy, or cytology results.
6. The colposcopist is unable to rule out invasive cancer.

Lesions with positive margins are more likely to recur after conization (**Table 16-8**) (100,101,103). Endocervical gland involvement is predictive of recurrence (23.6% with gland involvement compared with 11.3% without gland involvement) (108). When

compared with conization, LEEP is the simpler technique, and short-term results are similar to those obtained with conization or laser excision (72,109). In a prospective study examining the long-term effects of LEEP, conization, and laser excision, no difference in recurrence of dysplasia or in pregnancy outcomes was found (**Tables 16-6** and **16-7**) (110).

Hysterectomy

[18] Hysterectomy is the treatment of last resort for recurrent high-grade CIN. In a study of 38 cases of invasive cancer occurring after hysterectomy among 8,998 women (0.4%), the incidence of significant bleeding, infection, and other complications, including death, is higher with hysterectomy than with other means of treating CIN (76). There are some situations in which hysterectomy remains a valid and appropriate (although not mandatory) method of treatment for CIN:

1. Microinvasion
2. Histologically confirmed recurrent high-grade CIN
3. Co-occurring gynecologic pathology requiring hysterectomy, such as fibroids, prolapse, endometriosis, and pelvic inflammatory disease

VAGINAL INTRAEPITHELIAL NEOPLASIA

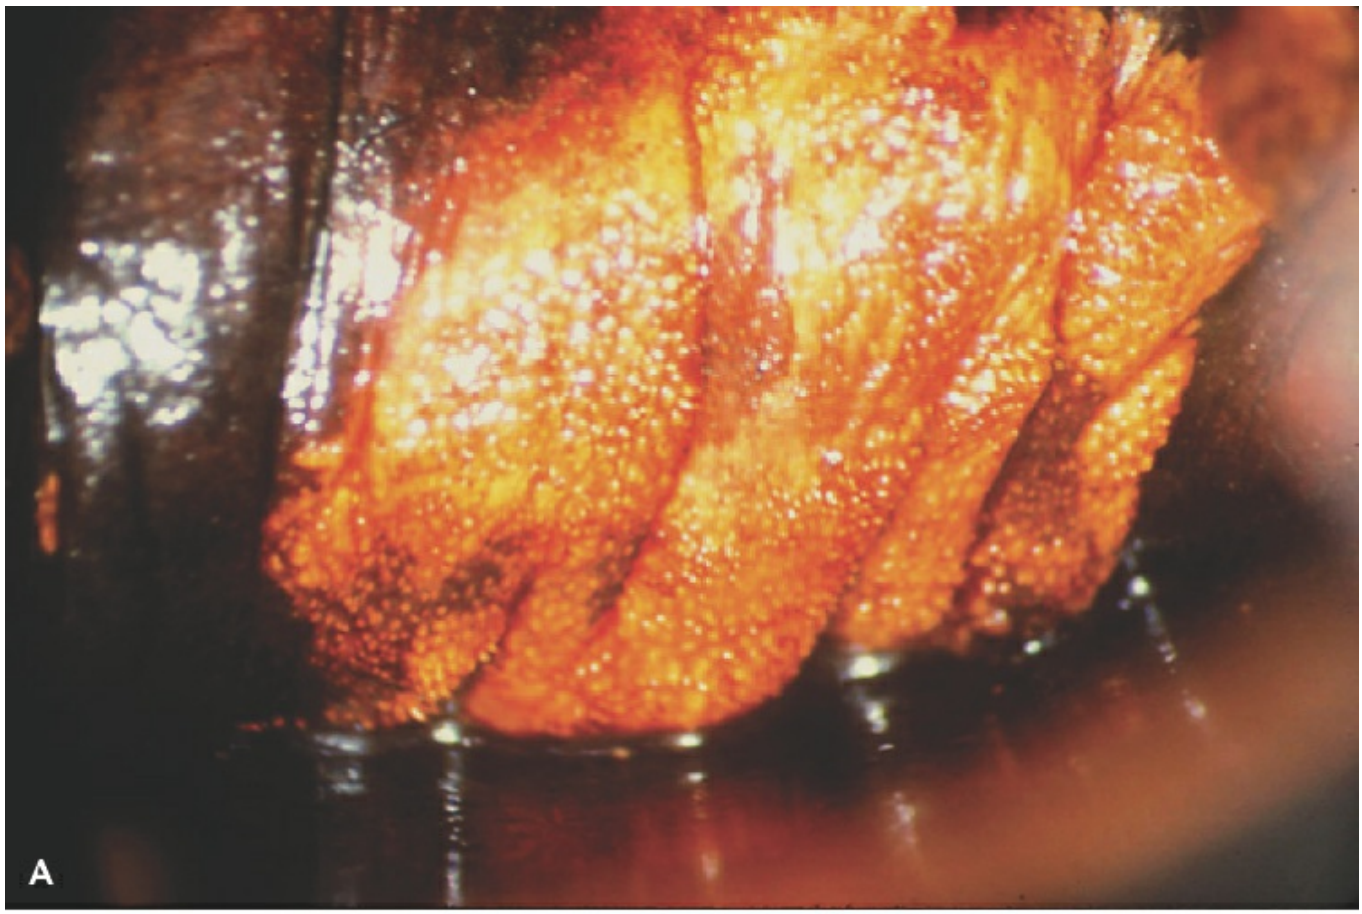
Vaginal intraepithelial neoplasia (VAIN) often accompanies CIN and shares a common etiology (111). Such lesions may be extensions onto the vagina from the CIN, or they may be satellite lesions occurring mainly in the upper vagina. Because the vagina does not have a transformation zone with immature epithelial cells to be infected by HPV, the mechanism of entry for HPV is by way of microabrasions resulting primarily from insertional sexual activity. As these abrasions heal with metaplastic squamous cells, the HPV may begin its growth in a manner similar to that in the cervical transformation zone. VAIN lesions are asymptomatic. Because they often accompany active HPV infection, the patient may report vulvar warts or an odoriferous vaginal discharge from vaginal warts.

Diagnosis

Women with an intact cervix should undergo routine cytologic screening. VAIN is nearly always accompanied by CIN and cytology is likely to be positive when VAIN is present. The vagina should be carefully inspected by colposcopic examination at the time of colposcopy for any CIN lesion. Particular attention should be paid to the upper vagina. **Women who have persistent abnormal cytology without evident cervical pathology and those with abnormal cytology after treatment of CIN should be examined carefully for VAIN.** For women in whom the cervix was removed for high-grade cervical neoplasia, Pap testing should be performed at regular intervals (e.g., yearly), depending on the diagnosis and severity of lesion.

