anastomosis. Those with segmental resection (hemicolectomy) had the worst outcome. None of the studies had a comparison group, and outcomes were variable and lacking validated measures. Morbidity associated with the operation included small bowel obstruction (median 18%, range 2% to 71%), need for reoperation (median 14%, range 0% to 50%), diarrhea (median 14%, range 0% to 46%), fecal incontinence (median 14%, range 0% to 52%), recurrent constipation (median 9%, range 0% to 33%), persistent abdominal pain (median 41%, range 0% to 90%), and permanent ileostomy (median 5%, range 0% to 28%). Mortality ranged from 0% to 6% (184). A QoL study revealed that the score correlated poorly with frequency of bowel movements. However, a lower score was seen in those patients who had persistent abdominal pain, diarrhea, fecal incontinence, and permanent ileostomies. Overall satisfaction with the procedure was very high and correlated with the QoL score (221,222). **Surgical alternatives to subtotal colectomy include ileostomy, cecostomy with antegrade continence enemas, and sacral nerve stimulation.** Subtotal colectomy has never been directly compared with ileostomy, but those who had a permanent diversion after subtotal colectomy had lower QoL scores. Patients undergoing cecostomy with antegrade continence enemas can expect to have satisfactory function approximately one-half of the time, with most requiring additional revision procedures secondary to stomal complications (223). Although sacral nerve stimulation has primarily been used for fecal incontinence, the results of a few small studies evoked optimism for its use in chronic constipation and slow-transit constipation (224–226). The Cochrane review of sacral nerve stimulation for fecal incontinence and constipation cannot support its use for constipation as the two trials included did not improve symptoms in patients with constipation (126).

Pelvic Organ Prolapse

Women with defecatory dysfunction or fecal incontinence may have a concomitant posterior vaginal wall prolapse (rectocele). The variety of surgical treatment techniques for the repair of rectocele include posterior colporrhaphy, defect-directed repair, transanal repair, and abdominal repair with sacral colpopexy. When an enterocele is present, a culdoplasty usually is performed. In cases of perineal descent, abdominal sacral colpoperineopexy is the procedure of choice. Suture rectopexy can be performed in conjunction with sacral colpoperineopexy if rectal prolapse is present. **Despite the routine use of these procedures, data are limited regarding symptomatic improvement of disordered defecation. Rectocele repair is indicated for bothersome prolapse bulge symptoms and not to be done with the intent of correcting disordered defecation.** A systematic review and practice recommendation out of the United Kingdom confirms that the use of rectovaginal reinforcement procedures for the purpose of improving constipation symptoms is not supported by the literature (227). Greater detail regarding the specific techniques for

many of these procedures will be provided in Chapter 30. This section will focus on surgical outcomes, including anatomic cure of prolapse, improvement of defecatory dysfunction symptoms, and morbidity associated with the procedure.

Posterior Colporrhaphy

Posterior colporrhaphy has been the surgical procedure for rectocele repair preferred by gynecologic surgeons for more than 100 years. Traditional posterior colporrhaphy narrows the vaginal caliber through plication of the rectovaginal septum and usually includes a perineorrhaphy, which narrows the introitus. Despite its broad use, there is a paucity of data regarding long-term anatomic success, symptomatic improvement, and sexual function following the procedure. The outcomes of several studies are summarized in Table 31-15 (228–247). Anatomic cure and relief of vaginal bulge occurred in 76% to 96% of patients. In these studies, the procedure was ineffective at treating constipation, vaginal digitations (splinting), and fecal incontinence. Dyspareunia developed in 7% to 26% of patients with and without levator plication (228–232,248). As early as 1961, high rates of dyspareunia have been reported with this procedure in as many as 50% of patients (249).

The successful anatomic support obtained with this procedure is offset by the modest relief of functional symptoms and high rate of *de novo* dyspareunia. However, a prospective case series of 38 women undergoing posterior colporrhaphy along with concomitant procedures for rectocele and obstructed defecation revealed markedly different results (250). Fascial plication was performed without levator plication, and perineal body reconstruction rather than routine perineorrhaphy was employed when indicated. Anatomic cure rate was 87% at 12 months and 79% at 24 months. Subjective cure rate was 97% at 12 months and 89% at 24 months. There was significant improvement in preoperative and postoperative symptoms for constipation (76% vs. 24%), digitations (100% vs. 16%), awareness of prolapse (100% vs. 5%), obstructed defecation (100% vs. 13%), and dyspareunia (37% vs. 5%). There was no difference in fecal incontinence and only one case of *de novo* dyspareunia. The authors attribute their improved anatomic and functional outcomes and combined improvement in dyspareunia to exclusion of levator plication, perineorrhaphy, and excision of vaginal epithelium. An additional benefit may be derived during mobilization of the vaginal epithelium, when scar tissue from prior episiotomy or surgery is divided. They found that preoperative defecating proctography was of limited value and have stopped its routine use as part of the preoperative evaluation for women with symptomatic rectoceles and obstructive defecation. This group has developed a classification system of the perineum that can help surgeons decipher when to use a perineorrhaphy and when to exercise less aggressive perineal reconstructive techniques (251).

Defect-Directed Repair

The goal of a defect-directed repair or site-specific repair is to restore normal anatomy (38). This procedure can be combined with a perineal body reconstruction, if necessary, but usually does not routinely involve perineorrhaphy. Table 31-15 lists the anatomic and functional outcomes for this type of repair. **Anatomic cure rates range from 82% to 100%, which are similar to those for posterior colporrhaphy. This procedure resulted in modest improvement for symptoms of difficult evacuation, vaginal bulge, and vaginal digitations** (234–238,248). Constipation symptoms significantly decreased in only one study (233,234). All studies reported low rates of *de novo* dyspareunia with good functional and anatomic outcomes, but the long-term durability of the procedure is unknown. All but one of these studies included concomitant prolapse and urinary incontinence procedures.

A randomized clinical trial of 106 women with stage II or greater posterior vaginal wall prolapse compared posterior colporrhaphy, defect-directed rectocele repair, and defect-directed repair augmented with a porcine small intestinal submucosal (252). Subjects completed validated pelvic floor instruments at baseline and 6 months, 1 year, and 2 years after surgery. Anatomic failure was defined as pelvic organ prolapse quantitation system (POPQ) point Bp > or = –2 at 1 year. There was a significant improvement in prolapse and colorectal scales in all groups with no differences between groups. The proportion of subjects with functional failures was 15% overall, and not significantly different between groups. **Posterior colporraphy and defect-directed repairs resulted in similar anatomic and functional outcomes, although the addition of a porcine-derived graft did not improve anatomic outcomes.** On average, all bowel symptoms evaluated were significantly improved 1 year after surgery, with no differences between treatment groups. The development of new "bothersome" bowel symptoms after surgery was uncommon (11%). After controlling for age, treatment group, comorbidities, and preoperative bowel symptoms, corrected postoperative vaginal support (stage 0/I) was associated with a reduced risk of postoperative straining (adj. OR 0.17 95% CI 0.03–0.9) and feeling of incomplete emptying (adj. OR 0.1 95% CI 0.01–0.52). **This led the authors to conclude that resolution or improvement in bowel symptoms can be expected in the majority of women after rectocele repair (**253). A similar study conducted in 2012 concluded that the underlying cause of the defecatory symptoms will likely dictate whether or not a woman finds improvement after rectocele repair and that women should be counseled that their defecatory symptoms and bowel habits may or may not improve after rectocele repair (233).

Transanal Repair

Transanal repair involves repair of the rectocele through a transanal incision with excision of redundant rectal mucosa and plication of the rectovaginal septum and

rectal wall. The procedure was developed and is primarily used by colorectal surgeons to treat constipation or obstructed defecation associated with "low" or distal rectoceles. The advantages of this approach include excision of redundant rectal mucosa and the ability to treat other anorectal pathologies, such as hemorrhoids or anterior rectal wall prolapse (254). Disadvantages include the inability to repair higher rectoceles, enteroceles, cystoceles, uterine prolapse, and defects in the perineal body or anal sphincter (255). Major complications of infection (6%) and rectovaginal fistula (3%) are relatively common compared to transvaginal repairs (202). Most studies did not require vaginal bulging or protrusion symptoms as a prerequisite for surgery. The results of several studies are summarized in **Table 31-15**. The anatomic cure rate was 70% to 98%, and symptoms of constipation, difficult evacuation, and vaginal digitations appeared to improve (243–248).

Reviews to compare transanal with transvaginal rectocele repair use the results of two small, randomized control trials (256–259). Women with compromised sphincter function and other symptomatic prolapse were excluded. **The results for transvaginal repair were superior to those for transanal repair with respect to subjective failure rate** (relative risk [RR] 0.36, 95% CI 0.13 –1) and objective failure rate (RR 0.24, 95% CI 0.09–0.64) (256). In one study, a significant decrease occurred in the depth of rectocele on postoperative defecography for the transvaginal group compared with the transanal group (2.73 cm vs. 4.13 cm, respectively) although the depth of rectocele on imaging does not correlate with symptoms (259). The transvaginal group had fewer problems with bowel evacuation, but this finding was not statistically significant. In one study, researchers discovered that 38% of patients developed fecal incontinence following transanal repair (228). In the two randomized trials, no significant differences were seen in the rate of fecal incontinence or dyspareunia, but the studies were underpowered to detect a difference (258,259). **Although a vaginal approach has been considered superior to a transanal approach for rectocele repair, studies are retrospective and impossible to compare because the indications for transanal repairs are generally different from those for transvaginal repairs.**

Posterior Fascial Reinforcement

Rectocele repair with graft augmentation became commonplace in the early to late 2000s despite a paucity of supporting evidence indicating its benefits over standard procedures. The reason for its emergence was the theory that vaginal hernia repairs behave similarly to abdominal hernia repairs, which have a documented decrease in recurrence when augmented with grafts. A variety of graft materials have been employed with posterior colporrhaphy and defect-directed repairs including autograft, allograft, xenograft, and synthetic mesh. Polypropylene type I monofilament, macroporous synthetic mesh is associated with lower complication rates compared with other nonabsorbable synthetic materials (260). The purpose of the graft is debatable. It

can either be intended to replace existing fascia as a permanent barrier or to provide an absorbable scaffold for collagen deposition, scar formation, and remodeling. The ideal material should have a low erosion rate, be relatively inexpensive, and decrease recurrence rates without causing bowel or sexual dysfunction. Experience has demonstrated that although reinforcement with graft augmentation may result in better anatomic outcomes, there is no difference in subjective success at the cost of higher complications such as mesh erosion and extrusion (261,262). Improvements in objective outcomes are limited to the anterior vaginal wall and do not extend to multicompartment or posterior vaginal wall mesh (261), thus confirming no role for synthetic mesh augmentation for posterior repair. **There is no evidence to suggest that the addition of a graft to the posterior compartment improves outcomes** (252,261–263).

Abdominal Rectocele Repair

The abdominal approach to rectocele repair may be of value when a superior defect in the rectovaginal fascia occurs in a patient with accompanying enterocele, uterine prolapse, or vault prolapse. If a patient is undergoing an abdominal or laparoscopic procedure such as a sacral colpopexy, the graft can be extended along the posterior vaginal wall to correct proximal defects in the rectovaginal septum (264). There are limited data regarding the efficacy of abdominal rectocele repair. The indication for this procedure, and the need for additional vaginal repair of distal defects, often is determined intraoperatively. An ancillary study from the Pelvic Floor Disorders Network evaluating bowel symptoms 1 year after sacrocolpopexy found that the majority of bothersome bowel symptoms resolve after this procedure. There was no difference in postoperative bowel symptoms among those who underwent a concomitant rectocele repair and those who did not. The study was not developed to evaluate the impact of concomitant rectocele repair on bowel symptom resolution and those who underwent a rectocele repair had more severe baseline bowel symptoms including worse obstructive symptoms (265).

Sacral Colpoperineopexy for Perineal Descent

Sacral colpoperineopexy is a modification of sacral colpopexy aimed at correction of apical prolapse combined with rectocele and perineal descent (39). A continuous graft is placed from the anterior longitudinal ligament of the sacrum down to the perineal body. This procedure can be accomplished either through a total abdominal approach or a combined abdominal and vaginal procedure. **If performing a total abdominal approach, the rectovaginal space is opened, and the rectum is dissected off the posterior vaginal wall and rectovaginal septum toward the perineal body. The graft is sutured to the perineal body or as close to it as possible.** A rectovaginal examination with the surgeon's nondominant hand facilitates this attachment by supporting the perineal body. The graft is secured to additional points along the

posterior vaginal wall and apex, and sacral colpopexy is completed in the usual fashion.

If performing a combined abdominal and vaginal approach, the graft is secured to the perineal body vaginally. The posterior vaginal wall is opened, and a defect-directed rectocele repair is performed. Sacral colpopexy is accomplished in the usual fashion except that the vaginal dissection is opened superiorly, creating a window to the abdominal dissection. The graft can be passed down from the abdominal field to the vaginal field and anchored inferiorly to the perineal body and laterally to the arcus tendineus fascia rectovaginalis **(Fig. 31-9)**.

Short-term outcomes for 19 patients who underwent sacral colpoperineopexy indicated good anatomic results for apical and posterior support and for perineal descent (39). Complete cessation of defecatory dysfunction symptoms was accomplished in 66% of patients. In a report of outcomes for a slightly different variation of the sacral colpoperineopexy, the authors' technique involved attachment of Marlex mesh to the perineal body using a needle carrier (266). The failure rate was 25% and mesh erosion rate was 5% for 205 patients with up to 10-year follow-up. A study of Mersilene mesh erosion rates related to sacral colpopexy and sacral colpoperineopexy noted similar erosion rates between sacral colpopexy and colpoperineopexy when the vagina was not opened, 3.2% versus 4.5%, respectively (267). However, the erosion rate was 16% with vaginal suture placement and 40% when the mesh was placed vaginally. The use of nonsynthetic grafts such as dermal allograft and xenograft may help prevent high erosion rates. In a case series of 11 patients, researchers performed sigmoid resection (if indicated) and suture rectopexy in conjunction with sacral colpoperineopexy using Alloderm for women with coexistent rectal prolapse, perineal descent, and defecatory dysfunction. Early follow-up (12.5 ± 7.7 months) revealed excellent improvement of defecatory dysfunction symptoms and QoL considerations, with an 82% cure of perineal descent (268). A retrospective cohort of 38 women revealed high satisfaction following abdominal sacral colpoperineopexy despite the persistence of obstructed defecation symptoms 5 years after surgery (269,270). **Sacral colpoperineopexy may have value for a select group of patients**, but larger prospective series with long-term anatomic and symptomatic outcomes are necessary to evaluate the durability of this procedure.

Rectal Prolapse

Rectal prolapse is an uncommon pelvic floor disorder with an incidence below 1% of the adult population; however, risk factors are similar between rectal prolapse and pelvic organ prolapse. Although considered a benign condition, symptoms can significantly negatively impact QoL. These include pain, bleeding, seepage, defecatory dysfunction, fecal incontinence, and mass symptoms. The prolapse may be occult (internal intussusception-producing symptoms but no visible protrusion), partial (mucosal prolapse only) or full thickness (all layers of the rectum come through the anus

as concentric rings). Prolapsed internal hemorrhoids are sometimes confused with rectal prolapse but are treated differently.

Although medical management may ease symptoms of rectal prolapse, a surgical consultation is usually warranted**. Surgical management is usually reserved for full-thickness complete rectal prolapse.** A number of surgical procedures are described for the treatment of rectal prolapse and are broadly categorized into perineal or abdominal approaches. The most commonly utilized perineal approaches are the Delorme procedure, which includes resection of redundant rectal mucosa and plication of redundant rectal mucosa, and the Altemeier (perineal rectosigmoidectomy) procedure that includes perineal resection of full-thickness rectum. These perineal approaches offer easier recuperation for patients, but have been considered to be less definitive in terms of preventing recurrent rectal prolapse. The abdominal approaches have been considered to be more durable, but with a higher incidence of surgical complications and more difficult recovery. This belief and practice that abdominal approaches have significantly lower recurrence rates has come from observational studies, but several randomized controlled trials, two Cochrane reviews, and a third systematic review have not been able to demonstrate this distinction (271). A true benefit/risk comparison of perineal and abdominal approaches is complicated by the significant variations in abdominal approaches, with major variations in; whether the retrorectal space is dissected, whether mesh is utilized, and whether a concurrent sigmoid resection is performed. Laparoscopic and robotic variations of these approaches have been described in an attempt to minimize the recovery time.

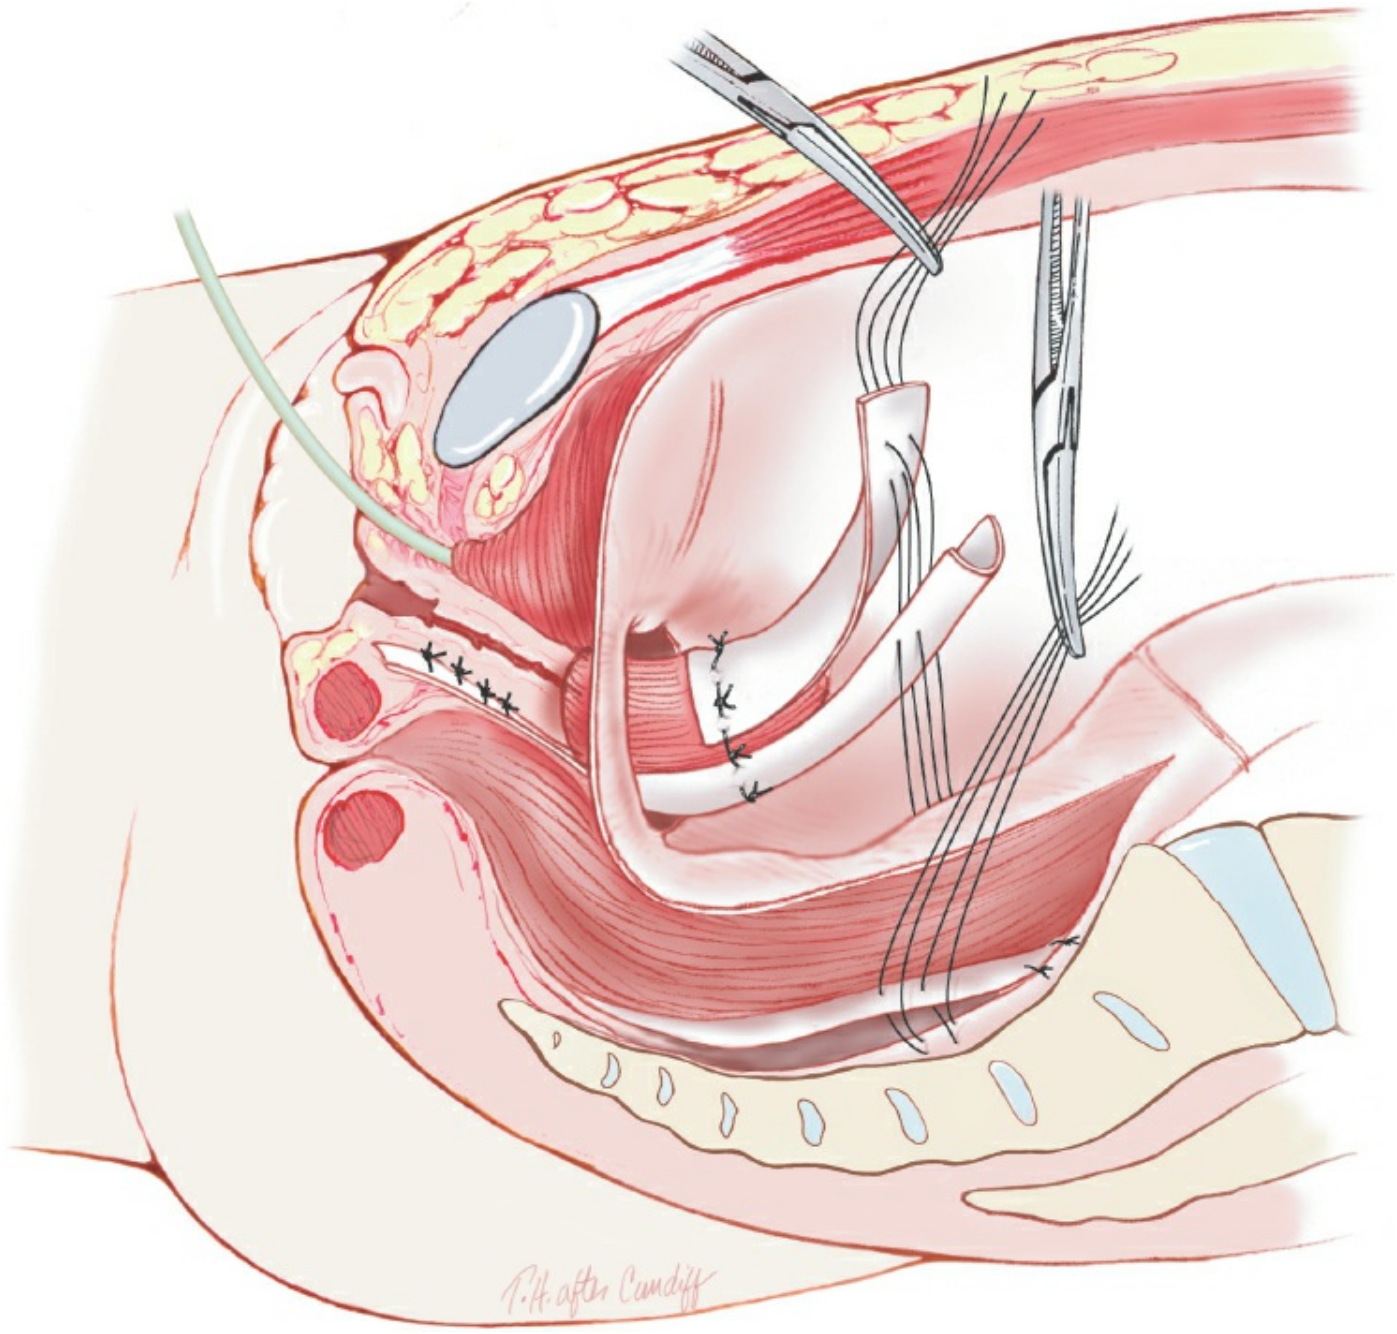

FIGURE 31-9 Abdominal sacral colpoperineopexy with sigmoid resection and suture rectopexy. This sagittal view shows the posterior graft sutured to the rectovaginal fascia and perineal body after defect-directed rectocele repair. The anterior graft is sutured to the pubocervical fascia. Both sheets will be secured to the sacral periosteum to the right of the rectum. Rectopexy sutures (*left*) have not yet been tied and secured. (Courtesy of Geoffrey W. Cundiff, MD.)

Perineal Procedures

Perineal procedures are more easily tolerated because they avoid laparotomy. They are ideal for patients at high-risk for perioperative and postoperative morbidity and mortality. There are basically two perineal procedures: the *Delorme procedure* and *perineal rectosigmoidectomy* (Altemeier operation). Perianal

encirclement procedures such as the Thiersch procedure are no longer used because of poor success rates, high recurrence rates, and fecal impaction.

The **Delorme procedure** was first described in 1900 and involves separation of the rectal mucosa from the sphincter and muscularis propria, followed by resection of the rectal mucosa, and plication of the distal rectal wall (muscularis propria) (272) **(Fig. 31-10)**. Recurrence rates range from 10% to 15% (273–276) and there is a low morbidity of 4% to 12%, which includes infection, urinary retention, bleeding, and fecal impaction. The recurrence rates were originally thought to be up to 38% (277), but new evidence indicates the range may be acceptable to patients who are eligible for abdominal surgery. There is a general improvement in fecal incontinence and constipation. Fecal incontinence, chronic diarrhea, and severe perineal descent are associated with failure of this procedure (278). The Delorme operation may be preferred in cases where the prolapsing segment is shorter than 3 to 4 cm or there is no circumferential full-thickness prolapse, making perineal rectosigmoidectomy difficult to perform (277,279).

Perineal rectosigmoidectomy (Altemeier operation) involves a transanal full-thickness resection of the prolapsed rectum and a coloanal anastomosis (280). Recurrence rates are described up to 30% but the only two randomized controlled trials comparing the Altemeier approach to an abdominal approach showed no statistically significant difference in recurrence rates, although the studies were not powered to show this (271). Patients generally have minimal pain and a relatively uneventful postoperative course. Recurrent prolapse probably reflects inadequate resection. Incontinence results are modest but seem to improve substantially with the addition of levatorplasty. The addition of levatorplasty appears to decrease the short-term recurrence rate (281), but there is no significant change in constipation with this procedure. Most agree that perineal rectosigmoidectomy with levatorplasty is the best procedure for very elderly patients and those with profound comorbidity. This is the preferred approach for patients with incarcerated, strangulated, or even gangrenous prolapsed rectal segments who are not candidates for abdominal rectopexy.

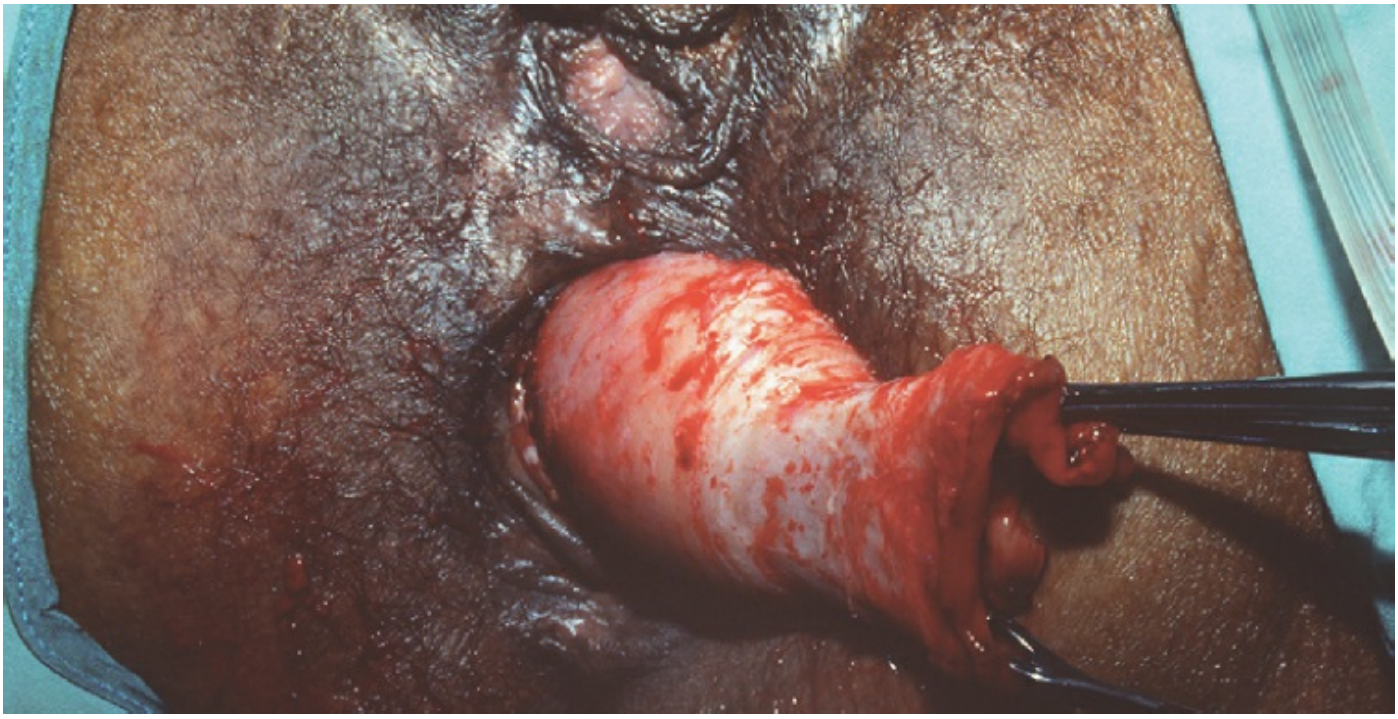

FIGURE 31-10 Delorme procedure. After mucosal stripping to the full extent of the prolapse, the circular smooth muscle or the rectum is plicated. A mucosa-to-mucosa anastomosis is then performed.

Abdominal Procedures

Abdominal procedures vary with respect to the extent of rectal mobilization, method of rectal fixation, and inclusion or exclusion of bowel resection.

The posterior approach is the most established and studied abdominal procedure. It begins with dissection of the retrorectal space to and beyond Waldeyer fascia. This dissection optimizes support by promoting fibrosis of the rectum to the sacrum, and includes the division of the lateral ligament stalks with a theoretical potential to cause an increased postoperative constipation as a result of rectal denervation. This association is supported by a Cochrane review of 15 randomized controlled trials (282). This may be balanced by a lower recurrence rate and may make this an attractive option for patients with fecal incontinence. The alternative to the posterior approach is the ventral rectopexy.

The posterior procedures include some method for anchoring the posterior rectum to the anterior sacrum. If performing a suture rectopexy, the fascia propria of the rectum is secured with sutures to the sacral periosteum from S1–S3 (283). The alternative is one of the mesh rectopexies**, posterior mesh rectopexy (Wells procedure), anterior mesh rectopexy (Ripstein, modified Ripstein), and ventral mesh rectopexy** (271,284,285). A variety of materials have been used for these procedures, including absorbable, autologous, and permanent mesh. The assumption is that the intervening material will provide increased support through increased fibrosis. The posterior mesh rectopexy has the mesh secured to the sacrum between the posterior rectum and the sacral promontory.

The ventral mesh rectopexy offers an alternative approach to the posterior approach. The ventral mesh rectopexy incorporates an anteriorly placed mesh support for fixation of the rectum to the sacral hollow. Rather than entering the retrorectal space, the rectovaginal septum is dissected to expose the proximal two-thirds of the rectovaginal septum (Denovillier fascia). A synthetic or biologic mesh buttress is sutured to the anterior wall of the rectum at the point of its intussusception and suspended to the sacral promontory. The available studies show acceptable short- and long-term complication rates (271). **There is insufficient evidence to argue that posterior rectal prolapse repairs are better or worse than anterior rectal prolapse repairs such as ventral mesh rectopexy** (271).

Aside from the dissection, and method of attachment, another surgical variation is performing a concurrent sigmoid resection with the rectopexy (Frykman–Goldberg resection rectopexy). The bowel resection is performed after mobilization and before suturing (286). The theoretical advantages of a rectosigmoid resection are: removal of abundant rectosigmoid, avoiding torsion or volvulus; additional fixation through straightening of the left colon and decreased mobility from the phrenocolic ligament; and creation of a dense area of fibrosis between the anastomotic suture line and the sacrum. It is typically reserved for patients with a long redundant sigmoid colon, although specific criteria have not been proposed. Mesh rectopexies are usually avoided at the time of a bowel resection because of concern for the increased complications and infections associated with placement of a foreign body near a new wound on the bowel.

Finally, minimally invasive approaches to abdominal rectopexies have been advocated as a means to decrease the recovery time. The laparoscopic approach has similar safety and efficacy to the open techniques, and the effect on continence and constipation tended to mirror the type of rectopexy performed. **In a small, randomized trial, there were significant short-term benefits with laparoscopic rectopexy compared with open rectopexy, including earlier ambulation, more rapid return to normal diet, shorter hospital stay, and lower morbidity** (287). Several studies have confirmed that recurrence rates are equivalent (4% to 8%) as are complication rates (10% to 33%) (271). Robotic surgery seems to be comparable to laparoscopic approaches.

Although there is a consensus that abdominal rectopexy is better than perineal approaches, the latest Cochrane review of 15 studies concludes that there is no difference in recurrence rates or postoperative complications. If constipation is a main symptom, bowel resection may help (282).

KEY POINTS

1 Spontaneous pregnancy loss is common, occurring in up to 20% of recognized conceptions.
2 Following an ectopic pregnancy, approximately 15% of women will have a subsequent ectopic pregnancy.
3 Laparoscopy is the preferred approach for surgical management of ectopic pregnancies.
4 Single-dose *methotrexate* appears to be the treatment of choice if medical therapy is indicated and selected.
5 Surgical management and medical therapy have similar future reproductive outcomes.

An abnormal gestation can be either intrauterine or extrauterine. Abnormal intrauterine pregnancy often results in pregnancy loss early in gestation. Such losses can be related to a number of factors such as age, previous pregnancy loss, and maternal smoking **(Table 32-1)**. Extrauterine or ectopic pregnancy occurs when the fertilized ovum becomes implanted in tissue other than the endometrium. Although 70% of ectopic gestations are located in the ampullary segment of the fallopian tube, such pregnancies may occur in other sites **(Fig. 32-1)** (1). With abnormal intrauterine and extrauterine gestation, early recognition is key to diagnosis and management. Establishing a woman's goals for her pregnancy may alter management. Providers often incorrectly assume that all spontaneous abortions or abnormal pregnancies were intended pregnancies, when it is established that approximately 50% of pregnancies are unintended and may be undesired (2). As with all pregnancies, management must be highly dependent on each woman's pregnancy goals and her perceptions of the different risks.

ABNORMAL INTRAUTERINE PREGNANCY

Spontaneous Abortion

Spontaneous abortion is a pathologic process resulting in unintentional termination of the pregnancy prior to 20 weeks' gestation. **[1] About 8% to 20% of known pregnancies terminate in spontaneous abortion (3,4). About 80% of spontaneous pregnancy losses occur in the first trimester; the incidence decreases with each gestational week** (5,6). A large multicenter trial indicated the risk of loss in a pregnancy with documented fetal cardiac activity at 10 to 13 weeks gestation had a

spontaneous abortion rate of 0.96% before 24 weeks gestation (7). In women who had one prior spontaneous abortion, the rate of spontaneous abortion in a subsequent pregnancy ranges from 13% to 20%; in women who had three consecutive losses, the rate is 33% to 43% (8,9). Patients should be reassured that, in most cases, spontaneous abortion does not recur. Risk factors for spontaneous abortion include increasing maternal age, closely spaced pregnancies (less than 3 to 6 months apart), history of previous spontaneous abortion, maternal diabetes, and maternal smoking during pregnancy (10–14). Age is a dose-dependent risk factor for miscarriage; in women less than 36 years of age, when fetal cardiac activity is confirmed by ultrasound, the risk of spontaneous abortion is less than 4.5%. For women older than 36, the risk of spontaneous abortion rises to 10%, and above 40 years may approach 30% (15).

Spontaneous abortion can be differentiated into various categories, based on examination findings and ultrasound findings. The following sections review each of these categories in detail.

Table 32-1 Potential Causes of Spontaneous Pregnancy Loss

Increased maternal age
Previous spontaneous abortion
Maternal smoking
Maternal systemic disease (diabetes mellitus, infection, thrombophilia, etc.)
Maternal alcohol consumption (moderate to high)
Increasing gravidity
Amphetamine use
Chromosomal or other embryologic abnormalities
Anembryonic gestation
Uterine anomalies
Intrauterine device in place
Placental anomalies
Severe maternal trauma
Extremes of maternal weight

Missed Abortion

Missed abortion is defined as a nonviable intrauterine pregnancy in the presence of a closed cervix and minimal abdominal cramping or vaginal bleeding. Transvaginal

ultrasound evaluation is key to diagnosing a missed abortion and guidelines are available to aid in diagnosis (Table 32-2). These criteria are *guidelines*. They are more conservative than the studies and data used to develop these guidelines with the goal of eliminating the risk of intervening in what may have been a viable intrauterine pregnancy. These guidelines should be used in combination with clinical judgment and the patient's desires and wishes in deciding next steps in management.

Missed abortion can be subdivided into anembryonic gestation and embryonic demise. **Anembryonic gestation** is a pregnancy where the embryo failed to develop. This is confirmed when the mean gestational sac diameter measured by transvaginal ultrasound is greater than 25 mm and no embryonic pole is present. When an embryo is present with crown–rump length greater than 7 mm and no cardiac activity, this is classified as **embryonic demise** and the pregnancy is nonviable (16).

Threatened Abortion

Threatened abortion **is defined as any vaginal bleeding before 20 weeks of gestation. It occurs in at least 20% of all pregnancies** (17). **This is distinct from missed abortion by ultrasound documentation of an intrauterine embryo or fetus with cardiac activity.** The bleeding is usually light and may be associated with mild

lower abdominal or cramping pain (16). The differential diagnosis in these patients includes consideration of possible cervical polyps, vaginitis, cervical carcinoma, gestational trophoblastic disease, ectopic pregnancy, trauma, and foreign body. On physical examination, the abdomen usually is not tender, and the cervix is closed. Bleeding can be seen coming from the os and usually there is no cervical motion or adnexal tenderness.

In the vast majority of cases, threatened abortion does not result in a pregnancy loss, but may be associated with poor outcomes later in pregnancy. In a review of over 4,500 women presenting with first trimester vaginal bleeding, 12% with bleeding had a miscarriage which was similar to the rate in pregnancies with no bleeding (18). There is no effective therapy for a threatened abortion. Bed rest and progesterone treatment, although often advocated, have been demonstrated to be ineffective and carry their own risks (19). Women with first trimester vaginal bleeding with continuing pregnancies have nearly three times the risk of preterm birth between 28 and 31 weeks as women without bleeding and a 50% higher likelihood of preterm birth between 32 and 36 weeks (20). First trimester bleeding may be associated with higher risk of intrauterine growth restriction, preterm premature rupture of membranes, and placental abruption (21).

Inevitable Abortion

With an *inevitable abortion,* the cervical os is open and effaced prior to 20 weeks, but no tissue has passed. Most patients have crampy lower abdominal pain and some have cervical motion or adnexal tenderness. When the cervical os has dilated or excessive bleeding is present, the patient should be offered medical or surgical management. Blood type and Rh determination and a complete blood count should be obtained if there is any concern about the amount of bleeding. **Rho(D) immune globulin (RhoGAM) should be given if the patient's blood is Rh negative. It is acceptable to give a dose of 50 lg until 12 completed weeks; if this dose is not available, the standard 300 lg dose may be given** (22).

Incomplete Abortion

An incomplete abortion is a partial expulsion of the pregnancy tissue. Lower abdominal cramping is invariably present and the pain may be described as resembling labor. On physical examination, the cervix is dilated and effaced, bleeding is present and products of conception may be visible in the cervical canal. Often clots are admixed with products of conception. If the bleeding is profuse the patient should be examined promptly for tissue protruding from the cervical os; removal of this tissue with a ring forceps may reduce the bleeding. A vasovagal bradycardia may occur and

responds to removal of the tissue. A complete blood count, maternal blood type, and Rh determination should be obtained; **Rh-negative patients should receive *RhoGAM*. If the patient is febrile, broad-spectrum antibiotic therapy should be administered.**

Management of Spontaneous Abortion

All discussions of management of early pregnancy should start with asking the woman about her pregnancy intentions and reproductive planning. Providers often incorrectly assume that all spontaneous abortions were intended pregnancies, when it is established that approximately 50% of pregnancies are unintended and may be undesired (2). Establishing a woman's goals for her pregnancy may alter management. In women with stable vital signs and mild vaginal bleeding, three management options exist: expectant management, medical treatment, and suction curettage.

For expectant management, although there is a wide range (25% to 76%) of success cited in the literature, it may be a desirable option for a stable and carefully counseled patient (23,24). Success of expectant management varies based on the type of miscarriage and patients should be counseled accordingly. Incomplete, missed, and anembryonic abortions have a 91%, 76%, and 66% success rates respectively (25). Women should be counseled that it may take up to 4 to 8 weeks for the pregnancy to pass in any of these situations (26). Expectant management is associated with an increase in unscheduled surgical evacuations, bleeding and blood transfusions but no difference in infection rates (26,27).

Medical management with misoprostol is often successful in avoiding a surgical procedure. Misoprostol can be used vaginally, orally, sublingually, or bucally and the dose typically ranges from 400 to 800 µg. The American College of Obstetricians and Gynecologists recommends medical treatment of missed abortions with 800 µg of *misoprostol* placed vaginally with efficacy up to 84% in achieving complete abortion (28,29). It is acceptable to use 600 µg sublingually. For incomplete abortion, the *misoprostol* dose *can* be reduced to 600 µg orally or 400 µg sublingually, with efficacy greater than 90% (30,31).

Studies have investigated the benefit of adding mifepristone to the medical regimen in the hopes of improving success rates as the use of mifepristone with misoprostol has been well-documented in the effective treatment of medical abortion terminations. A study of 300 women with early pregnancy loss demonstrated improved success of misoprostol when women are pretreated with 200 mg of mifepristone 24 hours prior. Approximately 83% of the women in the group pre-treated with mifepristone experienced treatment success without intervention by the first follow-up visit compared with only 67% in the misoprostol only group. There were no significant differences in adverse events, bleeding intensity, pain, or satisfaction between the two groups (32).

Suction curettage should be performed in women who desire surgical management or

who have excessive bleeding, unstable vital signs, or in whom reliable follow-up is a concern.

ECTOPIC GESTATION

Incidence

The incidence of ectopic pregnancy has historically been underestimated. Previous reports mainly had used hospital records and many ectopic pregnancies are treated on an outpatient basis either in surgery centers or in outpatient clinics with methotrexate (33). Reports using insurance claims databases have estimated the overall rate of ectopic pregnancy to be between 1% and 2%. In one study using the insurance claims database of private insurance the rate of ectopic was 0.64%, with significant differences by age group. The rate of ectopic pregnancy increases with age, with 0.3% of pregnancies among 15- to 19-year-old women and 1% of pregnancies among 24- to 44-year-old women (34). This study found that up to 16% of women who present with first trimester bleeding, pain, or both, will ultimately be diagnosed with ectopic pregnancy (35). While uncommon, ectopic pregnancy accounts for approximately 2.7% of all maternal deaths and increases the risk of recurrence in future pregnancies (35). Studies have shown a decreasing mortality rate in ectopic pregnancy, attributed to improved early diagnosis and treatment. Similar to most causes of maternal mortality, the mortality from ectopic pregnancy varies by race, with African American women having 6.8 times the risk of mortality from ectopic pregnancy than Caucasian American women (36).

Etiology and Risk Factors

Ectopic pregnancy results from various factors that interrupt the successful migration of the conceptus to the endometrium. Up to half of women who present with an ectopic pregnancy have no identifiable risk factor, therefore a high index of suspicion is critical. Any condition that delays or interferes with the passage of an embryo through the fallopian tube increases the risk of ectopic pregnancy. **[2] The most important risk factor for an ectopic pregnancy is a prior ectopic pregnancy with a recurrent risk of 10% to 15% after first ectopic pregnancy and 30% after second ectopic pregnancy (37).** Other risk factors include a history of tubal surgery including tubal ligation, *assisted reproductive technology*, and history of pelvic inflammatory disease (PID). Anything that causes inflammation of the fallopian tube or disruption of tubal motility increases the risk of ectopic pregnancy. Inflammation of fallopian tube is present in up to 90% of ectopic pregnancies with causes including PID, tubal endometriosis, and salpingitis isthmica nodosa. Many other risk factors, including smoking and multiple lifetime sexual partners, are weakly associated with ectopic

pregnancy. Intrauterine devices (IUDs) are an effective contraceptive method, with an annual failure rate of <0.1%. While the overall risk of pregnancy is incredibly low in women using this type of contraception, those rare pregnancies that do occur are more likely to be ectopic (38).

Prior Ectopic Pregnancy

A previous history of ectopic pregnancy is the strongest risk factor for another occurrence. The increased recurrence exists because of the previous factors that led to the initial ectopic combined with the potential damage to the fallopian tube from the prior ectopic pregnancy and its treatment. **The rates for intrauterine pregnancy (40%) and ectopic pregnancy (15%, range 4% to 28%) are similar after tubal removal or conservation** (39). Tubal patency appears to be variably affected by medical treatment with methotrexate. In one study of 121 women who received methotrexate treatment, hysterosalpingograms (HSGs) done 3 months after treatment revealed 72% of women had bilateral tubal patency, 19% had unilateral tubal patency, and 3% had bilateral tubal obstruction. Of the women who had bilateral tubal patency on HSG, over 90% had a subsequent pregnancy, 78% without reproductive assistance. Given that 97% of women in the study had no change in their fertility, an HSG is not indicated or cost-effective after methotrexate treatment (40).

Tubal Surgery

It is clear that tubal surgery is associated with an increased risk for ectopic pregnancy, what is unclear is whether the increased risk results from the surgical procedure or from the underlying problem. Although tubal sterilization remains one of the most effective forms of contraception and pregnancy is unlikely, failures do occur; when they do, they are more likely to result in ectopic gestation. A large Cochrane review published in 2016 found that depending on the technique, the failure rate of tubal sterilization ranges from 36.5/1,000 procedures (Filshie clip) to 7.5/1,000 procedures (postpartum salpingectomy and unipolar coagulation) (41). **The 10-year cumulative incidence of tubal pregnancy after any sterilization procedure is 7.3 per 1,000 procedures** (42). The risk depends on the sterilization technique and the woman's age at the time of sterilization: postpartum partial salpingectomy and unipolar coagulation have the lowest rates of ectopic pregnancy (1.5 and 1.8 per 1,000 procedures), while bipolar coagulation techniques had the highest incidence (17.1 per 1,000 procedures). Spring clip and band application techniques have 10-year ectopic rates similar to the general incidence, 8.5 and 7.3 per 1,000 procedures, respectively (42). Women younger than 28 years at the time of sterilization are more likely to have a failure than women over 34 years.

Sterilization reversal increases risk for ectopic pregnancy. The exact risk depends on the method of sterilization, site of tubal occlusion, residual tube length, coexisting

disease, and surgical technique. In general, the risk of any pregnancy after a reanastomosis of a cauterized tube is up to 8% for laparoscopic procedures based on recent studies (43). There is insufficient evidence for a rate of ectopic pregnancy after hysteroscopic sterilization, but retrospective data and models show overall pregnancy rates are higher than with laparoscopic sterilization (44,45).

Pelvic Infection

The relationship of pelvic infection, tubal obstruction and ectopic pregnancy is well-documented. In a study of 2,500 women with suspected PID who underwent diagnostic laparoscopy, the incidence of ectopic pregnancy in the subsequent pregnancy for those with laparoscopically confirmed disease was 9.1% compared with 1.4% in the women with normal laparoscopy (46). In a study of 415 women with laparoscopically proven PID, the incidence of tubal obstruction increased with successive episodes of PID: **13% after one episode, 35% after two, and 75% after three** (47). **Chlamydia is an important pathogen causing tubal damage and subsequent tubal pregnancy. Chlamydia was cultured from 7% to 30% of patients with tubal pregnancy** (48). Conception is three times as likely to be tubal in women with anti–*Chlamydia trachomatis* titers higher than 1:64 than in those women whose titers were negative (49). Women at risk for chlamydia infections should be diligently tested, treated when infection is present, and counseled about the risk of ectopic pregnancy.

Infertility

The incidence of ectopic pregnancy increases with age and parity, and there is a significant increase in nulliparous women undergoing infertility treatment (38,39,50). Additional risks for infertile women are associated with specific treatments, including reversal of sterilization, ovulation induction, and in vitro fertilization (IVF). Various studies examining risk factors for ectopic pregnancy found that infertility increased the odds of tubal pregnancy at least four times and perhaps as much as 40 times, depending on etiology of infertility (51).

Smoking

Alterations of tubal motility, ciliary activity, and blastocyst implantation are associated with nicotine intake. Cigarette smoking is associated with an increased risk for tubal pregnancy in a dose-dependent fashion. Two classic case-control studies demonstrated this relationship; compared with nonsmokers, smokers of more than 20 cigarettes a day had a relative risk of 3.5, and smokers of up to 10 cigarettes a day had a relative risk of 2.3 (1,52).