Colposcopic examination and directed biopsy are the mainstays of diagnosis of VAIN. Typically, the lesions are located along the vaginal ridges, are ovoid in shape and slightly raised, and often have surface spicules. VAIN 1 lesions usually are accompanied by a significant amount of koilocytosis, indicating their HPV origin (Fig. 16-16). VAIN 2 exhibits a thicker acetowhite epithelium, a more raised external border, and less iodine uptake (Fig. 16-17A). When VAIN 3 occurs, the surface may become papillary, and the vascular patterns of punctation and mosaic may occur (Fig. 16-17B). Early invasion is typified by vascular patterns similar to those of the cervix.

FIGURE 16-16 Human papillomavirus (HPV)/vaginal intraepithelial neoplasia grade 1 (VAIN 1). Note the surface spicules with partial uptake of Lugol's stain.



Treatment

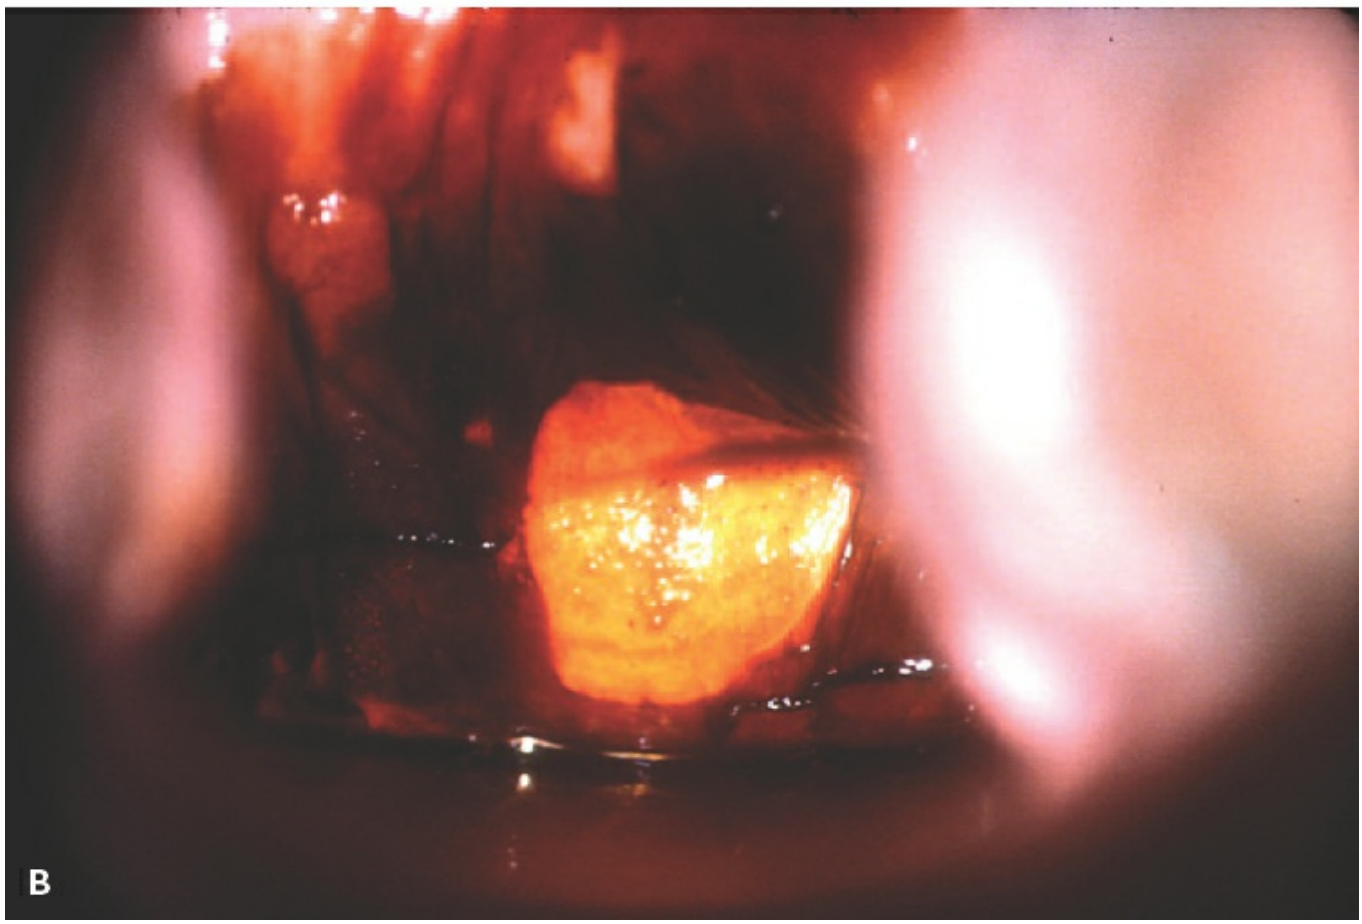
[19] Patients with VAIN 1/HPV or VAIN 2 do not require treatment and may be managed with surveillance. These lesions often regress, are multifocal, and recur quickly when treated with ablative therapy. VAIN 3 lesions are more likely to be associated with early invasive disease. In a study of 32 patients who underwent upper vaginectomy for VAIN 3, occult invasive carcinoma was found in 9 patients (28%)

(112). It is recommended in older patients that VAIN 3 lesions located in the dimples of the vaginal cuff be excised to rule out occult invasive cancer. **[19] VAIN 3 lesions that are adequately sampled to rule out invasive disease can be treated with laser therapy or excisional therapy. The major advantage of laser vaporization therapy is the ability to control the depth and width of destruction by direct vision through the colposcope.** The other advantage of laser therapy is the rapid posttreatment healing phase. This process takes about 3 to 4 weeks, after which time a new epithelium has formed completely and, in most cases, has a mature glycogen-containing epithelium.

Tissue Interaction

When the laser beam contacts tissue, its energy is absorbed by the water in the cells, causing it to boil instantly. The cells explode into a puff of vapor (thus the term *laser vaporization*). The protein and mineral content are incinerated by the heat and leaves a charred appearance at the base of the exposed area. The depth of laser destruction is a function of the power of the beam (in watts), the area of the beam (in millimeters squared), and the length of time the laser remains in the tissue. The beam must be moved uniformly across the tissue surface to prevent deep destruction. The laser beam vaporizes a central area and leaves a narrow zone of heat necrosis surrounding the laser crater. The goal of laser vaporization is to minimize the area of tissue necrosis. This goal is accomplished by using high wattage (20 W) with medium beam size (1.5 mm) and moving the beam uniformly but quickly over the surface. The zone of thermal necrosis will be 0.1 mm when the laser is used in this manner. Some lasers have a function called *super pulse,* in which the laser beam is electronically switched off and on thousands of times per second, thereby allowing the tissue to cool between pulses to create less thermal necrosis.

A



B

FIGURE 16-17 **A:** Vaginal intraepithelial neoplasia grade 2 (VAIN 2). **B:** Vaginal intraepithelial neoplasia grade 3 (VAIN 3).

Cryosurgery should not be used in the vagina because the depth of injury cannot be controlled and inadvertent injury to the bladder or rectum may occur. Superficial fulguration with electrosurgical ball cautery may be used under colposcopic control to observe the depth of destruction by wiping away the epithelial tissue as it is ablated. Excision is an excellent method for treatment of upper vaginal lesions in a small area. Occasionally, total vaginectomy will be required for a VAIN 3 lesion occupying the entire vagina. It should be accompanied by a split-thickness skin graft. This aggressive treatment for widespread vaginal lesions should not be used for VAIN 2.

The malignant potential of VAIN appears to be less than that of CIN. In a review of 136 cases of CIS of the vagina over a 30-year period, 4 cases (3%) progressed to invasive vaginal cancer despite the use of various treatment methods (111).

VULVAR INTRAEPITHELIAL DISEASE

Vulvar Dystrophies

In the past, terms such as *leukoplakia, lichen sclerosis et atrophicus, primary atrophy, sclerotic dermatosis, atrophic and hyperplastic vulvitis,* and *kraurosis vulvae* were used to denote disorders of epithelial growth and differentiation (113). In 1966, Jeffcoate suggested that these terms did not refer to separate disease entities because their macroscopic and microscopic appearances were variable and interchangeable (114). He assigned the generic term *chronic vulvar dystrophy* to the entire group of lesions.

The International Society for the Study of Vulvar Disease (ISSVD) recommended that the old *dystrophy* terminology be replaced by a new classification under the pathologic heading *nonneoplastic epithelial disorders of skin and mucosa.* This classification is shown in Table 16-11. In all cases, diagnosis requires biopsy of suspicious-looking lesions, which are best detected by careful inspection of the vulva in a bright light aided, if necessary, by a magnifying glass (115).

The malignant potential of these nonneoplastic epithelial disorders is low, and lesions with atypia are classified as vulvar intraepithelial neoplasia (VIN). Patients with lichen sclerosis and concomitant hyperplasia may be at particular risk (116).

Vulvar Intraepithelial Neoplasia

As with the vulvar dystrophies, there is confusion regarding the nomenclature for VIN. Four major terms are used: *erythroplasia of Queyrat, Bowen disease, carcinoma in situ simplex,* and *Paget disease.* In 1976, the ISSVD decreed that the first three lesions

were merely gross variants of the same disease process and that all of these entities should be included under the umbrella term *squamous cell carcinoma in situ* (stage 0) (92). In 1986, the ISSVD recommended the term *vulvar intraepithelial neoplasia* (Table 16-11).

Table 16-11 Classification of Epithelial Vulvar Diseases

Nonneoplastic epithelial disorders of the skin and mucosa
Lichen sclerosis (lichen sclerosis et atrophicus) Squamous hyperplasia (formerly hyperplastic dystrophy) Other dermatoses
Mixed nonneoplastic and neoplastic epithelial disorders
Intraepithelial neoplasia
Squamous intraepithelial neoplasia VIN 1 VIN 2 VIN 3 (severe dysplasia or carcinoma *in situ*)
Nonsquamous intraepithelial neoplasia Paget disease Tumors of melanocytes, noninvasive
Invasive tumors

VIN, vulvar intraepithelial neoplasia.
From **Committee on Terminology, International Society for the Study of Vulvar Disease.** New nomenclature for vulvar disease. *Int J Gynecol Pathol* 1989;8:83, with permission.

VIN is graded as 1 (mild), 2 (moderate), or 3 (severe or CIS) on the basis of cellular immaturity, nuclear abnormalities, maturation disturbance, and mitotic activity. In VIN 1, immature cells, cellular disorganization, and mitotic activity occur predominantly in the lower one-third of the epithelium, whereas in VIN 3, immature cells with scanty cytoplasm and severe chromatinic alterations occupy most of the epithelium (Fig. 16-18). Dyskeratotic cells and mitotic figures occur in the superficial layer. The appearance of VIN 2 is intermediate between VIN 1 and VIN 3. Additional cytopathic changes of HPV infection, such as perinuclear halos with displacement of the nuclei by the intracytoplasmic viral protein, thickened cell borders, binucleation, and multinucleation, are common in the superficial layers of VIN, especially in VIN 1 and VIN 2. These viral changes are not definitive evidence of neoplasia but are indicative of viral exposure (117). Most vulvar condylomas are associated with HPV-6 and -11, whereas HPV-16 is detected in more than 80% of VIN cases by molecular techniques.
[20] VIN 3 is a neoplastic precursor and can be unifocal or multifocal. Typically, multifocal VIN 3 presents with small hyperpigmented lesions on the labia majora (Fig.

16-19). Some cases of VIN 3 are more confluent, extending to the posterior fourchette and involving the perineal tissues. The term *bowenoid papulosis (bowenoid dysplasia)* was used to describe multifocal VIN lesions ranging from grade 1 to 3. Clinically, patients with bowenoid papulosis present with multiple small pigmented papules (40% of cases) that are usually less than 5 mm in diameter. Most women with these lesions are in their 20s, and some are pregnant. After childbirth, the lesions may regress spontaneously. The term *bowenoid papulosis* is no longer recommended by the ISSVD.

The American College of Obstetrics and Gynecology published a committee opinion on the management of VIN (118). **The report indicates that VIN 1 is no longer considered a precancerous lesion. It is most often an HPV lesion or may be overcalled, and does not require treatment. VIN 2 with p16 positive should be treated in the same manner as VIN 3. VIN 2 lesions with negative p16 can be observed.**

VIN Treatment

The treatment of VIN 3 varies from wide excision to the performance of a superficial or "skinning" vulvectomy (119–122). Although the treatment originally recommended for CIS of the vulva was wide excision, fears that the disease is preinvasive led to the widespread use of superficial vulvectomy (121). Because progression is relatively uncommon, typically occurring in 5% to 10% of cases, extensive surgery is not warranted (119). This is particularly important because many VIN 3 lesions are found in premenopausal women.

The therapeutic alternatives for VIN 3 are simple excision, laser ablation, and superficial vulvectomy with or without split-thickness skin grafting. Excision of small foci of disease produces excellent results and has the advantage of providing a histopathologic specimen. Although multifocal or extensive lesions may be difficult to treat by this approach, it offers the potential for the most cosmetic result. Repeat excision is often necessary but can usually be accomplished without vulvectomy (120,122).

FIGURE 16-18 Carcinoma *in situ* of the vulva (vulvar intraepithelial neoplasia grade 3, VIN 3).

The carbon dioxide laser can be used for multifocal lesions but is unnecessary for unifocal disease. The disadvantages are that it can be painful and costly and does not provide a histopathologic specimen (123).