Contraceptive Use

By reducing the overall likelihood of pregnancy, all contraceptive use reduces the overall risk of ectopic pregnancy. There is concern that because of the various

mechanisms of action of contraceptives, if a pregnancy were to occur, it might be more likely to be ectopic. In a meta-analysis of 13 studies examining the relationship between contraception and the risk of ectopic pregnancy, there was no increased risk in users of oral contraceptives or barrier methods compared with pregnant controls (53). There is no demonstrated increased risk in users of *depo-medroxyprogesterone* injections, emergency contraceptive pills or etonogestrel implants (54,55). Hormonal and copper-containing IUDs are highly effective at preventing intrauterine and extrauterine pregnancies, with failure rates of 0.2% in the first year of use and 0.7% in the first 5 years of use (56). **In the rare case that women conceive with an IUD in place the pregnancy is more likely to be ectopic.**

Diagnosis

The diagnosis of ectopic pregnancy is complicated by the wide spectrum of clinical presentations from asymptomatic cases to acute abdomen and hemodynamic shock. Until the location of the pregnancy is confirmed, the diagnosis remains a pregnancy of unknown location. The differential diagnosis of a pregnancy of unknown location includes early viable intrauterine pregnancy, early nonviable intrauterine pregnancy, stable ectopic pregnancy and unstable ectopic pregnancy. Making the diagnosis involves combining history and physical examination with clinical findings including laboratory and ultrasound data.

While the management of a ruptured ectopic pregnancy is directed at the primary goal of achieving hemostasis, the management of a pregnancy of unknown location in a stable patient is varied and depends on many patient and pregnancy-specific factors. It is critical to maintain a high degree of suspicion of ectopic pregnancy with pregnancies of unknown location, especially in areas of high prevalence. History and physical examination identify patients at risk, improving the probability of detection of ectopic pregnancy before rupture occurs.

History

The patient's history can be helpful in identifying patients at risk for ectopic pregnancies. Pertinent points in the history include the patient's age, menstrual history, previous pregnancy, infertility history, current contraceptive status, risk factor assessment, and current symptoms.

The classic symptom triad of ectopic pregnancy is pain, amenorrhea, and vaginal bleeding. This symptom group is present in about 50% of patients and is more typical in patients with a ruptured ectopic pregnancy. Abdominal pain is the most common presenting symptom, but the severity and nature of the pain vary widely. There is no pathognomonic pain for an ectopic pregnancy. Pain may be unilateral or bilateral and may occur in the upper or lower abdomen. The pain may be dull, sharp, or crampy

and either continuous or intermittent. With rupture, the patient may experience transient relief of the pain, as stretching of the tubal serosa ceases. Shoulder and back pain, thought to result from peritoneal irritation of the diaphragm may indicate intra-abdominal hemorrhage.

Physical Examination

The physical examination should include measurements of vital signs and examination of the abdomen and pelvis. Frequently, the findings before rupture and hemorrhage are nonspecific and vital signs are normal. The abdomen may be nontender or mildly tender, with or without rebound. The uterus may be slightly enlarged with findings similar to a normal pregnancy (57). Cervical motion tenderness may or may not be present. **An adnexal mass may be palpable in up to 50% of cases, but the mass varies markedly in size, consistency, and tenderness.** A palpable mass may be the corpus luteum and not the ectopic pregnancy. With rupture and intra-abdominal hemorrhage, the patient develops tachycardia followed by hypotension. Bowel sounds are decreased or absent. The abdomen is distended with marked tenderness and rebound tenderness. Cervical motion tenderness is present. Frequently, the findings of the pelvic examination are inadequate as a result of pain and guarding. History and physical examination may or may not provide useful diagnostic information. Additional tests are frequently required to differentiate between early viable intrauterine pregnancy, abnormal intrauterine pregnancy, and suspected ectopic.

Laboratory Assessment

Quantitative β-human chorionic gonadotropin (β-hCG) measurements are the diagnostic cornerstone for ectopic pregnancy. Urine pregnancy tests can detect β-hCG at ≥20 mIU/mL while serum pregnancy tests can detect levels >5 mIU/mL. **a-hCG levels cannot be used to predict gestational age (**58). **a-hCG levels peak at approximately 10 weeks gestation and the average peak level is approximately 100,000 with a wide normal range of variation.** There is the possibility of a phantom β-hCG, in which the presence of heterophile antibodies or proteolytic enzymes causes a low level false-positive serum β-hCG result. These antibodies are large glycoproteins and are not excreted in the urine, resulting in a negative urine pregnancy test. **In the patient with a-hCG levels less than 1,000 mIU/mL, a urine pregnancy test should be performed and confirmatory positive results obtained before instituting treatment** (59).

Single Human Chorionic Gonadotropin Level

A single a-hCG measurement has limited usefulness in the evaluation of a pregnancy of unknown location because there is considerable overlap in values between normal and abnormal pregnancies at a given gestational age. a-hCG levels do not correlate with pregnancy site (60). Many patients with pregnancy of unknown

location are uncertain about their menstrual dates. A single β-hCG level may be useful if negative to exclude the diagnosis of ectopic pregnancy. A single β-hCG level may facilitate the interpretation of ultrasonography when an intrauterine gestation is not visualized. **An a-hCG level greater than the ultrasound discriminatory zone indicates a possible extrauterine pregnancy; however caution must be used with previously defined discrimination zones, as recent research indicates that a much higher a-hCG level should be used for ruling out a normal intrauterine pregnancy** (16,61). Determination of serial β-hCG levels are usually needed to differentiate an ectopic pregnancy from an intrauterine pregnancy failure. Further tests are required for patients in whom ultrasonography examination results are inconclusive and β-hCG levels are below the discriminatory zone.

Serial Human Chorionic Gonadotropin Level

Serial a-hCG levels are usually required when the results of the initial ultrasonography examination are indeterminate (i.e., when there is no evidence of an intrauterine gestation or extrauterine findings consistent with an ectopic pregnancy). Traditionally the β-hCG level was expected to rise at least 66% over 48 hours with an 85% confidence interval, with 15% of normal pregnancies falling outside of this range. About the same number of ectopic pregnancies will have a greater than 66% rise (62). Data indicate that a more conservative cut-off of 53% gives a 99% confidence interval with less than 1% of viable intrauterine pregnancies having a slower rise (63). This data was based on a homogeneous patient population and women with unknown dating (i.e., unclear last menstrual period) were excluded from the study. A more conservative cut-off of greater than or equal to 35% was found in a larger study of over 1,000 ethnically and racially diverse women to adequately predict a viable intrauterine pregnancy and decrease the chance of misclassifying a pregnancy (64). This large study showed that having at least three serial values is helpful, especially if the starting β-hCG level is low. Follow-up research suggests that the expected rise in β-hCG is dependent upon starting β-hCG level. **If the initial a-hCG level is less than 1,500, 1,500 to 3,000, or greater than 3,000 mIU/mL, then the predicted rise at 48 hours is 49%, 40%, and 33%, respectively** (65). Based on these data the traditional 66% should no longer be used in diagnosing ectopic pregnancies. **A cut-off of 53% or even lower to 35% may be more appropriate and decrease the risk of intervening in what may be a viable intrauterine pregnancy.** β-hCG levels alone usually are not enough to make a diagnosis in a pregnancy of unknown location. The entire clinical picture including history, physical examination, and ultrasound findings, combined with β-hCG levels, are needed to make an accurate diagnosis.

If there is a plateau or decline in β-hCG levels, this is usually indicative of a nonviable pregnancy, either intrauterine or extrauterine. The decline in β-hCG levels can be helpful in diagnosing a pregnancy of unknown location. Ectopic pregnancies will

plateau or have a slower rate of decline than spontaneous abortions. Several studies have evaluated the expected decline to develop clinical guidelines. Data support that most spontaneous abortions are expected to decrease 21% to 35% 2 days after presentation and 60% to 84% at 7 days. The drop depends on the starting β-hCG level with faster decline noted with higher starting values of β-hCG (63). An updated model suggested that the range of the drop should be 35% to 50% at 2 days and 66% to 87% at 7 days from the first laboratory test (66). A large study did show that if there is an 85% drop within 4 days or a 95% drop in 7 days the risk of ectopic pregnancy appears to be 0 (67). These expected rates of decline can aid in detecting those women at risk for an ectopic pregnancy and warrant closer follow-up or even intervention, but should be combined with clinical judgment and not be used as absolutes in patient management.

Serum Progesterone

Earlier studies suggested that serum progesterone level could be used to diagnose ectopic pregnancies and identify viable intrauterine pregnancies. However, the level of progesterone in all pregnancies can vary greatly. There are progesterone thresholds that can aid in the evaluation of patient with pregnancy of unknown location. Progesterone levels greater than or equal to 25 ng/mL are associated with viable intrauterine pregnancies as only 1% to 2% of ectopic pregnancies will have levels this high (68). If the ectopic pregnancy does have a level above this threshold it is usually associated with cardiac activity and identifiable on ultrasound. Serum progesterone levels <5 mg/mL are associated with pregnancy failure. Less than 1% of viable intrauterine pregnancies are below this cut-off (69,70).

Other Endocrine Markers

In an effort to improve early detection of ectopic pregnancy various endocrine and protein markers have been evaluated. Useful biomarkers have not been identified for clinical use but further studies are underway.

Ultrasonography

Transvaginal ultrasound is the imaging modality of choice for evaluating the pelvic structures and the location of a newly diagnosed pregnancy (71,72). Transabdominal ultrasonography permits visualization of the pelvis and abdominal cavity and should be included as part of the complete ectopic pregnancy evaluation to detect adnexal masses and hemoperitoneum.

The earliest ultrasound finding of an intrauterine pregnancy is the gestational sac that characteristically has a round, thick echogenic ring surrounding a sonolucent center. As the pregnancy progresses this sac becomes eccentrically located within the endometrial cavity. Although the gestational sac is the first sign of a definitive intrauterine pregnancy it can be mimicked by an intrauterine fluid collection called a pseudogestational sac. Pseudosacs occur in 8% to 29% of patients with ectopic

pregnancy (73,74). This ultrasonographic lucency, centrally located, probably represents bleeding into the endometrial cavity by the decidual cast. Clots within this lucency may mimic a fetal pole.

Historically, identification of the double decidual sac sign (DDSS) is the best method of differentiating true sacs from pseudosacs. The double sac, believed to be the decidua capsularis and parietalis, is seen as two concentric echogenic rings separated by a hypoechogenic space. Although useful, this approach has some limitations in sensitivity and specificity—the DDSS sensitivity ranges from 64% to 95% (75). Pseudosacs may occasionally appear as the DDSS; intrauterine sacs of failed pregnancies may appear as pseudosacs. The DDSS is best observed on transabdominal ultrasound as this is frequently missed with transvaginal ultrasound (16). However, if abdominal ultrasound reveals a DDSS with an empty-appearing gestational sac, a transvaginal ultrasound should be performed as a yolk sac is often visible in this view and is a definitive diagnosis of intrauterine pregnancy.

The appearance of a yolk sac within the gestational sac is diagnostic of an intrauterine pregnancy, while the gestational sac alone is not sufficient because of the risk of misdiagnosis (76). Diagnosing an ectopic pregnancy on transvaginal ultrasound may or may not be straightforward. In the absence of an intrauterine pregnancy, if an adnexal gestational sac with a yolk sac or an embryo is present this is diagnostic of an ectopic pregnancy. However, this finding is the least sensitive sign of ectopic pregnancy, occurring in only 10% to 17% of cases (77).

The recognition of other characteristics of ectopic pregnancy improves ultrasonographic sensitivity. Adnexal rings (fluid sacs with thick echogenic rings) are visualized in less than 50% of ectopic pregnancies (77,78). The adnexal ring may not always be apparent because bleeding around the sac results in the appearance of a nonspecific adnexal mass**. Complex or solid adnexal masses are frequently associated with ectopic pregnancy; however, the mass may represent a corpus luteum, endometrioma, hydrosalpinx, ovarian neoplasm (e.g., dermoid cyst), or pedunculated fibroid** (5,78). The presence of free cul-de-sac fluid is frequently associated with ectopic pregnancy but is not considered evidence of rupture (79). The presence of ***intra-abdominal*** free fluid should raise concern about tubal rupture.

Historically ultrasound findings were correlated with a "discriminatory zone"—the level of β-hCG where an intrauterine pregnancy *should* be visualized. **Discriminatory zones for transvaginal ultrasonography are reported at levels from 1,000 to 2,000 mIU/mL** and vary by institution (15,73,75,77,78,80). **Studies have suggested raising the discriminatory zone to 3,510 mIU/mL in order to avoid false results** for an abnormal pregnancy (61). Discriminatory zones vary according to the expertise of the examiner, capability of the equipment, and pregnancy-related characteristics such as multiples.

Although there are guidelines for a discriminatory zone for intrauterine pregnancy, there is no such zone for ectopic pregnancy. Levels of β-hCG do not correlate with the size of ectopic pregnancy. Regardless of how high the β-hCG level may be, nonvisualization of the pregnancy outside the uterus does not exclude ectopic pregnancy. An ectopic pregnancy may be present anywhere in the abdominal cavity, making ultrasonographic visualization difficult.

Dilation and Curettage

Uterine curettage is performed when the pregnancy is confirmed to be nonviable or is not desired and the location of the pregnancy cannot be determined by ultrasonography. The decision to evacuate the uterus in the presence of a positive pregnancy test must be made with caution to avoid the unintentional disruption of a viable intrauterine pregnancy. Although suction curettage traditionally was performed in the operating room, it can be accomplished under local anesthesia on an outpatient basis. Endometrial sampling methods (e.g., a Novak curettage or Pipelle endometrial sampling device) are accurate in diagnosing abnormal uterine bleeding but their reliability for detecting intrauterine chorionic villi is low and these devices should not be used in the evaluation of a possible ectopic pregnancy (81,82).

It is essential to confirm the presence of trophoblastic tissue as rapidly as possible so that therapy may be instituted. There are many ways this tissue can be evaluated depending on setting of procedure. Traditionally these specimens were sent to pathology for formal evaluation. In this case, the presence of chorionic villi may be assessed rapidly with frozen section analysis, which avoids the waiting period of at least 48 hours for permanent histologic evaluation. Immunocytochemical staining techniques can be used to differentiate intermediate trophoblasts from decidual tissue (83).

More often these simple procedures are performed in an outpatient setting and the ability to immediately evaluate the tissue allows for rapid diagnosis of an intrauterine pregnancy. Surgeons experienced in evaluating tissue immediately after aspiration are at least as accurate as pathologists especially with accurately identifying the presence of the products of conception (84).

After tissue is obtained by curettage, it can be added to saline, in which it will float. Decidual tissue does not float. Chorionic villi are usually identified by their characteristic lacy frond appearance, as demonstrated in **Figure 32-2** above.

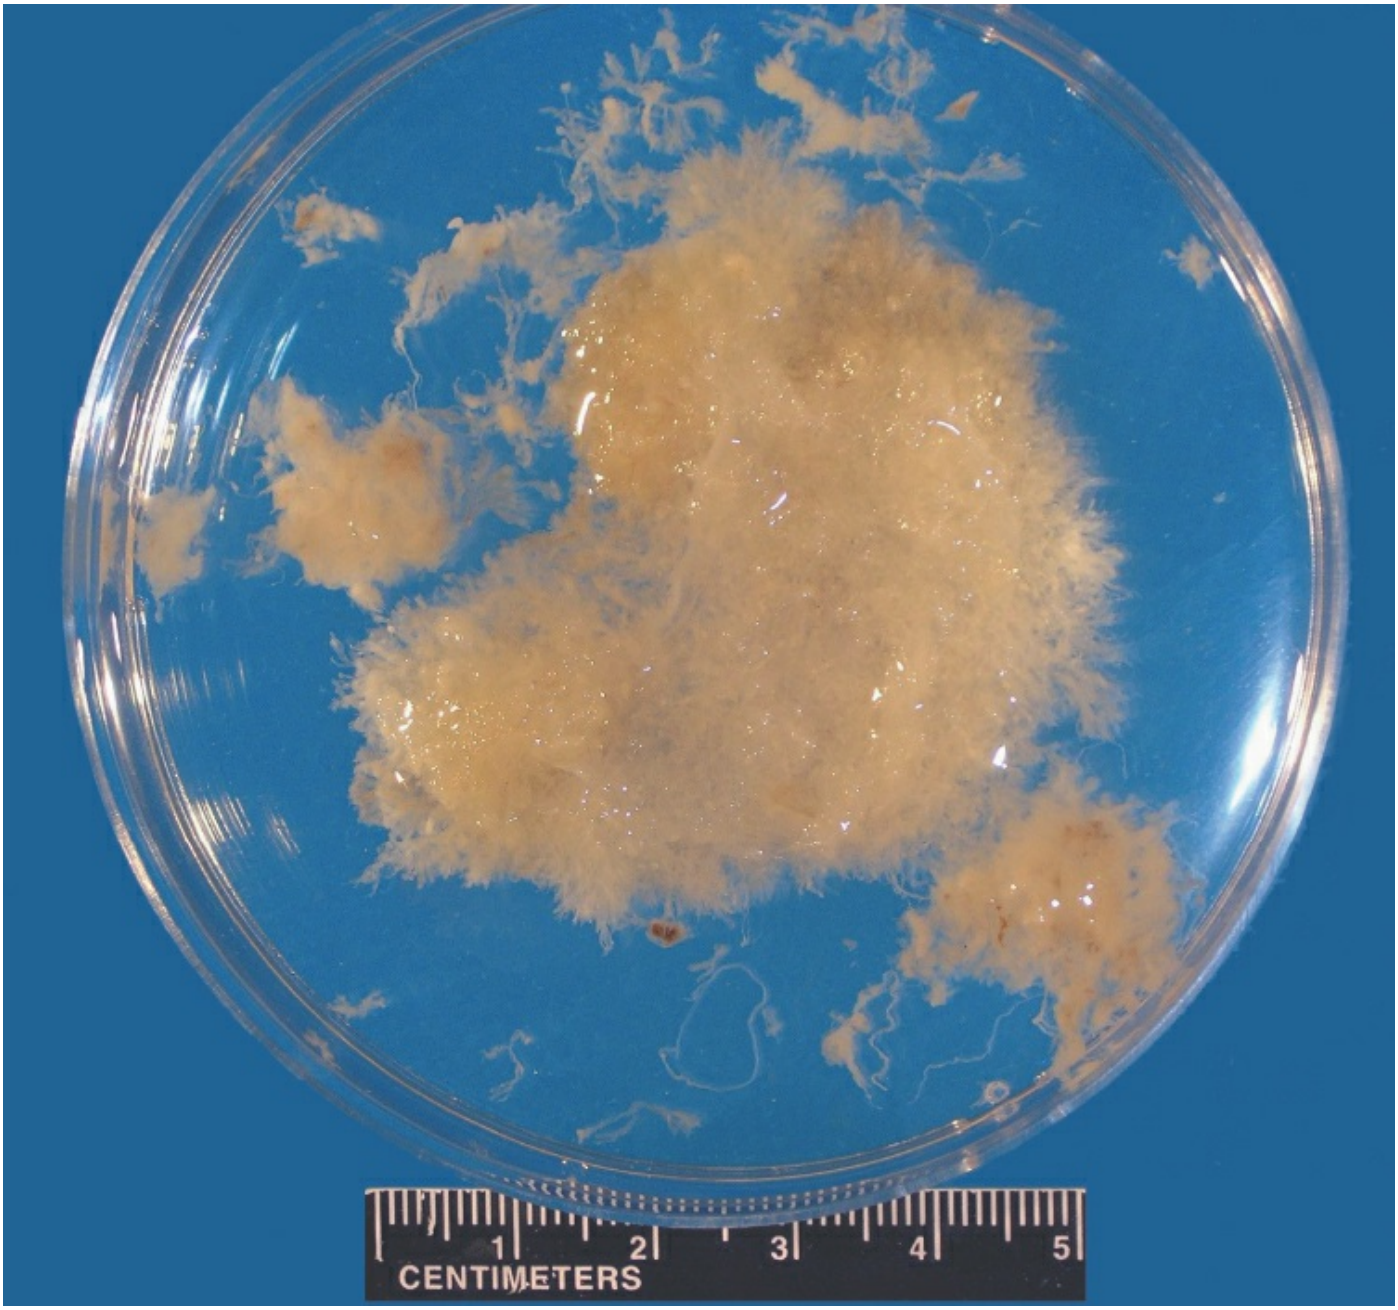

FIGURE 32-2 When floated in saline, chorionic villi are often readily distinguishable as lacy fronds of tissue. (From **Stovall TG, Ling FW.** Extrauterine Pregnancy: Clinical Diagnosis and Management. New York: McGraw-Hill, 1993:186, with permission.)

It is important to identify a gestational sac. Rare villi may be present in uterine aspirations in the presence of interstitial pregnancies, therefore identifying the gestational sac is required. Heterotopic pregnancies are rare but are increasing with advancements in artificial reproductive technologies. If suspicion for a heterotopic pregnancy is high the presence of villi and a gestational sac still warrants further investigation.

If chorionic villi are not confirmed β-hCG levels should be monitored. After evacuation of an abnormal intrauterine pregnancy, the β-hCG level decreases by greater

than 15% within 12 to 24 hours (50). It has been suggested that a fall of ≥50% within 24 hours following manual vacuum aspiration is predictive of an abnormal *intrauterine* pregnancy (85). A borderline fall may represent interassay variability. A repeat level should be obtained in 24 to 48 hours to confirm the decline. If the uterus is evacuated and the pregnancy is extrauterine, the β-hCG level will plateau or continue to increase, indicating the presence of extrauterine trophoblastic tissue.

Culdocentesis

Culdocentesis was historically widely used as a diagnostic technique for ectopic pregnancy. With the use of β-hCG testing and transvaginal ultrasonography, culdocentesis is rarely indicated and is considered obsolete in the evaluation of ectopic pregnancies (86).

Laparoscopy

Traditionally laparoscopy was the gold standard for the diagnosis of ectopic pregnancy. At the time of laparoscopy, the fallopian tubes are easily visualized and evaluated, but the diagnosis of ectopic pregnancy is missed in 3% to 4% of patients who have very small ectopic gestations. The ectopic gestation is seen distorting the normal tubal architecture. With earlier diagnosis, the possibility increases that a small ectopic pregnancy may not be visualized. Pelvic adhesions or previous tubal damage may compromise assessment of the tube. False-positive results occur when tubal dilation or discoloration is misinterpreted as an ectopic pregnancy, in which case the tube can be incised unnecessarily and damaged. With the advances in ultrasound technology, more ectopic pregnancies are being diagnosed earlier allowing for medical interventions and reducing the need for surgical management, thus laparoscopy is no longer considered the gold standard for diagnosis.

Diagnostic Algorithm

The presenting symptoms and physical findings of patients with unruptured ectopic pregnancies are similar to those of patients with normal intrauterine pregnancies (87). History, risk factor assessment, and physical examination are the initial steps in the management of suspected ectopic pregnancy. Patients in a hemodynamically unstable condition should undergo immediate surgical intervention. Patients with a stable, relatively asymptomatic condition may be assessed as outpatients.

There are several potential benefits if the diagnosis of ectopic pregnancy can be confirmed without laparoscopy. First, the anesthetic and surgical risks of laparoscopy are avoided; second, medical therapy becomes a treatment option. Because many ectopic pregnancies occur in histologically normal tubes, resolution without surgery may spare the tube from additional trauma and improve subsequent fertility. Previously, **an algorithm for the diagnosis of ectopic pregnancy without laparoscopy proved to be 100% accurate in a randomized clinical trial** (88,89).

This screening algorithm combined the results of history and physical examination, serial β-hCG levels, vaginal ultrasonography, and dilation and curettage **(Fig. 32-3)**. Serial β-hCG levels are used to assess pregnancy viability, correlated with transvaginal ultrasonography findings and measured serially after a suction curettage. For patients in a stable condition, a treatment decision is never based on a single β-hCG level. After the initial evaluation, the patient is seen again at 48 hours for a repeat β-hCG level. At this time, transvaginal ultrasonography often is repeated so the findings can be correlated with the two β-hCG levels. The algorithm has been updated to account for changes in the new recommendations for a discriminatory zone and expected changes in the β-hCG level with a viable intrauterine pregnancy.

In this algorithm, **transvaginal ultrasonography is used as follows:**

1. **The identification of an intrauterine gestational sac with yolk sac excludes the presence of an extrauterine pregnancy.** If the patient has a β-hCG level of more than 3,510 mIU/mL, and no intrauterine gestational sac is identified, the patient is considered to have an extrauterine pregnancy and can be treated without further testing.
2. **Adnexal gestational sac with a yolk sac or embryo, when seen, definitively confirms the diagnosis of ectopic pregnancy.**
3. **A tubal mass as small as 1 cm can be identified and characterized.**

Suction curettage is used to differentiate nonviable intrauterine pregnancies from ectopic gestations (less than 53%, or even as low as 35%, rise in a-hCG level over 48 hours, an a-hCG level of less than 3,510 mIU/mL, and indeterminate ultrasonography findings). Performance of this procedure avoids unnecessary use of *methotrexate* in patients with abnormal intrauterine pregnancy that can be diagnosed only by evacuating the uterus. An unlikely potential problem with suction curettage is missing either an early nonviable intrauterine pregnancy or combined intrauterine and extrauterine pregnancies.

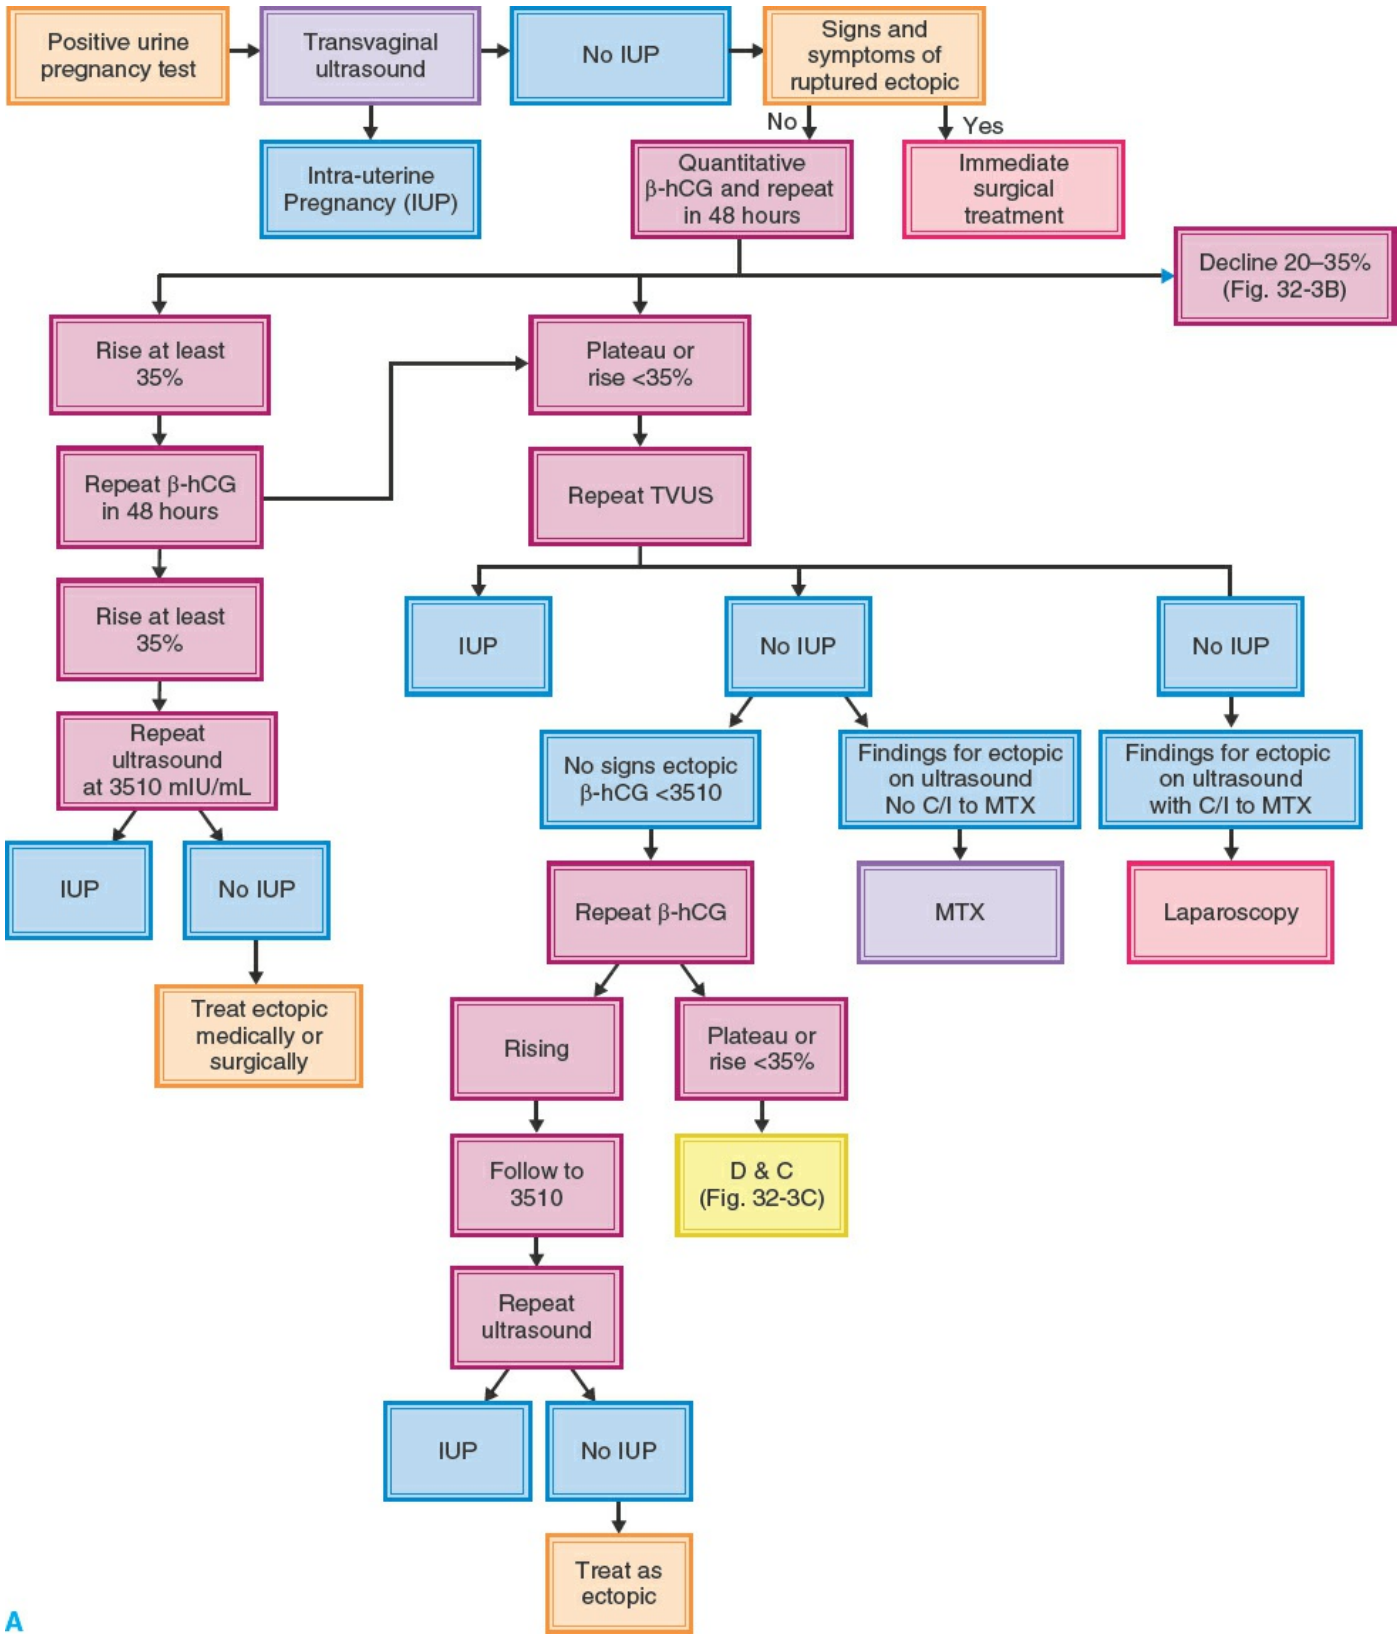
Treatment

Ectopic pregnancy can be effectively treated medically or surgically. Traditionally, exploratory laparotomy with unilateral salpingectomy was used for diagnosis and treatment for ectopic pregnancies. With techniques available that allow for early detection, including serum quantitative β-hCG levels and ultrasound, more conservative treatment options are available. Minimally invasive surgical techniques and medical management with *methotrexate* are the commonly used treatment options for ectopic pregnancies. **The treatment approach depends on the clinical circumstances, the site of the ectopic pregnancy and the available resources.**

Surgical Treatment

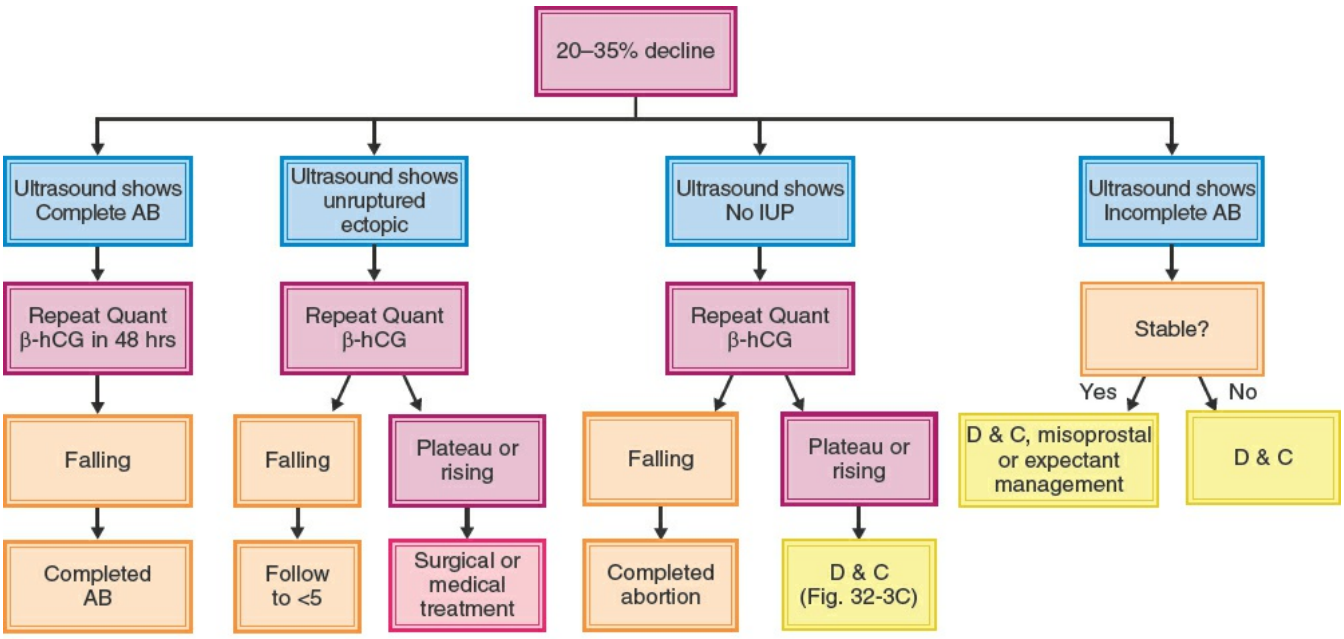
Operative management is the most widely used treatment for ectopic pregnancy. The surgical approach (laparotomy vs. laparoscopy) and procedure (salpingectomy vs. salpingostomy) used to treat ectopic pregnancies depend on the clinical circumstances, available resources, and provider skill level. Each approach and procedure has associated risks and benefits and the treatment employed must be individualized to best meet the needs of the patient and provider.

Laparotomy Versus Laparoscopy



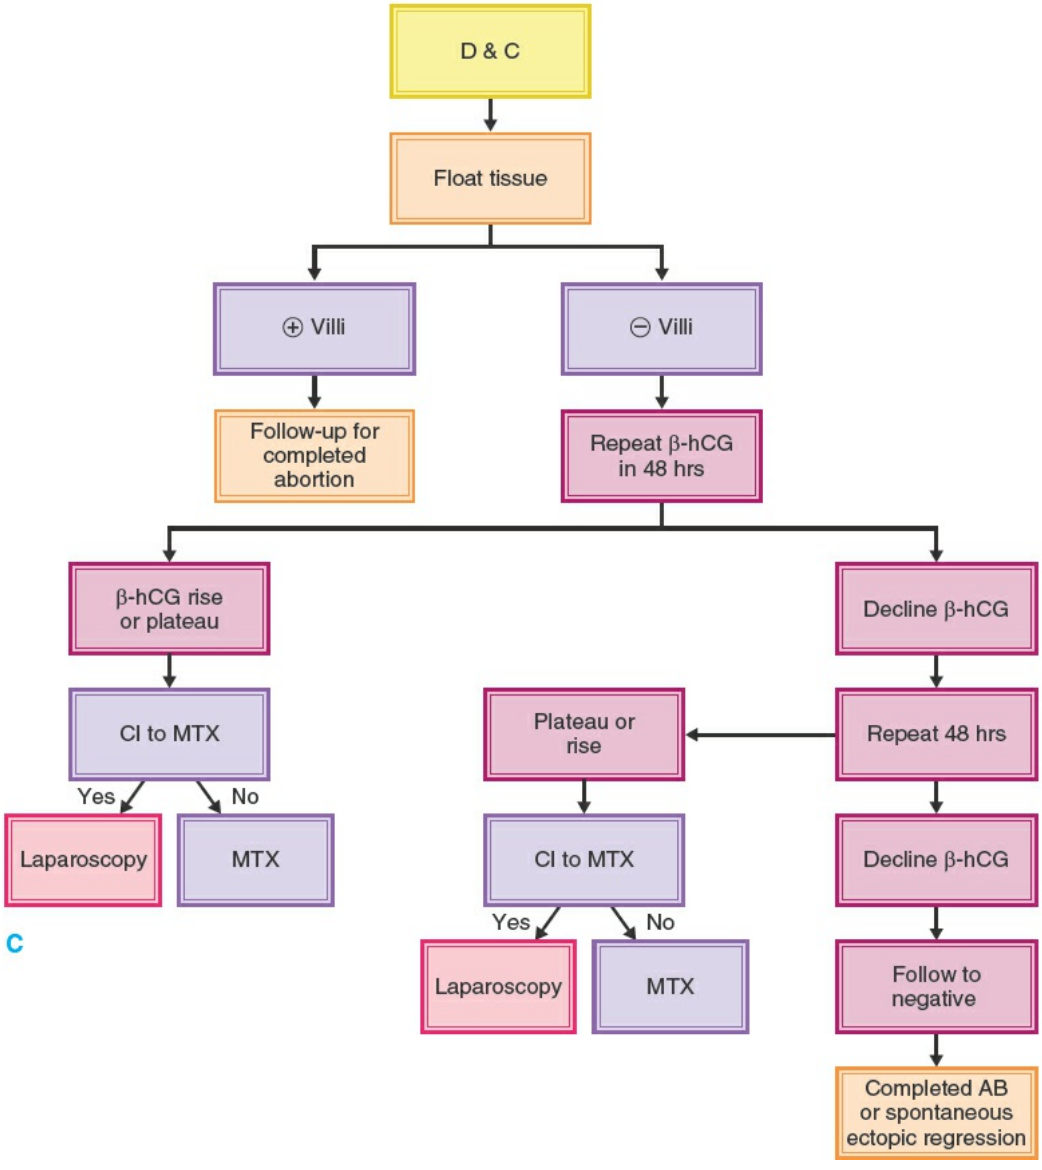
Treatment of an ectopic pregnancy can be accomplished by laparoscopy or laparotomy. The hemodynamic stability of the patient, size and location of the ectopic mass, and the surgeon's expertise all contribute to determining the appropriate surgical approach. **Laparotomy is indicated when the patient becomes hemodynamically unstable and an expedited abdominal entry is required. A ruptured ectopic pregnancy does not necessarily require laparotomy.** If the hemoperitoneum cannot be evacuated in a timely manner, laparotomy should be considered. Surgeon's experience with laparoscopy and the availability of laparoscopic equipment will determine the surgical approach.

In most cases, [3] **laparoscopy is superior to laparotomy for management of ectopic pregnancy. The indications for laparotomy include abdominal pregnancy, extensive abdominal or pelvic adhesive disease, and any other condition making laparoscopy difficult or unsafe.** In a case control study of 50 patients comparing the use of laparoscopy and laparotomy for ectopic pregnancy management, hospital stay was significantly shorter (1.3 ± 0.8 vs. 3.0 ± 1.1 days), operative time was shorter (78 ± 26 vs. 104 ± 27 minutes), and convalescence was shorter (9 ± 8 vs. 26 ± 16 days) in the laparoscopy group (90).



Laparoscopic management was associated with significant cost savings when compared with laparotomy ($4,368 ± $277 vs. $5,090 ± $168). Using a prospective analysis, 105 patients with tubal pregnancy were stratified with regard to age and risk factors and randomized to undergo either laparoscopic management or laparotomy (91). Subsequently, 73 patients underwent second-look laparoscopy to assess the degree of adhesion formation. Patients treated by laparotomy had significantly more adhesions at the surgical site than those treated by laparoscopy, but tubal patency rates were similar. A Cochrane review confirmed these findings and laparoscopic salpingostomy was associated with decreased cost, operative time, blood loss, and hospital stay when compared to salpingostomy at the time of a laparotomy (92).

An alternative to laparoscopy is the use of a mini-laparotomy incision. This approach has the advantage of not requiring laparoscopic equipment and utilizes a smaller incision that should result in decreased postoperative pain and shorter recovery times for patients. A randomized control trial comparing minilaparotomy to laparotomy



showed decreased complication rates and reduced costs associated with the mini-laparotomy incision with similar success rates in the treatment of the ectopic pregnancy (92,93).

Salpingectomy Versus Salpingostomy

Multiple studies have been conducted to compare management of ectopic pregnancy with a salpingostomy or salpingectomy. The decision to choose one technique over the other depends on the patient's fertility goals, clinical picture, and the condition of the affected and contralateral fallopian tubes.

Linear salpingostomy can be considered when the patient has an unruptured ectopic pregnancy, wishes to retain her potential for future fertility, and the affected fallopian tube appears otherwise normal. This is particularly important to consider if the contralateral tube appears damaged or has been previously removed.

In a salpingostomy, the products of conception are removed through an incision made into the tube on its antimesenteric border. The procedure can be accomplished with needle-tip cautery, laser, scalpel, or scissors. It can be done with operative laparoscopic techniques or via a laparotomy. Contraindications to a salpingostomy include ruptured fallopian tube, use of extensive cautery to obtain hemostasis, severely damaged tube and recurrent ectopic pregnancy in the same tube. The main risk of salpingostomy is a persistent ectopic pregnancy resulting from failure to remove the entire pregnancy. This was reported in 8% of cases in a recent large open-label study (94). Patients with high starting β-hCG levels, early gestations, and small ectopic pregnancies (<2 cm) are at greater risk of having a persistent pregnancy after a salpingostomy (95). Because of this risk, after salpingostomy, weekly β-hCG levels should be followed to ensure complete resolution of the ectopic pregnancy. β-hCG levels that persist or plateau can usually be treated successfully with a single dose of *methotrexate* (31). Historically, milking the tube to effect a tubal abortion was advocated; if the pregnancy is located within the fimbriae, this technique may be effective. However, when milking was compared with linear salpingostomy for ectopic pregnancies within the ampulla, milking was associated with a twofold increase in the recurrent ectopic pregnancy rate, thus this process is generally not recommended (96).

Reproductive Outcome

Reproductive outcome after ectopic pregnancy is evaluated by determining tubal patency by HSGs, the subsequent intrauterine pregnancy rate, and the recurrent ectopic pregnancy rate. Pregnancy rates are similar in patients treated by either laparoscopy or laparotomy, though a minimally invasive procedure is preferred due to lower overall risks and faster recovery. **Tubal patency on the ipsilateral side after conservative laparoscopic management is about 84%** (97). **In a study of 143 patients followed after undergoing laparoscopic procedures for ectopic pregnancy, the overall intrauterine pregnancy rates after laparoscopic salpingostomy (60%) and**

laparoscopic salpingectomy (54%) were not significantly different (98). However, if the patient had evidence of tubal damage, pregnancy rates (42%) were significantly lower than in those women who did not have tubal damage (79%). In another study, the reproductive outcome of 188 patients followed for a mean of 7.2 years (range 3 to 15 years) was reported after conservation by laparotomy for ectopic pregnancy (99). In randomized controlled trials comparing salpingectomy and salpingostomy, there was no overall difference in future intrauterine pregnancy rates or repeat ectopic pregnancy. However, in cohort studies, salpingostomy is associated with higher rate of repeat ectopic pregnancy (10% vs. 4% with salpingectomy, OR 2.27), but is associated with a slightly higher rate of intrauterine pregnancy (RR 1.24, CI 1.08–1.42) (100).

Medical Treatment

The drug most frequently used for medical management of ectopic pregnancy is *methotrexate,* although other agents have been studied, including potassium chloride (KCl), hyperosmolar glucose, prostaglandins, and *RU-486.* These agents may be given systemically (intravenously, intramuscularly, or orally) or locally (laparoscopic direct injection, ultrasound-guided injection, or retrograde salpingography). Other agents besides *methotrexate* are not recommended for the treatment of ectopic pregnancy because their safety and efficacy are not well-documented.

Methotrexate

Methotrexate is a folic acid analog that inhibits dehydrofolate reductase and thereby prevents synthesis of DNA. *Methotrexate* affects actively growing cells including trophoblastic tissues, malignant cells, bone marrow, intestinal mucosa and respiratory epithelium (101). It is used extensively in the treatment of gestational trophoblastic disease (see Chapter 41). Initially, *methotrexate* was used for the treatment of trophoblastic tissue left *in situ* after exploration for an abdominal pregnancy (102). In 1982, Tanaka et al. treated an unruptured interstitial gestation with a 15-day course of intramuscular *methotrexate and began treatment of ectopic pregnancies with this medication* (103). Multiple studies have documented the safety and efficacy of *methotrexate* therapy for the management of ectopic pregnancies; this is the first-line treatment for many providers. Approximately 35% of patients with ectopic pregnancies are candidates for primary therapy with *methotrexate* (104). *Methotrexate* may be given for the treatment of persistent ectopic pregnancies that fail surgical management.

Candidates for Methotrexate

Medical management of ectopic pregnancies with *methotrexate* is safe and effective, however, not all patients are candidates for this medical therapy. *Methotrexate* therapy can be considered for patients with confirmed, or high suspicion for ectopic pregnancy who are hemodynamically stable with no evidence of rupture. **Table 32-3** documents the absolute contraindications to *methotrexate* therapy including breastfeeding, hepatic,

renal, or hematologic disorders and known sensitivity to *methotrexate*. Relative contraindications to *methotrexate* therapy include gestational sac greater than 4 cm and embryonic cardiac motion on transvaginal ultrasound (Table 32-3). Prior to the administration of *methotrexate*, a patient should have a complete blood count, blood type, liver function tests, electrolyte panel including creatinine, and a chest x-ray if there is any history of pulmonary disease. These studies are usually repeated 1 week after administration of *methotrexate* to evaluate for any potential complications from the therapy (105).

Table 32-3 Contraindications to Medical Therapy

Absolute Contraindications
Intrauterine pregnancy
Hemodynamically unstable
Ruptured ectopic pregnancy
Breastfeeding
Immunodeficiency
Moderate to severe anemia, leukopenia or thrombocytopenia
Known sensitivity to *methotrexate*
Active pulmonary disease
Active peptic ulcer disease
Clinically important hepatic or renal dysfunction
Relative Contraindications
Ectopic pregnancy >4 cm in size by transvaginal ultrasound
Embryonic cardiac motion detected on transvaginal ultrasound
Unable to comply with medical management follow-up
High initial β-hCG concentration (>5,000 mIU/mL)
Refusal to accept blood transfusion

Adapted from The Practice Committee of the ASRM, Medical Treatment of Ectopic Pregnancy, 2013.

Methotrexate Dosing Regimens

Methotrexate is typically given via intramuscular injection but can be administered orally or by intravenous infusion. There are three published regimens for administration of methotrexate: single-dose regimen, a two-dose regimen, and a multidose regimen.

Methotrexate traditionally was administered using a multidose regimen, but single dosing protocols have improved patient compliance and have similar success rates of approximately 90% (92,106). The single-dose protocol also has fewer side effects, however an additional dose of methotrexate may be required in up to 25% of women who receive this treatment (92,106). This second dose is more often required in women with higher starting β-hCG levels.

Methotrexate Single-Dose Regimens

Single-dose regimens were designed to increase patient compliance and simplify the administration of *methotrexate*. This regimen is well studied and safe and effective in the treatment of ectopic pregnancies. The single-dose regimen is detailed in Table 32-4.

Table 32-4 *Methotrexate* Treatment Regimens

Single-Dose Regimen
Administer *MTX* 50 mg/m^2 on day 0
Measure β-hCG level on days 4 and 7
If levels drop by 15%, monitor β-hCG weekly until nonpregnant level
If levels do not drop by 15%, repeat dose of *MTX* and measure β-hCG on days 4 and 7
Multidose Regimen
Administer *MTX* 1 mg/kg IM days 1, 3, 5, 7
Administer *leucovorin* 0.1 mg/kg IM days 2, 4, 6, 8
Measure β-hCG levels on days 1, 3, 5, 7 until 15% decrease between two measurements
Once β-hCG levels drop 15%, stop *MTX* and monitor β-hCG weekly until nonpregnant level
Two-Dose Regimen
Administer *MTX* 50 mg/m^2 on days 0 and 4
Measure β-hCG level on days 4 and 7
If levels drop by 15%, monitor β-hCG weekly until nonpregnant level
If levels do not drop by 15%, repeat dose of *MTX* on days 7 and 11 and measure β-hCG on days 11 and 14. If levels drop 15%, monitor β-hCG weekly until nonpregnant level

MTX, methotrexate; IM, intramuscular; β-hCG, β-human chorionic gonadotropin.
Adapted from The Practice Committee of the ASRM, Medical Treatment of Ectopic Pregnancy, 2013.

Approximately 15% to 20% of patients in the single-dose regimen will require a second dose of *methotrexate* because of persistent β-hCG levels (106,107). The β-hCG level at the time of treatment appears to predict the subsequent success rate of single-

dose therapy. Patients with β-hCG levels greater than 5,000 mIU/mL have a 14.3% chance of treatment failure compared to only 3.7% for women with levels less than 5,000 mIU/mL. **[4] Compared with the multidose protocol, single-dose *methotrexate* is less expensive, patient acceptance is greater because less monitoring is required during treatment, and the treatment results and prospects for future fertility are comparable** (108).

Multidose Regimen

The multidose regimen is outlined in **Table 32-4**. Patients receive 1 mg/kg of *methotrexate* intramuscularly or intravenously on days 1, 3, 5, and 7 with leucovorin 0.1 mg/kg administered on days 2, 4, 6, and 8. As a result of the repeat dosing of *methotrexate*, side effects are more common. The leucovorin helps reduce these side effects and increases patients' tolerance of the treatment. A patient may not require all four doses of *methotrexate* and her β-hCG levels should be monitored on days 1, 3, 5, and 7. If the β-hCG level drops 15% between two measurements, the regimen can be stopped and weekly β-hCG monitoring initiated. If the *methotrexate* is discontinued early, the patient should receive leucovorin after her final dose of *methotrexate* to help reduce potential side effects. If a patient's β-hCG level plateaus or increases, a second round of *methotrexate* and leucovorin can be given 1 week later. Earlier studies indicated approximately 19% will require all four doses, and 17% of women will require only one dose with this regimen (109,110). A **meta-analysis showed 10% of women require only one dose, while nearly 54% will require all four doses** (106).

Methotrexate Two-Dose Regimen

The two-dose regimen was described as a cross between the single- and multidose regimens. Because only 54% require all four doses of the multidose regimen and 15% to 25% will require a second dose in the single-dose regimen, it is reasonable to consider a two-dose regimen of *methotrexate*. The protocol is outlined in **Table 32-4** and involves the administration of *methotrexate* on day 0 and day 4 with monitoring of β-hCG levels on days 4 and 7. If there is less than a 15% drop between the two measures, a repeat administration of *methotrexate* is given on days 7 and 11 and β-hCG levels drawn accordingly. A single study showed an 87% success rate with low complication rates and high patient satisfaction (111).

Effectiveness of Methotrexate

The overall effectiveness of *methotrexate* therapy ranges from 78% to 96% (112). Although the previously mentioned meta-analysis of 26 observational studies including 1,300 women revealed a slightly improved rate of success with multidose therapy, another meta-analysis including two randomized controlled trials showed no difference in success rates between the two regimens. However, the β-hCG levels in both of those studies were less than 3,000 mIU/mL (106,113,114). Systematic reviews have

demonstrated an overall failure rate of at least 14.3% when initial β-hCG is greater than 5,000 mIU/mL compared with a failure rate of less than 4% when the β-hCG is less than 5,000 mIU/mL (108). When comparing *methotrexate* to laparoscopic salpingostomy, the multidose regimen has similar success rates. The single-dose regimen has lower initial success rates. However, after women receive additional doses as needed, the success rates are comparable between laparoscopic salpingostomy and single-dose *methotrexate* protocols (106).

Table 32-5 Initiation of *Methotrexate*: Physician Checklist and Patient Instructions

***Physician* Checklist**
Obtain β-hCG level
Check CBC with differential, liver function tests, creatinine, blood type, and antibody screen
Administer RhoGAM if patient is Rh-negative
Identify unruptured ectopic pregnancy smaller than 4 cm (relative contraindication)
Obtain informed consent
Prescribe $FeSO_4$ 325 mg PO bid if hematocrit is less than 30%
Schedule follow-up appointment on days 4 and 7
Patient Instructions
Refrain from alcohol use, multivitamins containing folic acid, NSAID use and sexual intercourse until β-hCG level is negative
Call your physician if: You experience prolonged or heavy vaginal bleeding The pain is prolonged or severe (lower abdomen and pelvic pain is normal during the first 10–14 days of treatment)

About 4% to 5% of women experience unsuccessful *methotrexate* treatment and require surgery. β-hCG, human chorionic gonadotropin; SGOT, serum glutamic-oxaloacetic transaminase; BUN, blood urea nitrogen; CBC, complete blood count; *RhoGAM*, Rho(D) immune globulin; NSAIDs, nonsteroidal anti-inflammatory drugs; WBC, white blood cell; PO, by mouth; bid, twice daily.

Initiating Methotrexate

Outlined in Table 32-5 is a checklist that should be followed by the physician before initiating *methotrexate*. It includes instructions that are helpful to the patient.

Patient Follow-Up

After intramuscular administration of *methotrexate*, regardless of the dose regimen used, patients are monitored on an outpatient basis with weekly β-hCG levels. These levels need to be monitored until the β-hCG reaches nonpregnant levels. It is possible that tubal rupture may occur even if β-hCG levels are falling. Signs of a tubal

rupture include severe pain, hemodynamic instability, and a drop in hematocrit. Patients who report severe or prolonged pain should be evaluated by measuring hematocrit levels and performing transvaginal ultrasonography. The ultrasound findings during follow-up, although usually not helpful, can be used to provide reassurance that the tube is not ruptured (115). Cul-de-sac fluid is a common finding and the amount of fluid may increase if a tubal abortion occurs. It is not necessary to intervene surgically, unless the patient has a precipitous drop in hematocrit levels or she becomes hemodynamically unstable.

Side Effects

Side effects of *methotrexate* therapy are dose and frequency dependent. The most commonly reported side effects are the gastrointestinal symptoms of nausea, vomiting, stomatitis, and abdominal pain. The frequency of reported side effects ranges from 30% to 40% (106). As a result of these potential effects, women are cautioned against using alcohol and nonsteroidal anti-inflammatory medications during treatment with *methotrexate*. Other side effects include bone marrow suppression, hemorrhagic enteritis, alopecia, dermatitis, elevated liver enzyme levels, and pneumonitis (116). These side effects are usually mild and self-limited; few life-threatening side effects are reported. The risk of all side effects does appear to be higher for multidose regimens. For those patients on prolonged therapy, *leucovorin* can reduce the incidence of these side effects and is included in the "multidose" regimen. Long-term follow-up of women treated with *methotrexate* for gestational trophoblastic disease shows no increase in congenital malformations, spontaneous abortions, or tumors recurring after chemotherapy (117). Treatment of ectopic pregnancy differs from that of gestational trophoblastic disease in that a smaller total dose of *methotrexate* is required and shorter treatment duration is used. Although surgical management of ectopic pregnancy remains the mainstay of treatment worldwide, *methotrexate* treatment is appropriate in those patients who meet the treatment criteria.

Reproductive Outcome

Reproductive function after *methotrexate* treatment can be assessed on the basis of repeat ectopic pregnancy rates, tubal patency, and pregnancy outcome. The risk of subsequent ectopic pregnancy is approximately 10% following either *methotrexate* or salpingostomy (118,119). The tubal patency rates are reported to be higher than 80% in those patients treated with either single-dose or multidose regimens with no difference in rates compared with women treated with salpingostomy. A randomized trial comparing *methotrexate* to laparoscopic salpingostomy showed no difference in tubal patency rates among the two groups, although in this trial patency rates were lower than previously reported at 66% in the salpingostomy group (120). Subsequent spontaneous intrauterine pregnancy rates are similar between those women treated with *methotrexate* versus salpingostomy, with rates ranging from 36% to 64% (121,122). A

Cochrane review comparing interventions for ectopic pregnancy showed no difference in subsequent risk of a repeat ectopic pregnancy and future intrauterine pregnancy rates comparing surgically and medically treated patients. Studies evaluating ovarian reserve after treatment with methotrexate for an ectopic showed no impact on future ovarian reserve (123,124). **[5] Comparison of laparoscopically treated patients with *methotrexate*-treated patients indicates that the two methods have similar reproductive outcomes (92).**

Types of Ectopic Pregnancy

Spontaneous Resolution of Pregnancies of Unknown Location

Some ectopic pregnancies resolve by resorption or by tubal abortion, obviating the need for medical or surgical therapy. The proportion of ectopic pregnancies that resolve spontaneously and the factors that make this more likely are unknown. There are no specific criteria for predicting successful spontaneous resolution of an ectopic pregnancy. A falling β-hCG level is the most common indicator used, but tubal rupture can occur even with falling β-hCG levels. One recent study found that a ratio of β-hCG level at 48 hours compared with initial hCG level of <0.87 predicted a failing pregnancy of unknown location, better than absolute serum β-hCG levels at both of those time periods (125). Patients with low initial levels of β-hCG are generally the best candidates for expectant management, and there is a reported 88% success rate of spontaneous remission with an initial β-hCG level less than 200 mIU/mL (126,127). These patients should be followed with serial β-hCG levels, with a plan to initiate active management if levels plateau or rise or signs suggestive of tubal rupture occur.

Persistent Trophoblastic Tissue

Persistent ectopic pregnancy occurs when a patient underwent conservative surgery (e.g., salpingostomy, fimbrial expression) and viable trophoblastic tissue remains. Histologically, several criteria exist: there is no identifiable embryo, the implantation usually is medial to the previous tubal incision and residual chorionic villi are confined to the tubal muscularis. Peritoneal trophoblastic tissue implants may be responsible for persistence. Diagnosis is made when β-hCG levels plateau after conservative surgery. Risk factors for persistent ectopic pregnancy include the type of surgical procedure, the initial β-hCG level, the duration of amenorrhea, and the size of the ectopic pregnancy, with smaller, earlier pregnancies treated by salpingostomy carrying the highest risk (128). Patients treated with laparoscopic salpingostomy have a higher rate of persistent ectopic pregnancies compared to those treated with salpingostomy at the time of a laparotomy, with an incidence of **persistence after laparoscopic linear salpingostomy ranging from 4% to 15%** (39,92,94).

Management. **Persistent ectopic pregnancy can be treated surgically or**

medically; surgical therapy consists of either repeat salpingostomy or, more commonly, salpingectomy. *Methotrexate* offers an alternative to patients who are hemodynamically stable at the time of diagnosis. *Methotrexate* may be the treatment of choice because the persistent trophoblastic tissue may not be confined to the tube and, therefore, not readily identifiable during repeat surgical exploration (128).

Nontubal Ectopic Pregnancy

The majority of ectopic pregnancies diagnosed are found in the ampulla portion of the fallopian tube and the majority (93%) found within some part of the fallopian tube. Increasingly, more ectopic pregnancies are found in other locations within the abdomen and pelvis. These nontubal ectopic pregnancies are rare but are important to consider as they are associated with more adverse events caused by difficulty and delay in diagnosis and treatment.

Cervical Pregnancy

Diagnosis. **Pregnancy implanted within the cervix is the rarest of all ectopic pregnancies, accounting for less than 1% of all ectopic pregnancies** (1). The cause of cervical ectopic pregnancies is unknown and the rare occurrence prevents identification of known risk factors. The diagnosis may not be suspected until the patient is undergoing suction curettage for a presumed incomplete abortion and hemorrhage occurs. In some cases, bleeding is light, whereas in others there is hemorrhage. These types of ectopic pregnancies are diagnosed and distinguished from ongoing spontaneous abortion mainly with ultrasound findings, and serial β-hCG measurements. Distinguishing a cervical ectopic pregnancy from an incomplete process is often difficult, and many cervical ectopic pregnancies may be misdiagnosed (129). Suggested criteria can be found in Table 32-6. Other potential diagnoses that must be differentiated from cervical pregnancy include cervical carcinoma, cervical or prolapsed submucosal leiomyomas, trophoblastic tumor, placenta previa, and low-lying placenta. An MRI may be helpful in distinguishing between some of these entities if the ultrasound and β-hCG measurements are not clear.

Table 32-6 Ultrasound Criteria for Cervical Pregnancy

1. Gestational sac or placental tissue visualized within the cervix
2. Cardiac motion noted below the level of the internal os
3. No intrauterine pregnancy
4. Hourglass uterine shape with ballooned cervical canal
5. No movement of the sac with pressure from transvaginal probe (i.e., no “sliding sign” that is typically seen with incomplete abortions)

6. Closed internal os

Adapted from **Kung FT, Lin H, Hsu TY, et al.** Differential diagnosis of cervical ectopic pregnancy and conservative treatment with the combination of laparoscopy-assisted uterine artery ligation and hysteroscopic endocervical resection. *Fertil Steril* 2004;81:1642–1649.

Management. **Options for management of cervical ectopic pregnancies include medical treatment with *methotrexate* and surgical dilation and curettage.** The ideal regimen for medical management is unknown and success is reported with both the single- and multidose regimens. More advanced gestations, especially with fetal cardiac activity, may require a combination of multidose *methotrexate* and intra-amniotic/intra-fetal injection of KCl for fetal demise. These injections require skill to avoid rupture of membranes during the procedure. A retrospective study of 62 women with cervical ectopic pregnancies treated in China found that viable pregnancies treated with methotrexate had a higher rate of surgical intervention (43%) than nonviable pregnancies (13%) (130). As this was a retrospective chart review, the authors do not comment on whether some of the additional procedures were planned or if they were a result of methotrexate failure. As with tubal ectopic pregnancies, medical management is appropriate only for those patients who are hemodynamically stable (129).

Preventative surgical management of cervical ectopic pregnancy has been described. If the patient and physician elect to proceed with surgical management, the preoperative preparation should include blood typing and cross-matching, establishment of intravenous access, and detailed informed consent. This consent should include the possibility of hemorrhage that may require transfusion or hysterectomy. In a small study of 6 patients with cervical ectopic in China, all patients were treated with uterine artery embolism (UAE) followed by hysteroscopic endocervical resection (129). Treatment was successful in all six cases without any adjunctive methotrexate treatment and with minimal blood loss (mean 125 mL, range 50 to 250 mL). While this study is small, it suggests the safety of minimally invasive techniques. Patients should be counseled that the fertility effects of undergoing even a temporary UAE are not yet clear.

When a cervical ectopic pregnancy presents with bleeding or if bleeding occurs as part of treatment, various techniques can be used including uterine packing, UAE, lateral cervical suture placement to ligate the lateral cervical vessels, placement of a cerclage, and insertion of an intracervical 30-mL Foley catheter for cervical tamponade. When none of these methods is successful, hysterectomy is required.

Ovarian Pregnancy

Diagnosis. **A pregnancy confined to the ovary accounts for up to 3% of all ectopic pregnancies and is the most common type of nontubal ectopic pregnancy** (1,131). Though the clinical presentation of bleeding, abdominal pain, and positive pregnancy test is similar, ovarian pregnancy is not associated with PID, infertility, or tubal disease

like other ectopic pregnancies (132). The pathology diagnostic criteria were described in 1878 by Spiegelberg, listed in Table 32-7 (133). Ultrasound criteria are difficult as findings are typically a cystic ovarian mass, with a differential of corpus luteum cyst, hemorrhagic cyst, and tubal ectopic pregnancy.

Management. The treatment of ovarian pregnancy has changed. Whereas oophorectomy was advocated in the past, **ovarian cystectomy and/or wedge resection is utilized with success** and successful treatment with *methotrexate* has been reported (134–136).

Abdominal Pregnancy

Abdominal pregnancies are one of the rarest types of ectopic pregnancy, representing 1% to 1.4% of ectopic pregnancies (1,131). They are typically classified as primary or secondary. Pathology criteria for primary abdominal ectopic pregnancy have been established by Studdiford (see Table 32-8) and include normal tubes and ovaries, no evidence of uteroplacental fistula (137). Secondary abdominal pregnancies are more common, thought to result from tubal abortion or rupture or, less often, from subsequent implantation within the abdomen after uterine rupture. Risk factors for abdominal pregnancy include PID, multiparity, endometriosis, assisted reproductive techniques, and tubal damage. The most common area of implantation within the abdomen is the posterior cul-de-sac, and pregnancies have been confirmed in the mesosalpinx, omentum and bowel, liver, spleen, abdominal wall, and within broad ligament (131). **Abdominal pregnancy is associated with high morbidity and mortality, with the risk for death seven to eight times greater than from tubal ectopic pregnancy and 50 times greater than from intrauterine pregnancy**, most likely resulting from later diagnosis.

Table 32-7 Criteria for Ovarian Pregnancy Diagnosis

1. The fallopian tube on the affected side must be intact
2. The fetal sac must occupy the position of the ovary
3. The ovary must be connected to the uterus by the ovarian ligament
4. Ovarian tissue must be located in the sac wall

From **Spiegelberg O.** Casusistik der ovarialschwangerschaft. *Arch Gynaecol* 1878;13:73.

Table 32-8 Studdiford's Criteria for Diagnosis of Primary Abdominal Pregnancy

1. Presence of normal tubes and ovaries with no evidence of recent or past pregnancy
2. No evidence of uteroplacental fistula

3. The presence of a pregnancy related exclusively to the peritoneal surface and early enough to eliminate the possibility of secondary implantation after primary tubal nidation

Adapted from **Anderson PM, Opfer EK, Busch JM, et al.** An early abdominal wall ectopic pregnancy successfully treated with ultrasound guided intralesional methotrexate: A case report. *Obstet Gynecol Int* 2009; Article ID 247452.

Diagnosis. Ultrasound detects only approximately half of all abdominal ectopic pregnancies. Ultrasound features that have been suggested include gestational sac surrounded by loops of bowel, normal-appearing fallopian tubes, and ovaries (138). Differential includes intrauterine pregnancy with retroflexion or distorted by fibroids. When diagnosis is highly suspected, MRI may be helpful in assessing degree of vascular attachment to other abdominopelvic tissues. Abdominal ectopic pregnancies are one of the few ectopic pregnancies that may proceed out of the first trimester. In advanced abdominal pregnancy, the clinical presentation may include painful fetal movement, fetal movements high in the abdomen or sudden cessation of movements. Physical examination may disclose persistent abnormal fetal positioning, abdominal tenderness, a displaced uterine cervix, easy palpation of fetal parts, and palpation of the uterus separate from the gestation. The diagnosis may be suspected when there are no uterine contractions after *oxytocin* infusion.

Management. Because the pregnancy can continue to term, the potential maternal morbidity and mortality are very high. As a result, **surgical intervention is recommended when an abdominal pregnancy is diagnosed.** At surgery, the placenta can be removed if its vascular supply can be identified and ligated, but hemorrhage can occur, requiring abdominal packing that is left in place and removed after 24 to 48 hours. Options for management of hemorrhage include artery embolization. If the vascular supply cannot be identified, the cord is ligated near the placental base, and the placenta is left in place. Placental involution can be monitored using serial ultrasonography and assessment of β-hCG levels. Potential complications of leaving the placenta in place include bowel obstruction, fistula formation and sepsis as the tissue degenerates. There are concerns regarding the use of *methotrexate* treatment in abdominal pregnancies. Specifically, there is theoretically an increased risk of infection and sepsis resulting from the rapid tissue necrosis that occur following *methotrexate* administration. There are reports of successful treatment of abdominal pregnancies with *methotrexate* in patients not considered to be optimal surgical candidates (136,139). There are scattered reports of term abdominal pregnancies. When this occurs, perinatal morbidity and mortality are high, usually as a result of growth restriction and congenital anomalies such as fetal pulmonary hypoplasia, pressure deformities, and facial and limb asymmetry (140).

Interstitial Pregnancy

Diagnosis. **Interstitial pregnancies represent about 2.4% of ectopic pregnancies**

(1). This section of the fallopian tube is relatively thick with an increased capacity to expand prior to rupture. This ability along with increased vascularity of this area may allow these types of ectopic pregnancies to remain asymptomatic for 7 to 16 weeks of gestation (141). However, late presentations are rare; most patients typically present between 6 and 8 weeks of gestation (141). Differential diagnosis includes angular pregnancy, a viable pregnancy that implants within the uterine angle, medial to the ostia. Typically angular pregnancies are asymptomatic unless they end in miscarriages, which occurs approximately 38% of the time (141). In laparoscopy, these can be distinguished as a true interstitial pregnancy appears lateral to the round ligament.

Interstitial pregnancies represent a disproportionately large percentage of fatalities from ectopic pregnancy with a 2.5% mortality rate (142).

Management. These pregnancies were classically treated with laparotomy with cornual resection. Early detection allows for a more conservative management approach in hemodynamically stable patients without evidence of rupture. Medical management with *methotrexate* is well described, with the single- and multidose regimens. Approximately 10% to 20% of patients treated medically will ultimately require surgery and close follow-up is warranted as with all medically managed ectopic pregnancies (141).

Although cornual wedge resection by laparotomy is an acceptable surgical option, minimally invasive techniques exist, including cornual excision, minicornual excision and cornuostomy. Laparoscopic approaches are more widely used and are dependent on surgical skill. Transcervical suction evacuation under laparoscopic or ultrasound guidance has been reported (136,141). The appropriate surgical technique and approach depends on the individual patient presentation and the surgeon's expertise.

Cesarean Scar Ectopic Pregnancy

A pregnancy implanted within the uterine myometrium at the site of a healed cesarean scar is called a cesarean scar pregnancy (CSP). Historically, CSP has been an extremely rare occurrence. However, as cesarean deliveries are becoming more common, incidence has been slowly increasing with estimations among women with prior cesarean deliveries to be up to 1:500 pregnancies (136,143). Because of small numbers, it has not been determined if the number of cesarean deliveries or type of cesarean delivery (e.g., classical or Pfannenstiel incisions) affect risk of CSP.

Diagnosis. Ultrasound is the initial diagnostic tool for CSP, with signs suggestive of CSP including: (1) gestational sac located at the level of the prior scar; (2) surrounding Doppler flow with minimal separation from bladder; (3) outward bulging of the gestational sac within the scar; and (4) negative "sliding organs sign" where the gestational sac does not move with gentle pressure from transvaginal ultrasound (143). CSPs have been separated into two types based on prognosis; type 1 progressing toward uterine cavity; type 2 progressing toward the bladder.

Management. As CSP is quite rare and can present differently based on location and type, there is no management that has proved superior. Early treatment is recommended, as CSP can progress into placental accreta or even uterine rupture if left untreated. Management options include medical management with systemic or local injection of either methotrexate or KCl, surgical management with dilation and curettage with or without hysteroscopy, UAE, or some combination of these approaches. Medical management should only be offered to hemodynamically stable patients. Success rates for methotrexate doses systemically, locally, and combined systemic/local have been reported as 56%, 60%, and 77%, respectively. These cases had a hemorrhage rate of 7% and hysterectomy rate of 3% (143). For surgical management, dilation and curettage under ultrasound guidance had a reported success rate of 76% with a 30% hemorrhage risk and 3% hysterectomy risk (143). Hysteroscopic resection was used with a 62% risk of persistent trophoblastic disease and should be performed in combination with dilation and curettage. A combination of methotrexate followed by dilation and curettage has been reported with success rates up to 86%, hemorrhage risk of 14%, and hysterectomy risk of 4%. UAE can be performed prior to dilation and curettage or even prior to methotrexate therapy to reduce hemorrhage risk. If UAE is not done prophylactically, it can be done in the case of hemorrhage after other treatment options. In some cases, methotrexate was injected into uterine arteries prior to UAE. If used alone, UAE has a reported success rate of 81% with risk of hemorrhage 5%, and risk of hysterectomy 4% (143).

Heterotopic Pregnancy

Heterotopic pregnancy occurs when intrauterine and ectopic pregnancies coexist. The reported incidence is 1:30,000 (35). The diagnosis is often delayed as an intrauterine pregnancy is seen during ultrasonography examination and an extrauterine pregnancy may be overlooked. Patients undergoing ovulation induction with assisted reproductive technology are at risk of ovarian hyperstimulation syndrome (OHSS), which can cause similar ultrasound findings including enlarged ovaries and free fluid in the abdomen and is important to consider in differential diagnosis (144). Serial β-hCG levels are not helpful because the intrauterine pregnancy causes the β-hCG level to rise appropriately. Heterotopic pregnancy is much more common with assisted reproductive technology than spontaneous conception, with possible etiologies including multiple embryo transfers and previous tubal damage (144,145).

Management. The ectopic pregnancy is treated surgically if the intrauterine pregnancy is desired. When the ectopic pregnancy is removed, the intrauterine pregnancy continues in most patients. The rate of spontaneous abortion is higher with approximately one in three ending in miscarriage (145,146). It may be possible to treat the ectopic pregnancy using nonchemotherapeutic medical treatment, such as KCl, by transvaginal or laparoscopically directed injection; however, a reported 55% may

require additional surgical treatment (147).

Multiple Ectopic Pregnancies

Twin or multiple ectopic gestations occur less frequently than heterotopic gestations and may appear in a variety of locations and combinations. Multiple ectopic pregnancies are thought to be rare, but with the advent of assisted reproductive technologies the incidence appears to be rising. A review of bilateral tubal pregnancies reported 242 cases between 1918 and 2007, with 42 cases in the past 10 years alone. Fifty percent of these twin tubal pregnancies were associated with assisted reproductive technologies (148). Another review of 163 cases of tubal ectopic pregnancies had a reported rate of twin tubal pregnancies of 2.4% (149). Although most reports are confined to twin tubal gestations, ovarian, interstitial, and abdominal twin pregnancies have been reported. Management is similar to that of other types of ectopic pregnancy and is somewhat dependent on the location of the pregnancy.

Pregnancy After Hysterectomy

The most unusual form of ectopic pregnancy is one that occurs after vaginal or abdominal hysterectomy (150,151). Such a pregnancy may occur after supracervical hysterectomy because the patient has a cervical canal that may provide intraperitoneal access (149). Pregnancy may occur in the perioperative period with implantation of the already fertilized ovum in the fallopian tube. Pregnancy after total hysterectomy probably occurs secondary to a vaginal mucosal defect that allows sperm into the abdominal cavity. Only case reports are available and management options include surgical removal and systemic methotrexate, depending on location of pregnancy and patient characteristics.

- Other Factors
- Environmental Factors

Preconception Evaluation
- History
- Physical Examination
- Recommended Testing
- Tests with Unproven Utility

Postconception Evaluation

Therapy
- Genetic Abnormalities
- Anatomic Anomalies
- Endocrine Abnormalities
- Infections
- Immunologic Factors
  - *Immunostimulating Therapies: Leukocyte Immunization*
  - *Immunosuppressive Therapies*
  - *Antithrombotic Therapy*
- Psychological Support

Prognosis

KEY POINTS

1 Isolated spontaneous pregnancy loss is common and approximately 15% to 30% of recognized pregnancies end in miscarriage. Recurrent pregnancy loss defined by three or more miscarriages is rare, occurring in 1% of women.

2 Clinical evaluation of a couple with recurrent miscarriage is warranted after two miscarriages caused by similar prevalence of abnormal results for couples with two or three pregnancy losses.

3 The most common cause of first trimester miscarriage is fetal aneuploidy.

4 Evaluation of patients with recurrent miscarriage should include a detailed patient and family history and examination of anatomic, genetic, endocrine, and antiphospholipid syndrome abnormities.

5 Much of the traditionally accepted testing, such as thrombophilia screening and several immunologic screening tests, are not supported by current evidence.

6 At least 50% of couples will have no specific abnormal finding after an evaluation for recurrent miscarriage.

7 After several pregnancy losses, there remains a greater chance of having a viable birth than another miscarriage, even without treatment. Prognosis can improve with treatment of a known underlying etiology.

8 Controversial treatments for recurrent miscarriage, including in vitro fertilization with chromosomal screening of embryos, immunosuppression, and anticoagulation, remain under investigation.

9 Treatment for recurrent pregnancy loss should include close monitoring with β-human chorionic gonadotropin levels and ultrasound, psychological support, and karyotypic analysis of tissues from subsequent miscarriage.

Despite advances in research and technology, recurrent pregnancy loss remains a clinical and emotional challenge for patients and providers. Sporadic miscarriage is the most common complication of pregnancy affecting approximately 1 in 4 couples in their reproductive years. Approximately 70% of human conceptions fail to achieve viability, and an estimated 50% are lost before the first missed menstrual period (1). Studies using sensitive assays for human chorionic gonadotropin (hCG) indicate that the actual rate of pregnancy loss after implantation is 31% (2). **[1]** Miscarriage occurs in 15% to 25% of pregnancies that are clinically recognized before 20 weeks of gestation from last menstrual period (3,4). Traditionally, recurrent miscarriage has been defined as the occurrence of three or more clinically recognized (ultrasound or histopathologic evidence) pregnancy losses before 20 weeks from the last menstrual period (5). Using this definition, recurrent pregnancy loss occurs in approximately 1 in 300 pregnancies (2) and in less than 1% of women (337).

[2] Clinical investigation of pregnancy loss, however, may be initiated after two consecutive spontaneous miscarriages (338). A study of more than 1,000 patients with recurrent pregnancy loss reported no difference in the prevalence of abnormal results for evidence-based and investigative diagnostic tests when the diagnostic workup was initiated after two versus three or more losses (6). If clinical intervention is undertaken

in the form of investigation after two spontaneous miscarriages, approximately 1% of pregnant women will require evaluation (3). Even with a history of recurrent pregnancy loss, a patient is more likely to carry her next pregnancy successfully to term than to miscarry. For patients with a history of recurrent pregnancy loss, the risk of subsequent pregnancy loss is estimated to be 24% after two clinically recognized losses, 30% after three losses, and 40% to 50% after four losses (7). These data make clinical study of recurrent pregnancy loss and its treatment difficult because very large groups of patients must be studied to demonstrate the effects of any proposed therapeutic intervention.

ETIOLOGY

Recurrent pregnancy loss has been attributed to genetic, anatomic, immunologic, endocrine, thrombophilic, and infectious causes but etiology remains under investigation. **[6] Although the exact proportion of patients diagnosed with a particular abnormality varies by study, parental genetic abnormalities (2% to 5%), anatomic issues (10% to 12%), antiphospholipid syndrome (APS) (15%), and other identifiable issues (10%) have been found in couples with recurrent miscarriage. This leaves approximately 50% of couples with a diagnosis of unexplained recurrent miscarriage** (Table 33-1) (3,6,8,338). The lack of abnormal findings in the couple having recurrent pregnancy loss is not surprising given how common fetal aneuploidy is with conception.

[3] At least 60% of preclinical and early clinical pregnancy losses are the result of *de novo* fetal aneuploidy (9). Among women aged 35 or greater who experience recurrent pregnancy loss, spontaneous fetal chromosomal abnormalities are responsible for over 80% of losses (10). This is thought to be the cause of anembryonic pregnancy losses, whereas pregnancy losses occurring after 10 weeks of fetal development are much less likely to derive from fetal aneuploidy. Pregnancy losses resulting from *de novo* fetal aneuploidy, whether early and undocumented or documented through evaluation of chromosomal content in fetal tissues, cloud the results of many published studies. Their presence or absence must be documented in all investigations on recurrent pregnancy loss patients and their potential as a confounding factor discussed. The timing of fetal demise and tissue chromosomal analysis of any collected fetal tissues should be carefully weighed when diagnostic and therapeutic investigations into causes of recurrent pregnancy loss are being considered.

Genetic Factors

Approximately 3% to 5% of recurrent pregnancy loss can be associated with a parental balanced structural chromosome rearrangement and can be diagnosed with blood tests for karyotype for both partners (338). Chromosome rearrangements are most commonly

balanced reciprocal but can include robertsonian translocations, chromosomal inversions, insertions, and mosaicism (11–14). A balanced reciprocal translocation is a rearrangement in chromosomes in which breaks occur in two different chromosomes and the pieces are exchanged so that no genetic material is lost or gained in the process. Balanced rearrangements can only be detected with standard G-banding karyotype. High-density microarray technology and next-generation sequencing can detect smaller deletions and duplications, but are not able to differentiate balanced rearrangements from normal because the total genetic content is the same. When screening parents for chromosome rearrangement, the best test is a metaphase karyotype with G-banding. Embryos from a parent with a balanced translocation with a normal phenotype have either two normal chromosomes or inherit the balanced translocation; however, some embryos can have abnormal chromosome content and lead to babies born with birth defects if they inherit an unbalanced translocation. A robertsonian translocation is a form of chromosomal rearrangement with one of the short-arm chromosomes (13–15) in which there is a loss of part or all of the short arms and fusion of the long arms of the chromosomes. A balanced robertsonian translocation causes no health issues but unbalanced forms can result in trisomies or monosomies that usually result in miscarriage. Some chromosome inversions are benign and do not impact prognosis for patients with recurrent pregnancy loss. However, others may have significant reproductive phenotypes. All patients with balanced chromosome rearrangements should undergo genetic counseling prior to attempting conception to better understand their individual risks.

Neither family history alone nor a history of prior term births is sufficient to rule out a potential parental chromosomal abnormality. Whereas the frequency of detecting a parental chromosomal abnormality is inversely related to the number of previous spontaneous losses, the chance of detecting a parental chromosomal abnormality is increased among couples who have never experienced a live birth (13). Testing for parental karyotopes in couples with recurrent miscarriage is recommended but some argue it has a high cost for discovery of a rare cause for recurrent pregnancy loss with limited treatment options. Proponents of testing indicate it promotes benefits that include permitting patient autonomy in choosing options for treatment and identification of patients at risk for offspring with unbalanced translocations who may have birth defects. A couple with a balanced translocation has a high chance of live birth attempting to conceive via intercourse (339); or they have the option of screening embryos for chromosome arrangements with in vitro fertilization (IVF) (338). Studies to date evaluating the use of IVF with chromosomal screening for couples with recurrent pregnancy loss and translocations do not show a significantly higher chance of success compared to natural conception (235,340). These studies are limited in patient number and use older technology and techniques like fluorescent in situ hybridization (FISH) and single cell day 3 embryo biopsy (235,340). With advancements such as blastocyst

biopsy, alternate chromosome analysis techniques and others, future studies may show a benefit for use of IVF in this population. Based on the existing data, IVF with embryo screening is not strongly recommended for a couple with a balanced translocation and recurrent miscarriage.

Thrombophilias

After combining a known association between the presence of antiphospholipid antibodies, placental dysfunction, and miscarriage with evidence showing subsequent increase in live birth with anticoagulation medications in these patients with recurrent miscarriage (299), attention was turned to investigating inherited thrombophilias as a cause for recurrent pregnancy loss. The clotting cascade is a delicate balance of prothrombotic (see **Fig. 33-1**) and antithrombotic pathways (see **Fig. 33-2**) and dysregulation in either or both of these pathways can cause significant health consequences. Because alterations in coagulation occur naturally in pregnancy with relative maternal hypercoagulability secondary to increases in several procoagulant activities, decreases in select antithrombotic pathways and venous stasis, the delicate balance between pro- and antithrombotic would seem to be even more tenuous throughout gestation (see **Fig. 33-3**). **[5]** Despite the biologic plausibility that patients with recurrent miscarriage would have a higher prevalence of inherited thrombophilia and that anticoagulation of patients with these diagnoses would decrease risk of subsequent miscarriage, the evidence does not support the theories (341).

Table 33-1 Proposed Etiologies and Testing for Recurrent Spontaneous Miscarriage

Proposed Etiology	Proposed Incidence	Testing Supported by Evidence	Controversial Testing	Testing Not Recommended
Embryonic genetic abnormalities	60–80%			
1. Chromosomal imbalance 2. Other genetic defects		Karyotype of pregnancy tissue/ products of conception		
Parental genetic factors	2–5%			
1. Chromosomal 2. Single gene defects 3. Multifactorial		Karyotype for both female and male partners		
Anatomic factors	12–16%			
1. **Congenital** a. Incomplete müllerian fusion or septum resorption b. *Diethylstilbestrol* exposure c. Uterine artery anomalies d. Cervical incompetence 2. **Acquired** a. Cervical incompetence b. Synechiae c. Leiomyomas d. Adenomyosis		Uterine evaluation by hysterosalpingogram, 2D saline sonogram or 3D sonography (with or without saline infusion), office hysteroscopy		
Antiphospholipid syndrome	12–15%	Lupus anticoagulant Anticardiolipin IgG and IgM antibody, anti-β2-glycoprotein IgG and IgM	Testing for other phospholipid antibodies	
Endocrine factors	17–20%			
1. Diabetes mellitus 2. Thyroid disorders 3. Prolactin disorders 4. Luteal phase insufficiency 5. Polycystic ovarian syndrome, including insulin resistance and hyperandrogenism		HbA_{1C} TSH Prolactin	Insulin resistance screening Androgen testing	Endometrial biopsy for luteal phase defect Luteal phase progesterone levels
Infectious factors	7–56%			
1. **Acute infection** 2. **Chronic endometritis**			Cultures in lower genital track and endometrial biopsy for plasma cells	
Immunologic factors other than antiphospholipid syndrome	N/A			
1. Cellular mechanisms a. Suppressor cell or factor deficiency b. Alterations in major histocompatibility antigen expression c. Alterations in cellular immune regulation 1. TH1 immune responses to reproductive antigens (embryo or trophoblast) 2. TH2 cytokine or growth factor deficiency 3. Hormonal-progesterone, estrogen, prolactin, androgen alterations 4. *Tryptophan* metabolism 2. Other humoral mechanisms a. Antithyroid antibodies b. Antisperm antibodies c. Antitrophoblast antibodies d. Blocking antibody deficiency			Anti-thyroid antibodies Other immune cell testing and screening	Anti-sperm antibody testing Circulating natural killer cells, cytokine profiles, blocking antibodies, HLA typing, antipaternal leukocyte antibodies

(*continued*)

Proposed Etiology	Proposed Incidence	Testing Supported by Evidence	Controversial Testing	Testing Not Recommended
Thrombotic factors	N/A			
1. Heritable thrombophilias 2. Antiphopholipid syndrome—see above				Factor V Leiden Prothrombin gene Protein C def Protein S def Antithrombin Homocysteine levels MTHFR (unless strong personal or family history of thrombotic events)
Other factors	N/A			
1. Altered uterine receptivity (integrins, adhesion molecules) 2. Environmental a. Toxins b. Illicit drugs c. Cigarettes and caffeine 3. Placental abnormalities (circumvallate, marginate) 4. Maternal medical illnesses (cardiac, renal hematologic) 5. Male factors 6. Exercise 7. Dyssynchronous fertilization 8. Psychological		Patient history regarding exposures and medical issues	Uterine receptivity testing Sperm testing including DNA fragmentation and aneuploidy	

TH, T helper; MTHFR, methylene tetrahydrofolate reductase; N/A, not applicable.

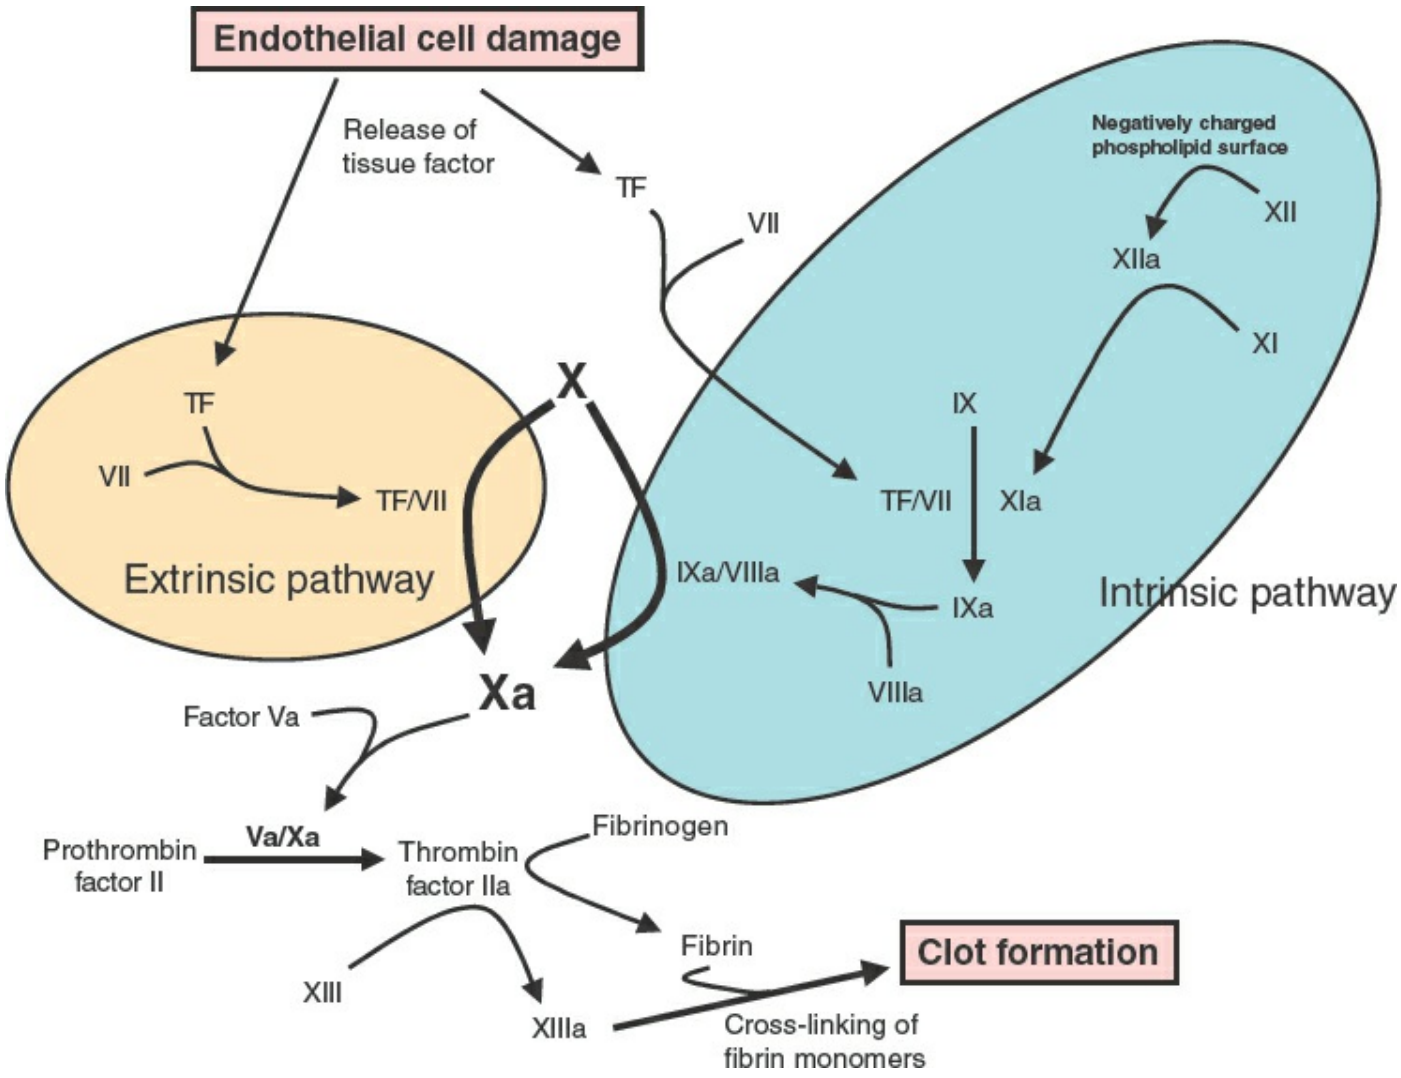

FIGURE 33-1 The clotting cascade. Physiologic clotting is initiated by endothelial cell damage or abnormal exposure of negatively charged phospholipids to serum and blood components. Procoagulant pathways in black are part of the clotting cascade and are prothrombotic. Both lead to activation of cascades of proteolytic enzymes and cleavage of clotting factors. The extrinsic and intrinsic pathways are initiated by distinct mechanisms. They merge at the activation of factor X to form the common pathway. For all coagulation factors, the subscript letter “a” denotes the activated form of the factor.