Superficial vulvectomy is appropriate to treat extensive and recurrent VIN 3 (122). The goal of the surgery is to extirpate all of the disease while preserving as much of the normal vulvar anatomy as possible. The anterior vulva and the clitoris should be preserved if possible. In some patients, the disease extends up the anus, which must be resected. An effort should be made to close the vulvar defect primarily, reserving the use of skin grafts for instances in which the vulvar defect cannot be closed because the resection is so extensive. Split-thickness skin grafts can be harvested from the thighs or buttocks, but the latter is more easily concealed (124).

Paget Disease of the Vulva

Extramammary Paget disease of the vulva (AIS) was described 27 years after the description by Sir James Paget of the mammary lesion that now bears his name (125).

Some patients with vulvar Paget disease have an underlying adenocarcinoma, although the precise frequency is difficult to ascertain.

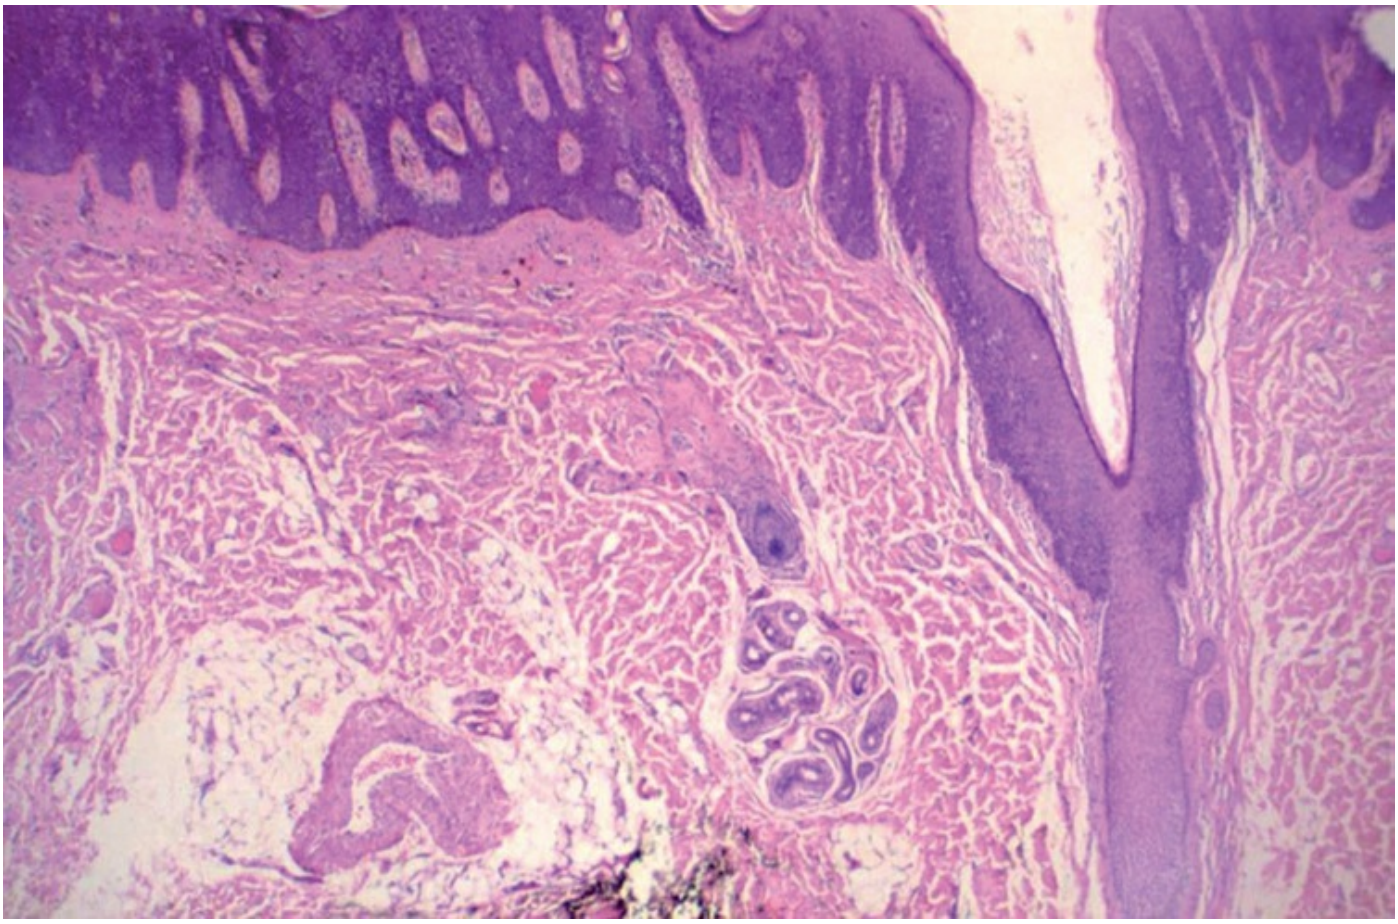


FIGURE 16-19 Vulvar carcinoma *in situ:* carcinoma *in situ* (VIN 3) extending into the hair follicle.