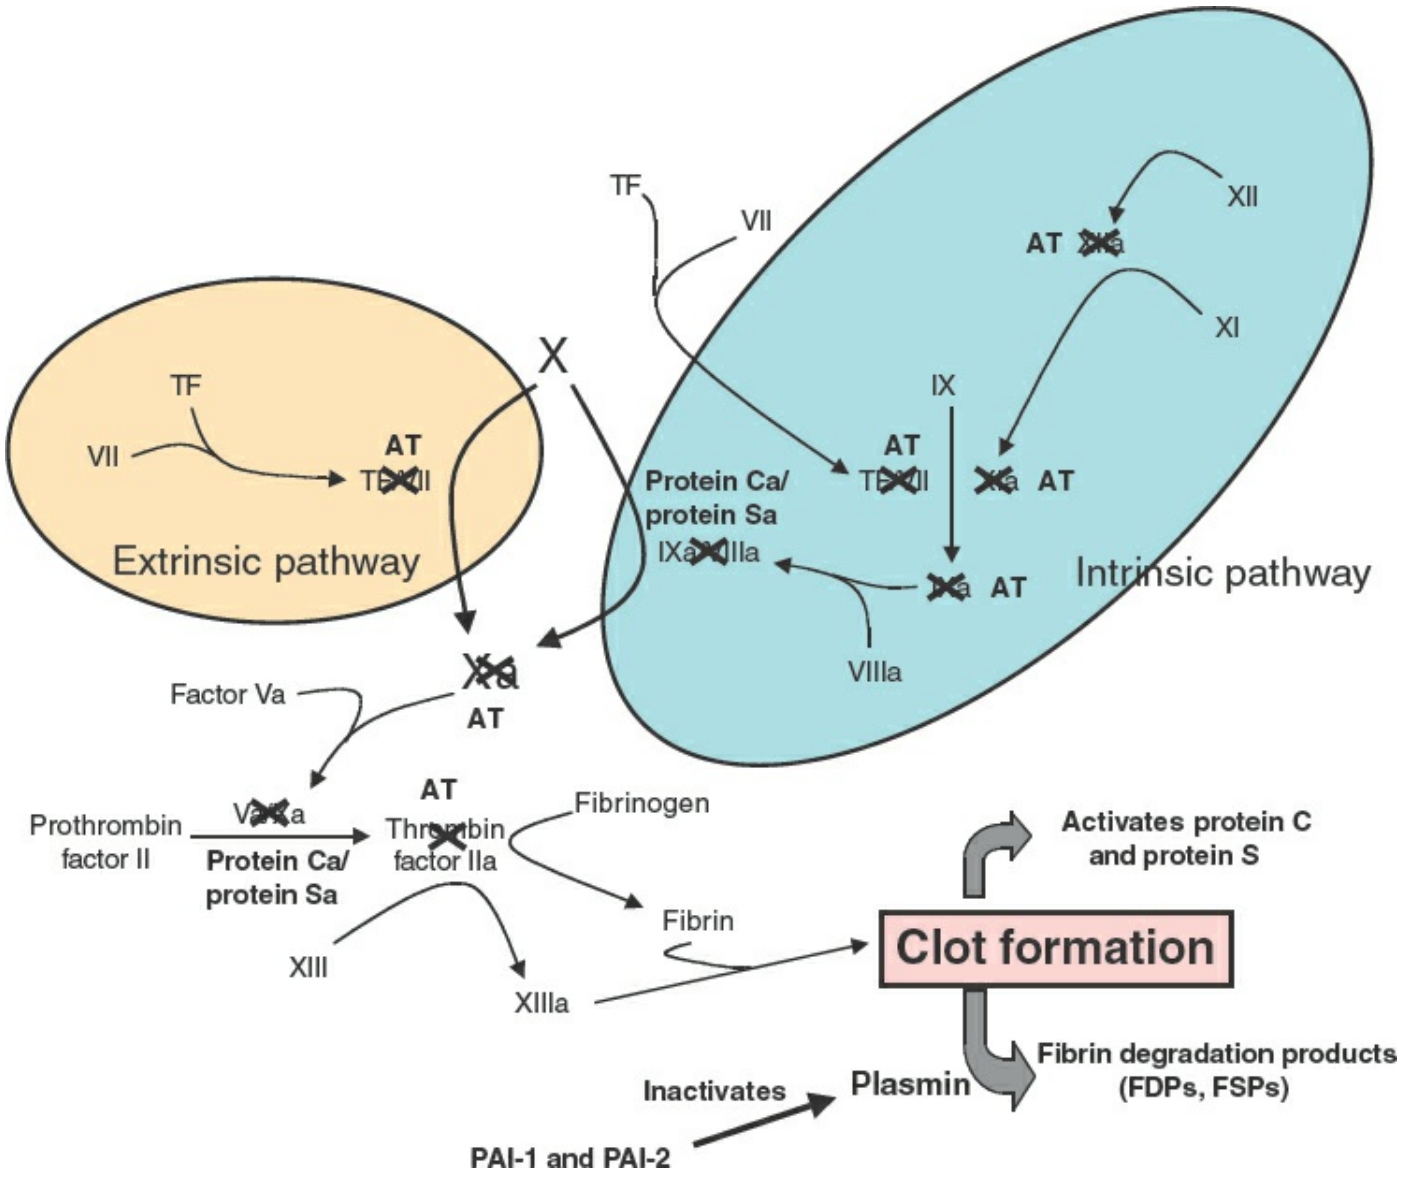

FIGURE 33-2 Physiologic mechanisms that counteract the clotting cascade. The procoagulant cascade is inhibited by several physiologic mechanisms. The balance between pro- and antithrombotic pathways determines the state of coagulability. Antithrombotic mechanisms include the action of antithrombin (AT) and of proteins C and S. The sites of inhibition by these substances are depicted by an "X." Plasminogen activator inhibitors-1 and -2 (PAI-1 and PAI-2) indirectly inactivate plasmin. Plasmin plays an important role in the dissolution of coagulated blood. For all coagulation factors, the subscript letter "a" denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

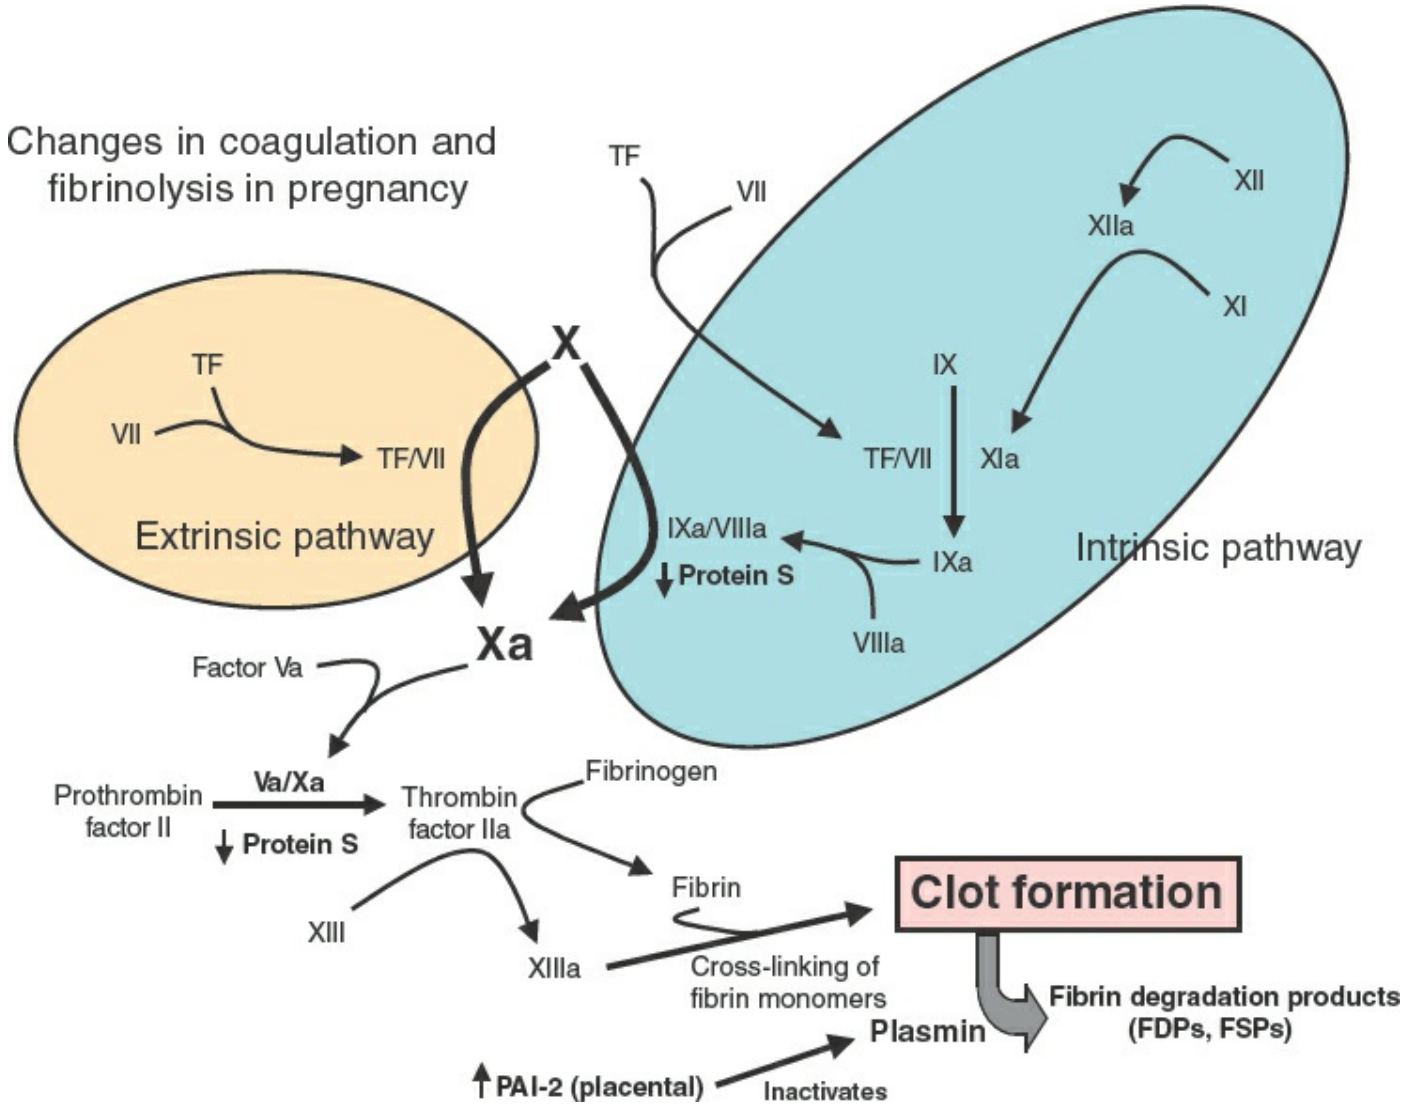

FIGURE 33-3 Alterations coagulation and fibrinolysis during normal pregnancy. Pregnancy is a state of hypercoagulability. Levels of factors VII, VIII, X, and XII are elevated throughout pregnancy, levels of factors II, V, and XIII rise in the first trimester, then return to normal values. The antithrombotic activity mediated by protein S decreases in pregnancy. The placenta produces plasminogen activator inhibitor-2 (PAI-2). For all coagulation factors, the subscript letter "a" denotes the activated form of the factor. FSP, fibrin split products; FDP, fibrin degradation products.

Inherited thrombophilia is a genetic predisposition to venous thromboembolism and traditionally includes factor V Leiden (FVL) mutation, prothrombin gene mutation, protein C deficiency, protein S deficiency, and antithrombin III deficiency. It is estimated that up to 15% of the Caucasian population carries an inherited thrombophilic mutation (15). FVL is a clotting protein that works in conjunction with activated factor X to convert prothrombin to thrombin. One comprehensive review shows that carriers for FVL have an increased relative risk of recurrent pregnancy loss (342), however, the absolute risk of miscarriage in this population is low (343). Prothrombin gene mutation results in a deficiency of thrombin and resulting increased concentration of prothrombin in the plasma. Some small studies

have shown a potential association between a mutation in the prothrombin gene and recurrent pregnancy loss but overall recommendations do not support an association with this mutation and any pregnancy complication including miscarriage, intrauterine growth restriction, or preeclampsia (342,343). **Protein S and Protein C in combination are required for factor V and VIII activation and thus deficiency in either can lead to a hypercoagulable state. Patients with protein S or protein C deficiencies may be at slightly higher risk of thrombosis in pregnancy but associations with miscarriage risk have not been definitively demonstrated** (344). **Antithrombin is a small protein that regulates clot formation by inactivating factor Xa and thrombin. Deficiency in this protein leads to high risk of thrombosis and increased risk of miscarriage** (344). Because of its low prevalence (1/2,500), antithrombin deficiency is not recommended for routine screening for recurrent miscarriage in the absence of significant family history of thrombosis (345).

Although not usually considered an inherited thrombophilia, a methylenetetrahydrofolate reductase (MTHFR) mutation may be associated with increased thrombosis risk and some suggest an association with recurrent pregnancy loss. MTHFR is an essential enzyme for folic acid metabolism and is responsible for converting homocysteine to methionine. A mutation in the enzyme may cause increased serum levels of homocysteine that may lead to a hypercoagulable state (see **Fig. 33-4**). There are two predominant mutations (C677T and A1298C) and they are common in certain populations with up to 40% of Caucasian and Hispanic populations being heterozygote for the C677T mutation (346). Some suggest that a mutation leads to lower function of the MTHFR enzyme resulting in higher homocysteine levels and increased risk of thrombosis and miscarriage but the association is controversial (347).

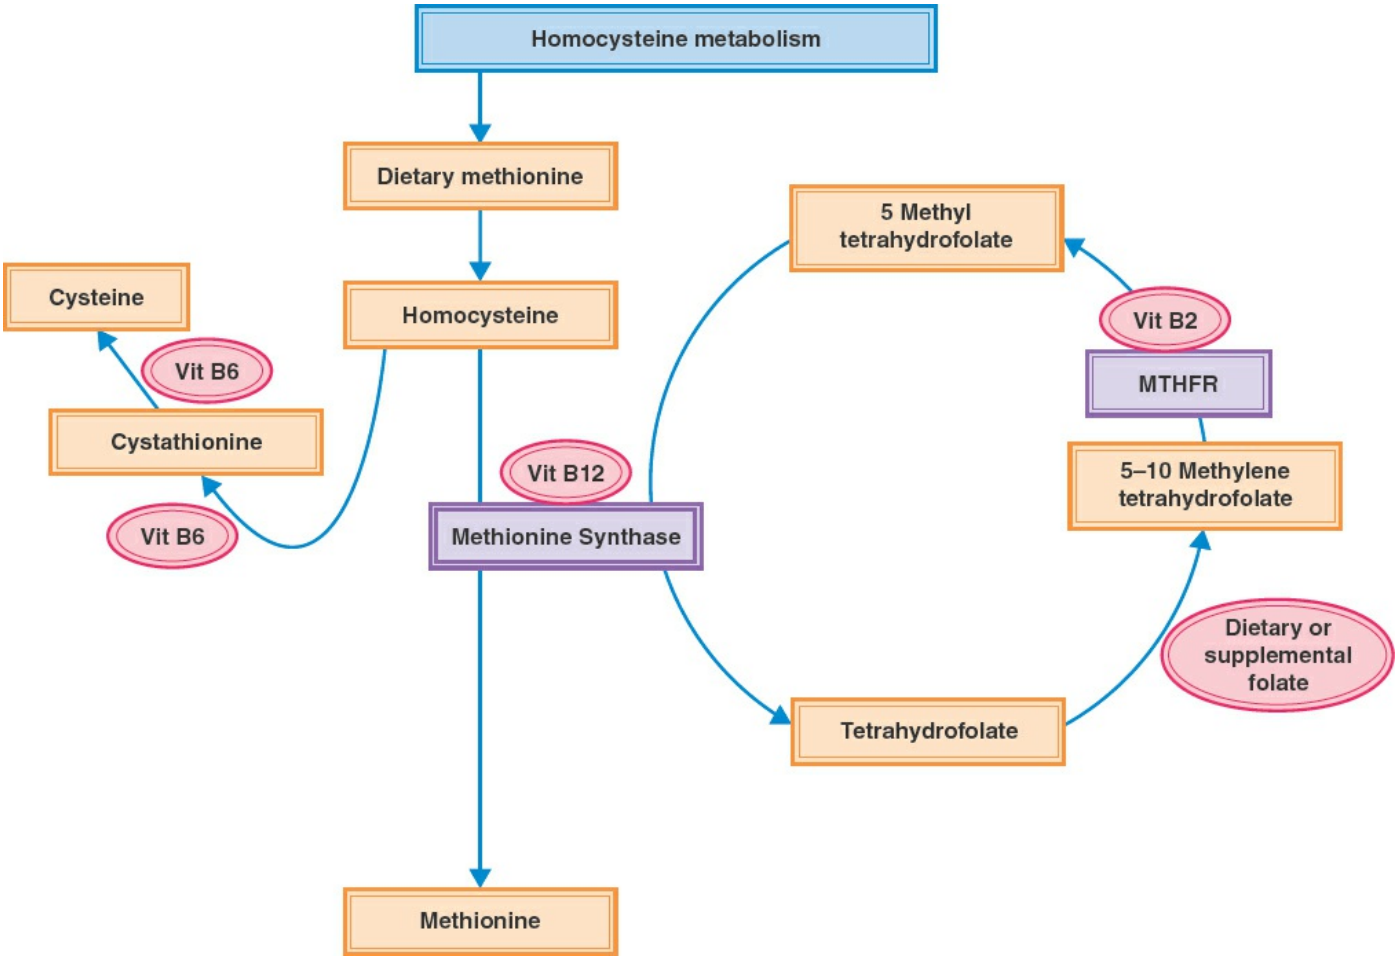

FIGURE 33-4 Homocysteine metabolism. Dietary methionine is metabolized either to cysteine or back into methionine. Homocysteine, a prothrombotic metabolite, is an intermediate in this process. Conversion of homocysteine to methionine requires transfer of a methyl group from 5-methyltetrahydrofolate. The conversion of folate to 5-methyltetrahydrofolate is a multistep process requiring vitamin B_2 as a cofactor for the enzyme, *methylene tetrahydrofolate reductase* (*MTHFR*). Vitamin B_{12} is a required cofactor for the enzyme methionine synthase. Vitamin B_6 is also required for metabolism of sulfur-containing amino acids such as *methionine.*

The proposed mechanistic basis for the association between adverse fetal outcomes and heritable thrombophilias has focused on impaired placental development and function, secondary to venous and/or arterial thrombosis at the maternal–fetal interface. These findings have been noted in the placentas of women with adverse fetal outcomes and known inherited thrombophilias and have been demonstrated in patients with similar outcomes, but lacking inherited thrombophilic risk (18–22). Detractors of placental thrombosis as causal in early pregnancy losses (<10 weeks' gestation) cite an elegant series of experiments demonstrating that maternal blood flow into the intervillous spaces of the human placenta does not occur until approximately 10 weeks of gestation (23–26). Prior to the establishment of intervillous circulation, nutrient transfer from maternal blood to fetal tissues appears to be dependent on transudation that, in turn, relies on flow through the uterine vasculature.

This suggests that maternal or fetal thrombotic episodes in the developing placental vasculature could be equally devastating prior to or after the establishment of intervillous circulation near 10 weeks of gestation. Very early pregnancy losses (biochemical, anembryonic) and known aneuploid fetal losses are unlikely to be altered by the presence of, or treatment for, an underlying thrombophilic state.

[5] Neither the American College of Obstetrician Gynecologists (ACOG) nor the American Society of Reproductive Medicine (ASRM) recommend screening for inherited thrombophilias or MTHFR mutations for patients with recurrent pregnancy loss or any adverse pregnancy outcome (338,345) unless other risk factors are present, such as a history of thrombosis in the patient or a close family member. Despite the lack of evidence and guidelines against routine screening for thrombophilia in recurrent pregnancy loss, many clinicians routinely order these tests (347,348).

Anatomic Abnormalities

Anatomic abnormalities of both the uterine cervix and the uterine body have been associated with recurrent pregnancy loss (28,29). **These anatomic causes may be either congenital or acquired.** During development, the uterus forms via the apposition of a portion of bilateral hollow tubes called the müllerian ducts. The dissolution of the walls of these ducts along their site of apposition allows formation of the intrauterine cavity, the intracervical canal, and the upper vagina. Congenital uterine anomalies may therefore include incomplete müllerian duct fusion, incomplete septum resorption, and uterine cervical anomalies. Although the causes underlying many of the congenital anomalies of the female reproductive tract are unclear, it has been well-documented that prenatal exposure to maternally ingested diethylstilbestrol (DES) results in complex congenital uterine, cervical, and vaginal changes.

Historically, all congenital reproductive tract abnormalities have been linked to isolated spontaneous pregnancy loss and recurrent pregnancy loss, although the presence of an intrauterine septum and prenatal exposure to DES demonstrate the strongest associations (30–32). Women with an intrauterine septum may have as high as a 60% risk for spontaneous miscarriage (33). Uterine septum–related losses most frequently occur during the second trimester (34). If an embryo implants into the poorly developed endometrium overlying the uterine septum, abnormal placentation and resultant first trimester losses may occur (35). The most common uterine congenital anomaly associated with *in utero* DES exposure is hypoplasia, which may contribute to first- or second-trimester pregnancy losses, incompetent cervix, and premature labor (36,37). Congenital anomalies of the uterine arteries may contribute to pregnancy loss via adverse alterations in blood flow to the implanted blastocyst and developing placenta (38).

Acquired anatomic anomalies have likewise been linked to isolated and recurrent

pregnancy losses. These abnormalities include such disparate conditions as intrauterine adhesions, uterine fibroids, and endometrial polyps. Endometrium that develops over an intrauterine synechiae or over a fibroid that impinges in the intrauterine cavity (submucous) may be inadequately vascularized (39). This may promote abnormal placentation for any embryo attempting to implant over such lesions. Although data supporting these concepts are limited, this abnormal placentation may lead to spontaneous pregnancy loss. Less clear is the association between intramural fibroids and recurrent pregnancy loss, but it is suggested that large (≥5 cm) intramural fibroids are associated with pregnancy loss and that removal improves outcomes (see Chapter 11) (32,40).

Endocrine Abnormalities

The endocrinology of normal pregnancy is complex. **Because spontaneous pregnancy is critically dependent on appropriately timed endocrinologic changes of the menstrual cycle, it is not surprising that those endocrine abnormalities that alter pregnancy maintenance may have their effects during the follicular phase of the cycle in which conception occurs, or even earlier.** Modifications in follicular development and ovulation, in turn, may be reflected in abnormalities of blastocyst transport and development, alterations in uterine receptivity to the implanting blastocyst, and improper functioning of the corpus luteum. Endocrinologic factors suggested to be associated with recurrent miscarriage include luteal phase insufficiency, hypersecretion of luteinizing hormone (LH), thyroid disease, and, potentially, insulin resistance and polycystic ovarian syndrome (PCOS), diabetes mellitus, hyperprolactinemia, and decreased ovarian reserve.

Beginning with ovulation and lasting until approximately 7 to 9 weeks of gestation, maintenance of early pregnancy depends on the production of progesterone by the corpus luteum. Normal pregnancies are characterized by a luteal–placental shift at about 7 to 9 weeks of gestation, during which the developing placental trophoblast cells take over progesterone production and pregnancy maintenance (41). Spontaneous pregnancy losses occurring before 10 weeks of gestation may result from a number of alterations in normal progesterone production or utilization. These include failure of the corpus luteum to produce sufficient quantities of progesterone, impaired delivery of progesterone to the uterus, or inappropriate utilization of progesterone by the uterine decidua. Pregnancy failures may occur near the time of the expected luteal–placental shift if the trophoblast is unable to produce biologically active progesterone following demise of the corpus luteum.

Luteal phase insufficiency or luteal phase defects are characterized by inadequate luteal milestones and most likely relate to adverse pregnancy outcome via inadequate or improperly timed endometrial development at potential implantation sites. An elegant

description of abnormalities at the site of implantation, which may be responsible for some cases of recurrent pregnancy loss, describes impaired decidualization of the endometrium as a mechanism for natural selection of human embryos (42). **Luteal phase defect has many causes, some of which are associated with hypersecretion of LH.** Although the mechanism underlying the association of elevated LH levels with recurrent pregnancy loss is incompletely understood, abnormal LH secretion may have direct effects on the developing oocyte (premature aging), on the endometrium (dyssynchronous maturation), or both. Many patients with elevated LH levels also display physical, endocrinologic, and metabolic characteristics of PCOS.

Some studies report ovarian radiologic evidence of PCOS in as many as 40% to 80% of recurrent pregnancy loss patients (43,44). In addition to inappropriately elevated LH levels, PCOS patients are frequently obese and often have elevated circulating androgen levels. Although controversial, both changes have been linked to recurrent pregnancy loss, and elevated androgen levels have been shown to adversely affect markers of uterine receptivity in women with a history of recurrent pregnancy loss (43–46). Many women with PCOS have metabolic alterations in glycemic control characterized by insulin resistance. This too may be directly or indirectly related to adverse pregnancy outcome, and it may explain increases in the rate of spontaneous pregnancy loss among women with type 2 diabetes mellitus (47). Women with overt insulin-dependent diabetes mellitus (IDDM) appear to exhibit a threshold of pregestational glycemic control above which spontaneous pregnancy loss is increased (48,49). Hyperglycemia has been directly linked to embryonic damage (50). In cases of advanced IDDM with accompanying vascular complications, compromised blood flow to the uterus may be mechanistically involved in subsequent pregnancy loss.

Patients with thyroid disease often have concomitant reproductive abnormalities, including ovulatory dysfunction and luteal phase defects. The metabolic demands of early pregnancy mandate an increased requirement for thyroid hormones. It is therefore not surprising that hypothyroidism has been associated with isolated spontaneous pregnancy loss and with recurrent pregnancy loss (51). The definition of hypothyroidism is itself now under scrutiny with many investigators suggesting that cutoff thyroid-stimulating hormone (TSH) values during pregnancy should be less than 2.5 mIU/mL (52). Others have suggested even lower TSH cutoff values (53). Although it has long been debated whether clinically euthyroid patients with antithyroid antibodies have higher rates of miscarriage and recurrent pregnancy loss, thyroid hormone supplementation was shown to reduce miscarriage in infertility patients with positive antithyroid antibodies and otherwise normal TSH levels undergoing IVF (54–60). The mechanism for an association between antithyroid antibody positivity and recurrent pregnancy loss remains unclear; however, these antibodies could be markers of more generalized autoimmunity or may predict an impaired ability of the thyroid gland to respond to the demands of pregnancy.

Elevated prolactin levels have been associated with miscarriage and recurrent miscarriage. Hyperprolactinemia has been associated with ovulatory dysfunction and may result in miscarriage via alterations in the hypothalamic–pituitary– ovarian axis resulting in impaired folliculogenesis, oocyte maturation or luteal phase dysfunction (61–63). One study in patients with hyperprolactinemia and recurrent pregnancy loss showed a higher live birth rate in a subsequent pregnancy after normalization of prolactin levels with a dopamine agonist (63).

Some studies have shown an association between diminished ovarian reserve (DOR) and recurrent miscarriage (64,65). Shahine et al. suggests that this link may result from an association between DOR and increased risk of aneuploid embryos (349). Aneuploidy (chromosomal aberrations) is the most common cause of first trimester miscarriage and women with DOR have a higher percentage of aneuploid embryos compared to age-matched controls in both the recurrent pregnancy loss (349) and the nonrecurrent pregnancy loss patient populations (350). Ovarian reserve testing (early follicular phase follicle stimulating hormone level, estradiol, and anti-müllerian hormone levels) is not currently recommended by ASRM for the evaluation of recurrent miscarriage. DOR can explain higher risk of miscarriage caused by higher risk of aneuploidy and help guide patients regarding the next steps in care. Increasingly, IVF with chromosomal screening of embryos is offered as a treatment option for women with recurrent pregnancy loss (351) but success is minimal in the setting of DOR and may not be higher than success without intervention (352).

Maternal Infection

The association of infection with recurrent miscarriage is among the most controversial and poorly explored of the potential causes for pregnancy loss. **Reproductive tract infection with bacterial, viral, parasitic, zoonotic, and fungal organisms have all been theoretically linked to pregnancy loss; however, mycoplasma, ureaplasma, chlamydia, and a-streptococcus are the most commonly studied pathogens** (66,67). There is data that directly addressed the roles of some of these proposed organisms in recurrent pregnancy loss. One prospective comparison trial involving 70 recurrent pregnancy loss patients reported no elevations in any markers for present or past infection with *Chlamydia trachomatis* when compared with controls (68). In contrast, a very large, prospective trial demonstrated a link between the detection of bacterial vaginosis and a history of second trimester pregnancy loss among 500 recurrent pregnancy loss patients (69). The risk of bacterial vaginosis detection was positively correlated with cigarette smoking in this study.

The etiologic mechanism linking specific organisms to either isolated or recurrent pregnancy loss remains unclear and must certainly differ among infectious organisms. Certain viral organisms, such as herpes simplex virus (HSV)

and human cytomegalovirus (HCMV), can directly infect the placenta and fetus (70,71). The resulting villitis and related tissue destruction may lead to pregnancy disruption. Another theoretic possibility warranting study is that infection-associated–early pregnancy loss may result from immunologic activation in response to pathologic organisms. A large body of evidence supports the role of this mechanism in adverse events later in gestation, such as intrauterine growth restriction, premature rupture of membranes, and preterm birth (72,73). Alternatively, mechanisms that protect the fetus from autoimmune rejection may protect virally infected placental cells from recognition and clearance. This could potentially promote periods of unfettered infectious growth for some of the pathogenic organisms gaining entry to the reproductive tract (74).

Chronic endometritis, defined as the asymptomatic presence of histologically documented plasma cells in an endometrial biopsy, may be associated with recurrent miscarriage. Studies have shown a prevalence of 7% to 13% based on morphologic assessment alone (353,354) and up to 56% in patients with recurrent pregnancy loss (354). Chronic endometritis is associated with previous infections and retained pregnancy tissue and, despite the difficulty of determining cause and effect, treatment with antibiotics shows a higher live birth rate in subsequent pregnancies in some studies (353,354). Endometrial biopsy for chronic endometritis diagnosis and treatment are not recommended by expert groups and larger studies are needed before implementing evaluation and treatment in routine practice.

Immunologic Phenomena

[5] Embryo implantation and pregnancy maintenance is a delicate interaction and balance between maternal and embryonic/fetal immune, hormonal, and coagulation systems. Maternal rejection of paternal antigens and immune system dysfunction as a cause of recurrent miscarriage has been explored extensively but remains controversial (75). Laboratory testing for immune dysfunction can be misleading and the treatments aimed at maternal immunosuppression can have significant side effects. Expert groups have omitted immune testing and recommended against extensive immunosuppression as a treatment for unexplained recurrent miscarriage (338).

A brief review of some of the important concepts in basic immunology is warranted to place testing and treatment discussions in context. **Immune responses classically are divided into innate and acquired responses. Innate responses represent the body's first line of defense against pathogenic invasion.** They are rapid and are not antigen specific. Cell types and mechanisms typically considered vital to innate immunity include complement activation, phagocytosis by macrophage, and lysis by natural killer (NK) and natural killer T (NKT) cells and possibly by TCR γ δ+ T cells. **Acquired immune responses, in contrast, are antigen specific and are largely mediated by T cells and B cells. Acquired responses can be further divided into primary (response**

associated with initial antigen contact) and secondary (rapid and powerful amnestic responses associated with subsequent contact to the same antigen).

Antigen specificity is regulated by two sets of genes in the major histocompatibility complex (MHC), located on chromosome 6 in humans. **MHC class I molecules (human leukocyte antigen [HLA]-A, -B, and -C) are present on the surface of nearly every cell in the human body and are important in defense against intracellular pathogens, such as viral infection and oncogenic transformation.** MHC class I molecules act as important ligands for both the T-cell receptor on CD8+ cytotoxic/suppressor T cells and for a variety of receptors on NK cells (76). **MHC class II molecules (HLA-DR, HLA-DP, and HLA-DQ), in contrast, are present on the surface of a limited number of antigen-presenting cells, including dendritic cells, macrophage and monocytes, B cells,** and tissue-specific cells such as the Langerhans cells in the skin. These molecules are important in defense against extracellular pathogens, such as bacterial invaders. The major ligand for MHC class II is the T-cell receptor on CD4+ T helper cells.

One very important concept in immunology that has particular application to pregnancy is that of immune tolerance. The passage of bone marrow–derived T cells through the fetal thymus during early development has been well described. In this developmental interval, the T cells encounter a process termed thymic education. During thymic education, T cells that express either the CD4 or the CD8 coreceptor are chosen, and autoreactive cells are effectively eliminated. This education promotes T-cell tolerance, allowing selection and survival exclusively of those T cells that recognize nonself and will not react against self (80,81).

Cellular Immune Mechanisms

Three main questions summarize much of the theoretical thinking surrounding pregnancy maintenance and reproductive immunology:

1. Which immune cells populate the reproductive tract, particularly at implantation sites?
2. How do the characteristics of antigen presentation differ at the maternal–fetal interface?
3. What regulatory mechanisms specifically affect reproductive tract immune cells?

Resident Cells: Natural Killer Cells and T Regulatory Cells

Immune cells populating the reproductive tract exhibit many characteristics that distinguish them from their peripheral counterparts. In particular, the human endometrium is populated by T cells, macrophage, and NK-like cells, but very few B cells are present. The relative proportions of these resident cells vary with the menstrual cycle and change dramatically during early pregnancy. Surrounding the time

of implantation, one particular cell type comprises between 70% and 80% of the total endometrial lymphocyte populations (82,83). This cell type is called a variety of names, including decidual granular lymphocytes (DGLs), large granular lymphocytes (LGLs), and decidual NK cells. This heterogeneity of names reflects the fact that this particular cell type differs from similar cells isolated from the periphery, although most believe it to be an NK cell variant. While most peripheral NK cells have low cell surface expression of CD56 ($CD56^{dim}$) and express high levels of CD16, the immunoglobulin receptor responsible for NK-mediated, antibody-dependent cellular cytotoxicity, those in the uterine decidua and at the placental implantation site, are largely $CD56^{bright}$ and $CD16^{dim}$ or CD16− (84). If these unusual endometrial cells are considered NK cells, the implantation site represents the largest accumulation of NK cells in any state of human health or disease. These decidual NK cells display fairly poor cytotoxic function but are robust cytokine secretors (85,86). The balance of activating and inhibitory receptors expressed on their cell surfaces determines their ultimate killing versus secretion patterns (87,88).

The role of NK cells in reproduction and recurrent pregnancy loss is controversial. Some studies show increased levels of CD56 NK cells (those with killer-type activating receptors) in peripheral blood of women with recurrent pregnancy loss compared to controls (89,90) and other studies do not show a difference (355,356). The studies showing a difference may be inherently flawed. Most of the recurrent miscarriage patients included in the study were nulliparous and the controls were multiparous (357); a previous successful pregnancy can induce permanent changes in NK subsets (358). Some studies have shown that a higher level of NK cytotoxicity in the peripheral blood before pregnancy resulted in a higher rate of pregnancy loss (359), while other studies showed similar NK cytotoxicity in recurrent pregnancy loss patients with subsequent pregnancy loss or live birth (360). Results from studies of NK cell levels in endometrial tissues in recurrent miscarriage vary; some showing higher levels of CD56 NK cells in the endometrial tissue from recurrent pregnancy loss patients (94) and others showing lower levels (95). Interpretation of NK cell levels in endometrial tissue can be limited by the inherent variability of levels throughout the different menstrual cycle stages and the questionable testing accuracy using either immunochemistry or flow cytometry (361). A strong argument against using any NK cell testing in the evaluation of recurrent miscarriage patients comes from a large prospective study showing that high NK toxicity before pregnancy did not impact subsequent pregnancy loss rate (362).

A subpopulation of CD4+ T cells has been described that, like all activated lymphocytes, strongly expresses CD25 on their cell surface (77). These CD4+ CD25+ cells are more specifically identified by the intracellular presence of the forkhead box P3 (Fox P3) transcription factor and have been called regulatory T lymphocytes (Treg cells). Treg cells, when activated by autoantigens, can suppress activated inflammatory

cells. They secrete regulatory cytokines, including interleukin-10 (IL-10) and transforming growth factor-β (TGF-β) (77–79). They may impact avoidance of tissue destruction associated with inflammation and may play a central role in pregnancy maintenance. In pregnant mice and women, these specialized CD4+ cells are systemically expanded in an alloantigen independent fashion and can suppress adverse maternal responses to the fetus (92) and to self (93).

The human decidua contains characteristic immune effector cells. These immune cell populations are reported to be altered in recurrent pregnancy loss patients but not in patients experiencing isolated spontaneous pregnancy losses (91,94–96). Most investigations into whether alterations in these cells (including T cells, decidual NK cells, and NKT cells) determine pregnancy outcome are hampered by insufficient patient numbers to allow meaningful conclusions. **[5]** Further research is needed to understand the role of NK cells and T regulatory cells in reproduction and miscarriage. Expert groups do not recommend testing recurrent pregnancy loss patients for NK cell cytotoxicity or Treg cells and any treatment targeted toward suppression of these immune cells should be conducted only in the setting of a clinical trial.

Antigen Presentation at the Maternal–Fetal Interface

Historically, it was proposed that the implanting trophoblastic allograft could make itself antigenically invisible to avoid immune detection by the maternal host. It could downregulate its expression of the MHC-encoded transplantation antigens (some of which would be of paternal origin) and thereby avoid recognition as nonself. Although immunology studies rendered this theory obsolete, the implanting fetus does utilize this strategy to the extent (97) that placental trophoblast cells do not express MHC class II molecules (98,99). **Unlike nearly every other cell in the human body, trophoblast cells do not express the classical MHC class I transplantation antigens HLA-A and -B.** Rather, a subpopulation of placental cells, specifically the extravillous cytotrophoblast cells, express the classical MHC class I HLA-C products, and the nonclassical HLA-E, -F, and -G products (74,100–104). These extravillous cytotrophoblast cells are of particular interest because they are characterized by remarkable invasive potential (105,106). These cells move from the tips of the anchoring villae of the human placenta, invading deeply into the maternal decidua, and some replace cells within the walls of decidual arterial vessels (105–107). Although the invasive characteristics of extravillous cytotrophoblast may reflect non-MHC–related mechanisms, including well-described integrin switching, the intimate contact of these fetal-derived cells with maternal immune effector cells exposes the fetus to recognition as nonself (108) and it is now apparent that the pregnant woman recognizes and responds to paternally-derived antigens. These responses appear to be essential to pregnancy maintenance but must be tightly regulated.

It is not known why all placental cells downregulate expression of HLA-A and -B,

whereas invasive extravillous cytotrophoblast express HLA-C, -E, and -G. This area of investigation is ripe with hypotheses and study. Because NK cells of the innate immune system recognize and kill cells that express no MHC, the complete downregulation of MHC should cause trophoblast cells to act as targets for those NK cells that are pervasive at sites of implantation (88,97). In addition to possible protection from direct NK cell–mediated killing, the expression of HLA-C, -E, and -G by trophoblast cells may serve a variety of alternate purposes. NK cell receptor–mediated interactions with extravillous cytotrophoblast MHC products modulate cytokine expression profiles at the maternal–fetal interface (85,86). **MHC expression aids in decidual and vascular invasion by the trophoblast, an activity essential for proper placental development** (109). Whereas definitive correlations between placental MHC class I expression patterns and recurrent pregnancy loss remain contentious, trophoblast expression of HLA-G was linked to other disorders of placental invasion, such as preeclampsia (109,110). Genetic mutations at the HLA-G locus have been linked to recurrent pregnancy loss in some, but not all studies (111–114). Soluble or secreted trophoblast MHC products may aid in the development of maternal immune tolerance toward the placenta (115). Soluble HLA-G has been shown to suppress T lymphocyte and NK cell function and to induce the expansion of Treg cells in humans (116).

Aberrant expression of class II MHC determinants, or enhanced expression of MHC class I on syncytiotrophoblast in response to IFN-γ (117) could mediate pregnancy loss by enhancing cytotoxic T cell attack (118). This theory appears unlikely, because the expression of classical MHC antigens does not seem to be induced on aborted tissues from women experiencing one or more pregnancy losses (118). MHC class II genotypes appear to affect susceptibility to a variety of diseases, including diabetes and other autoimmune diseases. **A similar link between MHC class II typing and adverse pregnancy outcome was reported for recurrent pregnancy loss** (119,120).

Regulation of Decidual Immune Cells

The characteristics of the interactions between decidual immune effector cells and the implanting fetus may be determined by factors other than those already mentioned. As might be predicted, these regulatory effects are often targets for investigative efforts, because they may offer more direct insight into potential therapies for immune-mediated disorders of pregnancy maintenance. **Three such regulatory mechanisms will be discussed here: (a) alterations in T helper cell phenotypes; (b) reproductive hormones and immunosuppression; and (c) tryptophan metabolism.**

Antigen-stimulated immune responses involving CD4± T cells can be divided into two major classes: T helper 1 (TH1) responses and T helper 2 (TH2) responses. This subclassification is overly simplified, but it has been useful in broadly defining types of immune responses based on the characteristics of the CD4± cells present, and their associated cytokines. Cytokines are signaling molecules secreted from immune cells that

bind to receptors on other immune cells to either stimulate or inhibit function. TH1 and TH2 immune cells express different cytokines with different functions and studies suggest that successful embryo implantation ultimately occurs in a TH2 dominant environment and that poor pregnancy outcomes may result if the balance favors a TH1 dominant environment (363). Studies have suggested that TH1-type cytokines can be harmful to implanting developing embryo (121,122) and that some patients with recurrent pregnancy loss exhibit a local dysregulation of their T helper cellular immune response to antigens, with typical shifts toward TH1 inflammatory responses at the maternal–fetal interface (123,124). This remains difficult to study and prove given that the dominant immune cell population (TH1 or TH2) is usually determined by peripheral blood levels of cytokines and cytokines display their results at close range. Measurements of cytokines in peripheral blood, endometrial biopsies, or flushing of decidual tissue are subject to technical difficulties and conclusions about cytokines and their role in recurrent pregnancy loss are yet to be determined. TNF-α is one cytokine that can usually be detected easily in the blood with most assays and may be a good marker for inflammation. Studies have shown higher levels of TNF-α in women with recurrent pregnancy loss in early pregnancy (364).

Although many mechanisms are aimed at avoiding maternal immune recognition of the implanting fetus, research in humans and animals indicates that immune responses to fetal antigens are present (126–128)**. Thus, the regulation of this response at the maternal–fetal interface may be critical.** Reproductive hormones have dramatic effects on peripheral cell–mediated immunity, as demonstrated by well-documented and notable gender differences in immune responsiveness (129). The levels of these potentially immunosuppressive hormones are quite elevated in the circulation of pregnant women. The fact that the levels of these hormones at the maternal–fetal interface may be dramatically higher than those in the maternal circulation during pregnancy may help to explain an apparent inconsistency: with some exceptions, overall immune responsiveness during pregnancy appears to change a little, while local modulation at the maternal–fetal interface may be vital (130).

It has been suggested that the immunosuppressive effects of progesterone within the reproductive tract are at least partially responsible for the maintenance of the semiallogeneic implanting fetus (131). In vitro studies have shown that progesterone mediates its suppression of T cell effector function by altering membrane-resident potassium channels and cell membrane depolarization. This action, in turn, affects intracellular calcium signaling cascades and gene expression and may be mediated by nonclassical steroid receptors or may not involve a receptor at all (132–134). Progesterone-mediated changes in T cell gene expression have been associated with the development of TH2-type T helper cell responses and with increased leukemia inhibitory factor (LIF) expression (135). Because a shift in the intrauterine immune environment from TH2 to TH1 has been linked with early spontaneous pregnancy loss,

the elevated intrauterine concentrations of progesterone characteristic of early pregnancy may promote an immune environment favoring pregnancy maintenance (123). To this point, in vitro evidence indicates that progesterone can inhibit mitogen-induced proliferation of and cytokine secretion by CD8+ T cells and can alter the expression of a transcription factor that drives the development of TH1 cells (136,137).

Levels of estrogen rise markedly during pregnancy, and attention has focused on the role of estrogen in immune modulation. A group of animal studies showed that estrogens improve immune responses in males after significant trauma and hemorrhage, suppress cell-mediated immunity after thermal injury, and protect against chronic renal allograft rejection (138–140). In vitro, estrogens appear to downregulate delayed-type hypersensitivity (DTH) reactions and promote the development of TH2-type immune responses, particularly at the elevated estrogen concentrations typical of pregnancy (141,142). In mice, elevations in estrogen have been shown to recruit Treg cells to the uterus (390).

One additional regulatory mechanism proposed for the induction of maternal tolerance to the fetal allograft involves the amino acid tryptophan and its catabolizing enzyme indoleamine 2,3-dioxygenase (IDO). The IDO hypothesis of tolerance in pregnancy rests on data showing that T cells need tryptophan for activation and proliferation (143) and local alterations in tryptophan metabolism at the maternal–fetal interface could either activate or fail to suppress maternal–antifetal immunoreactivity (144). Studies in mice have shown that the inhibition of IDO leads to loss of allogeneic, but not syngeneic, fetuses, and that this effect is mediated by lymphocytes (145). Further support lies in studies demonstrating that hamsters fed diets high in tryptophan have increased rates of fetal wastage (146). Extending this theory to humans requires further investigation. However, the demonstration of IDO expression in human uterine decidua, and the documentation of alterations in serum tryptophan levels with increasing gestational age during human pregnancy support further interest in this potential local immunoregulatory mechanism (147,148).

Humoral Immune Mechanisms and Antiphospholipid Syndrome

Humoral responses to pregnancy-specific antigens exist, and patients with recurrent pregnancy loss can display altered humoral responses to endometrial and trophoblast antigens (123,149). Nevertheless, most literature surrounding humoral immune responses and recurrent pregnancy loss focus on organ nonspecific autoantibodies associated with the antiphospholipid syndrome (APS). Historically, these immunoglobulin-G (IgG) and IgM antibodies were considered to be directed against negatively charged phospholipids. Those phospholipids most often implicated in recurrent pregnancy loss are cardiolipin and phosphatidylserine. However, antiphospholipid antibodies often are directed against a protein cofactor, β2 glycoprotein 1, which assists antibody association with phospholipid (150–154).

Antiphospholipid antibodies were originally characterized solely by prolonged phospholipid-dependent coagulation tests in vitro (activated partial thromboplastin time [aPTT], Russell viper venom time) and by thrombosis in vivo. The association of these antiphospholipid antibodies with thrombotic complications has been termed the APS, and although many of these complications are systemic, some are pregnancy specific—spontaneous miscarriage, stillbirth, intrauterine growth retardation, and preeclampsia (155,156). A reassessment of the criteria used to diagnose APS resulted in additions to the prior Sapporo criteria for diagnosis of APS and continues to include adverse pregnancy outcomes. These criteria, which have been validated clinically, are as follows (156–158):

For a patient to be diagnosed with antiphospholipid syndrome, one or more clinical and one or more laboratory criteria must be present:

Clinical

1. **One or more confirmed episode of vascular thrombosis of any type:**
    - **Venous**
    - **Arterial**
    - **Small vessel**
2. **Pregnancy complications:**
    - **Three or more consecutive spontaneous pregnancy losses at less than 10 weeks of gestation with exclusion of maternal anatomic and hormonal abnormalities and exclusion of paternal and maternal chromosomal abnormalities**
    - **One or more unexplained deaths of a morphologically normal fetus at or beyond 10 weeks of gestation (normal fetal morphology documented by ultrasound or direct examination of the fetus)**
    - **One or more premature births of a morphologically normal neonate at or before 34 weeks of gestation secondary to severe preeclampsia or placental insufficiency**

Laboratory

Testing must be positive on two or more occasions with evaluations 12 or more weeks apart:

1. Positive plasma levels of anticardiolipin antibodies of the IgG or IgM isotype at medium to high levels
2. Positive plasma levels of lupus anticoagulant

3. Anti-β2 glycoprotein-1 antibodies of the IgG or IgM isotype in titers greater than the 99th percentile

The presence of antiphospholipid antibodies (anticardiolipin or lupus anticoagulant) and anti-β2 glycoprotein-1 antibodies during pregnancy is a major risk factor for an adverse pregnancy outcome (150,151,159). In a large series of couples with recurrent pregnancy loss, the incidence of the APS was between 3% and 5% (66). The presence of anticardiolipin antibodies among patients with known systemic lupus erythematosus portends less favorable pregnancy outcomes (160).