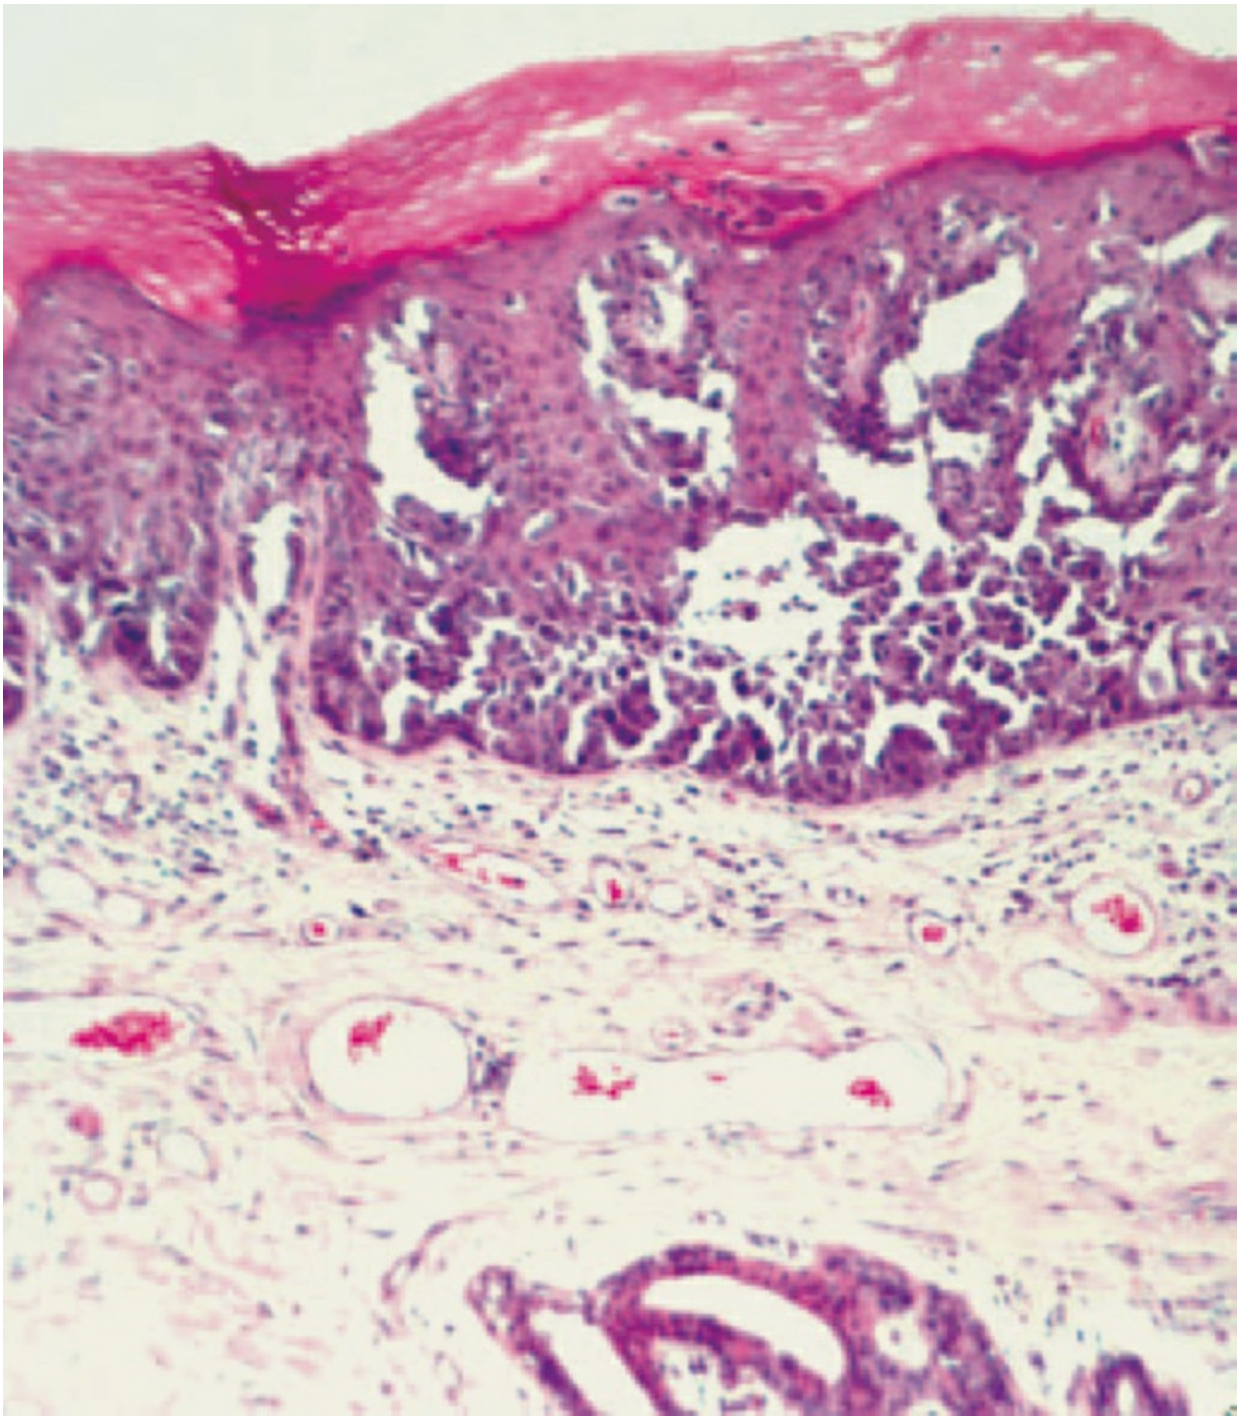

FIGURE 16-20 Paget disease of the vulva. The epidermis is permeated by abnormal cells with vacuolated cytoplasm and atypical nuclei. This heavy concentration of abnormal cells in the parabasal layers is typical of Paget disease.

Histology

Most cases of vulvar Paget disease are intraepithelial. Because these lesions demonstrate apocrine differentiation, the malignant cells are believed to arise from undifferentiated basal cells, which convert into an appendage type of cell during carcinogenesis (Fig. 16-20). The "transformed cells" spread intraepithelially throughout

the squamous epithelium and may extend into the appendages. In most patients with an underlying invasive carcinoma of the apocrine sweat gland, Bartholin gland, or anorectum, the malignant cells are believed to migrate through the dermal ductal structures and reach the epidermis. In such cases, metastasis to the regional lymph nodes and other sites can occur.

Paget disease must be distinguished from superficial spreading melanoma. All sections should be studied thoroughly using differential staining, particularly periodic acid–Schiff (PAS) and mucicarmine stains. Mucicarmine has routinely positive results in the cells of Paget disease and negative results in melanotic lesion.

Clinical Features

Paget disease of the vulva predominantly affects postmenopausal white women, and the presenting symptoms are usually pruritus and vulvar soreness. The lesion has an eczematoid appearance macroscopically and usually begins on the hair-bearing portions of the vulva (**Fig. 16-21**). It may extend to involve the mons pubis, thighs, and buttocks. Extension to the mucosa of the rectum, vagina, or urinary tract is described (126). The more extensive lesions are usually raised and velvety in appearance.

A second synchronous or metachronous primary neoplasm is associated with extramammary Paget disease in about 4% of patients, which is much less common than previously believed (127). Associated carcinomas were reported in the cervix, colon, bladder, gallbladder, and breast. When the anal mucosa is involved, there usually is an underlying rectal adenocarcinoma (116).

Treatment

Unlike squamous cell VIN 3, in which the histologic extent of disease correlates closely with the macroscopic lesion, Paget disease usually extends well beyond the gross lesion (128). This extension results in positive surgical margins and frequent local recurrence unless a wide local excision is performed (129). Underlying adenocarcinomas are apparent clinically, but this finding does not occur invariably; therefore, the underlying dermis should be removed for adequate histologic evaluation. For this reason, laser therapy is unsatisfactory in treating primary Paget disease. If underlying invasive carcinoma is present, it should be treated in the same manner as a squamous vulvar cancer. This treatment usually requires radical vulvectomy and at least an ipsilateral inguinal–femoral lymphadenectomy.

FIGURE 16-21 Paget disease of the labium majus.

Recurrent lesions are almost always *in situ,* although there was at least one report of an underlying adenocarcinoma in recurrent Paget disease (127). It is reasonable to treat recurrent lesions with surgical excision.

Female Genital Mutilation
Conclusion

KEY POINTS

1 Sexual problems are common, especially painful sex. Dyspareunia may affect two-thirds of women during their lifetime. Genito-pelvic penetration pain disorder includes the former term "vaginismus"—an involuntary reflex precipitated by real or imagined attempts at vaginal entry and other types of chronic dyspareunia including the most common type— vestibulodynia, which has a prevalence of 15%.