Several mechanisms have been proposed by which antiphospholipid antibodies might mediate pregnancy loss (161). Antibodies against phospholipids could increase thromboxane and decrease prostacyclin synthesis within placental vessels. The resultant prothrombotic environment could promote vascular constriction, platelet adhesion, and placental infarction (162–164). Alternatively, in vitro evidence from trophoblast cell lines indicates that IgM action against phosphatidylserine inhibits formation of syncytial trophoblast (165). Syncytialization is required for proper placental function. One study demonstrated that both extravillous cytotrophoblast and syncytiotrophoblast cells synthesize β2 glycoprotein-1, the essential cofactor for antiphospholipid antibody binding (166). Although it gives insight into pathophysiology, the prognostic value of serum levels of specific antibodies against β2 glycoprotein-1 with respect to pregnancy outcome among recurrent pregnancy loss patients is contentious and may be poorer than that of standard anticardiolipin antibodies (167–169). Some have proposed that sera from antibody positive recurrent pregnancy loss patients are particularly adept at inhibiting trophoblast adhesion to endothelial cells in vitro (170). Others noted rapid development of atherosclerosis in the decidual spiral arteries of patients who test positive for antiphospholipid antibodies (171). Still others have demonstrated that levels of the placental antithrombotic molecule—annexin V—are reduced within the placental villa from those women with recurrent pregnancy loss who are antiphospholipid antibody positive (172). However, placental pathologic evidence that supports causal involvement of the antiphospholipid syndrome in pregnancy loss is equivocal. The characteristic lesions for this syndrome (placental infarction, abruption, and hemorrhage) are typically missing in women with antiphospholipid antibodies, and these same pathologic lesions can be found in placentae from women with recurrent miscarriages who do not have biochemical evidence of antiphospholipid antibodies (161,173–175).

One additional group of autoantibodies that have been linked to recurrent pregnancy loss is the antithyroid antibodies. Although the data remain somewhat controversial, several investigators demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities (52,56,57,176–178).

Other antibody-mediated mechanisms for recurrent pregnancy loss have been proposed, including antisperm and antitrophoblast antibodies, and blocking antibody deficiency but none have withstood the test of time.

It is important to suggest during this in-depth discussion of the immune-mediated mechanisms of isolated and recurrent pregnancy loss that pregnancy may not require an intact maternal immune system. Supporting this concept are data showing that agammaglobulinemic animals and women can successfully reproduce (180). Further, viable births occur among women with severe immune deficiencies and in murine models that lack T and B cells (severe combined immunodeficiency [SCID] mice) and those that display a congenital absence of their thymus (nude mice).

[5] Despite the knowledge that most first trimester miscarriages are caused by aneuploidy and that the only immune-related issue recommended for routine evaluation and treatment for recurrent miscarriage by expert groups is APS, providers around the world still test and treat for many different immune issues in couples with recurrent pregnancy loss. Patients and providers feel pressured for answers and interventions in the setting of unexplained recurrent pregnancy loss and immune issues play into the woman's feelings of guilt and worry that there is something wrong with her that is causing her to reject her pregnancy. Immune-related dysfunction in relationship to miscarriage and recurrent pregnancy loss remains up for debate, additional research, and better understanding. Immunosuppressive treatments can result in harm and until more is understood, intervention should be limited to investigations in the setting of Institutional Review Board (IRB)-approved clinical trials.

Male Factors

Most publications that review testing and treatment for recurrent pregnancy loss couples, including this chapter, recommend only a single test for the male partner in the couple—a peripheral blood karyotype. The role of the male partner in the etiology of recurrent pregnancy loss is understudied, but there is a growing body of literature suggesting that the development and validation of novel testing and treatment regimens for the male may prove beneficial (181,182). Detailed peripheral chromosomal testing of men whose partners experienced recurrent pregnancy loss revealed an increased incidence of Y chromosome microdeletions when compared to male partners in fertile and infertile couples (183). Small studies demonstrated that male partners in couples experiencing recurrent pregnancy loss have an increased incidence of sperm chromosomal aneuploidy, particularly sex chromosome disomy, when compared to fertile men (184,365–367). The addition of specialized testing to a standard semen analysis among men in couples with recurrent loss revealed reductions in sperm functional testing (hypo-osmotic swelling, acrosome status, nuclear chromatin decondensation) and increased DNA fragmentation and lipid peroxidation when

compared to fertile men or historical controls (185–187). The latter results suggest that these men may have abnormal levels of reactive oxygen species in their semen or that their sperm cells are particularly sensitive to these compounds. Paternal carriage of the MTHFR C677T mutation and hyperhomocysteinemia were associated with DNA damage and recurrent pregnancy loss (188). A single, small, uncontrolled treatment study using antioxidants among male partners in recurrent pregnancy loss couples who had high levels of sperm DNA damage or semen lipid peroxidation suggested favorable treatment outcomes (186). The only evidence-based recommended test for a male partner in a couple with recurrent pregnancy loss is a peripheral blood karyotype and the other tests and interventions remain under investigation. With more focus on male factor in all aspects of reproduction, more information may surface about the male factor in miscarriage.

Other Factors

It is increasingly evident that the implantation of the blastocyst within the uterine decidua involves an exquisitely scripted crosstalk between embryo and mother. Alterations in this dialogue often result in improper implantation and placental development. For instance, recurrent pregnancy loss has been linked to a dysregulation in the expression patterns of vascular endothelial growth factors (VEGFs) in the developing placenta and their requisite receptors within the maternal decidua (189). Cellular and extracellular matrix adhesion properties may be involved in this dialogue. The concept of uterine receptivity has been emboldened by the description of endometrial integrins and the timing of integrin switching during implantation (190). Others have reported decreased levels of endometrial mucin secretion and reductions in the endometrial release of soluble intercellular adhesion molecule I among women with histories of recurrent pregnancy loss (191,192). Programmed cell death (apoptosis) may play an essential role in normal placental development. Alterations in two important apoptotic pathways—Fas-Fas ligand and bcl2—have been linked to recurrent pregnancy loss and poor pregnancy outcome (75,193).

Environmental Factors

A variety of environmental factors have been linked to sporadic and recurrent early spontaneous pregnancy loss. These are difficult studies to perform, because, in humans, they all must be retrospective and all are confounded by alternative or additional environmental exposures. Nevertheless, the following factors have been linked to pregnancy loss: exposure to medications (e.g., antiprogestogens, antineoplastic agents, anti-inflammatory agents, and inhalation anesthetics), exposure to ionizing radiation, prolonged exposure to organic solvents, and exposure to environmental toxins, especially phthalates, bisphenol-A, and heavy metals (194–197). The latter two

exposures have been demonstrated to have endocrine and immune effects that could lead to poor placentation and subsequent pregnancy loss (198,199). Lathi et al. showed that maternal BPA levels were directly associated with increased risk of miscarriage (368). Associations between spontaneous pregnancy loss and exposures to video display terminals, microwave ovens, high-energy electric power lines, and high altitudes (e.g., flight attendants) are not substantiated (200,201). There is no compelling evidence that moderate exercise during pregnancy is associated with spontaneous miscarriage. Association between stress and miscarriage risk is controversial (369). In the absence of cervical anatomic abnormalities or incompetent cervix, coitus does not appear to increase the risk for spontaneous pregnancy loss (202,203).

Exposure to four particular substances—alcohol, cigarettes, marijuana, and caffeine—deserves specific attention; all have been linked with increased risk of miscarriage through studies with widely varied findings. Although some conflicting data exist, one very large epidemiologic study has shown that **alcohol consumption during the first trimester of pregnancy, at levels as low as three drinks per week, is associated with an increased incidence of spontaneous pregnancy loss** (204–206). **Cigarette smoking has been linked to early spontaneous pregnancy loss;** however, this is not without controversy (207–209). **Alcohol and tobacco intake in the male partner correlates with the incidence of domestic violence, which in turn is associated with early pregnancy loss** (210). **Marijuana has not been shown to necessarily increase the risk of miscarriage in the one study investigating association found in the literature to date** (370)**, however studies have shown poor effects on female** (371) **and male** (372) **fertility and patients should be counseled to refrain until further studies can evaluate risk further.** Evidence adds to a growing body of literature that suggests **consumption of coffee and other caffeinated beverages during early pregnancy is linked to adverse pregnancy outcomes** (207,211). One report casts doubt on the definition of a lower limit for safe use of caffeine in the first trimester of pregnancy (207).

Maintaining a healthy weight may decrease risk of miscarriage as being underweight (373) and overweight (374) have been associated with increased risk of miscarriage. Risk of sporadic and recurrent miscarriage are increased with obesity and etiologic theories include impact on both gamete quality and uterine receptivity in autologous conception (375) and donor egg pregnancies (212).

PRECONCEPTION EVALUATION

[4] Investigative measures that are potentially useful in the evaluation of recurrent spontaneous miscarriage include obtaining a thorough history from both partners, performing a physical assessment of the woman (with attention to the pelvic

examination), and a limited amount of laboratory testing (Table 33-2).

Table 33-2 Investigative Measures Useful in the Evaluation of Recurrent Early Pregnancy Loss

History
1. Pattern, trimester, and characteristics of prior pregnancy losses 2. History of subfertility or infertility 3. Menstrual history 4. Prior or current gynecologic or obstetric infections 5. Signs or symptoms of thyroid, prolactin, glucose tolerance, and hyperandrogenic disorders (including polycystic ovarian syndrome) 6. Personal or familial thrombotic history 7. Features associated with the antiphospholipid syndrome (thrombosis, false positive test for syphilis) 8. Other autoimmune disorders 9. Medications 10. Environmental exposures, illicit and common drug use (particularly caffeine, alcohol, cigarettes, marijuana, and *in utero diethylstilbestrol* exposure) 11. Genetic relationship between reproductive partners 12. Family history of recurrent spontaneous abortion, of obstetric complications, or of any syndrome associated with embryonic or fetal losses 13. Previous diagnostic tests and treatments, including, if available, chromosome testing on products of conception
Physical Examination
1. General physical examination with attention to: a. Obesity b. Hirsutism/acanthosis c. Thyroid examination d. Breast examination/galactorrhea e. Pelvic examination 1. Anatomy 2. Infection 3. Trauma 4. Estrogenization 5. Masculinization
Laboratory
1. Parental peripheral blood karyotype (both partners) 2. Chromosome testing on products of conception 3. Hysterosalpingography, three-dimensional transvaginal sonography, sonohysterography, or office hysteroscopy, followed by hysteroscopy/laparoscopy, if indicated 4. Serum thyroid stimulating hormone level

5. Serum prolactin level
6. Serum HbA_{1c}
7. Antiphospholipid screening
   a. Anticardiolipin antibody levels (IgG and IgM)
   b. Lupus anticoagulant (activated partial thromboplastin time or Russell viper venom)
   c. Anti-β2-glycoprotein-1 antibodies (IgG and IgM)

History

A description of all prior pregnancies, their sequence and whether histologic assessment and karyotype determinations were performed on previously aborted tissues are important aspects of the history. **Approximately 60% of pregnancies lost before 8 weeks of gestation are reported to be chromosomally abnormal; most of these pregnancies are affected by some type of trisomy, particularly trisomy 16** (215,216). **The most common single chromosomal abnormality is monosomy X (45X), especially among anembryonic conceptuses** (217). Aneuploid losses are particularly prevalent among women with recurrent pregnancy loss who are over the age of 35 (8). Research suggests a higher rate of aneuploid miscarriage in recurrent pregnancy loss women with DOR at a younger age (349). Although somewhat controversial, the detection of aneuploidy in miscarriage specimens may be lower when the couple experiencing recurrent miscarriages is euploidic. Alternatively, some investigators have suggested that, because aneuploidy is common among miscarriage specimens from patients experiencing isolated and recurrent spontaneous pregnancy losses, if aneuploidy is documented in fetal tissues from a recurrent pregnancy loss patient, this loss does not affect their prognosis for future pregnancy maintenance (13).

Most women with recurrent pregnancy loss tend to experience spontaneous miscarriage at approximately the same gestational age in sequential pregnancies (218). Unfortunately, the gestational age when pregnancy loss occurs, as determined by last menstrual period, may not be informative, because there is often a 2- to 3-week delay between fetal demise and signs of pregnancy expulsion (219). If patients have had ultrasounds in the first trimester, careful history and detailed record review can reveal a more accurate time of fetal demise than gestational age by last menstrual period or patient's recall. The designation into either primary or secondary categories is not helpful in the diagnosis or management of couples experiencing recurrent miscarriage. Approximately 10% to 15% of couples cannot be classified into either the primary or secondary category because, although their first pregnancy resulted in a loss, it was followed by a term delivery prior to subsequent losses. Expert groups exclude biochemical miscarriages, defined as positive pregnancy test but miscarriage before ultrasound or histopathologic evidence can be obtained, from guidelines. This recommendation is not without controversy. Biochemical miscarriages can be

distressing for patients and providers can feel obligated or unsure about investigating further. Some evidence suggests women with recurrent biochemical miscarriages or a mix of biochemical and clinical miscarriages have similar poor prognosis for subsequent pregnancies (376,377). Investigation is encouraged for recurrent clinical miscarriage (ultrasound or histopathologic evidence) (338) but not biochemical miscarriages.

It is important to glean any history of subfertility or infertility among couples with recurrent pregnancy loss. This is defined as the inability to conceive after 12 months of unprotected intercourse. By definition, 15% of all couples will meet these criteria; this number increases to 33% among couples with recurrent pregnancy losses. Because many pregnancies are lost before or near the time of missed menses, subfertility among recurrent pregnancy loss patients may, in some cases, reflect recurrent preclinical losses. Menstrual cycle history may provide information about the possibility of oligo-ovulation or other relevant endocrine abnormalities in recurrent pregnancy loss patients. A personal and family history of thrombotic events or renal abnormalities may provide vital information. A family history of pregnancy losses and obstetric complications should be addressed specifically. Detailed information about drug and environmental exposure should be obtained.

Physical Examination

A general physical examination should be performed to detect signs of metabolic illness, including PCOS, diabetes, hyperandrogenism, and thyroid or prolactin disorders. During the pelvic examination, signs of infection, DES exposure, and previous trauma should be ascertained. Estrogenization of mucosal tissues, cervical and vaginal anatomy, and the size and shape of the uterus should be determined.

[4] Recommended Testing

[5] Laboratory assessment of couples with recurrent pregnancy losses should include the following:

1. **Chromosome analysis of the products of conception**
2. **Parental peripheral blood karyotyping with banding techniques**
3. **Assessment of the intrauterine cavity with either office hysteroscopy, sonohysterography, three-dimensional transvaginal sonography, or hysterosalpingography, followed by operative hysteroscopy if a potentially correctable anomaly is found** (220)
4. **Thyroid function testing, including serum TSH levels**
5. **Anticardiolipin antibodies, anti-β2 glycoprotein-1 antibodies, and lupus**

anticoagulant testing (aPTT or Russell viper venom testing)

6. **Prolactin**
7. **HbA_{1c}**

Tests with Unproven Utility

A number of laboratory assessment tools are under investigation for use in patients with a history of recurrent pregnancy loss. Results are either too preliminary to warrant unfettered recommendation or studies of their use have been too contradictory to allow final determination of their value.

Tests under investigation with evidence in favor of utilizing:

1. **Evaluation of ovarian reserve using day 3 serum follicle–stimulating hormone, estradiol, and anti-müllerian hormone levels. It appears that decreased ovarian reserve may predict higher risk of aneuploid embryos and miscarriage in all patients, including those with recurrent pregnancy loss** (64,65,349).
2. **Testing for antithyroid antibodies among women with recurrent pregnancy loss remains controversial, but is rapidly gaining support** (52–54,57,176–178). **Investigators have demonstrated an increased prevalence of these antibodies among women with a history of recurrent pregnancy loss, even in the absence of thyroid endocrinologic abnormalities** (53,54,56,177).
3. **Endometrial biopsy for plasma cells/chronic endometritis**

Tests under investigation and the majority of research shows No clinical benefit

a. **Thrombophilia testing (FVL, prothrombin gene mutation, protein C deficiency, protein S deficiency, antithrombin III deficiency, homocysteine levels, MTHFR mutation). Once popular for patients with recurrent pregnancy loss, evidence shows limited value in testing and or treatment of thrombophilia testing to prevent miscarriage or poor pregnancy outcome unless patients have a personal or family history of thrombosis**
b. **Testing for peripheral evidence of TH1/TH2 cytokine dysregulation.**
c. **NK cell testing in peripheral blood or endometrium**
d. **Cervical cultures for mycoplasma, ureaplasma, and chlamydia may be considered.**
e. **Testing for serologic evidence of PCOS using LH or androgen values may be useful** (43–46).

Tests not recommended for evaluation in patients with recurrent pregnancy loss:

1. Evaluations that involve extensive testing for serum or site-specific auto- or

alloantibodies (including antinuclear antibodies and antipaternal cytotoxic antibodies) are expensive and unproven. Their use often verifies the statistical tenet that if the number of tests performed reaches a critical limit, the results of at least one will be positive in every patient.
2. Testing for parental HLA profiles is never indicated in outbred populations. Findings that HLA sharing is associated with poor pregnancy outcomes are strictly limited to those specific populations studied, which have very high and sustained levels of marriage within a limited community (179).
3. Use of mixed lymphocyte cultures has not proved useful. Use of other immunologic tests is unnecessary unless these studies are performed, with informed consent, under a specific study protocol in which the costs of these experimental tests are not borne by the couple or their third-party payers.
4. Further work is necessary before suppressor cell or factor determinations, cytokine, oncogene, and growth factor measurements, or embryotoxic factor assessment can be clinically justified.
5. Endometrial biopsy for luteal phase defect

POSTCONCEPTION EVALUATION

Following conception, close monitoring of patients with histories of recurrent pregnancy loss is advised to provide emotional support and to confirm intrauterine pregnancy and its viability. Although controversial, some studies recommend close monitoring in the first trimester of women with a history of recurrent pregnancy loss resulting from a higher incidence of ectopic pregnancy and complete molar gestation in this population (56,222–226). **Determining serum levels of a-hCG may be helpful in monitoring early pregnancy until an ultrasonographic examination can be performed; however, not all failing pregnancies will be preceded by inadequate a-hCG levels** (227). **If used, serum a-hCG levels should be serially monitored from the time of a missed menstrual period until the level is approximately 1,200 to 1,500 mIU/mL, at which time an ultrasonographic scan is performed and blood sampling is discontinued.** Other hormonal determinations are rarely of benefit because levels are often normal until fetal death or miscarriage occurs (228).

If a pregnancy has been confirmed, but clinical follow-up has met newly defined criteria for a failed pregnancy (378), intervention is recommended to expedite pregnancy termination and to obtain tissue for karyotype analysis. **[9] The importance of obtaining karyotypic analysis from tissues obtained after pregnancy demise in a woman experiencing recurrent losses cannot be overemphasized. Results may suggest karyotypic anomalies in the parents and patients report their appreciation of receiving the information** (379). **The documentation of aneuploidy may have**

important prognostic implications and may direct future interventions. Cost analysis has demonstrated that karyotypic analysis is financially prudent among patients with histories of recurrent pregnancy loss (229). Analysis by traditional karyotype fails 20% to 40% of the time because of difficulties in growing cells from products of conception and interpretation of results can be limited as a result of maternal cell contamination (380). Techniques for analysis like comparative genomic hybridization provide results in more than 90% of cases and can differentiate 46XX results from maternal cell contamination (230,380). This technology can be used without fresh samples needed for cell growth and can even be used in specimens that have been in formalin or paraffin (231).

In continuing pregnancies, first trimester screening using cell-free fetal DNA, maternal chemistries, and fetal nuchal lucency measurement or chorionic villus sampling is recommended for obstetrical indications. Amniocentesis may be recommended to assess the fetal karyotype based on prior screening results. In the future, fetal karyotype assessment may be performed using DNA isolated from nucleated fetal erythrocytes in maternal blood (232) or from sampling of the lower genital tract (381).

THERAPY

Advances in the treatment of patients with recurrent pregnancy loss have been slow. Despite a rapid expansion in understanding the molecular and subcellular mechanisms involved in implantation and early pregnancy maintenance, extension of these concepts to prevention of recurrent early pregnancy loss has lagged. Progress toward treatment of most causes of recurrent pregnancy loss has been hampered by a variety of factors. The condition itself has been inconsistently defined. **The results of clinical trials involving recurrent pregnancy loss patients are nearly impossible to compare and evaluate.** Trial design is frequently substandard, with lack of rationale, lack of appropriate control groups, and poor statistical analysis, limiting the ability to draw concrete conclusions from reported results. Epidemiologic data indicate that most patients with a history of recurrent pregnancy loss will, in fact, have a successful pregnancy the next time they conceive (7). For these reasons, with few exceptions, most therapies for recurrent pregnancy loss must be considered experimental. Until further study is completed, treatment protocols involving these therapies should be undertaken only with informed consent and in the setting of a well-designed, double-blind, placebo-controlled clinical trial.

[9] Common but controversial therapeutic options for patients with recurrent pregnancy loss include the use of IVF with preimplantation chromosomal screening of embryos, use of donor oocytes or sperm, antithrombotic interventions, the repair of anatomic anomalies, the correction of any endocrine abnormalities, the

treatment of infections, and a variety of immunologic interventions and drug treatments. Treatment for patients with recurrent miscarriage should include close monitoring of pregnancy, psychological counseling and support, and karyotypic analysis of tissues from subsequent miscarriage.

Genetic Abnormalities

Evidence suggests that, in women with a history of three or more spontaneous pregnancy losses, a subsequent pregnancy loss has a 58% chance of chromosomal abnormality (382). Among women with recurrent pregnancy loss who are age 35 or older, the aneuploidy rate is much higher at 80% (8). Most chromosomal abnormalities identified in miscarriages are autosomal trisomies and considered to result from maternal nondisjunction. Maternal age appears as a consistent and important risk factor for trisomy in most studies. DOR can be associated with higher aneuploidy rate in young women with recurrent pregnancy loss (349). There are several options for patients who suffer from recurrent pregnancy loss who have an identified miscarriage caused by trisomy. The first is to conceive again without any specific change in medical management, as these abnormalities are sporadic and unlikely to recur. Studies examining patients with recurrent pregnancy loss show that women who miscarry chromosomally abnormal conceptions are more likely to achieve a live birth with subsequent pregnancy than those who miscarry chromosomally normal conceptions (13,233). A second treatment option is chromosomal screening of embryos before implantation, commonly referred to as preimplantation genetic screening (PGS), and a third option involves the use of donor gametes.

Because chromosomal abnormalities are the most commonly identified cause of miscarriage, some have argued that the use of chromosomal screening of embryos is indicated for patients with recurrent pregnancy loss. This technique involves biopsying a single cell from a cleavage stage embryo (day 3) or many labs are biopsying several cells from blastocysts (day 5 or 6). Genetic testing can be performed on these cells to determine abnormalities in chromosome number and morphology. Embryos that are diagnosed with genetic abnormalities would be discarded and only those embryos with euploid results considered appropriate for transfer into the uterus. The biopsying of cells from embryos to screen for specific disease causing mutations like cystic fibrosis or sickle cells disease, commonly referred to as preimplantation genetic diagnosis (PGD), is used in many internationally recognized assisted reproductive technology centers, however the use of chromosomal screening via biopsying embryos remains controversial, especially for recurrent pregnancy loss patients.

The use of chromosomal screening of embryos has the potential to reduce the incidence of pregnancy loss arising from a chromosome issue within the embryo. However, definitive studies in this population have not yet been done. The use of this

technology requires the patient to undergo an IVF cycle to obtain embryos for biopsy at significant cost and medical intervention. Although there are several retrospective studies showing reduced miscarriage rates with this technique, several prospective trials using the outcome of successful pregnancy per started cycle fail to show significant benefit (234–244). IVF is invasive and costly and many patients with recurrent pregnancy loss conceive quickly without intervention and have a high likelihood of live birth with their subsequent pregnancy. Therefore, the optimal control group for a study of IVF with chromosomal screening in the recurrent pregnancy loss population is debated. Should it be natural conceptions or IVF without testing of embryos? Finally, the prognosis for a patient with recurrent pregnancy loss does seem to be linked to the chromosome analysis of prior miscarriages. Recurrent pregnancy loss patients who miscarry chromosomally abnormal embryos, seem to have better prognosis than those who miscarry chromosomally normal conceptions, again arguing for expectant management for recurrent pregnancy loss patients with a history of aneuploid loss. On the other hand, patients with poorer prognosis are those who miscarry chromosomally normal embryos and therefore would not benefit from IVF and chromosomal screening of embryos. One intent to treat analysis showed similar pregnancy outcomes in recurrent pregnancy loss patients who chose expectant management compared to those who chose IVF with chromosomal screening (383). The efficacy of chromosomal screening of embryos in the treatment of patients with recurrent pregnancy loss continues to be investigated, and the methods of embryo biopsy and genetic testing continue to evolve (242,243). As these techniques improve and the understanding of aneuploidy and recurrence improves, there may be a subset of recurrent pregnancy loss patients, such as carriers of parental translocations, who might benefit from this intervention. IVF with chromosomal screening of embryos can be considered, but not strongly recommended, for patients with recurrent pregnancy loss.

An additional option for patients with recurrent miscarriage is the use donor eggs or sperm. This treatment is useful for recurrent pregnancy loss patients with specific parental genetic factors and couples with DOR. Patients with robertsonian translocations involving homologous chromosomes have a genetic anomaly which always results in unbalanced gametes, and the use of donor oocyte or donor sperm is recommended. Use of donor gametes among patients with a history of recurrent pregnancy loss can be useful in other cases where couples are at higher risk for unbalanced offspring because one or both prospective parents carries other chromosomal rearrangements, such as reciprocal translocations. In these cases, use of donor gametes was demonstrated to be as effective as its use in matched patients without such a history (245). In all cases of balanced translocations or embryonic aneuploidy, genetic counseling is recommended. Couples with DOR and/or advanced reproductive age have a higher risk of miscarriage, aneuploidy (349), and limited success with IVF with chromosomal screening and therefore should be counseled about

the option of using donor eggs.

Anatomic Anomalies

Hysteroscopic resection represents state-of-the-art therapy for submucous leiomyomas, intrauterine adhesions, and intrauterine septa. Although its efficacy has been debated, this approach appears to limit postoperative sequelae while maintaining improved reproductive outcomes (30,31,245–249). **Use has been safely extended to patients with DES exposure, hypoplastic uteri, and complicated septal anomalies** (30,31,250). Attempts to improve on standard hysteroscopic metroplasty, which is typically performed in the operating room using general anesthesia, often with laparoscopic guidance, are under investigation. Ultrasonographically guided transcervical metroplasty is reported to be safe and effective (246). Ambulatory, office-based procedures, including septum resection under fluoroscopic or ultrasound guidance, are attractive options (247).

For patients with a history of loss secondary to cervical incompetence, placement of a cervical cerclage is indicated. This is usually performed early in the second trimester after documentation of fetal viability. Cervical cerclage should be considered as a primary intervention for women with DES-associated uterine anomalies.

Endocrine Abnormalities

Some investigators have proposed the use of ovulation induction for the treatment of recurrent pregnancy loss (248,249). The theory behind its use in these patients rests on hypotheses that ovulation induction is associated with healthier oocytes. Healthier oocytes, in turn, may decrease the incidence of luteal phase insufficiency through a more receptive hormonal environment, which should result in improved pregnancy maintenance. This approach grossly oversimplifies the mechanisms involved in implantation and early pregnancy maintenance. Until appropriately studied, use of empiric ovulation induction for treatment of unexplained recurrent pregnancy loss should be viewed with caution. Evidence from small studies indicates such use is not effective (248). Still, use of ovulation induction in some subsets of patients with recurrent pregnancy loss could be of benefit. For instance, stimulating folliculogenesis with ovulation induction or luteal phase support with progesterone should be considered for women with luteal phase insufficiency. The efficacy of these therapies, however, is not substantiated (250). Ovulation induction might be beneficial for women with androgen and LH hypersecretion disorders, especially following pituitary desensitization with gonadotropin-releasing hormone agonist therapy (66). This treatment remains controversial because the only large, prospective, randomized controlled trial reports no therapeutic efficacy; none for prepregnancy pituitary

suppression nor for luteal phase progesterone supplementation (251).

Links between PCOS, hyperandrogenism, hyperinsulinemia, and recurrent pregnancy loss make use of insulin-sensitizing agents in the treatment of recurrent pregnancy loss associated with PCOS attractive (43–46). Although further study is needed, there are an increasing number of reports that support its use for this application (252,253). Prepregnancy glycemic control is particularly important for women with overt diabetes mellitus (47,49). Thyroid hormone replacement may be helpful in cases of hypothyroidism. There are data indicating that thyroid hormone therapy may be of some benefit in euthyroid recurrent loss patients with antithyroid antibodies and possibly even in all pregnant women with "euthyroid" TSH levels between 2.5 and 5.0 mIU/L (52–54,177). Use of dopamine agonists to normalize prolactin levels in patients with recurrent pregnancy loss has improved subsequent pregnancy outcomes in limited studies (63), but remains controversial (384). There does not appear to be a place in the medical management of recurrent pregnancy loss for administering bromocriptine to women who do not have a prolactin disorder.

Infections

Empiric antibiotic treatment has been used for couples with recurrent miscarriage but its efficacy is unproven. Elaborate testing for infectious factors among recurrent pregnancy loss patients and use of therapeutic interventions is not justified unless a patient is immunocompromised or a specific infection has been documented (67). For cases in which an infectious organism has been identified, appropriate antibiotics should be administered to both partners, followed by posttreatment culture to verify eradication of the infectious agent before attempting conception.

Chronic endometritis, defined as the asymptomatic presence of histologically documented plasma cells in an endometrial biopsy, may be associated with recurrent miscarriage. In suspected cases of chronic endometritis, it is difficult to determine cause and effect but treatment with antibiotics shows a higher live birth rate in subsequent pregnancies in some studies (353,354). Treatment for chronic endometritis is not recommended by expert groups and larger studies are needed before implementing evaluation and treatment in routine practice.

Immunologic Factors

[5] Immune-mediated recurrent pregnancy loss has received more attention than any other single etiologic classification of recurrent pregnancy loss. Nevertheless, the diagnosis and subsequent treatment of the majority of cases remain unclear (56,118,254–256). **Most therapies for proposed immune-related recurrent pregnancy loss can have harmful side effects and must be considered experimental.**

Immunostimulating Therapies: Leukocyte Immunization

Stimulation of the maternal immune system using alloantigens on either paternal or pooled donor leukocytes has been promoted for patients with immunologic recurrent pregnancy loss, but data do not support its use and side effects can be dangerous. One of the largest trials evaluating the efficacy of leukocyte immunization in patients with unexplained recurrent pregnancy loss is a part of the Recurrent Miscarriage (REMIS) study (258). This investigation was large (over 90 patients per treatment arm), prospective, placebo controlled, randomized, and double blinded. It demonstrated no efficacy for paternal leukocyte immunization in couples with unexplained recurrent pregnancy loss. The best of the meta-analyses definitively rejects use of this therapy in patients with recurrent loss (259). Leukocyte immunization poses a significant risk to the mother and her fetus (231,232,260). Several cases of graft-versus-host disease, severe intrauterine growth retardation, and autoimmune and isoimmune complications have been reported (257,260–264). Alloimmunization to platelets contained in the paternal leukocyte preparation is associated with cases of potentially fatal fetal thrombocytopenia. The routine use of this therapy for recurrent miscarriage is not clinically justified.

Other immunostimulating therapies have been proposed and abandoned. Intravenous preparations consisting of syncytiotrophoblast microvillus plasma membrane vesicles have been used to mimic the fetal cell contact with maternal blood that normally occurs in pregnancy (265). The efficacy of this therapy has not been established (259,265,266). The use of third-party seminal plasma suppositories has been attempted, based on the misconception that TLX was part of an idiotype–anti-idiotype control system (267,268). Third-party seminal plasma suppositories for recurrent miscarriage have no scientifically credible rationale and should not be used.

Immunosuppressive Therapies

Immunosuppressive and other immunoregulating therapies have been advocated for cases in which miscarriage was believed to result from antiphospholipid antibodies or inappropriate cellular immunity toward the implanting fetus. Study design problems, including small numbers of recruited patients, lack of prestratification by maternal age and number of prior losses before randomization, and other methodologic and statistical inaccuracies preclude definitive statements regarding therapeutic efficacy for most of the proposed immunosuppressive approaches.

Intravenous Immunoglobulin

Intravenous immunoglobulins (IVIgs) are composed of pooled samples of immunoglobulins harvested from a large number of blood donors. Studies on the use of IVIg therapy in the treatment of recurrent pregnancy loss are based on the theory that some recurrent pregnancy loss patients have an overzealous immune reactivity to their implanting fetus. IVIgs do have immunosuppressive effects, but the mechanisms

underlying this immune modulation are only partially understood. Based on a large number of relatively small studies using a variety of treatment protocols, there remains no conclusive evidence to suggest that use of IVIg in the treatment of patients with unexplained (and presumed immunologic) recurrent pregnancy loss has any benefit (261,269–273). This includes a recent trial using IVIg in women with secondary recurrent pregnancy loss that was ended early because interim analyses revealed no effect (269). The Cochrane review of immune therapy for recurrent pregnancy loss addressed IVIg therapy and reported that its use did not alter pregnancy outcomes in patients with otherwise unexplained recurrent pregnancy loss (259,266). Improved posttreatment pregnancy rates may be seen, however, when IVIg is used in those specific patients with autoimmune-mediated pregnancy loss associated with APS (274,275). Therapy with IVIgs for recurrent pregnancy loss is expensive, invasive, and time-consuming, requiring multiple intravenous infusions over the course of pregnancy (276). Use of IVIgs for recurrent pregnancy loss is not supported by current evidence and may result in significant side effects such as nausea, headache, myalgias, and hypotension (262). More serious adverse effects include anaphylaxis (particularly in patients with IgA deficiency) (277).

Progesterone

As mentioned earlier, progesterone has known immunosuppressive effects and empiric progesterone supplements for women with a history of recurrent pregnancy loss is a relatively common practice (129–132,136,137). A number of studies using in vitro cellular systems relevant to the maternal–fetal interface have demonstrated that progesterone either inhibits TH1 immunity or causes a shift from TH1- to TH2-type responses that are more favorable for successful pregnancies (136,137,278). Clinical trials evaluating progesterone use in recurrent miscarriage patients show varying results. In 2013, a Cochrane review of multiple studies showed a benefit of progesterone supplementation in women with recurrent pregnancy loss; however, the studies differed in sample size, timing, dose, and type of progesterone supplementation (385). In 2015, Coomarasamy et al. performed a randomized controlled trial of vaginal progesterone in women with three or more first trimester miscarriages. Women were randomized to 400 mg vaginal micronized progesterone twice daily or matched placebo starting with positive pregnancy test but no later than 6 weeks of gestation (386). Similar live birth rates were achieved in the two groups and arguments against routine progesterone use in recurrent pregnancy loss patients could be made despite the late start of progesterone (up to 6 weeks gestation) in some patients. Some research suggests an earlier start to progesterone supplementation is beneficial for outcomes despite the side effects of luteal phase progesterone, including delayed onset of menses, which can be distressing for women trying to conceive (387). Progesterone has been administered intramuscularly and intravaginally for the treatment of recurrent pregnancy loss. It is

thought that vaginal administration may increase local, intrauterine concentrations of progesterone better than systemic administration. Vaginal formulations may provide a better method of attaining local immunosuppressive levels of progesterone while decreasing adverse systemic side effects.

Intralipid Infusion

The relative paucity of inflammatory diseases among the Greenland Inuit population, who consume a diet high in fish oils, led investigators to study the immune modulatory effects of lipid emulsions in total parenteral nutrition preparations for preoperative patients and for burn and trauma victims (279–282). The wide range of demonstrated effects, including lipid preparations that reduced NK cell activity, reduced monocyte proinflammatory cytokine production and increased susceptibility to infection, led investigators to hypothesize, as early as 1994, that lipid infusions might promote an immune environment that would favor pregnancy maintenance (283). Since that time, a small number of publications have addressed the effects of lipid infusions (intralipids) in women with a history of pregnancy loss (284,285). These investigations have demonstrated a decrease in peripheral NK cell activity in women treated with one to three infusions of intralipids. This effect lasted from 4 to 9 weeks after the last infusion (284). The authors did not address NK cell cytokine secretion patterns nor did they assay decidual NK cell function. Despite this paucity of data, intralipid infusions are being administered to recurrent pregnancy loss patients with increasing frequency. The existing data do not support this practice and side effects can include flushing, dizziness, myalgias, nausea, anaphylactic reactions, kidney and liver dysfunction, infection, and thrombosis. Intralipid infusions in recurrent pregnancy loss patients is not recommended clinically and should be administered only under an institutional review board–approved protocol and in a study setting.

TNF-α Inhibition

Interest in the potent proinflammatory cytokine, TNF-α, as a mediator of pregnancy loss came out of the description of the TH1 and TH2 paradigm (125). There have been several publications that link maternal serum TNF-α levels and activating TNF-α gene promoter polymorphisms to recurrent pregnancy loss (286–288). The development of antagonists of TNF-α in the form of blocking antibodies (adalimumab, infliximab) and inhibitory recombinant proteins (etanercept) has permitted successful treatment of several autoimmune disorders, including rheumatoid arthritis, psoriasis, and Crohn disease. Their use has not been associated with universally positive outcomes and may worsen some disorders, including multiple sclerosis (289). These products are associated with rare but worrisome side effects, including liver failure, aplastic anemia, interstitial lung disease, and anaphylaxis (290). Although there exists only a single, small, retrospective, observational, nonrandomly assigned case series that involved treatment of recurrent pregnancy loss patients with inhibitors of TNF-α, these positive

preliminary results have led a growing number of clinics to offer this therapy to patients, often at a significant cost (291). The safety of these compounds in pregnancy has not been appropriately studied and preliminary reports associating exposure to TNF-α inhibitors during early pregnancy to fetal VACTERL syndrome is concerning (292). As with intralipid therapy, use of TNF-**α** inhibition for the treatment of recurrent pregnancy loss should be implemented only under an institutional review board–approved protocol in a study setting and should not generate clinical income.

Other immunoregulating therapies theoretically useful in treating recurrent pregnancy loss include the use of cyclosporine, pentoxifylline, and nifedipine, although maternal and fetal risks with these agents preclude their clinical use. Plasmaphoresis has been used to treat women with recurrent miscarriage and antiphospholipid antibodies (293). Generalized immunosuppression with corticosteroids, such as prednisone, has been advocated during pregnancy for women with recurrent losses and chronic intervillositis and those with recurrent pregnancy loss and APS (294). Although corticosteroids have shown some treatment promise in these patients, maternal and fetal side effects, such as gestational diabetes and intrauterine growth restriction, and the availability of alternative therapies have limited their use (294,295). The efficacy and side effects of prednisone plus low-dose aspirin was examined in a large, randomized, placebo-controlled trial treating patients with autoantibodies and recurrent pregnancy losses. Pregnancy outcomes for treated and control patients were similar; however, the incidence of maternal diabetes and hypertension and the risk of premature delivery were all increased among those treated with prednisone and aspirin (296).

Antithrombotic Therapy

Therapy for patients with recurrent pregnancy losses associated with APS has shifted toward the use of antithrombotic medications. Unlike immunosuppressive treatments, this approach appears to address the effect (hypercoagulability), but not the underlying cause (e.g., genetic, APS) of recurrent pregnancy loss. There are reports that heparin, one typical anticoagulant, may exert direct immunomodulatory effects by binding to antiphospholipid antibodies and may decrease movement of inflammatory cells to sites of alloantigen exposure (297,298). The combined use of low-dose aspirin (75 to 81 mg per day) and subcutaneous unfractionated heparin (5,000 to 10,000 units twice daily) during pregnancy has been best studied among women with APS and appears to be efficacious (299–303). A typical regimen for women with antiphospholipid syndrome would include use of aspirin (81 mg every day) beginning with any attempts to conceive. After pregnancy has been confirmed, 5,000 IU unfractionated sodium heparin is administered subcutaneously twice daily, throughout gestation. Patients using this therapy should be treated in conjunction with a perinatologist because of their increased risks for preterm labor, premature rupture of the membranes, intrauterine growth restriction, intrauterine fetal demise, and preeclampsia. Other potential risks include

gastric bleeding, osteopenia, and abruptio placenta.

Attempts have been made to extend the finding that antithrombotic therapy is efficacious when used to treat patients with APS and recurrent pregnancy loss. These attempts include the use of low–molecular-weight heparins (LMWHs), the use of antithrombotic therapy in non-APS patients with thrombophilia and recurrent pregnancy loss, and even its use among recurrent pregnancy loss patients without thrombophilia (unexplained recurrent losses).

New formulations of heparin, termed LMWHs, have been demonstrated to be superior to unfractionated heparin in the treatment of many clotting disorders (304–306). LMWH has the advantage of an increased antithrombotic ratio when compared with unfractionated heparin. This results in improved treatment of inappropriate clotting with fewer bleeding side effects and LMWH has been associated with a decreased incidence of thrombocytopenia and osteoporosis when compared with its unfractionated counterpart. LMWH has a long half-life and requires less frequent dosing and monitoring, thereby improving patient compliance. **LMWH appears to be safe for use in pregnancy, and has shown promise when combined with low-dose aspirin in the treatment of recurrent pregnancy loss associated with APS** (300,305,307). A few studies have compared the use of unfractionated heparin and aspirin to LMWH and aspirin in the treatment of women with APS and adverse pregnancy outcomes (303,308). The therapies had similar effects in one study (308). A meta-analysis suggested that unfractionated heparin was superior to LMWH, however, there was significant heterogeneity between studies (303).

Anticoagulation for recurrent pregnancy loss patients with thrombophilia but no personal or family history of thrombosis is controversial. Early studies showed efficacy for LMWH treatment for patients with recurrent pregnancy loss associated with other thrombophilias, including activated protein C resistance associated with FVL, mutations in the promoter region of the prothrombin gene, and decreases in protein C and protein S activities (309–311,317). The use of LMWH for this indication appears to have a reassuring safety profile for mother and fetus (307,312,313). Studies and expert groups argue that, despite the biologic plausibility that patients with recurrent pregnancy loss would have a higher chance of inherited thrombophilia and that anticoagulation of patients with these diagnoses would decrease risk of subsequent miscarriage, the evidence does not support the theories (338,341).

The prophylactic use of daily low-dose aspirin has become common practice within the lay public based on its perceived cardiovascular effects combined with its low incidence of side effects. Its sole use in the treatment of recurrent pregnancy loss has likewise gained momentum, and many patients with histories of recurrent loss will either be self-prescribing this therapy or will inquire about its usefulness. There are no good data supporting its use either in patients with heritable thrombophilias or in the general recurrent pregnancy loss population. Although studies are small, the use of low-

dose aspirin alone has not been shown to be effective in the treatment of recurrent pregnancy loss associated with APS (301,314,315). When used in these patients, it should be in combination with unfractionated or LMWH. Large randomized prospective trials examining the empiric use of aspirin alone or in combination with prophylactic doses of heparin have shown no benefit of these therapies in unexplained recurrent pregnancy loss (315). The use of aspirin in early pregnancy has been called into question with reports of an increased incidence of isolated spontaneous pregnancy loss among women who used this medication (213,214). These reports are poorly designed and do not adequately address the level of aspirin exposure 81 mg versus 325 mg. Although reviews have touted the overall safety of aspirin in pregnancy, outside of use in combination with heparin for patients with recurrent pregnancy loss and APS, this medication should be used only with justification in the well-informed patient during early pregnancy (316).

As mentioned previously, vitamins B_6, B_{12}, and folate are important in homocysteine metabolism, and hyperhomocysteinemia is linked to recurrent pregnancy loss in some studies (15,17,27,388). Women with recurrent pregnancy loss and isolated fasting hyperhomocysteinemia should be offered supplemental folic acid (0.4 to 1.0 mg per day), vitamin B_6 (6 mg per day), and possibly vitamin B_{12} (0.025 mg per day) (318–321). Fasting homocysteine levels should be retested after treatment. If levels are normalized or remain only marginally elevated, no further therapy is necessary. Homocysteine levels will predictably decrease during pregnancy.

Treatment of women with recurrent pregnancy loss and an identified inherited or acquired thrombophilia should be based on accompanying history. There are no published large prospective controlled trials examining the benefit of anticoagulation for the prevention of miscarriage in the absence of APS, and, therefore, anticoagulation recommendations for patients with inherited thrombophilias are based on individualized risk of venous thromboembolic events in pregnancy (16).

- **If a venous thromboembolic event occurs during the index pregnancy, posthospitalization management requires therapeutic anticoagulation.**
  UFH: 10,000 to 15,000 U subcutaneous every 8 to 12 hours (monitor to keep aPTT 1.5 to 2.5 times normal) OR
  LMWH: enoxaparin 40 to 80 mg subcutaneous twice a day or dalteparin 5,000 to 10,000 U subcutaneous twice a day). Consider monitoring trough factor Xa levels in the third trimester.
- **If there is a personal history of venous thromboembolic events (particularly in a previous pregnancy or with hormonal contraceptive use) or a strong thrombophilic family history, treat with therapeutic anticoagulation. Thrombotic risk is greatest during the postpartum period.**

- **Anticoagulation should be reinitiated after delivery in doses reflecting predelivery treatment regimens. Postpartum anticoagulation should be continued for 6 to 12 weeks postpartum** (305). Women may continue injectable therapy or transition to oral anticoagulants (e.g., coumarin). Use of heparin or of coumarin derivatives does not prohibit breastfeeding.

Psychological Support

There is no doubt that experiencing isolated and recurrent losses can be emotionally devastating. The risk of major depression is increased greater than twofold among women with spontaneous pregnancy loss; in most women it arises in the first weeks following delivery (322). A caring and empathetic attitude is prerequisite to all healing. Acknowledgment of the pain and suffering couples have experienced because of recurrent miscarriage can be a cathartic catalyst enabling them to incorporate their experience of loss into their lives rather than focusing their lives on their experience of loss (66). **Referrals to support groups and counselors should be offered.** Self-help measures, such as meditation, yoga, exercise, and biofeedback may also be useful.

PROGNOSIS

[7] The prognosis for successful pregnancy depends on the potential underlying cause of pregnancy loss and (epidemiologically) on the number of prior losses. Epidemiologic surveys indicate that the chance of a viable birth even after four prior losses may be as high as 60%. Depending on the study, **the prognosis for successful pregnancy in couples with a cytogenetic etiology for reproductive loss varies from 20% to 80%** (323–325). **Women with corrected anatomical anomalies may expect a successful pregnancy in 60% to 90% of cases** (28,323,326–329). **A success rate higher than 90% has been reported for women with corrected endocrine abnormalities** (324). **Between 70% and 90% of pregnancies reported among women receiving therapy for antiphospholipid antibodies have been viable** (330,331).