2 Sexual response reflects the fundamental interplay between the mind and body: psychological, interpersonal, cultural, environmental, and biologic (hormonal, vascular, muscular, neurologic) factors interact and modulate sexual experience.

3 Factors that can affect sexual response include mood, relationship duration and quality, age and stage in life, past sexual experiences—desired, coercive, or abusive— personal psychological factors stemming from relationships in childhood with parental figures, previous losses and traumas, and ways of coping with emotions, current and past illness, fertility concerns, and use of medication, alcohol, and illicit drugs.

4 Sexual dysfunction can arise from gynecologic diseases such as endometriosis; procedures such as those associated with infertility; and treatments including pelvic radiation, urinary incontinence surgeries, and medications, for example, aromatase inhibitors or gonadotropin-releasing hormone (GnRH) antagonists. Sexual abuse can have long-lasting effects on sexuality and women seen in gynecology clinics may have comorbid illnesses that interrupt their sexual function.

5 Physical, psychological, and economic stressors of pregnancy may negatively affect emotional and sexual intimacy. Sexual value systems, folklore, religious beliefs, physical changes, and medical restrictions influence sexual attitudes and behavior during pregnancy and postpartum.

6 Many of the sexual problems couples encounter result from a deficit of knowledge or experience, sexual misconceptions, or inability of the couple to communicate about their sexual preferences.

7 Despite the importance of issues relating to sexuality, many women find it difficult to initiate discussions with their physicians about sexual concerns, and many physicians are uncomfortable discussing sexual issues with their patients. Asking about sexual concerns gives physicians an opportunity to educate patients about the risk of sexually transmitted infections (STIs), encourage safer sex practices, evaluate the need for contraception, dispel sexual misconceptions, and identify potential sexual dysfunction. Many men and women have a number of serial sexual partners but use condoms inconsistently, thereby exposing themselves to STIs and unintended pregnancies.

8 Recent research confirms that 43% of 1,202 American women, including those in poor health, rated sexual health as an important component of quality of life—recording 4 or 5 on a 5-point Likert scale (1). There is need to provide patients with information about normal sexual changes that occur with puberty, pregnancy and postpartum, menopause, and older age as well as in association with gynecologic conditions.

SEXUALITY

The spectrum of normal sexual response varies from one woman to another

throughout a woman's lifetime. Physicians need to be sensitive to their patients' sexual values, attitudes about specific practices, and concerns about their sexuality. Maintaining open communication with patients about their sexuality confirms the physician's willingness to address problems when they arise.

Sexual Activity, Sexual Orientation, and Sexual Attraction

In keeping with recent large surveys, a continuous rather than categorical distribution of sexual orientation is described. Requesting women (and men) to choose between heterosexual, mostly heterosexual, bisexual, mostly gay/lesbian or gay/lesbian, showed that 71% of the total 803 women indicated heterosexual and 6% gay/lesbian while 20% checked "mostly heterosexual" (2). The latter group had more same-sex attraction and, although less frequent than the occurrence of same-sex attraction, more same-sex partners than strictly heterosexual women. This information is important to physicians, to avoid assumptions that sexual attraction and activity necessarily conform to a limited choice of hetero, bi, or gay label leading to potential misunderstanding risks of STI's pregnancy, and sexual dysfunction.

The average age for first intercourse for both men and women in the United States is 17 years and for at least 20% this is without contraception (3). **By age 19, 50% of women have had intercourse but while some 86% report using contraception on their last occasion of intercourse, only 1 in 5 women use dual protection** (4). **Many men and women have serial sexual partners and even older adults use condoms inconsistently, thereby exposing themselves to sexually transmitted infections (STIs) and unintended pregnancies.** A recent large British survey found that 22.8% of women reported one or more sexual difficulties including problematic orgasm, low sexual interest, and arousal or painful sex. Applying the new criteria to designate a sexual disorder as listed in the American Psychiatric Association's *Diagnostic and Statistical Manual,* fifth version (DSM-5) (5), 3.6% of the total met all three criteria (6). These criteria include symptom persistence for >6 months, symptom presence in >75% of occasions, and associated distress. The study excluded nonsexually active women some of whom may have stopped activity as a result of sexual dysfunction.

Genital Anatomy

For most women, their clitoral tissue is the most sexually sensitive part of their anatomy, and its stimulation produces the most intense sexual feelings and the most intense orgasms. Many women first need to experience both nonphysical and nongenital physical stimulation before clitoral stimulation can be enjoyed. In the absence of arousal, direct clitoral stimulation can be unpleasant and be perceived as so

intense as to be painful. Immunohistologic studies identified neurotransmitters thought to be associated with sensation concentrated right under the epithelium of the glans clitoris. Clitoral tissue extends far beyond the visible portion when the clitoral hood is retracted. It includes the clitoral head, shaft, rami running along the pubic arch, periurethral tissue in front of the anterior vaginal wall, and the bulbar tissue under the superficial perineal muscles surrounding the anterior distal vagina—such that sexual sensations and arousal arise from massaging these areas, not just the clitoral shaft and head. Other sexually sensitive areas include the nipples, breasts, labia, much of the skin generally, and to some extent, the vagina. Although the lower third of the vagina is responsive to touch, the upper two-thirds are sensitive primarily to pressure. The rich supply of nerves in the fascia anterior to the upper vagina (Halban's fascia) and the proximity of the clitoral type of spongy tissue around the urethra anterior to the vagina contribute to the pleasurable sensations of intercourse. Many women experience orgasm more easily from direct clitoral touch, possibly provided at the same time as intercourse.

There is speculation about the existence of a "G-spot," an area of the vagina, located anteriorly midway between the symphysis pubis and cervix, which can be exquisitely sensitive to deep pressure. Stimulation of this area can be associated with orgasm and loss of fluid which can be dilute urine or fluid from Skene's glands (7). Women who are normally continent might leak urine at orgasm; urodynamic studies have demonstrated that orgasm may provoke uninhibited detrusor overactivity and sometimes sphincter relaxation. Usually medical intervention is not needed.

Sexual Response Cycle

[2] Sexual response reflects the fundamental interplay between the mind and body: psychological, interpersonal, cultural, environmental, and biologic (hormonal, vascular, muscular, neurologic) factors interact and modulate sexual experience. At the outset of sexual engagement, especially in new relationships, women may sense heightened sexual desire. However, in long-term relationships, women (and men), may be motivated by factors other than, or additional to, sexual desire (8). Women initiate or consent to sex for many reasons, including a wish to increase emotional intimacy with their partners (9,10). By directing her attention to sexual sensations from stimulation (physical, visual, fantasy, auditory), a woman's subjective sexual arousal/pleasure/excitement develops and triggers sexual desire. Desire and arousal coexist and compound each other **(Fig. 17-1)**. Sexual satisfaction (with one, many, or no orgasms) can be achieved if she can retain focus, continue to enjoy sensations of arousal, if the duration of stimulation is sufficiently long, and there is no negative outcome (e.g., pain or partner dysfunction). The response is circular, with phases overlapping and in variable order (e.g., desire may follow arousal, and higher arousal

may follow the first orgasm). Desire, once triggered, increases the motivation to respond to sexual stimuli and to agree to or request more intensely erotic forms of stimulation. Any initial spontaneous desire will augment the response. This circular type of sequence can be experienced multiple times on any one occasion of sexual interaction. This motivation/incentives module reflecting the importance of the mind's appraisal of sexual stimuli is supported by empirical research (10–12).

Physiology

Desire and Arousability

Sexual desire provides one of many motivations to be sexual. Feelings of desire and arousal may be triggered by internal (e.g., fantasies, memories, feelings of arousal) and external (e.g., an interested and interesting partner, visual or written erotica) stimuli. Sexual cues are dependent on adequate neuroendocrine function. Multiple neurotransmitters, peptides, and hormones modulate desire and subjective arousal (13). Substances that promote sexual response include norepinephrine, dopamine, oxytocin, melatonin, and serotonin acting on some receptors. Prolactin, serotonin acting on other receptors, endocannabinoids, opioids, and γ-aminobutyric acid inhibit sexual response. These peptides and neurotransmitters are themselves modulated by sex hormones that direct the synthesis of enzymes involved in the production of neurotransmitters and the synthesis of their receptors. Biologic factors do not act independently from environmental factors, a finding in human and animal models. Dopamine and progesterone, acting on receptors in the hypothalamus, facilitate sexual behavior in female rats following oophorectomy and received estrogen. The presence of a male animal in an adjacent cage caused an identical change in sexual behavior (14). Likewise, ability to be aroused and intensity of response can be increased in some women by giving them a modest dose of testosterone, by administering *bupropion* (dopaminergic), or by a change of partner (8,15,16). Even in rodents, complex networks exist whereby the female assesses the context of potential sexual activity and relates it to past experience and expectation of reward (17). In women, sexual interest is influenced by their mood, psychological mindset, beliefs and values, expectations, sexual orientation, preferences, and the presence of a safe and erotic environmental setting. Even in the absence of a clinical depression, negative affect is found to negatively modify sexual function while the sexual experiences modulate affect the next day (18,19). Moreover, other research concludes that cognitive factors (i.e., lack of erotic thoughts and being distracted or concerned about sexual behavior) were the best predictors of difficulty in triggering sexual desire: other dimensions including relationship factors, psychopathology, and medical problems appeared to have an indirect impact on sexual desire with the cognitive factors acting as the mediators (20). Sexual desire, interest, and arousability are most strongly influenced by mental health

and feelings for the partner, both generally and specifically, at the time of sexual interaction (21–23). Sexual desire is strongly influenced by fatigue; as a result, sex late at night is not usually attractive to busy individuals. Similarly, chronic illness typically reduces desire and arousability (24).

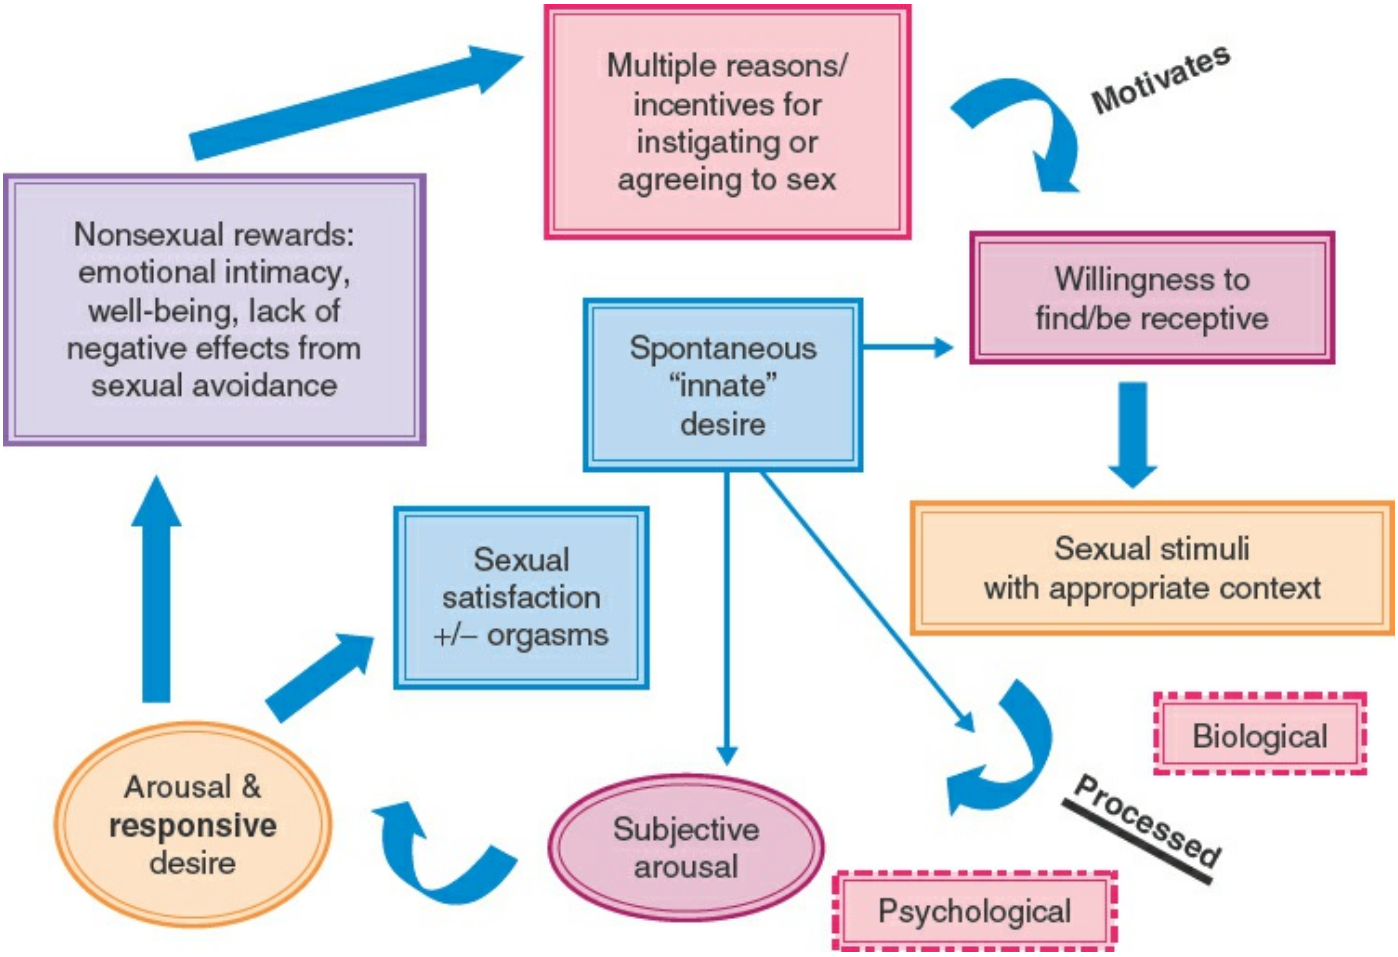

FIGURE 17-1 The blended sex response cycle showing the many reasons/incentives for initiating/accepting sexual activity.