Many forms of pre- or postconceptional tests have been proposed to help predict pregnancy outcome (221,332,333,389); **none have been fully substantiated in large, prospective trials. The documentation of fetal cardiac activity on ultrasound may offer prognostic value; however, it appears that its predictions may be greatly affected by any underlying diagnosis.** In one study, the live birth rate following documentation of fetal cardiac activity between 5 and 6 weeks from the last menstrual period was approximately 77% in women with two or more unexplained spontaneous miscarriages (334). It may be important to note that most of the patients in this study had evidence of inappropriate antitrophoblast cellular immunity. Others have shown that 86% of patients with antiphospholipid antibodies and recurrent pregnancy loss had fetal

cardiac activity detected prior to subsequent demise (335). **A prospective, longitudinal, observational study of 325 patients with unexplained recurrent pregnancy losses demonstrated that only 3% of 55 miscarriages occurred following the detection of fetal cardiac activity using transvaginal ultrasonography** (336). The majority of couples with recurrent pregnancy loss will go on to have live birth and reminding patients of this throughout evaluation and treatment can be an invaluable tool for psychological and emotional support through the process.

Hirsutism
Ovulation Induction

KEY POINTS

1 Primary amenorrhea is defined as absence of menses at age 13 years when there is no visible development of secondary sexual characteristics or age 15 years in the presence of normal secondary sexual characteristics.

2 Absent or irregular menses may be an indication that a woman has a medical condition that can affect her overall health. The health implications can vary depending on the etiology of the amenorrhea. Therefore, a cause for amenorrhea should be established whenever possible.

3 When gonadal failure occurs in conjunction with primary amenorrhea, it is associated with a high incidence of abnormal karyotype.

4 The most important elements in the diagnosis of amenorrhea include physical examination for secondary sexual characteristics and anatomic abnormalities, measurement of human chorionic gonadotropin (hCG) to rule out pregnancy, serum prolactin and thyroid stimulating hormone (TSH) levels, and assessment of follicle-stimulating hormone (FSH) levels with estradiol to differentiate between hypergonadotropic and hypogonadotropic forms of hypogonadism. It may be helpful to measure anti-müllerian hormone (AMH).

5 Therapeutic measures may include specific therapies (medical or surgical) aimed at correcting the primary cause of amenorrhea, hormone therapy to initiate and maintain secondary sexual characteristics and provide symptomatic relief, treatments to maximize and maintain peak bone mass including hormone therapy, calcium, and vitamin D for women or girls with low circulating estrogen levels, and ovulation induction for patients desiring pregnancy.

6 The anatomic causes of amenorrhea are relatively few, and may be diagnosed by history, physical examination, and imaging.

A complex hormonal interaction must take place in order for normal menstruation to occur. The hypothalamus must secrete gonadotropin-releasing hormone (GnRH) in a pulsatile fashion, which is modulated by neurotransmitters and hormones. The GnRH stimulates secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the pituitary, which promotes ovarian follicular development and ovulation. A normally functioning ovarian follicle secretes estrogen prior to ovulation. After ovulation, the follicle is converted into a corpus luteum, and progesterone is secreted in addition to estrogen. These hormones stimulate endometrial development and maturation

for embryo implantation. If pregnancy does not occur, estrogen and progesterone secretion decrease and withdrawal bleeding begins. If any of the components (hypothalamus, pituitary, ovary, uterus, and outflow tract) are nonfunctional, bleeding cannot occur.

The mean age of menarche became younger during the previous several decades. Therefore, [1] primary amenorrhea is now defined as the absence of menses by 13 years of age when there is no visible development of secondary sexual characteristics or by 15 years of age in the presence of normal secondary sexual characteristics. The ages defining primary amenorrhea were decreased by 1 year to continue to represent two standard deviations above the mean age of developing secondary sexual characteristics and menses (1). **To detect the cause of primary amenorrhea, it is useful to determine whether secondary sexual characteristics are present (Fig. 34-1). The absence of secondary sexual characteristics indicates that a woman was never exposed to estrogen**. Failure to begin breast development by age 13 always warrants investigation. **[2] Absent or irregular menses may be an indication that a woman has a medical condition that can affect her overall health. The health implications can vary depending on the etiology of the amenorrhea. Therefore, a cause for amenorrhea should be established whenever possible.**

A woman who previously menstruated can develop secondary amenorrhea, which is defined as absence of menstruation for three menstrual cycles or 3 months (2). A woman with regular cycles and a delay of menses of even a week may warrant assessment with a pregnancy test. **It is advisable to evaluate a woman who has fewer than nine cycles per year or cycle length longer than 35 days. With a few exceptions, the causes of primary amenorrhea are similar to the causes of secondary amenorrhea (Fig. 34-2). Therefore, it is important not to overemphasize a distinction between primary and secondary amenorrhea.**

Patients may develop slight alterations in the hypothalamic– pituitary–ovarian axis that are not severe enough to cause amenorrhea but instead cause irregular menses (oligomenorrhea) associated with absent or infrequent ovulation. These patients may bleed excessively during menstruation because estrogen is unopposed. The etiologies of oligomenorrhea overlap with the etiologies of amenorrhea, with the exception that certain anatomic (e.g., absent uterine development) and karyotypic abnormalities (e.g., Turner syndrome), are largely associated with primary amenorrhea.

The World Health Organization (WHO) described three classes of amenorrhea. WHO group I (hypogonadotropic hypogonadism) includes women with no evidence of endogenous estrogen production, normal or low FSH levels, normal prolactin levels, and no lesion in the hypothalamic-pituitary region. WHO group II (normogonadotropic anovulation) is associated with evidence of estrogen

production and normal levels of prolactin and FSH. WHO group III (hypergonadotropic hypogonadism) includes individuals with elevated serum FSH indicating gonadal insufficiency or failure. Not originally included in the classification, a fourth category (hyperprolactinemic anovulation) was added to include women who are anovulatory specifically because of hyperprolactinemia. While not often used clinically, this historic classification system can be helpful in the understanding of the etiology of amenorrhea.

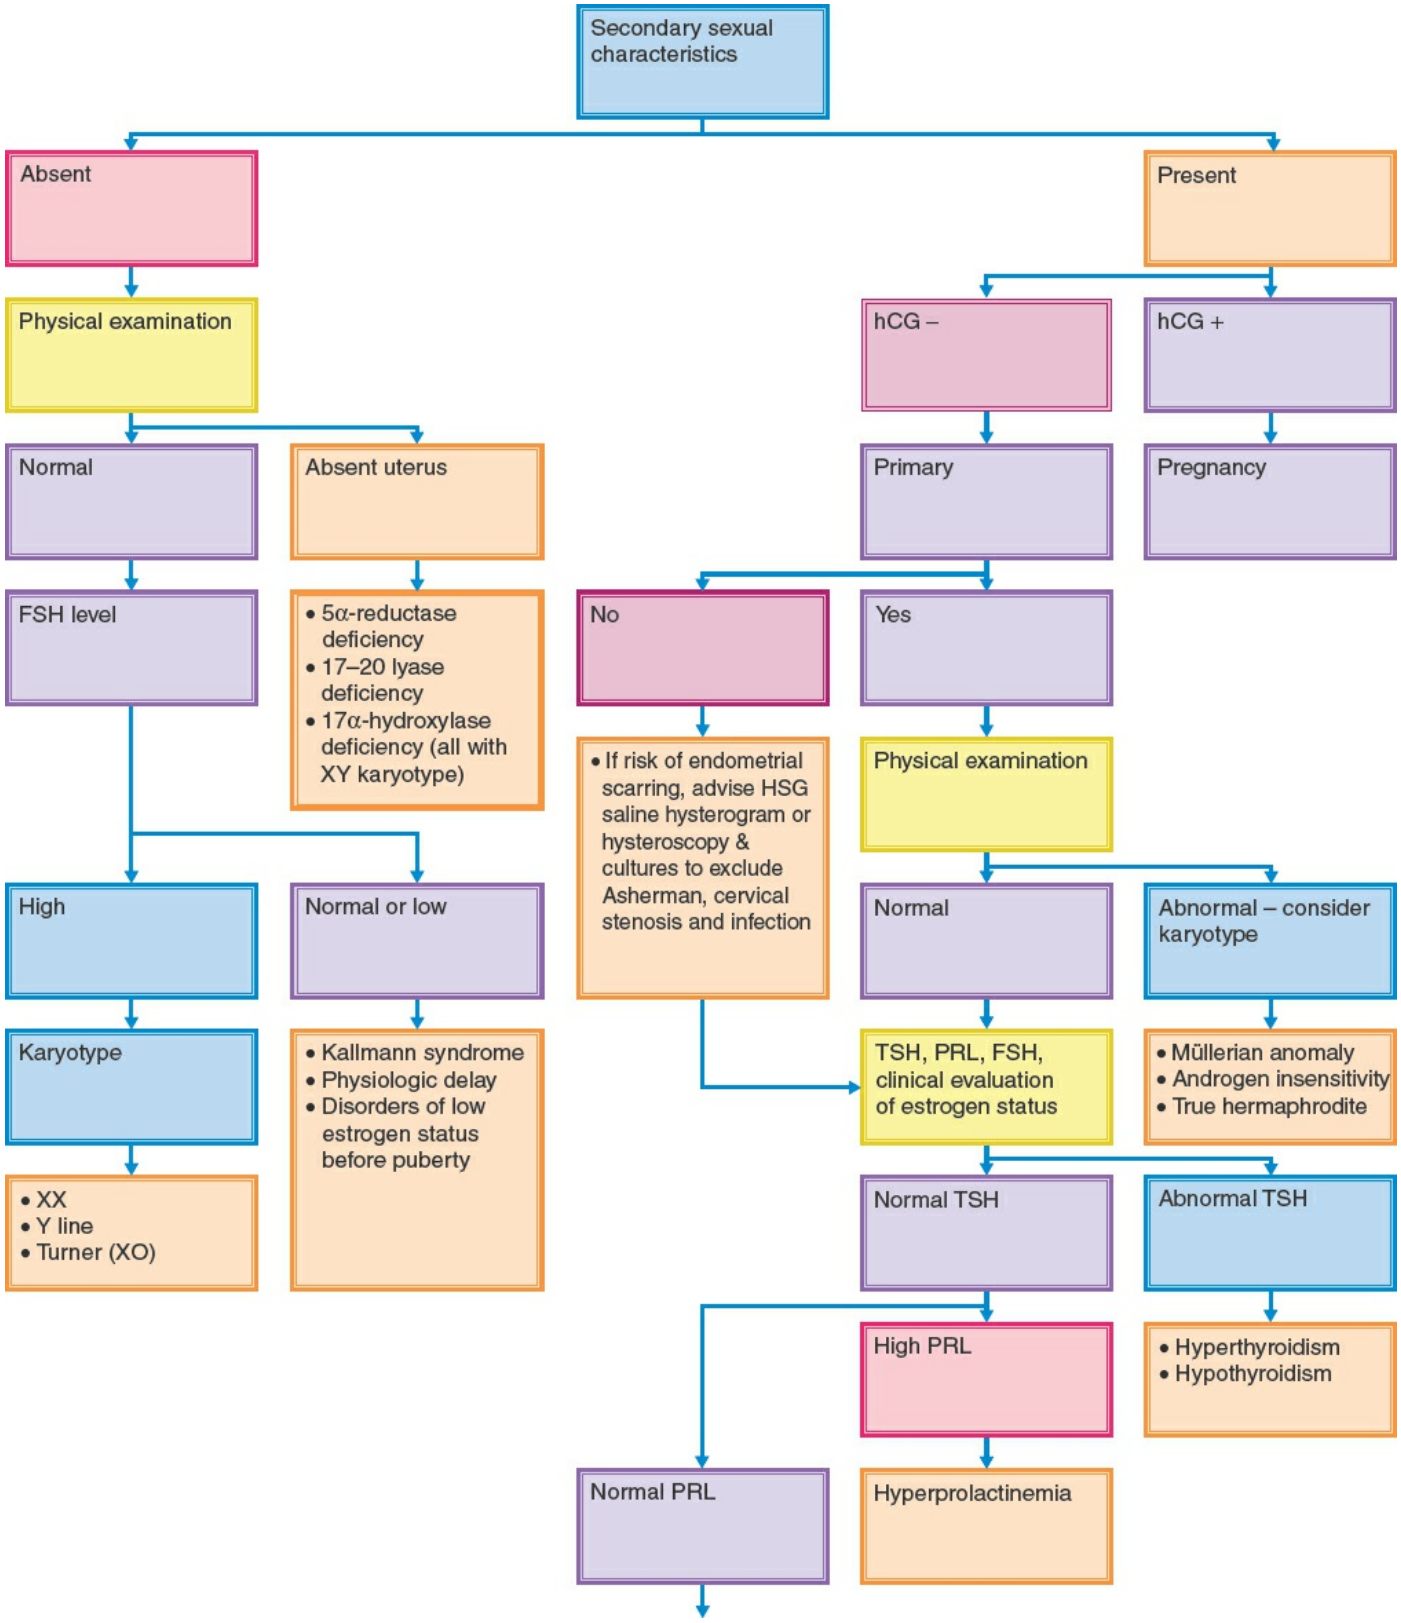
AMENORRHEA WITHOUT SECONDARY SEXUAL CHARACTERISTICS

Disorders associated with hypogonadism may present as primary amenorrhea. **Because breast development is the first sign of estrogen exposure in puberty, patients without secondary sexual characteristics typically have primary, not secondary, amenorrhea** (Fig. 34-1). It is helpful to categorize the causes of amenorrhea in the absence of breast development on the basis of gonadotropin status.

Causes of Primary Amenorrhea

Hypergonadotropic Hypogonadism Associated With Absence of Secondary Sexual Characteristics

Gonadal dysgenesis is a term typically used to describe abnormal development of the gonads, typically resulting in streak gonads. **Gonadal dysgenesis is associated with high levels of LH and FSH** because the gonad fails to produce the steroids and inhibin that would normally feed back to the hypothalamus and pituitary gland to suppress pituitary production of GnRH, LH and FSH. **[3] Karyotypic abnormalities are common in women with primary amenorrhea associated with gonadal failure** (Table 34-1). In one series, approximately 30% of patients with primary amenorrhea had an associated karyotypic abnormality (3). **Turner syndrome (45,X) and its variants represent the most common form of hypergonadotropic hypogonadism in women with primary amenorrhea** (3,4). Other disorders associated with primary amenorrhea include structurally abnormal X chromosomes, mosaicism (e.g., 45,X in some cells and another karyotype such as 46,XX or 46,XXX in other cells), pure gonadal dysgenesis (46,XX and 46,XY individuals with gonadal streaks resulting from lack of gonad development), enzyme deficiencies that prevent normal estrogen production, and gonadotropin-receptor inactivating mutations. Individuals with these conditions have gonadal failure and cannot synthesize ovarian steroids. Gonadotropin levels are elevated because of the lack of negative estrogen feedback on the hypothalamic–pituitary axis. Most patients with these conditions have primary amenorrhea and lack secondary sexual characteristics. Occasionally patients with a



partial deletion of the X chromosome, mosaicism, or pure gonadal dysgenesis (46,XX) may synthesize enough estrogen in early puberty to induce breast development and a few episodes of uterine bleeding and thus have secondary amenorrhea. Ovulation and, occasionally, pregnancy are possible.

Genetic Disorders

Turner Syndrome

Patients with Turner syndrome (45,X) initially have normal ovarian development in utero. Amenorrhea is the result of accelerated atresia of the follicles. The fibrotic ovaries are called streak ovaries.

In addition to gonadal failure, there are associated stigmata with Turner syndrome that include short stature, webbed neck, shield chest, cubitus valgus (increased carrying angle of the arms), low hair line, high-arched palate, multiple pigmented nevi, and short fourth metacarpals (4,5). X inactivation is a process that inactivates most of the genes on one X chromosome. Of the genes on the X chromosome, 20% escape X inactivation, and it is believed that loss of the second copy of these genes in a 45, X patient causes the stigmata associated with Turner syndrome (6). Reports about the relationship between karyotype and dysmorphic features have shown conflicting results, with a general finding of a more severe phenotype associated with monosomy 45X0 compared with a mosaic karyotype (7,8). A Y cell line should be excluded by karyotype, fluorescence *in situ* hybridization, and DNA analysis if necessary (9). Gonadectomy is recommended if a Y cell line is present because of the increased risk of gonadoblastoma and subsequent gonadal germ cell tumors.

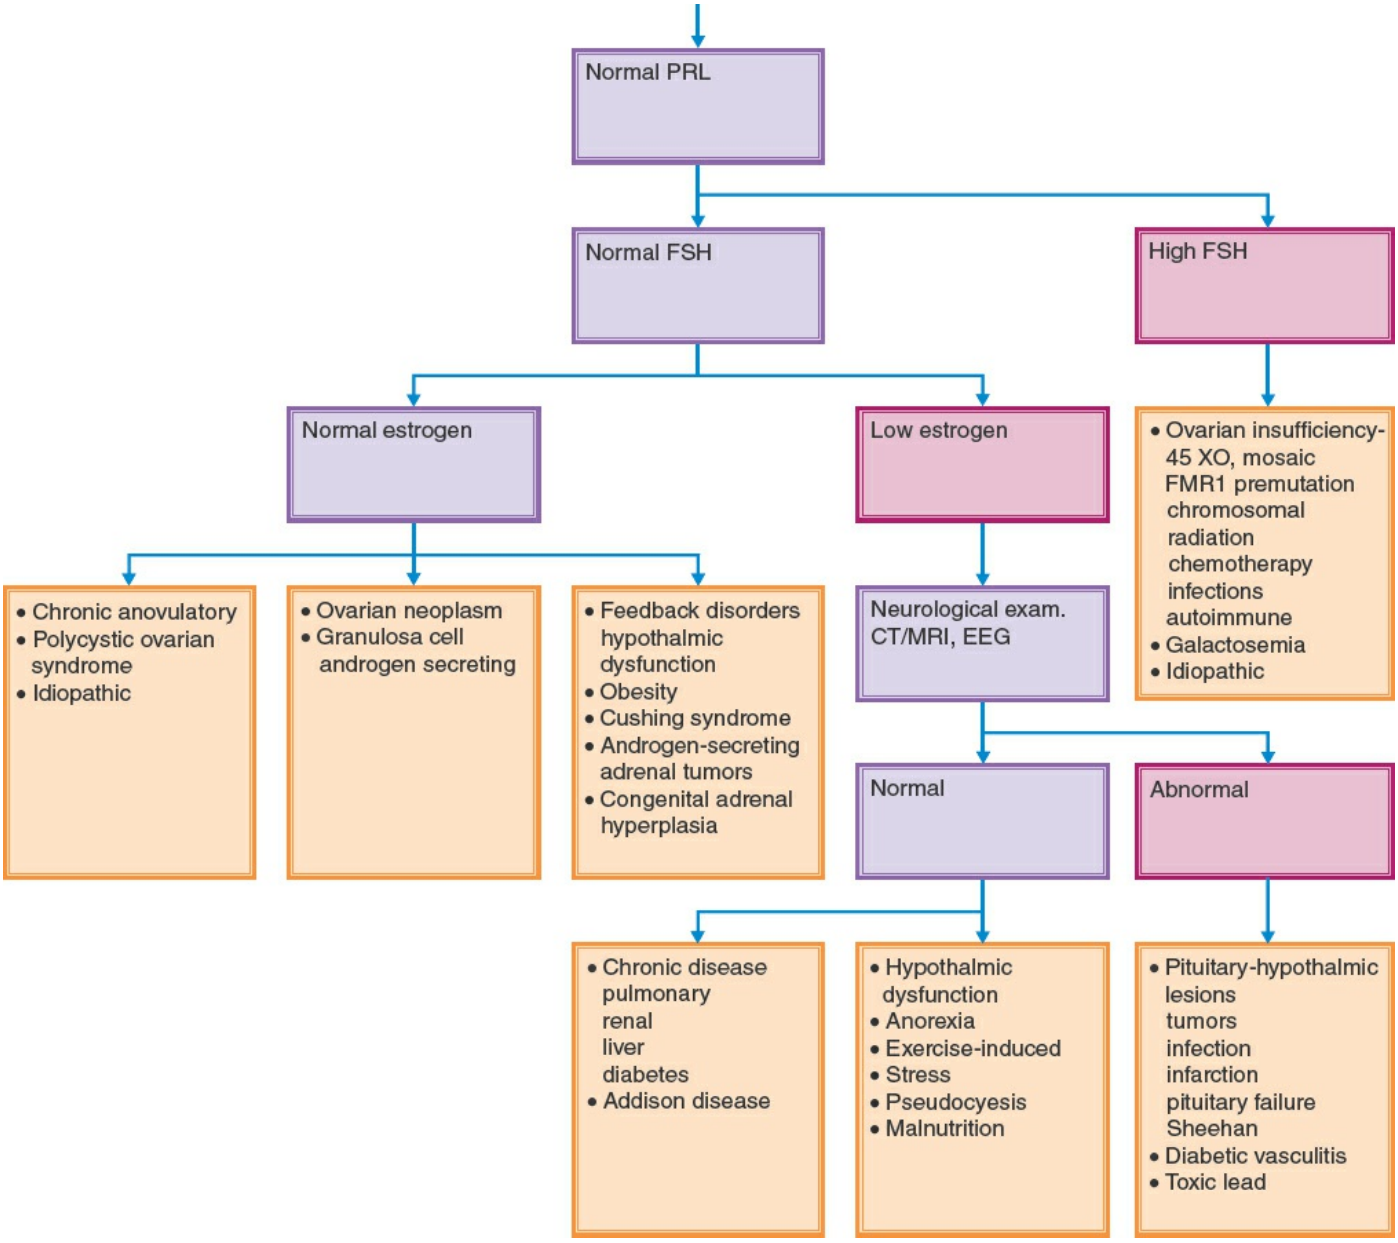

FIGURE 34-1 Decision tree for evaluation of amenorrhea. FSH, follicle-stimulating hormone; HCG, human chorionic gonadotropin; HSG, hysterosalpingogram; TSH, thyroid-stimulating hormone; PRL, prolactin; CT, computed tomography; MRI, magnetic resonance imaging; EEG, electroencephalogram; SHG, saline hysterogram (also known as saline infusion sonogram).

After the diagnosis of Turner syndrome is confirmed by karyotype, studies should be performed to ensure that cardiac (30% have coarctation of the aorta), renal (especially horseshoe kidney), and autoimmune (thyroiditis) abnormalities are diagnosed and treated. Evaluation should be performed in childhood to identify potential attention-deficit or nonverbal learning disorders. **Women with Turner syndrome should be screened for diabetes mellitus, aortic enlargement, hypertension, and hearing loss throughout their lives** (5,8).

Abnormal X Chromosome

Those 46,XX individuals with partial deletions of the X chromosome have variable phenotypes, probably depending on the amount and location of the missing genetic material. Smaller X chromosome deletions cause distinct features which overlap with features of Turner syndrome, but women with these smaller deletions are not considered to be within the definition of Turner syndrome (8). The pseudoautosomal region of the short arm of the X chromosome escapes X inactivation, thus resulting in two copies remaining transcriptionally active. The effective monosomy created by the deletion of Xp is thought to lead to some of the phenotypic features of Turner syndrome (6). The short stature homeobox (SHOX) gene is located in the distal region of Xp, with deletion directly associated with short stature and skeletal deformities. However, women and girls with a small distal deletion of the short arm of the X chromosome do not appear to be at higher risk for cardiac anomalies or ovarian failure, which are often present in women with Turner syndrome and a 45,X karyotype. Most patients with a ring X have ovarian failure and some phenotypic features similar to Turner syndrome, although some are able to reproduce successfully. These patients differ from those with Turner syndrome in that they are more likely to have intellectual disability. Patients with isochrome of the long arm of the X chromosome (i[Xq]) are similar to XO patients, with the exception that autoimmune disorders are more common. A balanced translocation of the X chromosome to an autosome may lead to gonadal failure (10). Gonadal failure can be caused by the chromosomal break occurring in a gene that is required for ovarian function, abnormal meiosis, or X inactivation of the translocated X and adjacent autosomal genes (6,10). Despite these and other reported associations between karyotype and phenotype, it is important to emphasize that a specific karyotype does not always predict phenotype (8).

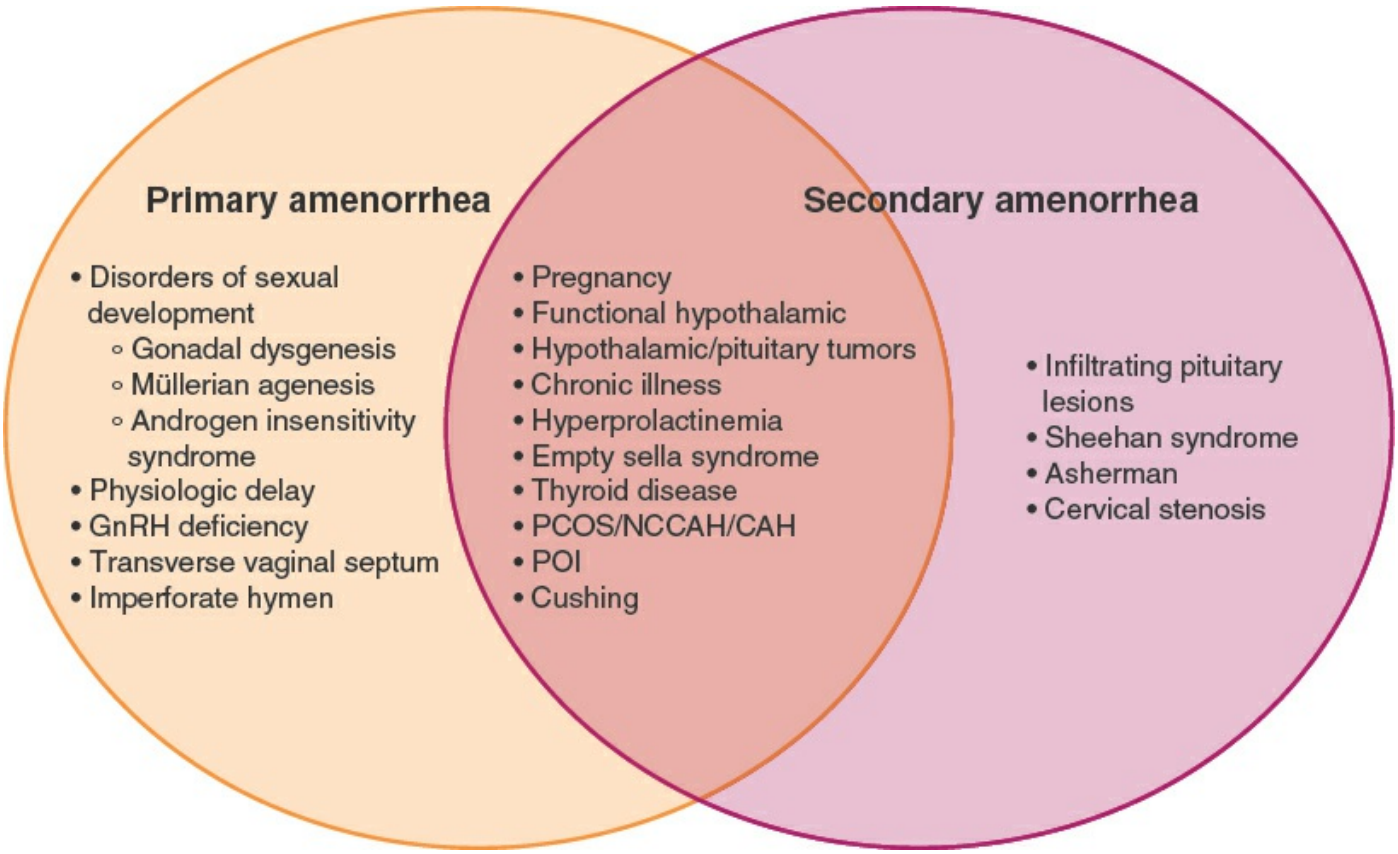

FIGURE 34-2 Schematic illustrating the overlap of the causes of primary and secondary amenorrhea.

Table 34-1 Amenorrhea Associated With a Lack of Secondary Sexual Characteristics

Abnormal pelvic examination
5α-reductase deficiency, 17,20-lyase deficiency, or 17α-hydroxylase deficiency in XY individual
Congenital lipoid adrenal hyperplasia
Luteinizing hormone receptor defect
Hypergonadotropic hypogonadism
Gonadal dysgenesis
Follicle-stimulating hormone receptor defect
Partial deletion of X chromosome
Sex chromosome mosaicism
Environmental and therapeutic ovarian toxins
17α-hydroxylase deficiency in XX individual
Galactosemia
Congenital lipoid adrenal hyperplasia in XX individual

Hypogonadotropic hypogonadism
Physiologic delay
Kallmann syndrome
Central nervous system tumors
Hypothalamic/pituitary dysfunction

Mosaicism

Primary amenorrhea is associated with various mosaic states, the most common of which is 45,X/46,XX (11). The clinical findings in 45,X/47,XXX and 45,X/46,XX/47,XXX are similar to those in 45,X/46,XX and vary in estrogen and gonadotropin production, depending on the number of follicles which ultimately survive in the gonads. When compared with the pure 45,X cell line, individuals with 45,X/46,XX are taller and have fewer abnormalities, although many of those with 45,X/46,XX mosaics are shorter than their peers.

Pure Gonadal Dysgenesis

Individuals who are phenotypically female with sexual infantilism, primary amenorrhea, normal stature, and no karyotypic abnormalities (46,XX or 46,XY) have pure gonadal dysgenesis. The gonads are usually streaks, but there may be some development of secondary sexual characteristics, and a few episodes of uterine bleeding. Pure gonadal dysgenesis in a 46,XY individual (previously known as Swyer syndrome) can occur when mutations in the SRY (sex-determining region gene on the Y chromosome) located at Yp11 result in XY females without proper gonad development (12,13). Mutations in many other genes such as SOX9, DAX1, WT1, and SF1, which affect testicular differentiation and inhibit anti-müllerian hormone production, result in XY pure gonadal dysgenesis (14).

With XX gonadal dysgenesis, the condition is likely to be caused by gene mutations that lead to ovarian insufficiency before pubertal development or after the development of secondary sexual characteristics. Perrault syndrome is a rare autosomal recessive disease with pure gonadal dysgenesis (46,XX) and sensorineural hearing loss (15). XX pure gonadal dysgenesis can be caused by the presence of small Y chromosome fragments in the genome. If Y sequences are present, gonadectomy is recommended.

Mixed Gonadal Dysgenesis

Most patients with mixed gonadal dysgenesis are XY and have ambiguous genitalia with a streak gonad on one side and a malformed testis on the opposite. A small proportion of these patients have mutations in the *SRY* gene.

Rare Enzyme Deficiencies

Congenital Lipoid Adrenal Hyperplasia

Patients with this autosomal recessive disorder are unable to convert cholesterol to pregnenolone, which is the first step in steroid hormone biosynthesis. The initial rate-limiting step in steroidogenesis is the transport of cholesterol from the outer to the inner mitochondrial membrane facilitated by steroidogenic acute regulatory protein (StAR). 48 different mutations have been identified in the StAR (16). Once in the mitochondria, cholesterol is cleaved by the p450scc enzyme. Several cases of p450scc deficiency have been reported (17). These patients present in infancy with hyponatremia, hyperkalemia, and acidosis. Both XX and XY individuals have external female genitalia, however 46 XY patients do not have a uterus and without hormone replacement they will remain sexually infantile. XX patients may acquire secondary sexual characteristics at puberty but develop large ovarian cysts and early ovarian failure (18). Genetic clusters of the disorder are found in the Japanese, Korean, and Palestinian Arab populations. With appropriate mineralocorticoid and glucocorticoid replacement, these patients can survive into adulthood.

17α-Hydroxylase and 17,20-Lyase Deficiency

Mutations in the *CYP17* gene cause abnormalities in the 17α-hydroxylase and 17,20-lyase functions of the protein that is active in the adrenal and gonadal steroidogenic pathways. Over 100 mutations that alter the reading frame of the gene have been associated with combined 17-hydroxylase/17,20-lyase deficiency (19). Patients have either 46,XX or 46,XY karyotypes. The uterus is absent in individuals with 46,XY karyotype, a feature distinguishing them from individuals with the 46,XX karyotype. Individuals with CYP17 mutations have primary amenorrhea, no secondary sexual characteristics, female phenotype, hypertension, and hypokalemia (19). The diminished levels of 17α-hydroxylase that characterize this disorder lead to a reduction in cortisol production, which in turn causes an increase in adrenocorticotropic hormone (ACTH). 17α-hydroxylase is not required for production of mineralocorticoids; thus, excessive amounts of mineralocorticoid are produced, resulting in sodium retention, loss of potassium, and hypertension. **Patients with 17α-hydroxylase deficiency have primordial follicles, but gonadotropin levels are elevated because the enzyme deficiency prevents synthesis of sex steroids.**

Aromatase Deficiency

This very rare autosomal recessive abnormality prevents the affected individual from aromatizing androgens to estrogen (20). This syndrome may be suspected even before birth because most mothers of affected children become virilized during pregnancy. This occurs because the placenta cannot convert the fetal androgens to estrogen and they diffuse into the maternal circulation. At birth, a female child has clitoromegaly and posterior labioscrotal fusion (ambiguous genitalia). At puberty, there is no breast development, primary amenorrhea, worsening virilization, absent growth spurt, delayed

bone age, and multicystic ovaries. The diagnostic hormonal pattern consists of an elevation of FSH, LH, testosterone, and dehydroepiandrosterone sulfate (DHEAS) levels, and undetectable levels of estradiol. Estrogen therapy improves the ovarian and skeletal abnormalities but must be titrated to mimic normal estrogen levels. Estrogen administration should be minimal during childhood and increased at puberty (21).

Galactosemia

In girls, galactosemia often is associated with ovarian failure, but this condition usually is detected by newborn screening programs. A galactose-1-phosphate uridyltransferase level can be measured to assess the patient for galactosemia or carrier status (22).

Rare Gonadotropin Receptor Mutations

Luteinizing Hormone Receptor Mutation

Inactivation of LH receptors is identified in XY patients who have disorders of sexual development (DSD) with primary amenorrhea in the absence of secondary sexual characteristics caused by homozygous premature stop codon, deletions, and missense mutations in the LHR gene located on chromosome 2. The Leydig cells in these individuals are unable to respond to LH, causing Leydig cell hypoplasia. This leads to early testicular failure and prevents masculinization. XX siblings with the same mutations develop normal secondary sexual characteristics but are amenorrheic with elevated LH levels, normal FSH levels, and cystic ovaries (23,24).

Follicle-Stimulating Hormone Receptor Mutation

An autosomal recessive single amino acid substitution in the extracellular domain of the FSH receptor, which prevents FSH binding, was identified in six families in Finland. This condition leads to primary or early secondary amenorrhea, variable development of secondary sexual characteristics, and high levels of FSH and LH (25). A novel homozygous mutation in the FSH receptor gene leading to primary ovarian insufficiency (POI) has been reported (26).

Other Causes of Primary Ovarian Failure Without Secondary Sexual Characteristics

Severe damage to the ovaries before the onset of puberty can lead to ovarian insufficiency and failure to develop secondary sexual characteristics. Ovarian dysfunction can occur in association with irradiation of the ovaries, chemotherapy with alkylating agents (e.g., *cyclophosphamide*), or combinations of radiation and other chemotherapeutic agents (27). Other causes of premature ovarian failure (also known as POI) are more commonly associated with amenorrhea after the development of secondary sexual characteristics, as described below.

Hypogonadotropic Hypogonadism Associated With the Absence of Secondary Sex Characteristics

Primary amenorrhea resulting from hypogonadotropic hypogonadism occurs when the hypothalamus fails to secrete adequate amounts of GnRH or when a pituitary disorder associated with inadequate production or release of pituitary gonadotropins is present.

Physiologic Delay

Physiologic or constitutional delay of puberty is the most common manifestation of hypogonadotropic hypogonadism. Amenorrhea may result from the lack of physical development caused by delayed reactivation of the GnRH pulse generator. Levels of GnRH are functionally deficient in relation to chronologic age but normal in terms of physiologic development.

Kallmann Syndrome

The second most common hypothalamic cause of primary amenorrhea associated with hypogonadotropic hypogonadism is insufficient pulsatile secretion of GnRH (Kallmann syndrome), which has varied modes of genetic transmission. Insufficient pulsatile secretion of GnRH leads to deficiencies in FSH and LH (28). Kallmann syndrome is often associated with anosmia (inability to perceive odors), although a woman may not be aware of her impaired sense of smell. The hypogonadism and anosmia arise because of failure of proper neuronal migration during fetal development.

Other Causes of Gonadotropin-Releasing Hormone Deficiency

Deficiencies in GnRH may be caused by developmental or genetic defects, inflammatory processes, tumors, vascular lesions, or trauma. **Central nervous system (CNS) tumors that lead to primary amenorrhea, the most common of which is craniopharyngioma, are usually extracellular masses that interfere with the synthesis and secretion of GnRH or stimulation of pituitary gonadotropins.** Virtually all of these patients have disorders in the production of other pituitary hormones and LH and FSH (29,30). Prolactin-secreting pituitary adenomas are rare in childhood and more commonly occur after development of secondary sexual characteristics.

Genetic Disorders

5α-Reductase Deficiency

The possibility of 5α-reductase deficiency should be considered in the evaluation of amenorrhea. 5α-Reductase converts testosterone to its more potent form, dihydrotestosterone which is the hormone responsible for triggering masculinization of the male external genitalia during early sexual development (31). Patients with 5α-reductase deficiency are genotypically XY with ambiguous genitalia, frequently experience virilization at puberty, have testes (because of functioning Y chromosomes), and have no müllerian structures as a result of functioning AMH. **Patients with 5α-reductase deficiency differ from patients with androgen insensitivity because they**

do not develop breasts at puberty (Fig. 34-3). These patients have low gonadotropin levels as a result of testosterone levels that are sufficient to suppress breast development and allow normal feedback mechanisms to remain intact. Normal male differentiation of the urogenital sinus and external genitalia do not occur because dihydrotestosterone is required for this development. Normal internal male genitalia derived from the wolffian ducts are present because this development requires only testosterone. Male pattern hair growth, muscle mass, and voice deepening are testosterone dependent.

Gonadotropin-Releasing Hormone Receptor Mutations

Mutations have been identified in the GnRH receptor gene, which lead to abnormal GnRH function (32). Most affected patients are compound heterozygotes, but homozygous autosomal recessive mutations have been identified. The GnRH receptor is a G-protein–coupled receptor. Functional studies show that the mutations cause marked decrease in binding of GnRH to its receptor or prevent second messenger signal transduction. Without a functional signal transduction, FSH and LH are not stimulated and are unable to promote follicular growth. All patients are normosomic.

Follicle-Stimulating Hormone Deficiency

Patients with FSH deficiency usually seek treatment for delayed puberty and primary amenorrhea associated with hypoestrogenism. Patients with this rare disorder are distinguished from other hypoestrogenic patients by having decreased FSH levels and increased LH levels. These patients have low serum androgen levels despite the abnormal LH-to-FSH ratio, indicating that FSH-stimulated follicular development is a prerequisite for thecal cell androgen production. In some of these patients, autosomal recessive mutations in the FSHβ subunit, which impair dimerization of α and β subunits and prevent binding to the FSH receptor, have been identified (33). Pregnancy has been reported after induction of ovulation with injectable gonadotropins (34).

Other Hypothalamic/Pituitary Dysfunctions

Functional gonadotropin deficiency results from malnutrition, malabsorption, weight loss or anorexia nervosa, excessive exercise, chronic disease, neoplasia, and marijuana use, although these conditions are more commonly associated with amenorrhea accompanied by secondary sexual characteristics that developed before the onset of the problem (35,36). **Hypothyroidism, polycystic ovarian syndrome (PCOS), Cushing syndrome, hyperprolactinemia, and infiltrative disorders of the CNS are more commonly associated with amenorrhea in the presence of development of secondary sexual characteristics, but have been reported to lead to amenorrhea accompanied by delayed puberty** (37,38). **Constitutional delay without underlying causes is less common in girls than in boys,**

and the reason for lack of development should be vigorously pursued.

Evaluation of Women With Amenorrhea Associated With the Absence of Secondary Sexual Characteristics

A careful history and physical examination are necessary to appropriately diagnose and treat primary amenorrhea associated with hypogonadism. The physical examination may be particularly helpful in patients with Turner syndrome. A history of short stature but consistent growth rate, a family history of delayed puberty, and normal physical findings (including assessment of smell, optic discs, and visual fields) may suggest physiologic delay. Headaches, visual disturbances, short stature, symptoms of diabetes insipidus, and weakness of one or more limbs suggest CNS lesions (39). Galactorrhea may be seen with prolactinoma, a condition more commonly associated with secondary amenorrhea in the presence of normal secondary sexual characteristics.

FIGURE 34-3 A well-developed patient with complete androgen insensitivity. Note the characteristic paucity of pubic hair and well-developed breasts. (From S**ouhail R, Amine S, Nadia A, et al**. Complete androgen insensitivity syndrome or testicular feminization: Review of literature based on a case report. Pan Afr Med J 2016;25:199. Figure 1 used with permission.)

The diagnostic workup for primary amenorrhea is summarized as follows:

[4] The initial laboratory test should be assessment of serum FSH and LH levels unless the history and physical examination suggest otherwise to differentiate hypergonadotropic and hypogonadotropic forms of hypogonadism. If the FSH level is elevated, a karyotype should be obtained. An elevated FSH level in combination with a 45,X karyotype confirms the diagnosis of Turner syndrome. Partial deletion of the X chromosome, mosaicism, pure gonadal dysgenesis, and mixed gonadal dysgenesis are diagnosed by obtaining a karyotype.

1. **Because of the association with coarctation of the aorta (up to 30%) and thyroid dysfunction, patients with Turner syndrome should undergo echocardiography every 3 to 5 years and thyroid function studies yearly. Cardiac MRI is considered an important component of the cardiac evaluation** (5,8). Patients with Turner syndrome should be evaluated for hearing loss, renal malformations, diabetes, and hypertension.
2. **If the karyotype is abnormal and contains the Y chromosome, as in gonadal dysgenesis, the gonads should be removed to prevent tumors** (14).
3. **If the karyotype is normal and the FSH level is elevated, it is important to consider the diagnosis of 17α-hydroxylase deficiency because it may be a life-threatening disease if untreated.** The characteristic symptoms of 17α-hydroxylase deficiency include hypertension, hypokalemia, and abnormal sexual development. The hormone imbalances include an elevated serum progesterone (>2.0 ng/mL) level, a low to normal 17α-hydroxyprogesterone (10 to 100 ng/mL) level, an elevated serum 11-deoxycorticosterone (100 to 1,000 ng/dL) level, an elevated corticosterone (4,000 to 40,000 ng/dL), and low levels of cortisol, DHEAs, testosterone, and estradiol (19,40). The diagnosis is confirmed with an ACTH stimulation test. After ACTH bolus administration, affected individuals have markedly increased levels of corticosterone and 11-deoxycorticosterone compared with baseline levels and no change in serum 17α-hydroxyprogesterone levels.
4. **If the screening FSH level is low, the diagnosis of hypogonadotropic hypogonadism is established. CNS lesions should be ruled out by imaging using computed tomography (CT) or MRI, especially if galactorrhea, headaches, or visual field defects are identified.** Pituitary adenomas account for over 80% of all sellar and parsellar lesions (41). Rathke cleft cyst, craniopharyngioma, and meningioma are the most common nonadenomatous sellar masses. CNS malignancy and cancer metastases can impact pituitary function and result in hypogonadotropic hypogonadism.
5. **Physiologic delay is a diagnosis of exclusion that is difficult to distinguish from insufficient GnRH secretion.** The diagnosis can be supported by a history suggesting physiologic delay, an x-ray showing delayed bone age, and the absence of

a CNS lesion on CT or MRI scanning.

Treatment of Amenorrhea Associated With the Absence of Secondary Sexual Characteristics

[5] Individuals with primary amenorrhea associated with all forms of gonadal failure and hypergonadotropic hypogonadism need cyclic estrogen and progestogen therapy to initiate, mature, and maintain secondary sexual characteristics. Prevention of osteoporosis is an additional benefit of estrogen therapy:

1. **Therapy is usually initiated with 0.3 to 0.625 mg per day of oral *conjugated estrogens* or 0.5 to 1 mg per day of oral *estradiol*.**
2. **If the patient is short in stature, higher doses should not be used because premature closure of the epiphyses should be avoided.** Most of these patients are of normal height, and higher *estrogen* doses may be used initially and reduced to the maintenance doses after several months.
3. **Estrogen can be given daily in combination with progestogen (*medroxyprogesterone acetate* or *progesterone*) to prevent hyperplasia that could result from unopposed estrogen stimulation of the endometrium in patients with a uterus.** *Medroxyprogesterone* acetate may be administered at a dose of 2.5 mg daily every day of the month or 5 to 10 mg for 12 to 14 days per month. Oral micronized *progesterone* may be administered at a daily dose 100 mg every day of the month or 200 mg daily for 12 to 14 days per month. Cyclic hormone therapy (with 12 to 14 days of *progestogen* per month) more closely mimics the natural menstrual cycle. Progesterone vaginal suppositories may be administered at a dose of 50 mg daily or 100 mg for 12 to 14 days monthly. Progesterone bioadhesive vaginal gel is another option indicated for the treatment of secondary amenorrhea, with a starting dose of 4% (45 mg), and possible increase to 8% (90 mg) for women who have failed to respond to the 4% dose, both used in a cyclic fashion.
4. **Occasionally, individuals with mosaicism and gonadal streaks may ovulate and be able to conceive either spontaneously or after the institution of *estrogen* therapy.**
5. **If 17α-hydroxylase deficiency is confirmed, treatment is instituted with corticosteroid replacement and** estrogen. *Progestogen* should be added to protect the endometrium from hyperplasia.

[5] If possible, therapeutic measures are aimed at correcting the primary cause of amenorrhea:

1. **Craniopharyngiomas may be resected with a transsphenoidal approach or during craniotomy,** depending on the size of the tumor. Studies show similar survival rates with limited tumor removal followed by adjuvant radiotherapy compared to radical gross total resection with an improved quality of life after treatment (42,43).
2. **Germinomas are highly sensitive to radiation and chemotherapy, therefore surgery is rarely indicated** (44).
3. **Prolactinomas and hyperprolactinemia often may respond to dopamine agonists (*bromocriptine* or *cabergoline*)** (45).
4. **Specific therapies are directed toward malnutrition, malabsorption, weight loss, anorexia nervosa, exercise amenorrhea, neoplasia, and chronic diseases.** Logically, it would appear that patients with hypogonadotropic hypogonadism of hypothalamic origin should be treated with long-term administration of pulsatile *GnRH*. This form of therapy is impractical because it requires the use of an indwelling catheter and a portable pump for prolonged periods and there is a lack of availability of this equipment in the United States. The primary focus of treatment should be to correct the underlying problem that is causing the menstrual dysfunction (e.g., malnutrition). **For individuals with anorexia, intensive treatment to achieve weight gain and emotional well-being is preferable to long-term treatment with hormone therapy** (46). If a patient is unable to correct the underlying condition, she may be treated with cyclic *estrogen* and *progestogen* therapy at least until sexual maturity is achieved. When sexual maturation is achieved, hormone therapy can be continued to treat hypoestrogenic symptoms until the underlying disorder leading to amenorrhea can be adequately treated.
5. **Patients with Kallmann syndrome, and patients with other etiologies for hypothalamic amenorrhea, can be treated with hormone replacement.**
6. **If the patient has physiologic delay of puberty, the only management required is reassurance** that the anticipated development will occur eventually.

Individuals whose karyotypes contain a Y cell line (45,X/46,XY mosaicism, or pure gonadal dysgenesis 46,XY) are predisposed to gonadal ridge tumors, such as gonadoblastomas, dysgerminomas, and yolk sac tumors. The gonads of these individuals should be removed when the condition is diagnosed to prevent malignant transformation. There is some evidence that hirsute individuals without Y chromosomes should undergo gonad removal. One patient with hirsutism and the karyotype 45,X was noted to have a streak gonad; the contralateral gonad was dysgenic and contained developing follicles, well-differentiated seminiferous tubules, and Leydig cells. This patient was found to be HY antigen–positive (47).

Clomiphene citrate is often ineffective for inducing ovulation in patients with

hypogonadism who desire pregnancy because such patients are hypoestrogenic. In patients with hypogonadism, ovulation induction with injectable gonadotropins is generally successful. In patients without ovarian function, oocyte donation may be appropriate. **There are reports of death in pregnant patients with Turner syndrome resulting from aortic dissection and rupture** (48,49). Careful counseling and investigation should be undertaken in patients with Turner syndrome before treating them with donated oocytes.

AMENORRHEA WITH SECONDARY SEXUAL CHARACTERISTICS AND ABNORMALITIES OF PELVIC ANATOMY

Causes

Outflow and Müllerian Anomalies

[6] Primary amenorrhea is caused by a congenital abnormality of the female reproductive organs in approximately 20% of cases. Amenorrhea occurs if there is blockage of the outflow tract, if the outflow tract is missing, or if there is no functioning uterus (Table 34-2). Most women with müllerian abnormalities will have normal ovarian function and thus will have normal secondary sexual characteristic development.

Transverse Blockages

Any transverse blockage of the müllerian system will cause amenorrhea. Such outflow obstructions include imperforate hymen, transverse vaginal septum, and absence of the cervix or vagina. Transverse blockage of the outflow tract with an intact endometrium frequently causes cyclic pain without menstrual bleeding in adolescents. The blockage of blood flow can cause hematocolpos, hematometra, or hemoperitoneum, and endometriosis.

Müllerian Anomalies

Mayer–Rokitansky–Küster–Hauser (MRKH) syndrome includes vaginal agenesis with variable development of the uterus accompanied in some cases by renal, skeletal, and auditory abnormalities (50,51). Karyotype is 46,XX. Müllerian agenesis accounts for approximately 10% to 15% of cases of primary amenorrhea (2). Two subtypes are recognized: (1) isolated müllerian aplasia; and (2) müllerian anomaly accompanied by other anomalies which may include renal malformations (such as an absent, pelvic, horseshoe kidney, or double urinary collecting system) skeletal abnormalities, congenital heart defects, and hearing impairment. The exact cause of MRKH syndrome remains largely unknown (52). One study demonstrated a low

prevalence of mutations in two known causative genes (WNT4 and HNF1B), but found copy number variants (CNVs) in certain regions that may be involved (53). Other promising candidate genes and the possibility of epigenetic changes will require further study before any conclusions can be drawn.

Table 34-2 Anatomic Causes of Amenorrhea

Secondary sexual characteristics present
Müllerian anomalies
Imperforate hymen
Transverse vaginal septum
Mayer–Rokitansky–Küster–Hauser syndrome
Androgen insensitivity
Ovotesticular disorder
Absent endometrium
Asherman syndrome
Secondary to prior uterine or cervical surgery
Curettage, especially postpartum
Cone biopsy/ loop electroexcision procedure
Secondary to infections
Pelvic inflammatory disease
Tuberculosis
Schistosomiasis

Absence of Functioning Endometrium

Amenorrhea may occur if there is no functioning endometrium. When the findings of the physical examination are normal, anatomic abnormalities of the uterine cavity should be considered. A congenitally absent endometrium is a rare finding in patients with primary amenorrhea (54). **Intrauterine adhesions, referred to as Asherman syndrome, is more common with secondary amenorrhea or hypomenorrhea**. Adhesions typically result from endometrial trauma during a surgical procedure, but may also result from infection. The most common cause of Asherman syndrome is uterine curettage for pregnancy-related complications (55). Adhesions can develop following myomectomy, curettage of the nongravid uterus, infections related to use of an intrauterine device, tuberculosis, and schistosomiasis. Cervical stenosis resulting from

surgical removal of dysplasia (cone biopsy, loop electroexcision procedure) may lead to amenorrhea.

Androgen Insensitivity

Phenotypic females with complete congenital androgen insensitivity (previously called testicular feminization) have breast development, little or no axillary and pubic hair, and primary amenorrhea (Fig. 34-3) (56). **Genotypically, they are male (XY) but have a defect that prevents normal androgen receptor function, leading to the development of the female external phenotype. The testes, often palpable in the inguinal area or labia, produce müllerian-inhibiting substance that induces the regression of the müllerian structures (fallopian tubes, uterus and upper 1/3 of the vagina). Serum testosterone is in the normal male range.**

The gene for the androgen receptor is located on the X chromosome and inheritance is X-linked recessive. Defects in the androgen receptor gene include complete absence of the gene and mutations that disrupt the binding domains of the receptor. Androgen receptor deficits are diverse and may result from diminished receptor function or concentration. **The diagnosis of this disorder is based on physical examination, serum testosterone concentration, and karyotype. On physical examination, the patients have a blind vaginal pouch, scant or absent axillary and pubic hair, and** breast development at puberty. The breasts, however, have pale areolae and the nipples are immature. At puberty, the conversion of testosterone to estrogen stimulates breast growth. Patients are unusually tall with eunuchoidal tendency (long arms with big hands and feet). The testes should be removed after puberty because of the increased risk of developing testicular cancer (2% to 5%). Research suggests that gonadectomy may be deferred until adulthood because of the low risk of malignancy (57).

Ovotesticular Disorder of Sexual Development

Ovotesticular disorder of sexual development is a rare condition that should be considered as a possible cause of amenorrhea (58). **Both male and female gonadal tissues are present in these patients. Both müllerian and wolffian structures are present and correspond to the ipsilateral gonad.** Genotypes are variable with the majority being 46,XX, with the remaining mosaic and 46,XY. Patients with 46,XX karyotype may menstruate. The external genitalia usually are ambiguous, and breast development frequently occurs in these individuals.

Evaluation of Women With Amenorrhea, Normal Secondary Sexual Characteristics, and Suspected Anatomic Abnormalities

[6] Most congenital abnormalities can be diagnosed by physical examination. In the evaluation of primary amenorrhea, the single most important step is to determine if

the uterus is present. In addition, the vagina and cervix should be examined. Ultrasonography or MRI is useful to identify the müllerian anomaly when the abnormality cannot be found by physical examination. The patient should be examined for skeletal malformations and assessed with intravenous pyelography or renal ultrasound to detect concomitant renal abnormalities.

1. **An imperforate hymen can be differentiated from other transverse blockages by the finding of a perirectal mass that protrudes from the introitus with Valsalva.**
2. **It is difficult to differentiate a transverse septum or complete absence of the cervix and uterus in a female from a blind vaginal pouch in a genotypic male (46,XY) with female sex reversal caused by androgen insensitivity syndrome. Androgen insensitivity is likely when pubic and axillary hair is absent.** To confirm the diagnosis, a karyotype determination should be performed to see whether a Y chromosome is present. In some patients, the defect in the androgen receptor is not complete and virilization occurs.
3. **A congentially absent endometrium is an outflow tract abnormality that cannot be diagnosed by physical examination in a patient with primary amenorrhea.** This abnormality is very rare and is seen in a patient who has normal physical findings (normal vagina, cervix, and uterus), and a normal endocrine evaluation. Although in most cases performance of the progestogen challenge test is not recommended, this test may be of value to confirm the rare diagnosis of congenitally absent endometrium. In this case, progestogen can be administered to a woman who appears to have normal estrogen production (or if estrogen status is questioned, 2.5 mg *conjugated estrogen* or 2 mg *micronized estradiol* can be given for 25 days with 5 to 10 mg of *medroxyprogesterone acetate* added for the last 10 days). Congenital absence of the endometrium is confirmed if no bleeding occurs with this regimen in a patient with primary amenorrhea and no physical abnormalities. Transvaginal ultrasound to assess endometrial thickness may be helpful, with a thickened endometrial lining indicating endometrial response to estrogen. Hysteroscopy with endometrial biopsy should be performed to confirm the diagnosis (54).
4. ***Asherman syndrome* cannot be diagnosed by physical examination. It is diagnosed by performing hysterosalpingography, saline infusion sonography (also known as saline hysterogram), or hysteroscopy.** These tests will show either complete obliteration or multiple filling defects caused by synechiae. If tuberculosis or schistosomiasis is suspected, endometrial cultures should be performed.

Treatment of Women With Amenorrhea, Normal Secondary Sexual Characteristics, and Abnormalities of Pelvic Anatomy

The treatment of congenital anomalies can be summarized as follows:

1. **Treatment of an imperforate hymen involves making a cruciate incision to open the vaginal orifice.** Most imperforate hymens are not diagnosed until a hematocolpos forms. It is unwise to place a needle into a hematocolpos without completely removing the obstruction because a pyocolpos may occur.
2. **If a transverse septum is present, surgical removal is required.** Forty-six percent of transverse septa occur in the upper third of the vagina, and 40% occur in the middle third of the vagina (59). Vaginal dilators should be used to distend the vagina until it is healed to prevent vaginal adhesions and prevent reobstruction (60,61). Patients have a fully functional reproductive system after surgery. Early studies suggested that patients with a repaired complete transverse septum in the middle or upper vagina may have an increased risk of infertility, but other studies have demonstrated normal conception rates following surgical repair (62).
3. **Hypoplasia or absence of the cervix in the presence of a functioning uterus is more difficult to treat than other outflow obstructions.** Previously, a hysterectomy was thought to be required. Conservative laparoscopic uterovaginal anastomosis has been described and is the recommended first-line treatment (63,64). Hysterectomy may be needed if conservative surgery is not successful. Endometriosis is a common finding, and it is questionable whether this condition should be treated initially with surgery or if it will resolve spontaneously after surgical repair of the obstruction. If hysterectomy is needed, the ovaries should be retained to provide the benefits of estrogen and permit the possibility of future childbearing by removing mature oocytes for in vitro fertilization and transfer of embryos to a gestational carrier.
4. **If the vagina is absent or short, progressive dilation is usually successful in making it functional** (60,65,66). If dilation fails or the patient is unable to perform dilation, the McIndoe split thickness graft technique, the Vecchietti procedure, or other surgical approaches may be considered (67–69). The initial use of vaginal dilators is required to maintain a functional vagina.
5. **In patients with complete androgen insensitivity, the testes should be removed after pubertal development is complete to prevent malignant degeneration** (57). In patients with testes, approximately 14% develop a neoplasia, most often a gonadoblastoma. Almost one-half of the testicular neoplasms are malignant (dysgerminomas), but transformation usually does not occur until after puberty (70). In patients who develop virilization and have a XY karyotype, GnRH agonist therapy can be utilized to delay puberty until the individual can develop and determine their gender identity. After puberty the testes should be removed. Bilateral laparoscopic gonadectomy is the preferred procedure for removal of intra-abdominal testes.

6. **Adhesions in the cervix and uterus (Asherman syndrome) can be removed using hysteroscopic resection with scissors or electrocautery** (71,72). It is reasonable to place a pediatric Foley catheter in the uterine cavity for 7 to 10 days postoperatively (along with systemic administration of broad-spectrum antibiotic therapy). A month course of high-dose estrogen therapy with progestogen withdrawal is used to prevent reformation of adhesions. Forty percent to 80% of patients thus treated achieve pregnancy, but complications including miscarriage, preterm labor, placenta previa, and placenta accreta can occur. Cervical stenosis can be treated by cervical dilation.

AMENORRHEA WITH SECONDARY SEXUAL CHARACTERISTICS AND NORMAL PELVIC ANATOMY

Although the complete list of potential causes is long, the most common causes of amenorrhea in women with normal secondary sexual characteristics and normal pelvic examination are pregnancy, PCOS, hyperprolactinemia, thyroid disease, POI (also known as premature ovarian failure), and hypothalamic dysfunction. Pregnancy must be considered in all women of reproductive age with amenorrhea.

Causes

Polycystic Ovarian Syndrome

PCOS is one of the most common endocrine disorders affecting women with a prevalence between 6% and 10%. The syndrome is characterized by hyperandrogenism, ovulatory dysfunction, and polycystic-appearing ovaries (73–75). All definitions of PCOS exclude patients with significantly elevated prolactin, significant thyroid dysfunction, adult-onset congenital adrenal hyperplasia, and androgen-secreting neoplasms from being classified as PCOS. The National Institutes of Health (NIH) 1990 criteria required hyperandrogenism and oligomenorrhea or amenorrhea for the diagnosis for PCOS. **The Rotterdam 2003 criteria required two of three of the following for the PCOS diagnosis: hyperandrogenism, oligomenorrhea or amenorrhea, polycystic ovaries by ultrasound** (76). In 2012, an expert panel workshop at the NIH agreed to utilize the Rotterdam criteria (77). The number of antral follicles to define a polycystic ovary has been debated given the fact that ultrasound is now capable of visualizing small antral follicles accurately (78).

Although insulin resistance and obesity is noted among women with PCOS, it is not included in any of the diagnostic criteria. Insulin resistance is more prevalent in women who are obese with hyperandrogenism and chronic anovulation. Women with PCOS are often subfertile caused by infrequent or absent ovulation. PCOS can have other general

health implications, including increased risk for endometrial hyperplasia and cancer, diabetes, and cardiovascular disease.

Even though **PCOS usually causes irregular bleeding rather than amenorrhea, it remains one of the most common causes of amenorrhea** (2). The etiology of PCOS remains largely unknown.

Not all patients who are hirsute and amenorrheic have PCOS. The possibility of androgen-secreting adrenal tumors or congenital adrenal hyperplasia (79) **should be considered.** Elevations in androgens (e.g., Sertoli–Leydig, hilus, and lipoid cell tumors) and estrogens (e.g., granulosa cell tumors) by ovarian tumors may lead to abnormal menstrual patterns, including amenorrhea. A history of rapid onset of hirsutism is suggestive of a tumor.

Hyperprolactinemia

Hyperprolactinemia is a common cause of anovulation in women. Elevation of prolactin produces abnormal GnRH secretion, which can lead to menstrual disturbances (80). Prolactin levels rise in pregnancy, but typically return to normal within 6 months after delivery in nursing mothers and within weeks in nonnursing mothers. Dopamine release suppresses prolactin secretion. Levels of prolactin can be increased by pituitary adenomas that produce prolactin, by other CNS lesions that disrupt the normal transport of dopamine down the pituitary stalk, and by medications that interfere with normal dopamine secretion (such as antidepressants, antipsychotics including *risperidone, metoclopramide,* some antihypertensives, opiates, and H_2 receptor blockers).

If elevated TSH and elevated prolactin levels are found together, the hypothyroidism should be treated before hyperprolactinemia is treated. Often, the prolactin level will normalize with treatment of hypothyroidism because thyroid-releasing hormone, which is elevated in hypothyroidism, stimulates prolactin secretion.

Primary Ovarian Insufficiency (Premature Ovarian Failure)

POI is suggested as a preferred term for the condition that otherwise was referred to as premature ovarian failure or premature menopause (81,82). Others have suggested premature ovarian insufficiency. POI is defined as the presence of amenorrhea for 4 months or more accompanied by two serum FSH levels in the menopausal range for a woman who is less than 40 years of age. Ovarian "insufficiency" is suggested to be more appropriate than "failure" in part because ovarian function can wax and wane, and function can resume even after it appears that a woman transitioned into menopause. In one large cohort, 24% of women had some resumption of ovarian function after diagnosis of POI (83).

Ovarian insufficiency may be caused by decreased follicular endowment, accelerated follicular atresia, or follicle dysfunction (81). Over 75% of women with POI will have

at least intermittent symptoms including hot flushes, night sweats, and emotional lability (84). Symptoms are uncommon among women with primary amenorrhea who never received estrogen. The incidence of POI has been estimated to be about 1% (85,86).

If the ovary does not develop or stops its hormone production before puberty, the patient will not develop secondary sexual characteristics without exogenous hormone therapy. If ovarian insufficiency begins later in life, the woman will have normal secondary sexual characteristics.

POI clearly compromises the chance of a woman conceiving with autologous oocytes. However, 5% to 10% of women with a diagnosis of premature ovarian failure achieve pregnancy, with approximately 80% of these pregnancies resulting in the delivery of a healthy child (87). It can be difficult to determine which women will be able to conceive. Published studies of testing for ovarian reserve have not specifically focused on the POI populations, and pregnancies may occur with or without treatment despite very unfavorable results for tests of ovarian reserve such as serum FSH, estradiol, and AMH (88). In general, there is no convincing evidence that adjuvant therapies are effective in inducing ovulation for women with premature ovarian failure who no longer respond to gonadotropin therapy (89). Greater understanding of the factors affecting primordial follicle activation may lead to improvements in the success of experimental treatments such as in vitro activation (90–92). Oocyte donation and embryo donation are the only proven effective fertility treatments for women with POI (93).

POI is a heterogeneous disorder with many potential causes (81,94). POI may be caused by sex chromosome disorders, by **fragile X mental retardation 1 (*FMR1*)** premutations, and mutations of single genes (52). Radiation or chemotherapy may lead to POI. The cause of POI may be autoimmune. **The cause remains unknown in a majority of cases** (Table 34-3).

Sex Chromosome and Single Gene Disorders Associated with Primary Ovarian Insufficiency

Absence of one X chromosome (Turner syndrome) is associated with POI, despite normal initial development of the ovaries, because of accelerated atresia of the follicles (95). Although Turner syndrome may often be associated with primary amenorrhea with absence of secondary sexual characteristics, breast development may occur if ovarian function is initially present. Mosaicism of an XO or XY cell line may cause ovarian insufficiency. **Individuals with a 47,XXX karyotype may develop ovarian failure** (96). The most common physical features of 47,XXX are tall stature, epicanthal folds, hypotonia, and clinodactyly.

Table 34-3 Causes of Ovarian Insufficiency or Failure After Development of Secondary Sexual Characteristics

Chromosomal etiology (e.g., Turner mosaic)

FMR1 premutation
Iatrogenic causes: radiation, chemotherapy, surgical damage to ovarian blood supply or removal of ovaries
Infections
Autoimmune-lymphocytic oophoritis
Infections
Galactosemia
Perrault syndrome
Idiopathic (80–90% of cases, includes genetic mutations not detected in routine clinical care)

At least 23 genes are known to have mutations associated with POI and many more are likely to be identified (52,97). However, only two of these genes (*FMR1* and *NR5A1*) account for >3% to 4% of POI patients. A deletion of a portion of the X chromosome may be present in patients with POI. The Xq21-28 region appears to be critical, with several genes in this region identified as the cause of early ovarian insufficiency in humans (*POF1B* gene located at Xq21, the *DIAPH2* gene located at distal Xq21, and the *XPNPEP2* gene located at Xq25 (98,99). Other examples of known mutations are *BMP15* gene (100) and FOXL2 leading to ovarian failure and ptosis (101). An autosomal recessive form of POI is associated with hearing loss in Perrault syndrome (102).

FMR1 *Premutation Carriers*

The most clinically significant gene known to be associated with POI is the *FMR1* gene. Fragile X syndrome, the most common cause of inherited (X-linked) intellectual disability, is caused by inactivation of the *FMR1* gene located on Xq27.3. This inactivation occurs as a result of expansion of a cytosine–guanine–guanine (CGG) triplet repeat of more than 200 copies (103). ***FMR1* premutation carriers (typically defined as greater than 55 but under 200 CGG repeats) may have POI and impaired fertility.** The prevalence of POI in women who carry the ***FMR1*** premutation is estimated to be between 13% and 26%. The risk of having POI appears to increase with increasing premutation repeat size between 59 and 99. It is possible that there is an increased risk of POI among women who carry intermediate-size allele (approximately 41 to 58 repeats), but this is not conclusively proven. The risk plateaus or decreases for women with repeat sizes of 100. Women with full mutations (200 or more CGG repeats) are not at higher risk for POI. It is hypothesized that expression of abnormal *FMR1* mRNA produced by patients with the premutation causes dysfunction in the ovary, which does not occur when the *FMR1* gene is inactivated and not transcribed. The incidence of having a premutation is 0.8% to 7.5%

of women with sporadic POI and up to 13% of women with familial POI.

***FMR1* premutations carried by women are unstable and can expand in the next generation to transmit fragile X syndrome to the male offspring,** especially if women have more than 100 repeats. The smallest repeat to expand to the full mutation in one generation is approximately 59. In contrast to potential expansion in women, the repeat sequence is transmitted from fathers to daughters in a relatively stable manner.

Iatrogenic Causes of Primary Ovarian Insufficiency

Radiation and chemotherapy (especially alkylating agents such as *cyclophosphamide*) may lead to POI (104,105). Other iatrogenic causes of POI include **surgical interference with ovarian blood supply or removal of ovarian tissue which can cause ovarian insufficiency or failure from early loss of follicles.** Ovarian suppression with GnRH agonists has been tried, but has not been clearly proven to preserve fertility (106). Although cigarette smoking decreases the age at which menopause will occur, smoking would not be expected to be the primary cause of amenorrhea occurring before the age of 40. In rare cases, infections have been suggested to be associated with POI.

Autoimmune Disorders

In one series, 4% of women with POI were noted to have steroidogenic cell immunity with lymphocytic oophoritis as the mechanism for follicle dysfunction (107). **Autoimmune lymphocytic oophoritis is associated with a theca cell infiltrate that spares granulosa cells** (108). Ultrasound examination reveals the presence of numerous ovarian follicles, despite elevated serum FSH levels and hypoestrogenism (81). Ovarian antibody testing is not clinically reliable for diagnosing the disorder, as women with biopsy-proven autoimmune oophoritis may have a negative test for ovarian antibody. However, women with autoimmune lymphocytic oophoritis appear to reliably test positive for adrenal antibodies. The most readily available antibody is the 21-hydroxylase antibody. Ideally, antibody to the adrenal gland itself, as assessed by indirect immunofluorescence, is reasonable to test if available. Testing for 21-hydroxylase antibody is strongly recommended for women who are determined to have POI because women who test positive for this antibody are at risk for potentially fatal hypoadrenalism. Signs that suggest a risk for potentially fatal adrenal insufficiency include hyperpigmentation, weakness, nausea, vomiting, diarrhea, and weight loss.

POI may be part of a polyglandular autoimmune syndrome. Antibodies are present in a variable number of patients with POI, depending on the autoimmune studies performed. **Presence of antithyroid antibodies does not confirm that there is an autoimmune cause for POI.**

Galactosemia

Galactosemia is caused by a lack of functional galactose-1-phosphate uridyltransferase

(22). **Galactosemia is a rare cause of POI and is typically diagnosed in childhood prior to presentation with amenorrhea**. Galactose metabolites appear to have toxic effects on ovarian follicles, causing their premature destruction. Although about 90% of women with classic galactosemia develop POI, the pregnancy rate for these women may be higher than for other causes of POI (109).

Pituitary and Hypothalamic Lesions

Hypothalamic Tumors

For normal menstruation to occur, the hypothalamus must be able to secrete GnRH, and the pituitary must be able to respond with production and release of FSH and LH. Tumors of the hypothalamus or pituitary, such as craniopharyngiomas, germinomas, tubercular or sarcoid granulomas, or dermoid cysts, may prevent appropriate hormonal secretion. Patients with these disorders may have neurologic abnormalities, and secretion of other hypothalamic and pituitary hormones may be abnormal. Craniopharyngiomas are the most common tumors. They are located in the suprasellar region and frequently cause headaches and visual changes. The surgical and radiologic treatment of tumors may in itself cause further abnormalities in hormone secretion **(Table 34-4)**.

Table 34-4 Pituitary and Hypothalamic Lesions

Pituitary and hypothalamic
Craniopharyngioma
Germinoma

Hormone-secreting adenomas
Prolactinoma
Cushing disease
Acromegaly
Infarction
Lymphocytic hypophysitis

Surgical or radiologic ablations
Sheehan syndrome
Diabetic vasculitis

Pituitary Lesions

Hypopituitarism is rare because a large portion of the gland must be destroyed before decreased hormonal secretion affects the patient clinically. The pituitary gland may be destroyed by tumors (nonfunctioning or hormone secreting), infarction, or infiltrating lesions such as lymphocytic hypophysitis, granulomatous lesions, and surgical or radiologic ablations. **Sheehan syndrome is associated with postpartum necrosis of the pituitary resulting from a hypotensive episode that, in its severe form (pituitary apoplexy), presents with the patient in shock.** The patient may develop a localized, severe, retro-orbital headache or abnormalities in visual fields and visual acuity. Patients with a mild form of postpartum pituitary necrosis cannot lactate, lose pubic and axillary hair, and do not menstruate after delivery.

Diabetic vasculitis and sickle cell anemia rarely manifest as pituitary failure. Hypopituitarism is associated with hyposecretion of ACTH and thyroid-stimulating hormone (TSH) and gonadotropins; therefore, thyroid and adrenal function must be evaluated. **If hypopituitarism occurs before puberty, menses and secondary sexual characteristics will not develop.**

Growth hormone (GH), TSH, ACTH, and prolactin are secreted by the pituitary, and the excess production of each by pituitary tumors causes menstrual abnormalities. The menstrual abnormalities are caused by adverse effects of these hormones on the GnRH pulse generator and not by direct effects on the ovary. Prolactinomas are the most common hormone-secreting tumors in the pituitary, as described above.

Altered Hypothalamic Gonadotropin-Releasing Hormone Secretion

Abnormal secretion of GnRH is a common cause of amenorrhea. The term functional hypothalamic amenorrhea implies that correction of causal factors will restore ovulatory function (110). Chronic disease, malnutrition, stress, psychiatric disorders, eating disorders, and exercise inhibit GnRH pulses, thus altering the menstrual cycle (Table 34-5). Other hormonal systems that produce excess or insufficient hormones can cause abnormal feedback and adversely affect GnRH secretion. In hyperprolactinemia, Cushing disease (excess ACTH), and acromegaly (excess GH), excess pituitary hormones are secreted that inhibit GnRH secretion.

Table 34-5 Abnormalities Affecting Release of Gonadotropin-Releasing Hormone

Congenital adrenal hyperplasia
Androgen-secreting adrenal tumors
Androgen-secreting ovarian tumors
Granulosa cell tumor
Idiopathic

[a]Severity of the condition determines estrogen status—the more severe, the more likely to manifest as hypoestrogenism.

When the decrease in GnRH pulsatility is severe, amenorrhea results. With less severe alterations in GnRH pulsatility, anovulation and oligomenorrhea can occur. The pulsatile secretion of GnRH is modulated by interactions with neurotransmitters and peripheral gonadal steroids. Kisspeptin plays a critical role in the initiation of GnRH secretion during puberty (110). Endogenous opioids, corticotropin-releasing

hormones (CRH), melatonin, and α-aminobutyric acid (GABA) inhibit the release of GnRH, whereas catecholamine, acetylcholine, and vasoactive intestinal peptide stimulate GnRH pulses. Dopamine and serotonin have variable effects (111).

Decreased leptin levels are associated with hypothalamic amenorrhea, regardless of whether it is caused by exercise, eating disorders, or is idiopathic (112). Leptin is a hormone secreted by adipocytes that is involved in energy hemostasis. Receptors are found in the hypothalamus and bone, making it an excellent candidate for a modulator of menstrual function and bone mass. Levels correlate with nutritional changes and body mass index. Administration of leptin to women with hypothalamic amenorrhea increased levels of LH, estradiol, insulin-like growth factor-1 (IGF-1), and thyroid hormone. Ovulation and increased bone mass occurred in these patients (113). However, weight loss occurring with leptin administration limits the utility of using leptin as a potential therapeutic agent.

Eating Disorders

Anorexia nervosa is an eating disorder that affects many adolescent women. The criteria for diagnosis of anorexia nervosa in the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-5) include low body weight (defined in a somewhat open-ended fashion as less than minimally normal weight in adults, or less than minimally expected weight in children and adolescents) **and a refusal to maintain a minimally normal or expected weight** (114). **Patients with anorexia may either state the refusal or demonstrate behavior which indicate a refusal to maintain a normal weight.** Patients attempt to maintain their low body weight by food restriction, laxative abuse, and intense exercise. **Anorexia nervosa is a life-threatening disorder with a significant mortality rate** (115). Amenorrhea may precede, coincide, or follow the weight loss. Multiple hormonal patterns are altered. The 24-hour patterns of FSH and LH may show constantly low levels as seen in childhood or increased LH pulsatility during sleep consistent with the pattern seen in early puberty. Hypercortisolism is present despite normal ACTH levels, and the ACTH response to CRH administration is blunted. Circulating triiodothyronine (T_3) is low, yet circulating inactive reverse T_3 concentrations are high. Patients may develop cold and heat intolerance, lanugo hair, hypotension, bradycardia, and diabetes insipidus. They may have yellowish discoloration of the skin resulting from elevated levels of serum carotene caused by altered vitamin A metabolism.

Binge eating is associated with bulimia consisting of vomiting, laxative abuse, and diuretics to control weight. Signs of bulimia include tooth decay, parotid gland hypertrophy (chipmunk jowls), hypokalemia, and metabolic alkalosis.

Weight Loss and Dieting

Weight loss can cause amenorrhea even if weight does not decrease below normal.

Loss of 10% body mass in 1 year is associated with amenorrhea. Some but not all of these women have an underlying eating disorder. Prognosis is good for the return of menses if the patients recover from the weight loss. Dieting without weight loss and changes in diet can lead to amenorrhea (116).

Exercise

In patients with exercise-induced amenorrhea, there is a decrease in the frequency of GnRH pulses, which is assessed by measuring a decreased frequency of LH pulses. These patients are usually hypoestrogenic, but less severe alterations may cause minimal menstrual dysfunction (anovulation or luteal phase defect). The decrease in GnRH pulsatility can be caused by hormonal alterations, such as low levels of leptin or high levels of ghrelin, neuropeptide Y, and corticotrophin-releasing hormone (117). Runners and ballet dancers are at higher risk for amenorrhea than swimmers (118). It was previously suggested that a minimum of 17% body fat is required for the initiation of menses and 22% body fat for the maintenance of menses (119). However, studies suggest that inappropriately low caloric intake during strenuous exercise is more important than body fat (120). **Higher-intensity training, poor nutrition, stress of competition, and associated eating disorders increase an athlete's risk for menstrual dysfunction**. **Osteoporosis may result in stress fractures during training and lifelong increased fracture risk.** Stress fractures most commonly occur in the weight-bearing cortical bone such as the tibia, metatarsal, fibula, and femur. These athletes may fail to reach peak bone mass and have abnormal bone mineralization.

Stress

Stress-related amenorrhea can be caused by abnormalities in neuromodulation in hypothalamic GnRH secretion, similar to those that occur with exercise and anorexia nervosa. Excess endogenous opioids and elevations in CRH secretion inhibit the secretion of GnRH (111). These mechanisms are not fully understood but appear to be the common link between amenorrhea and chronic diseases, pseudocyesis, and malnutrition. Cognitive behavioral therapy has shown some promise in initiating neuroendocrine recovery (121).

Obesity

Most obese patients have normal menstrual cycles, but the percentage of women with menstrual disorders increases for women with obesity compared with women of normal weight. The menstrual disorder is more often irregular uterine bleeding with anovulation rather than amenorrhea. **Obese women have an excess number of fat cells in which extraglandular aromatization of androgen to estrogen occurs. They have lower circulating levels of sex hormone–binding globulin, which allows a larger proportion of free androgens to be converted to estrone. Excess estrogen creates a**

higher risk for endometrial cancer for these women. The decrease in sex hormone–binding globulin allows an increase in free androgen levels, which initially are eliminated by an increased rate of metabolic clearance. This compensatory mechanism diminishes over time, and hirsutism can develop. Frequently, these patients are classified as having PCOS. Alterations in the secretion of endorphins, cortisol, insulin, GH, and IGF-1 may interact with the abnormal estrogen and androgen feedback to the GnRH pulse generator to cause menstrual abnormalities.

Other Hormonal Factors

The secretion of hypothalamic neuromodulators can be altered by feedback from abnormal levels of peripheral hormones. Excesses or deficiencies of thyroid hormone, glucocorticoids, androgens, and estrogens can cause menstrual dysfunction. Excess secretion of GH, TSH, ACTH, and prolactin from the pituitary gland can cause abnormal feedback inhibition of GnRH secretion, leading to amenorrhea. **GH excess causes acromegaly, which may be associated with anovulation, hirsutism, and polycystic-appearing ovaries as a result of stimulation of the ovary by IGF-1. More commonly, GH excess is accompanied by amenorrhea, low gonadotropin levels, and elevated prolactin levels. Acromegaly is recognized by enlargement of facial features, hands, and feet; hyperhidrosis; visceral organ enlargement; and multiple skin tags. Cushing disease is caused by an ACTH-secreting pituitary tumor, which is manifested by truncal obesity, moon facies, hirsutism, proximal weakness, depression, and menstrual dysfunction.**

Evaluation for Women With Amenorrhea in the Presence of Normal Pelvic Anatomy and Normal Secondary Sexual Characteristics

A pregnancy test (urine or serum human chorionic gonadotropin [hCG]) should be performed in a reproductive-age woman who has amenorrhea with normal secondary sexual characteristics and a normal pelvic examination. If the results of the pregnancy test are negative, the evaluation of amenorrhea is as follows:

1. **Clinical assessment of estrogen status**
2. **Serum TSH**
3. **Serum prolactin**
4. **Serum FSH level**
5. **Vaginal ultrasound for assessment of antral follicle count in the ovaries can be considered (may help establish the diagnosis of PCOS or suggest POI)**
6. **[4] Imaging of the pituitary and hypothalamic assessment if prolactin is elevated or if hypothalamic amenorrhea is suspected (particularly if CNS symptoms are present or there is no clear explanation for hypothalamic amenorrhea).**

Assessment of Estrogen Status

The presence of vaginal dryness or hot flashes increases the likelihood of a diagnosis of hypoestrogenism. A serum estradiol level higher than 40 pg/mL is considered indicative of significant estrogen production, but interassay discrepancies often exist and serum estrogen levels can vary greatly on a day-to-day basis for a given woman. Vaginal ultrasound demonstrating a thin endometrium suggests that a patient is hypoestrogenic, unless there is reason to suspect that the patient lacks functional endometrium. A dual-energy x-ray absorptiometry (DEXA) scan to determine bone mineral density should be considered for a patient in whom long-term hypoestrogenism is suspected.

There is little utility in routine performance of a progestogen challenge test to determine the patient's estrogen status. False positives and false negatives are common.

Thyroid and Prolactin Disorders

Consideration should be given to thyroid disorders and hyperprolactinemia in women with amenorrhea because of the relatively common incidence of these conditions.

1. **Sensitive TSH assays can be used to evaluate hypothyroidism and hyperthyroidism.** Further evaluation of a thyroid disorder is required if abnormalities in TSH levels are found. Mild degrees of thyroid dysfunction are unlikely to cause amenorrhea. Given the general health implications of thyroid dysfunction and readily available treatments, routine assessment of TSH is reasonable for women with amenorrhea.
2. **Prolactin is most accurately obtained in a patient who is fasting and who has not had any recent breast stimulation to avoid concluding that a patient is hyperprolactinemic on the basis of a transient prolactin elevation.** If a patient still has some menstrual cycles, it is advisable to obtain the prolactin level in the follicular phase.

Follicle-Stimulating Hormone Levels

Assessment of serum FSH levels is required to determine whether the patient has hypergonadotropic, hypogonadotropic, or eugonadotropic amenorrhea. **A circulating FSH level of greater than 25 to 40 mIU/mL indicated on at least two blood samples is indicative of hypergonadotropic amenorrhea.** Hypergonadotropism implies that the cause of amenorrhea is ovarian insufficiency. The history should establish whether the cause of ovarian insufficiency is chemotherapy or radiation therapy.

Anti-müllerian hormone (AMH) is a circulating biomarker, which correlates with the size of the pool of ovarian follicles (122). AMH is produced by the granulosa cells of preantral and early antral follicles (123). Although it is not formally included in the

diagnosis of POI, AMH becomes undetectable several years before the final menses and thus may aid in the early diagnosis of POI. **AMH levels are low in women with POI and high in women with PCOS.**

If the diagnosis of POI is confirmed, the patient should be tested for:

1. ***FMR1* premutation**
2. **Karyotype**
3. **21-hydroxylase antibody**

FMR1 premutation testing will reveal women at risk for bearing a child with fragile X syndrome, which may be important information for other family members. The goal of the peripheral blood karyotype is to identify an absent or abnormal X chromosome and to identify whether or not any portion of a Y chromosome is present. It is important to identify Y chromosomal material so it may be removed to prevent malignant degeneration. Although commonly suggested that karyotype only be performed if the patient is younger than the age of 30, it should be noted that rare patients with Turner syndrome developed amenorrhea after age 35. In addition, some patients who present older than the age of 30 may have actually had the onset of POI at a younger age but were unaware because of the use of oral contraceptives. Therefore, consideration should be given to performance of karyotype, regardless of the patient's age. Testing for 21-hydroxylase antibody will identify women at risk for adrenal crisis.

If a diagnosis of PCOS is suspected, the patient should have:

1. **Documentation of hyperandrogenism**—either by serum total testosterone and sex hormone binding globulin or free testosterone and/or by presence of physical findings such as acne, hirsutism, and androgenic alopecia.
2. **Serum 17-hydroxyprogesterone to exclude congenital adrenal hyperplasia resulting from 21-hydroxylase deficiency, particularly if the patient is at increased risk**—highest prevalence is among Ashkenazi Jews, Hispanics, Yugoslavs, Native American Inuits in Alaska, and Italians.
3. **If the diagnosis of PCOS is made, the patient should undergo screening for diabetes and a fasting lipid profile**.

Assessment of the Pituitary and Hypothalamus

If the patient is hypoestrogenic and the FSH level is not high, pituitary and hypothalamic lesions should be excluded.

1. **A complete neurologic examination** may help localize a lesion.
2. **Either CT or MRI scanning should be performed** to confirm the presence or absence of a tumor. MRI will identify smaller lesions than CT; if a lesion is too

small for identification by CT, it may be clinically insignificant. MRI offers the advantage of avoiding exposure to x-ray.

3. **The patient's history of weight changes, exercise, eating habits, and body image is an important factor in determining whether anorexia nervosa, malnutrition, obesity, exercise, or stress may be responsible for amenorrhea.**

Patients with certain specific clinical findings should undergo screening for other hormonal alterations:

1. **Androgen levels should be assessed** in any hirsute patient to ensure that adrenal and ovarian tumors are not present and to aid in the diagnosis of PCOS.
2. **Acromegaly** is suggested by coarse facial features, large doughy hands, and hyperhidrosis and **may be confirmed by measuring IGF-1 levels.**
3. In patients with truncal obesity, hirsutism, hypertension, and erythematous striae, **Cushing syndrome should be ruled out** by assessing 24-hour urinary cortisol levels or performing a 1-mg overnight *dexamethasone* suppression test or late night salivary cortisol (124). It is important to confirm that the patient is not taking exogenous glucocorticoid.

Treatment for Women With Amenorrhea in the Presence of Normal Pelvic Anatomy and Normal Secondary Sexual Characteristics

The treatment of nonanatomic causes of amenorrhea associated with normal secondary sexual characteristics varies widely according to the cause. The underlying disorder should be treated whenever possible. Patients who are pregnant may be counseled regarding the options for continued care. **When thyroid abnormalities are detected, thyroid hormone, radioactive iodine, or antithyroid drugs may be administered as appropriate. If hyperprolactinemia is present, treatment may include discontinuation of contributing medications, treatment with dopamine agonists such as *bromocriptine* or *cabergoline,*** and, rarely, surgery for particularly large pituitary tumors. **When POI causes amenorrhea, hormone replacement should be considered to improve quality of life and to prevent osteoporosis** (125). Counseling regarding the risks and benefits of hormone replacement therapy is indicated. Gonadectomy is required when a Y cell line is present.

Surgical removal, radiation therapy, or a combination of both is advocated for treatment of CNS tumors other than prolactinomas. It may be necessary to treat individuals who have panhypopituitarism with various replacement regimens after all the deficits are elucidated. These regimens include estrogen and progestogen replacement for lack of gonadotropins, corticosteroid replacement for lack of ACTH,

thyroid hormone for lack of TSH, and *desmopressin acetate* (*1-deamino-8-D-AVP* [*DDAVP*]) to replace vasopressin.

The treatment of amenorrhea associated with hypothalamic dysfunction depends on the underlying cause:

1. **Hormonally active ovarian tumors are surgically removed (rare).**
2. **Obesity, malnutrition or chronic disease, Cushing syndrome, and acromegaly should be specifically treated.**
3. **Stress-induced amenorrhea may respond to psychotherapy.**
4. **Exercise-induced amenorrhea may improve with moderation of activity and weight gain, when appropriate.** If hypoestrogenism persists, higher doses of estrogen may be needed in these women than in older menopausal women to maintain bone density. In addition, 1,200 to 1,500 mg of calcium and 400 to 800 IU of vitamin D daily are advised. Bisphosphonates do not improve bone density in amenorrheic athletes because it is lack of bone formation rather than increased resorption that causes the osteopenia. In addition, the use of bisphosphonates is not advised because they can be deposited into the bone, and long-term effects, especially during pregnancy, are unknown.
5. **Treatment of eating disorders such as anorexia nervosa generally demands a multidisciplinary approach, with outpatient family-based therapy, the first line particularly for adolescents, and hospitalization reserved for severe cases** (126).
6. **Chronic anovulation associated with PCOS may be treated after identifying the desires of the patient.** Patients may be concerned about their lack of menstruation, not hirsutism, or infertility. **The endometrium of these individuals should be protected from the environment of unopposed estrogen** that accompanies the anovulatory state. Oral contraceptives are a good alternative for those patients who require contraception. For those patients who are not candidates for oral contraceptive use, cyclic administration of progestogen is advised. Progestogen withdrawal will occur if there is an adequate estrogenic environment to induce proliferation of the endometrium, and it is not sufficient to cause withdrawal bleeding in patients who are hypoestrogenic (e.g., those who have amenorrhea associated with anorexia nervosa). Women with PCOS may require treatment for insulin resistance, dyslipidemia, and obesity. Regular periodic screening for diabetes and a lipid panel is recommended for women with PCOS. Reduction in weight in obese women with PCOS leads to improved pregnancy rates, decreases hirsutism, and improves glucose and lipid levels. Insulin-sensitizing medications such as *metformin* and cholesterol-lowering medications such as statins can be considered. Ovulation induction is performed if pregnancy is desired, as described

below.

A common progestogen used to induce withdrawal bleeding and thus protect the endometrium from hyperplastic transformation is *medroxyprogesterone acetate* (10 mg for 12 to 14 days per month). Occasionally, ovulation may occur; therefore, patients should be made aware that pregnancy is possible, and appropriate contraceptive measures should be used. *Medroxyprogesterone acetate* should not be used in early pregnancy. Alternatively, *progesterone* suppositories (50 to 100 mg) or oral *micronized progesterone* (200 mg) can be given for 12 to 14 days per month to protect the endometrium from hyperplasia and induce withdrawal bleeding.

In hypoestrogenic individuals such as those with POI, estrogen replacement must be added to the progestogen for successful menstrual regulation and prevention of osteoporosis. The doses of estrogen needed for relief of symptoms in young women with POI are often higher than those that are used for older menopausal women (127). Women with POI (who would normally still be making hormone if the ovaries were functioning normally) are different from those reaching menopause at a median age of 51. Therefore, data regarding hormone therapy that were collected from women reaching menopause at the median age should not be extrapolated to younger women. Although there are no comparative data and no long-term prospectively collected data regarding hormone therapy for women with POI, **the risks of hormone therapy are likely to be lower and the benefits potentially greater for younger women than for older women reaching menopause after the age of 50** (125).

When chronic anovulation is caused by congenital adrenal hyperplasia, glucocorticoid administration (i.e., *dexamethasone* 0.5 mg at bedtime) is sometimes successful in restoring the normal feedback mechanisms, thereby permitting regular menstruation and ovulation.

Hirsutism

Patients who have oligomenorrhea or amenorrhea resulting from chronic anovulation may have hirsutism. The most common cause of hirsutism and oligo-ovulation is PCOS. After ruling out androgen-secreting tumors and congenital adrenal hyperplasia, treatment may be aimed at decreasing coarse hair growth.

Oral Contraceptives

Oral contraceptives may be effective for hirsutism by decreasing ovarian androgen production and increasing circulating levels of sex hormone–binding globulin, leading to decreased free androgen in the circulation.

Antiandrogens

Spironolactone decreases androgen production and competes with androgens at the androgen receptor. Side effects include diuresis and dysfunctional uterine bleeding. The

use of spironolactone is typically combined with oral contraceptives to avoid irregular bleeding and to prevent pregnancy from occurring while on *spironolactone. Flutamide* is approved by the U.S. Food and Drug Administration (FDA) for adjuvant therapy in prostatic cancer but not specifically for treatment of hirsutism. A low dose of *flutamide* may be effective in treating hirsutism (128). Liver function should be monitored because of the rare complication of hepatotoxicity. *Cyproterone acetate,* a strong progestin and antiandrogen, is used in some countries, but is not available in the United States. It is usually administered in combination with *ethinyl estradiol* in an oral contraceptive and has a high efficacy (129) by decreasing circulating androgen and LH levels, and by inducing antagonism of androgen effects at the peripheral level. *Finasteride,* a 5α-reductase inhibitor, is approved by the FDA for the treatment of benign prostatic hypertrophy (*Proscar*) and male pattern baldness (*Propecia*). It may be effective in treating hirsutism, but with inconsistent results (130).

All antiandrogens are teratogenic as they may lead to feminization of the external genitalia of a male fetus (ambiguous genitalia) if the patient should conceive while taking the medication. Therefore, antiandrogens are typically used in combination with oral contraceptives.

Cosmetic Approaches

Medical treatment can be combined with cosmetic treatment for optimal efficacy (131). *Eflornithine hydrochloride* is a topical cream that is approved by the FDA for use on the face and chin. Improvements in facial hirsutism may be seen in 4 to 8 weeks of twice-daily applications. Short-term options include shaving, chemical depilation, plucking, threading, waxing, and bleaching. Long-term treatments include electrolysis, laser therapy, and intense pulse light therapy.

Ovulation Induction

A large subset of patients with amenorrhea or oligomenorrhea and chronic anovulation seek care because they are unable to conceive. Ovulation induction therapy is generally the treatment of choice for such patients, but pretreatment counseling should be provided in sufficient detail to ensure realistic expectations. The patient should be provided with information regarding the chances of a successful pregnancy (considering age of the patient and treatment modality), potential complications (hyperstimulation and multiple gestation), expense, time, and psychological impact involved in completing the course of therapy. **The selective estrogen receptor modulator, *clomiphene citrate,* is a common first choice for ovulation induction for many patients because of its relative safety, efficacy, oral route of administration, and relatively low cost**. *Clomiphene citrate* is indicated primarily in patients with adequate levels of estrogen and normal levels of FSH and prolactin. It is less effective in hypogonadotropic patients who already have a poor

estrogen supply.