Sexual Arousal

Recent brain imaging reflects the complexity of sexual arousal, confirming that multiple networks in the brain are involved in sexual response. Brain imaging of healthy people during visual sexual stimulation identifies a model of sexual arousal involving complex brain circuitry, including cortical, limbic, and paralimbic areas known to be involved in cognition, motivation, and emotions linked to changes within the autonomic nervous system (25). Specific inhibitory regions deactivate these sexual responses (26). In a small study, sexually functional surgically menopausal women, receiving no hormonal therapy, viewed erotic videos during functional magnetic resonance imaging. The women failed to show the brain activation typical of premenopausal women and also typical of themselves when they were treated with both

testosterone and estrogen, and yet, they reported sexual arousal from the erotic videos with, and without, hormonal supplementation (27). Recent work on brain activation during subliminal and supraliminal sexual stimuli shows an interesting difference between male and female subjects. Exposure to supraliminal sexual images was associated with activation in arousal-related areas and in inhibitory regions in both men and women. Exposure to subliminal sexual images was associated mainly with activation in the arousal-related areas, and in women there was increased activation in some inhibitory regions, but that did not appear in men. This suggests that when women appraise stimuli as sexual, there will be both arousal and control responses—even when the sexual cues are subliminal. The authors note that the various outcomes associated with sex including pregnancy and abuse, pose a relatively bigger potential threat to women than to men (28).

Accompanying the subjective excitement and erotic feelings of arousal are a number of physical changes. These changes include genital swelling; increased vaginal lubrication; engorgement of the breasts and nipple erection; increases in skin sensitivity to sexual stimulation; changes in heart rate, blood pressure, muscle tone, breathing, body temperature; mottling of the skin; and a "sex flush" of vasodilatation over the chest, breasts, and face. With sexual stimulation, brain function in the hypothalamus and other areas influencing the genital response is activated, triggering the autonomic nervous system to allow increased blood flow to the vagina. Vasodilatation of the arterioles in the submucosal vaginal plexus increases transudation of interstitial fluid, which moves from capillaries between the epithelial intercellular spaces and into the vaginal lumen. Simultaneously, the autonomic nervous system allows relaxation of the smooth muscle cells surrounding blood spaces (sinusoids) in the extensive clitoral tissue and labia, causing clitoral swelling and vasodilatation in the labia. Immunohistologic studies indicate nerves containing nitric oxide are present in the genital skin covering the clitoris and labia.

With arousal, the vagina lengthens, distends, and dilates, and the uterus elevates out of the pelvis. With increased sexual stimulation, vasocongestion reaches a maximum intensity. Genitally, the labia become more swollen and darker red and the lower third of the vagina swells and thickens to form an "orgasmic platform." The clitoris becomes more swollen and elevates to a position near the symphysis pubis, and the uterus elevates fully out of the pelvis. The breasts become more engorged, the skin more mottled, and the nipples more erect.

The neurobiology of arousal is incompletely understood but the genital vasocongestive responses appear to be highly automated, occurring within seconds of an erotic stimulus (12). Pelvic autonomic nerves release nitric oxide and vasoactive intestinal polypeptide (VIP), mediating vasodilatation. Acetylcholine (ACh) blocks noradrenergic vasoconstrictive mechanisms and promotes nitric oxide release from

endothelium. Some pelvic autonomic nerves primarily release (vasoconstrictive) noradrenaline and adenosine triphosphate, but others release ACh, nitric oxide, and VIP. Recent work suggests all pelvic autonomic nerves are sympathetic (29). Nitric oxide is thought to be the major neurotransmitter involved in vulvar engorgement. In the vagina, VIP, nitric oxide, and other unidentified neurotransmitters are involved.

Even in women without any sexual dysfunction, there is highly variable correlation between the degree of subjective sexual excitement and the increase in congestion around the vagina (12). This poor correlation was shown repeatedly over the past 39 years based on psychophysiologic studies using the vaginal photoplethysmograph. Congestion in response to a sexual video is reduced in women with disruption of the autonomic nerves supplying the vulva and vagina (e.g., from nonnerve-sparing radical hysterectomy). Otherwise healthy women complaining of absent sexual arousal show increases in vaginal congestion from erotic stimuli that are similar those in control women (12).

Laboratory-demonstrated reflexes may be involved in the physiology of arousal. A cervicomotor reflex can be elicited from cervical touch with a balloon-tipped catheter to replicate penile pressure, causing a reduction in pressure in the upper portion of the vagina and an increase in pressure in the middle and lower portions. Simultaneously, an increase in electromyographic activity in the levator ani and puborectalis muscles was recorded. It is thought that during intercourse penile thrusting on the cervix might cause contraction of the pelvic muscles to facilitate "ballooning" of the upper vagina, perhaps to facilitate pooling of semen. The same muscle contraction constricts the lower vagina, which may afford increased stimulation of the partner's penis, thereby maintaining rigidity (30). A further reflex demonstrated in laboratory studies shows reduced uterine tone in response to mechanical or electrical stimulation of the glans of the clitoris. Background activity of the uterine muscle was abolished by clitoral stimulation, but not if either the glans clitoris or the uterus was anesthetized. Uterine pressure decreased with clitoral stimulation. This reflex may underlie the known increase in size and the elevation of the uterus with sexual arousal (30).

Orgasm

Orgasm is a brain event, typically triggered by genital stimulation, but can occur during sleep or from stimulation of other body parts including the breast and nipple or by fantasy, occasionally by medication, and in spinal cord injured women by vibrostimulation of the cervix. In able-bodied women, it involves a myotonic response of smooth and striated muscle associated with feelings of sudden release of the sexual tension built up during arousal. It is described as the most intensely pleasurable of the sexual sensations. Reflex rhythmic contractions (3 to 20, 0.8/s) of the muscles surrounding the vagina and anus occur. Some women may subjectively perceive uterine contractions during orgasm and some may report a difference in their

perception of orgasm after hysterectomy, but this is not objectively documented. An objective quantitative measure was established that shows strong correspondence with the subjective experience of orgasm. Rectal pressure while volunteers imitated orgasm, tried to achieve orgasm and failed, or experienced orgasm was significantly different during orgasm as opposed to both control tasks (31).