The aromatase inhibitor, *letrozole*, has been demonstrated to be effective for ovulation induction in women with PCOS (132). **In systematic reviews and meta-analyses of randomized trials, ovulation induction with letrozole was found to result in higher pregnancy rate** compared with clomiphene (133,134) and letrozole can be recommended as first-line treatment because of higher ovulation pregnancy and live birth rate (134). However, it should be noted that letrozole is FDA approved only for breast cancer, not for ovulation induction.

As many as 80% of patients can be expected to ovulate after either *letrozole* or *clomiphene citrate* therapy. Contraindications to the use of *clomiphene citrate* or *letrozole* include pregnancy, liver disease, and pre-existing large ovarian cysts. Side effects can include hot flashes. In addition, clomiphene is associated with a risk of visual changes, which generally are viewed as an indication to discontinue subsequent *clomiphene citrate* use. The risk of multiple pregnancy is increased with *clomiphene citrate*. The majority of multiple gestations are twins; triplets and higher order multiple gestations are rare. In a meta-analysis examining use of letrozole for ovulation induction in anovulatory women, letrozole led to a lower rate of multiple pregnancy compared with *clomiphene* (134).

The most commonly recommended treatment regimen for *clomiphene citrate* is 50 mg daily for 5 days, beginning on the 3rd to 5th day of menstrual or withdrawal bleeding. Letrozole is typically prescribed at a starting dose of 2.5 mg or 5 mg daily for 5 days. Cycles may be monitored by measuring midcycle LH levels to assess the hormonal signal for ovulation. Ovulation may be confirmed by measuring midluteal progesterone levels. Ultrasonographic monitoring to assess folliculogenesis may be helpful, especially when *hCG* is used to induce ovulation. Endometrial thinning may be detected with midcycle ultrasound. With these data, it is possible to immediately adjust the dose in the subsequent cycle if a given regimen is ineffective.

Although a large randomized trial demonstrated that *clomiphene* alone is superior to *metformin* alone in achieving live birth in women with PCOS (135), **a meta-analysis suggests that for some patients with PCOS, *metformin* and *clomiphene* combined may increase the likelihood of ovulation compared with *clomiphene* alone** (134). Thinning of the endometrium at midcycle in the face of adequate midcycle estradiol or lack of success with repeated cycles of *letrozole* or *clomiphene* are generally indications to consider injectable gonadotropins.

Women with PCOS who do not ovulate or become pregnant with *clomiphene citrate or letrozole,* and **women with hypogonadotropic hypoestrogenic anovulation, may be candidates for therapy with injectable gonadotropins.** Available preparations include recombinant FSH and LH and products purified from the urine of menopausal women (FSH or FSH–LH combinations). Administration protocols and

dosages vary widely and should be adjusted to individual needs. Safe administration requires careful monitoring of ovarian response with ultrasonography and, in some cases, serial estradiol measurements. In general, gonadotropins are administered at a dose of 37 to 150 IU per day by subcutaneous injection for 3 to 5 days, after which time estradiol and follicular monitoring commence. In most cycles, gonadotropin is administered for 7 to 12 days. Ovulation is triggered by subcutaneous or intramuscular injection of 5,000 to 10,000 IU *hCG* or subcutaneous injection of 250 μg of *recombinant hCG* when the lead follicle reaches 16 to 20 mm in diameter based on ultrasonographic assessments. Ovulation generally occurs approximately 38 to 40 hours after *hCG* administration. Luteal phase support may be provided with the administration of *progesterone* supplementation.

The two major complications associated with induction of ovulation with gonadotropins are multiple pregnancy (10% to 30%) and ovarian hyperstimulation syndrome. The incidence of both of these complications can be reduced but not eliminated by careful monitoring. Cycles complicated by the recruitment of numerous follicles or by high estradiol levels may be canceled by withholding the ovulatory dose of *hCG.* Selected patients may be converted safely to in vitro fertilization. Because severe ovarian hyperstimulation syndrome is life-threatening and may lead to prolonged hospitalization, ovulation induction with gonadotropins generally is performed by experienced practitioners who devote a significant portion of their practice to the treatment of infertility.

Ovulation induction with pulsatile *GnRH* may be effective in patients who have chronic anovulation associated with low levels of estrogen and gonadotropins. For therapy to be successful, a functional ovary and pituitary gland must be present. Patients with ovarian or pituitary failure do not respond to *GnRH* therapy. To be effective, *GnRH* must be administered in a pulsatile fashion, either intravenously or subcutaneously by a programmable pump. Ovulation induction with *GnRH*, as compared with gonadotropins, is associated with a relatively low incidence of ovarian hyperstimulation and multiple births. In addition, the need for appropriate timing of the ovulatory dose of *hCG* is avoided because patients treated with pulsatile *GnRH* have an appropriately timed endogenous LH surge. Disadvantages are mainly related to maintaining the programmable pump and injection site and lack of availability of an appropriate pump in the United States. After ovulation, luteal phase support is necessary and may be provided with *hCG*, *progesterone*, or continuation of the *GnRH* therapy.

For women with overt POI (also known as premature ovarian failure), there is no good evidence to suggest that any treatment can increase the chance of conception with autologous oocytes (87,89). **Treatments that were tried include ovulation induction with *clomiphene* or *gonadotropin,* initial suppression of gonadotropin levels by pretreatment with high-dose estrogen or GnRH agonist**

followed by expectant management or gonadotropin stimulation, standard-dose hormone therapy followed by gonadotropin, and corticosteroid pretreatment followed by gonadotropin. If POI is diagnosed while a patient still has a significant supply of oocytes, fertility preservation could be considered if the patient is not able to consider conception at the time of diagnosis. In most cases, patients with prolonged amenorrhea are not diagnosed at a time when significant numbers of reproductively competent oocytes are present. Fertility preservation is an option for patients about to undergo gonadotoxic chemotherapy (136) or if a patient is known (e.g., based on family history) to be at risk for POI. Either embryos or oocytes can be cryopreserved, but in most cases, oocyte cryopreservation is preferable so that the source of sperm for fertilization of the oocytes can be decided at a future time and/or based on personal feelings about having embryos frozen. Ovarian tissue freezing can be considered if oocyte cryopreservation is not possible, such as when chemotherapy must be initiated immediately.

Patients with POI who desire pregnancy will in most cases have a high chance of having a child with the help of oocyte donation. Oocytes from donors may be harvested after ovulation induction, fertilized with sperm from the intended father or sperm donor, and transferred into the recipient's uterus after the endometrium is appropriately prepared with estrogen and progesterone. Special concern is warranted for women with Turner syndrome who have been reported to have an increased risk of maternal mortality of 2% (49). Rupture of the aorta may occur even if an echocardiogram shows no dilatation (137). In women with Turner syndrome who have a spontaneous pregnancy, the risk of cardiovascular morbidity may be lower (138). It is suggested that all women with Turner syndrome who are considering pregnancy undergo a full cardiac evaluation at a center with expertise in cardiovascular imaging (5,8), and that women with Turner syndrome receive expert consultation regarding whether or not it is safe to consider carrying a pregnancy.

CHAPTER 35

Endocrine Disorders

Kurt R. Peterson, Megan Link, C. Matthew Peterson

Hyperandrogenism
- Hirsutism
- Polycystic Ovary Syndrome
- Treatment of Hyperandrogenism and PCOS
- Cushing Syndrome
- Congenital Adrenal Hyperplasia
- Androgen-Secreting Ovarian and Adrenal Tumors
- Androgen-Producing Ovarian Neoplasms
- Stromal Hyperplasia and Stromal Hyperthecosis
- Virilization During Pregnancy
- Virilizing Adrenal Neoplasms

Prolactin Disorders
- Prolactin Secretion
- Hyperprolactinemia

Thyroid Disorders
- Thyroid Hormones
- Evaluation
- Autoimmune Thyroid Disease

KEY POINTS

1 Hyperandrogenism (HA) most often presents as hirsutism, which usually arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands. By contrast, virilization is rare and indicates marked elevation in androgen levels.

2 The most common cause of HA and hirsutism is polycystic ovarian syndrome (PCOS). The

diagnostic schema for PCOS requires two of three criteria (HA [clinical or biochemical], ovarian dysfunction, and or PCO morphology) and identifies four phenotypes: (1) HA (clinical or biochemical) with ovarian dysfunction and PCO morphology, (2) HA (clinical or biochemical) with ovarian dysfunction, (3) HA (clinical or biochemical) with PCO morphology, (4) ovarian dysfunction and PCO morphology. Caution is recommended in affixing the PCOS diagnosis in adolescence. Patients with PCOS frequently exhibit insulin resistance and hyperinsulinemia.

3 Combination oral contraceptives (OCs) decrease adrenal and ovarian androgen production and reduce hair growth in nearly two-thirds of hirsute patients.

4 Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

5 Excluding cases that are of iatrogenic or factitious etiology, adrenocorticotropic hormone–independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest.

6 Congenital adrenal hyperplasia is an autosomal recessive disorder. Deficiency of 21-hydroxylase is responsible for more than 90% of cases of adrenal hyperplasia resulting from an adrenal enzyme deficiency.

7 Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. Ovarian neoplasms are the most frequent androgen-producing tumors.

8 Elevations in prolactin may cause amenorrhea, galactorrhea, both, or neither. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women. Normal prolactin levels are found in 50% of women with isolated galactorrhea. Two thirds of women with both galactorrhea and amenorrhea have hyperprolactinemia and one-third will have a pituitary microadenoma.

9 Because levels of thyroid-stimulating hormone (TSH) are sensitive to excessive or deficient levels of circulating thyroid hormone, and because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland, TSH levels are used to screen for these disorders. Autoimmune thyroid disorders are the most common thyroid abnormalities in women and represent the combined effects of the multiple antibodies produced. Severe primary hypothyroidism is associated with amenorrhea or anovulation. The classic triad of exophthalmos, goiter, and hyperthyroidism are diagnostic for Graves disease.

The endocrine disorders encountered most frequently in gynecologic patients are those related to disturbances in the regular occurrence of ovulation and accompanying menstruation. The most prevalent of these disorders, polycystic ovary syndrome, is characterized by androgen excess and is often accompanied by insulin resistance. Less common conditions associated with hyperandrogenism, hirsutism and ovulatory dysfunction are also reviewed. Common disorders of the pituitary and thyroid are reviewed in this chapter.

HYPERANDROGENISM

[1] Hyperandrogenism (HA) most often presents as hirsutism. Hirsutism arises as a result of androgen excess related to abnormalities of function in the ovary or adrenal glands, the constitutive increase in expression of androgen effects at the level of the pilosebaceous unit, or both. **By contrast, virilization is rare and indicates marked**

elevations in androgen levels. Virilization commonly is caused by an ovarian or adrenal neoplasm that may be benign or malignant.

Hirsutism

Hirsutism, the most frequent manifestation of androgen excess in women, is defined as excessive growth of terminal hair in a male distribution pattern. This refers particularly to midline hair, side burns, moustache, beard, chest or intermammary hair, and inner thigh and midline lower back hair entering the intergluteal area. The response of the pilosebaceous unit to androgens in these androgen-responsive areas transforms vellus hair (fine, nonpigmented, and short) that is normally present into terminal hair (coarse, stiff, pigmented, and long).

Androgen effects on hair vary in relation to specific body surface regions. Hair that shows no androgen dependence includes lanugo, eyebrows, and eyelashes. The hair of the limbs and portions of the trunk exhibits minimal sensitivity to androgens. Pilosebaceous units of the axilla and pubic region are sensitive to low levels of androgens, such that the modest androgenic effects of adult levels of adrenal androgens are sufficient to result in the substantial expression of terminal hair in these areas. Follicles in the distribution associated with male patterns of facial and body hair (midline, facial, inframammary) require higher levels of androgens, as seen with normal testicular function or abnormal ovarian or adrenal androgen production. Scalp hair is inhibited by gonadal androgens, in varying degrees, as determined by age and genetic determination of follicular responsiveness, resulting in the common frontal–parietal balding seen in some males and in virilized females. **Hirsutism results from increased androgen production and skin sensitivity to androgens. Skin sensitivity depends on the genetically determined local activity of 5α-reductase, the enzyme that converts testosterone to dihydrotestosterone (DHT), the bioactive androgen in hair follicles.**

Hair follicles demonstrate cyclic activity between growth (anagen), involution (catagen), and resting (telogen) phases. The durations of the growth and resting phases vary according to region of the body, genetic factors, age, and hormonal effects. The cycles of growth, rest, and shedding are normally dyssynchronous, but when synchronous, entry into telogen phase in follicles is triggered by major metabolic or endocrine events, such as pregnancy and delivery, or severe illness, and dramatic (although transient) hair loss may occur in the following months (telogen effluvium).

Hirsutism is a relative, rather than absolute, designation. What is normal in one setting may be considered abnormal in others; social and clinical reactions to hirsutism can vary significantly, reflecting ethnic variation in skin sensitivity to androgens and cultural ideals. Androgen-dependent hair (excluding pubic and axillary hair) occurs in only 5% of premenopausal white women and is considered abnormal by white women of North America. In contrast, considerable facial and male pattern hair in other areas

may be more common and more often considered acceptable and normal among groups such as the Inuit and women of Mediterranean background.

Hypertrichosis and Virilization

Two conditions should be distinguished from hirsutism. **Hypertrichosis is the term reserved for androgen-independent terminal hair in nonsexual areas, such as the trunk and extremities.** This may be the result of an autosomal-dominant congenital disorder, a metabolic disorder (such as anorexia nervosa, hyperthyroidism, porphyria cutanea tarda), or medications (e.g., *acetazolamide*, anabolic steroids, *androgenic progestins*, *androgens*, *cyclosporine*, *diazoxide*, dehydroepiandrosterone [DHEA], heavy metals, *interferon*, *methyldopa*, *minoxidil*, *penicillamine*, *phenothiazines*, *phenytoin*, *streptomycin*, *reserpine*, *valproic acid*). **Virilization is a marked and global masculine transformation that includes coarsening of the voice, increase in muscle mass, clitoromegaly (normal clitoral dimensions é standard deviation [SD] are 3.4 + 1 mm width by 5.1 + 1.4 mm length) and features of defeminization (loss of breast volume and body fat contributing to feminine body contour)** (1). Although hirsutism accompanies virilization, **the presence of virilization indicates a high likelihood of more serious conditions that are more common than with hirsutism alone and should prompt evaluation to exclude ovarian or adrenal neoplasm.** Although rare, these diagnoses become likely when onset of androgen effects is rapid and/or sufficiently pronounced to produce the picture of virilization.

The history should focus on the age of onset and rate of progression of hirsutism or virilization. **A rapid rate of progression or virilization is associated with a more severe degree of HA and should raise suspicion of ovarian and adrenal neoplasms or Cushing syndrome.** This is true whether rapid progression or virilization occurs before, during, or after puberty. Anovulation, manifesting as amenorrhea or oligomenorrhea, increases the probability that there is underlying HA. Hirsutism occurring with regular cycles is more commonly associated with normal androgen levels and thus is attributed to increased genetic sensitivity of the pilosebaceous unit and is termed *idiopathic hirsutism.* When virilization is present, anovulation virtually always occurs.

In determining the extent of hirsutism, a sensitive and tactful approach by the physician is mandatory and should include questions regarding the use and frequency of shaving and/or chemical or mechanical depilatories. Typically, clinical evaluation of the degree of hirsutism is subjective. Most physicians arbitrarily classify the degree of hirsutism as mild, moderate, or severe. Objective assessment is helpful, however, especially in establishing a baseline from which therapy can be evaluated. The Ferriman–Gallwey Scoring System for Hirsutism quantitates the extent of hair growth in the most androgen-sensitive sites. It is a scoring scale of androgen-sensitive hair in nine body areas rated on a scale of 0 to 4 (2). A total score higher than 8 is

defined as hirsutism (Fig. 35-1) (3). Although widely used, this scoring system has its limitations, one of which is the fact that the scale does not include the sideburn, buttocks, and perineal areas. Substantial hirsutism may be confined to one or two areas without exceeding the cutoff value in total hirsutism score. This score does not reflect the extent to which hirsutism affects a woman's well-being (3,4).

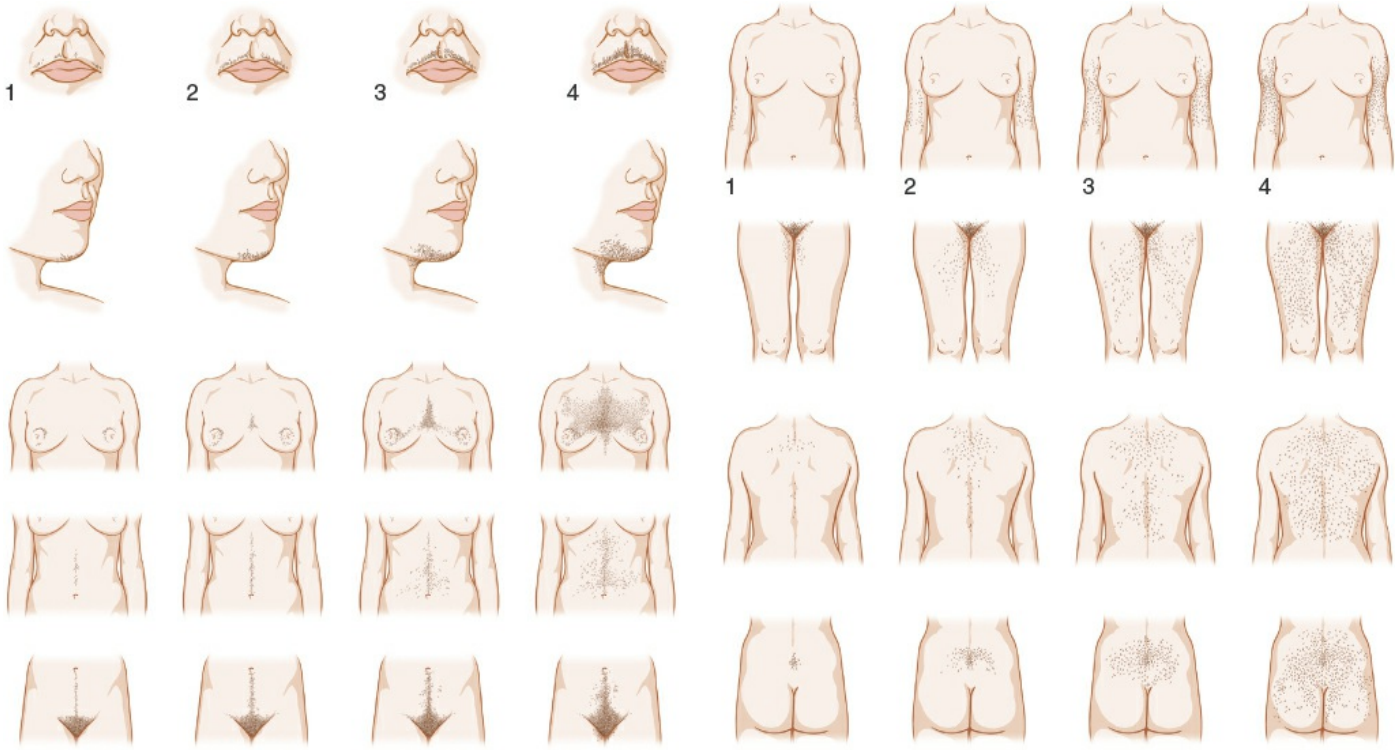

FIGURE 35-1 Ferriman–Gallwey hirsutism scoring system. Each of the nine body areas most sensitive to androgen is assigned a score from 0 (no hair) to 4 (frankly virile), and these separate scores are summed to provide a hormonal hirsutism score. (Reproduced from **Hatch R, Rosefield RL, Kim MH, et al**. Hirsutism: implications, etiology, and management. *Am J Obstet Gynecol* 1981;140:815–830. © Elsevier.)

A family history should be obtained to disclose evidence of idiopathic hirsutism, PCOS, congenital or adult-onset adrenal hyperplasia (CAH or AOAH), diabetes mellitus, and cardiovascular disease. A history of drug use should be obtained. In addition to drugs that commonly cause hypertrichosis, anabolic steroids and testosterone derivatives may cause hirsutism and even virilization. During the physical examination, attention should be directed to the presence of obesity, hypertension, galactorrhea, male-pattern baldness, acne (face and back), and hyperpigmentation. With virilization, the presence of an androgen-producing ovarian neoplasm or Cushing syndrome must be considered. In many cases of Cushing syndrome, the patient's presenting symptom is hirsutism which in early stages may masquerade as disorders such as PCOS or AOAH. When considering the possibility of Cushing syndrome, the physician should search for the physical signs of the syndrome. A moon-shaped face, upper body obesity, proximal muscle weakness (difficulty arising from a squatting position), and the development of a

pad of fat between the shoulder blades are particularly notable to patients and diagnosticians considering the diagnosis of Cushing syndrome.

Role of Androgens

Androgens and their precursors are produced by the adrenal glands and the ovaries in response to their respective trophic hormones, adrenocorticotropic hormone (ACTH), and luteinizing hormone (LH) (Fig. 35-2). Biosynthesis begins with the rate-limiting conversion of cholesterol to pregnenolone by side-chain cleavage enzyme. Thereafter, pregnenolone undergoes a two-step conversion to the 17-ketosteroid DHEA along the Δ-5 steroid pathway. This conversion is accomplished by CYP17, an enzyme with 17α-hydroxylase and 17,20-lyase activities. In a parallel fashion, progesterone undergoes transformation to androstenedione in the Δ-4 steroid pathway. The metabolism of Δ-5 to Δ-4 intermediates is accomplished via a Δ-5-isomerase, 3β-hydroxysteroid dehydrogenase (3β-HSD).

Adrenal 17-Ketosteroids

Secretion of adrenal 17-ketosteroids increases prepubertally and independently of pubertal maturation of the hypothalamic–pituitary–ovarian axis. This alteration in adrenal steroid secretion is termed *adrenarche* and is characterized by a dramatic change in the response of the adrenal cortex to ACTH and with preferential secretion of Δ-5 steroids, including 17-hydroxypregnenolone, DHEA, and dehydroepiandrosterone sulfate (DHEAS). The basis for this action is related to the increase in the zona reticularis and in the increased activity of the 17-hydroxylase and the 17,20-lyase enzymes. Independent of the increase in ovarian androgen secretion accompanying puberty, the increase in adrenal androgens owing to adrenarche can account for significant increases in pubic and axillary hair and sweat production by the axillary pilosebaceous units.

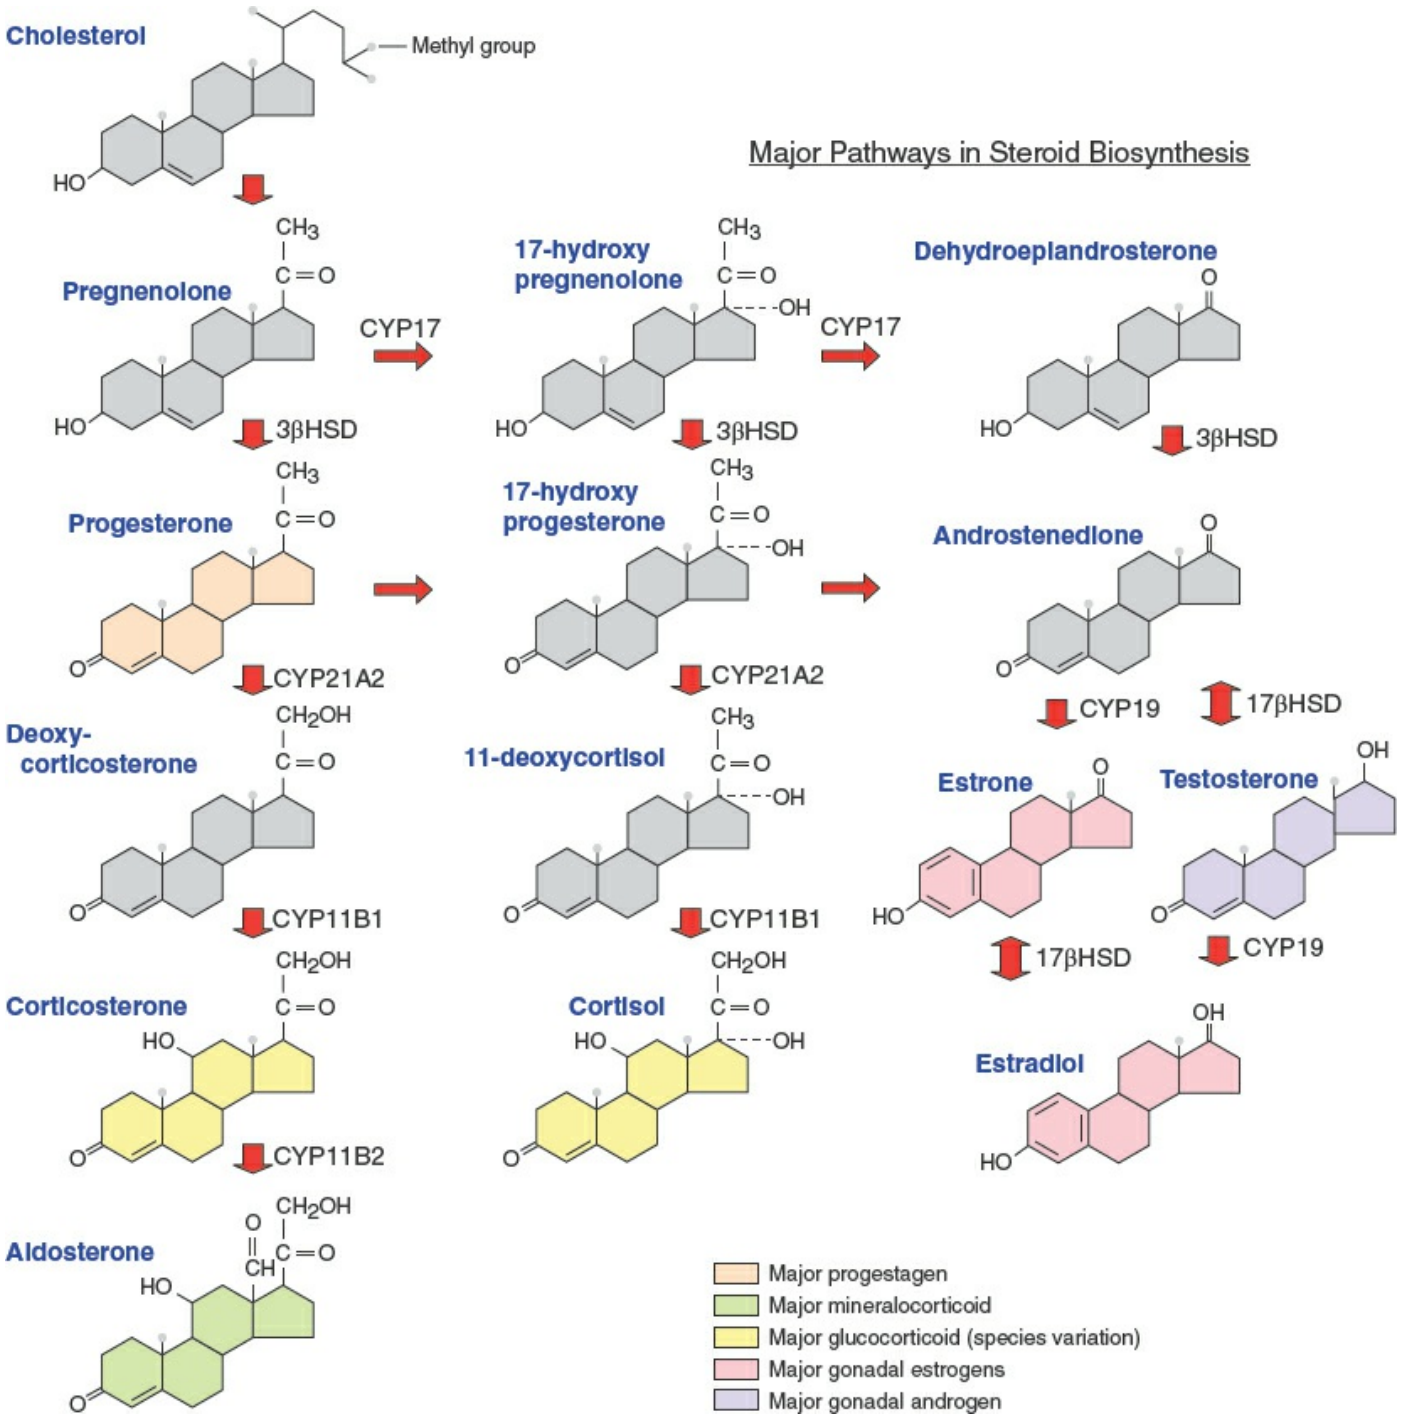

FIGURE 35-2 Major steroid biosynthesis pathway.

Testosterone

Approximately half of a woman's serum testosterone is derived from peripheral conversion of secreted androstenedione and the other half is derived from direct glandular (ovarian and adrenal) secretion. The ovaries and adrenal glands contribute about equally to testosterone production in women. The contribution of the adrenals is achieved primarily through secretion of androstenedione.

Approximately 66% to 78% of circulatory testosterone is bound to sex hormone–

binding globulin (SHBG) and is considered biologically inactive. Most of the proportion of serum testosterone that is not bound to SHBG is weakly associated with albumin (20% to 32%). A small percentage (1% to 2%) of testosterone is entirely unbound or free. **The fraction of circulating testosterone that is unbound by SHBG has an inverse relationship with the SHBG concentration.** Increased SHBG levels are noted in conditions associated with high estrogen levels. Pregnancy, the luteal phase, use of estrogen (including oral contraceptives [OCs]), and conditions causing elevated thyroid hormone levels and cirrhosis are associated with reduced fractions of free testosterone as a result of elevated SHBG levels. Conversely, levels of SHBG decrease and result in elevated free testosterone fractions in response to androgens, androgenic disorders (PCOS, adrenal hyperplasia or neoplasm, Cushing syndrome), androgenic medications (i.e., progestational agents with androgenic biologic activities, such as *danazol*, glucocorticoids, and growth hormones), hyperinsulinemia, obesity, and prolactin.

Laboratory Assessment of Hyperandrogenemia

In hyperandrogenic states, increases in testosterone production are not proportionately reflected in increased total testosterone levels because of the depression of SHBG levels that occurs concomitant with increasing androgen effects on the liver. Therefore, when moderate HA, characteristic of many functional hyperandrogenic states, occurs, elevations in total testosterone levels may remain within the normal range, and only free testosterone levels will reveal the HA. **Severe HA, as occurs in virilization and that results from neoplastic production of testosterone, is reliably detected by measures of total testosterone.** Therefore, in practical clinical evaluation of the hyperandrogenic patient, determination of the total testosterone level in concert with clinical assessment is frequently sufficient for diagnosis and management. When more precise delineation of the degree of HA is desired, measurement or estimation of free testosterone levels can be undertaken and will more reliably reflect increases in testosterone production. These measurements are not necessary in evaluating the majority of patients, but they are common in clinical research studies and may be useful in some clinical settings. Because many practitioners measure some form of testosterone level, they should understand the methods used and their accuracy. Although equilibrium dialysis is the gold standard for measuring free testosterone, it is expensive, complex, and usually limited to research settings. **In a clinical setting, free testosterone levels can be estimated by assessment of testosterone binding to albumin and SHBG.**

Testosterone that is nonspecifically bound to albumin (AT) is linearly related to free testosterone (FT) by the equation:

$$AT = K_a[A] \times FT$$

where AT is the albumin-bound testosterone, K_a is the association constant of albumin for testosterone, and [A] is the albumin concentration.

In many cases of hirsutism, albumin levels are within a narrow physiologic range and thus do not significantly affect the free testosterone concentration. When physiologic albumin levels are present, the free testosterone level can be estimated by measuring the total testosterone and SHBG. In individuals with normal albumin levels, this method has reliable results compared with those of equilibrium dialysis. It provides a rapid, simple, and accurate determination of the total and calculated free testosterone levels as well as the concentration of SHBG.

The bioavailable testosterone level is based on the relationship of albumin and free testosterone and incorporates the actual albumin level with the total testosterone and SHBG. This combination of total testosterone, SHBG, and albumin level measurements —bioavailable testosterone level—can be applied to derive a more accurate estimate of available bioactive testosterone and thus the androgen effect derived from testosterone. Bioactive testosterone determined in this manner provides a superior estimate of the effective androgen effect derived from testosterone (5).

Pregnancy can alter the accuracy of measurements of bioavailable testosterone. During pregnancy, high circulating estradiol levels occupy a large proportion of SHBG binding sites, so that measurement of SHBG levels can overestimate the binding capacity of SHBG for testosterone. Derived estimates of free testosterone, as opposed to direct measure by equilibrium dialysis, are therefore inaccurate during pregnancy. Testosterone measurements in pregnancy are primarily of interest when autonomous secretion by tumor or luteoma is in question, and for these, total testosterone determinations provide sufficient information for diagnosis.

For testosterone to exert its biologic effects on target tissues, it must be converted into its active metabolite, DHT, by 5α-reductase (a cytosolic enzyme that reduces testosterone and androstenedione). Two isozymes of 5α-reductase exist: type 1, which predominates in the skin, and type 2, or acidic 5α-reductase, which is found in the liver, prostate, seminal vesicles, and genital skin. The type 2 isozyme has a 20-fold higher affinity for testosterone than type 1. Both type 1 and 2 deficiencies in males result in ambiguous genitalia, and both isozymes may play a role in androgen effects on hair growth. Dihydrotestosterone is more potent than testosterone, primarily because of its higher affinity and slower dissociation from the androgen receptor. Although DHT is the key intracellular mediator of most androgen effects, measurements of circulating levels are not clinically useful. The relative androgenicity of androgens is as follows: DHT = 300, Testosterone = 100, Androstenedione = 10, DHEAS = 5.

Until adrenarche, androgen levels remain low. Around 8 years of age, adrenarche is heralded by a marked increase in DHEA and DHEAS. The half-life of free DHEA is extremely short (about 30 minutes) but extends to several hours, if DHEA is sulfated. Although no clear role is identified for DHEAS, it is associated with stress, and levels

decline steadily throughout adult life. **After menopause, ovarian estrogen secretion ceases, and DHEAS levels continue to decline, whereas testosterone levels are maintained or may even increase.** Although postmenopausal ovarian steroidogenesis contributes to testosterone production, testosterone levels retain diurnal variation, reflecting an ongoing and important adrenal contribution**.** Peripheral aromatization of androgens to estrogens increases with age, but because small fractions (2% to 10%) of androgens are metabolized in this fashion, such conversion is rarely of clinical significance.

Laboratory Evaluation

The 2008 Endocrine Society Clinical Practice Guidelines suggested testing for elevated androgen levels in women with moderate (Ferriman–Gallwey hirsutism score 9 or greater) or severe hirsutism or hirsutism of any degree when it is sudden in onset, rapidly progressive, or associated with significant acne, obesity, or clitoromegaly. These guidelines suggested against testing for elevated androgen levels in women with isolated mild hirsutism, such as is associated with PCOS, because the likelihood of identifying a medical disorder that would change management or outcome is extremely low (Fig. 35-3) (4).

When laboratory testing for the assessment of hirsutism is indicated, either a bioavailable testosterone level (includes a total testosterone, SHBG, and albumin level) or a calculated free testosterone level (if albumin levels are assumed to be normal) provides the most accurate assessment of the effective androgen effect derived from testosterone. In clinical situations requiring a testosterone evaluation, the addition of 17-hydroxyprogesterone (17-OHP) will screen for adult-onset adrenal hyperplasia, when indicated (Table 35-1). When hirsutism is accompanied by absent or abnormal menstrual periods, assessment of prolactin and thyroid-stimulating hormone (TSH) values is required to diagnose an ovulatory disorder. Hypothyroidism and hyperprolactinemia may result in reduced levels of SHBG and may increase the fraction of unbound testosterone levels, occasionally resulting in hirsutism. In cases of suspected Cushing syndrome, patients should undergo screening with a 24-hour urinary cortisol (most sensitive and specific) assessment or an overnight *dexamethasone* suppression test. For this test, the patient takes 1 mg of *dexamethasone* at 11 pm, and a blood cortisol assessment is performed at 8 am the next day. Cortisol levels of 2 μg/dL or higher after overnight *dexamethasone* suppression require a further workup for evaluation of Cushing syndrome. Elevated 17-OHP levels identify patients who may have AOAH, found in 1% to 5% of hirsute women. The 17-OHP levels can vary significantly within the menstrual cycle, increasing in the periovulatory period and luteal phase, and may be modestly elevated in PCOS. Standardized testing requires early morning testing during the follicular phase.

FIGURE 35-3 Evaluation of hirsute women for hyperandrogenism. Evaluation includes more than the assessment of the degree of hirsutism. When hirsutism is moderate (>9) or severe or if mild hirsutism is accompanied by features that suggest an underlying disorder, elevated androgen levels should be ruled out. Disorders to be considered include endocrinopathies, of which PCOS is the most common, and neoplasms. Plasma testosterone is best assessed in the early morning on days 4 to 10 in regularly cycling women. A 17-hydroxyprogesterone is also indicated when symptoms warrant a bioavailable testosterone measurement. *3β-hydroxysteroid dehydrogenase deficiency in severe forms presents with mineralocorticoid and cortisol deficiency. Mild forms are diagnosed with a mean post-ACTH(1-24) stimulation: 17-hydroxypregnenolone/17-hydroxyprogesterone ratio of 11 compared with 3.4 in normals. 11β-hydroxylase deficiency presents with hypertension in the first years of life in two-thirds of patients. The mild form presents with vitalization or precocious puberty without hypertension. Undiagnosed adults demonstrate hirsutism, acne, and amenorrhea. Diagnosis is confirmed with an 11-desoxycortisol level >25 ng/mL 60 minutes after ACTH(1-24) stimulation. ACTH, adrenocorticotropic hormone; AOAH, adult-onset adrenal hyperplasia; DHEAS, dehydroepiandrosterone sulfate; HAIR-AN, hyperandrogenemia, insulin resistance-acanthosis nigricans (see references (2–11,15)).

Table 35-1 Normal Values for Serum Androgens[a]

Testosterone (total)	20–80 ng/dL
Free testosterone (calculated)	0.6–6.8 pg/mL
Percentage free testosterone	0.4–2.4%
Bioavailable testosterone	1.6–19.1 ng/dL
SHBG	18–114 nmol/L
Albumin	3,300–4,800 mg/dL
Androstenedione	20–250 ng/dL
Dehydroepiandrosterone sulfate	100–350 µg/dL
17-Hydroxyprogesterone (follicular phase)	30–200 ng/dL

[a]Normal values may vary among different laboratories. Free testosterone is calculated using measurements for total testosterone and sex hormone–binding globulin, whereas bioavailable testosterone is calculated using measured total testosterone, sex hormone–binding globulin, and albumin. Calculated values for free and bioavailable testosterone compare well with equilibrium dialysis methods of measuring unbound testosterone when albumin levels are normal. Bioavailable testosterone includes free plus very weakly bound (non-SHBG, nonalbumin) testosterone. Bioavailable testosterone is the most accurate assessment of bioactive testosterone in the serum without performing equilibrium dialysis.

According to the Endocrine Society clinical guidelines, patients with morning follicular phase 17-OHP levels of less than 300 ng/dL (10 nmol/L) are likely unaffected. When levels are greater than 300 ng/dL but less than 10,000 ng/dL (300 nmol/L), ACTH testing should be performed to distinguish between PCOS and AOAH. Levels greater than 10,000 ng/dL (300 nmol/L) are virtually diagnostic of congenital adrenal hyperplasia.

Precocious puberty (PP) precedes the diagnosis of adult-onset congenital adrenal hyperplasia in 5–20% of cases. Measurement of 17-OHP should be performed in

patients presenting with PP and a subsequent ACTH stimulation test is recommended if basal 17-OHP is greater than 200 ng/dL. A study using a 200 ng/dL threshold for basal 17-OHP plasma levels to prompt ACTH stimulation testing offered 100% (95% confidence interval [CI], 69 to 100) sensitivity and 99% (95% CI, 96 to 100) specificity for the diagnosis of adult-onset congenital adrenal hyperplasia within the cohort with PP (6).

Because increased testosterone production is not reliably reflected by total testosterone levels, the clinician may choose to rely on typical male pattern hirsutism as confirmation of its presence, or may elect measures that reflect levels of free or unbound testosterone (bioavailable or calculated free testosterone levels). Total testosterone does, however, serve as a reliable marker for testosterone-producing neoplasms. **Total testosterone levels greater than 200 ng/dL should prompt a workup for ovarian or adrenal tumors.**

Although the ovary is the principal source of androgen excess in most of PCOS patients, between 20% and 30% of patients with PCOS will demonstrate elevated levels of DHEAS, particularly when overweight. Measuring circulating levels of DHEAS has very limited diagnostic value, and overinterpretation of DHEAS levels should be avoided (7).

Previously, testing for androgen conjugates (e.g., 3α-androstenediol G [3α-diol G] and androsterone G [AOG] as markers for 5α-reductase activity in the skin) was advocated. Routine determination of androgen conjugates to assess hirsute patients is not recommended, because hirsutism itself is an excellent bioassay of free testosterone action on the hair follicle and because these androgen conjugates arise from adrenal precursors and are likely markers of adrenal and not ovarian steroid production (8).

In the zona reticularis layer of the adrenal cortex, DHEAS is generated by *SULT2A1* (9). This layer of the adrenal cortex is thought to be the primary source of serum DHEAS. DHEAS levels decline as a person ages and the reticularis layer diminishes in size. In most laboratories, the upper limit of a DHEAS level is 350 µg/dL (9.5 nmol/L). A random sample is sufficient because the level of variation is minimized as a result of the long half-life characteristic of sulfated steroids. DHEAS is used as a screen for androgen-secreting adrenocortical tumors (ACT-AS); however, moderate elevations are a common finding in the presence of PCOS, obesity, and stress, which reduces its specificity in testing for ACT-AS (10).

A study of women with ACT-AS (N = 44), compared to women with nontumor androgen excess (NTAE) (N = 102), sheds additional light on the choice of hormones used to screen for an adrenocortical tumor. In the study, the demographics and prevalence of hirsutism, acne, and oligo/amenorrhea were not different. Free testosterone (free T) was the most commonly elevated androgen in ACT-AS (94%), followed by androstenedione (A) (90%), DHEAS (82%), and total testosterone (total T) (76%), and all three androgens were simultaneously elevated in 56% of the cases.

Serum androgen levels became subnormal in all ACT-AS patients after the tumor was removed. In NTAE alone, the most commonly elevated androgen was androstenedione (93%), while all three androgens (T, A, and DHEAS) were elevated in only 22% of the cases. Free testosterone values above 6.85 pg/mL (23.6 pmol/L) had the best diagnostic value for ACT-AS (sensitivity 82%, 95% CI 57% to 96%; specificity 97%, 95% CI 91% to 100%; Table 35-2). The large overlap of androstenedione, testosterone, and DHEAS levels between ACT-AS and androgen excess groups suggests that thoughtful consideration should be employed when choosing hormone studies for this evaluation (11).

The heterogeneity of hormone secretion patterns in the adrenocortical tumor group reveals the complexities of hormone-level screening for adrenocortical tumors: 7 of 44 patients (15.9%) had tumors secreting androgens alone, 2 of 44 (4.5%) had tumors secreting androgens and estrogens, and 28 of 44 (63.6%) had tumors secreting both androgens and cortisol, and 7 of 44 (15.9%) had tumors secreting androgens, cortisol, and estrogens. Compound S or 11-desoxycortisol was increased (≥10 ng/mL or 28.9 nmol/L) in 23 of 27 ACT-AS patients (85%), 20 of 21 patients with malignant tumors, and 3 of 6 patients with apparently benign tumors, although 11-desoxycortisol was normal and inferior to 6 ng/mL (17.3 nmol/L) in 35 of 35 NTAE patients (100%). Youden's index displayed that 11-desoxycortisol level above 7 ng/mL (20.2 nmol/L) has a sensitivity of 89% (95% CI 71% to 98%) and a specificity of 100% (95% CI 90% to 100%) for the detection of ACT-AS (11,12).

Thus, when signs of androgen excess reach the point of virilization or the free testosterone level is above 6.85 pg/mL (23.6 pmol/L), follow-up testing with an 11-desoxycortisol >7 ng/mL, DHEAS >3.6 lg/mL, and 24-hour urinary cortisol >45 lg per day are the most sensitive and specific for the detection of an ACT-AS. Careful consideration of the sensitivity and specificity, diurnal variation, and age-related variation of potentially measureable androgens will aid in choosing the most useful measurements (Table 35-2). Clinically, assessment of androgens is uncommon in routine practice and is performed when hirsutism is sudden in onset, rapidly progressive, or associated with significant acne, obesity, or clitoromegaly. Mild hirsutism associated with clinical findings of PCOS very rarely yields actionable results.

Table 35-2 Sensitivity and Specificity of Basal Hormone Levels in the Evaluation of Female Patients With Androgen-Secreting Adrenocortical Tumors (ACT-AS) and Nontumor Causes of Androgen Excess (NTAE)

	ACT-AS (*n*)	NTAE (*n*)	Sensitivity% (CI)	Specificity% (CI)
Total testosterone >1.25 ng/mL	42	102	60 (45–74)	94 (90–99)
Free testosterone >6.85 pg/mL	17	77	82 (57–96)	97 (91–100)
Androstenedione >4.65 ng/mL	38	99	66 (49–80)	80 (71–87)
DHEAS >3.6 µg/mL	39	97	79 (64–91)	79 (70–87)
17OHP >1.95 ng/mL	36	79	67 (49–81)	86 (76–93)
11-desoxycortisol >7 ng/mL	27	35	89 (71–98)	100 (90–100)

Thresholds were selected using Youden's index, as described in the methods.

Polycystic Ovary Syndrome

PCOS is one of the most common endocrine disorders in women of reproductive age, affecting 5% to 10% of women worldwide. This familial disorder appears to be inherited as a complex genetic trait (13). It is characterized by a combination of HA (either clinical or biochemical), chronic anovulation, and polycystic ovaries. It is frequently associated with insulin resistance (IR) and obesity (14). PCOS receives considerable attention because of its high prevalence and possible reproductive, metabolic, and cardiovascular consequences. **It is the most common cause of HA, hirsutism, and anovulatory infertility in developed countries** (15,16). The association of amenorrhea with bilateral polycystic ovaries and obesity was first described in 1935 by Stein and Leventhal (17). Its genetic origins are likely polygenic and/or multifactorial (18).

Diagnostic Criteria

In an international conference on PCOS organized by the National Institutes of Health (NIH) in 1990, diagnostic criteria for PCOS were based on consensus rather than clinical trial evidence. Their diagnostic criteria recommended clinical and/or biochemical evidence of HA, chronic anovulation, and exclusion of other known disorders. These criteria were an important initial step in standardizing diagnosis and led to a number of landmark randomized clinical trials in PCOS (19).

Since the 1990 NIH-sponsored PCOS conference, evolving perception is that the syndrome may constitute a broader spectrum of signs and symptoms of ovarian dysfunction than those set forth in the original NIH diagnostic criteria. The 2003 Rotterdam Consensus Workshop concluded that PCOS is a syndrome of ovarian dysfunction along with the cardinal features HA and polycystic ovary (PCO) morphology (Table 35-3).

It is recognized that women with regular cycles, HA, and PCO morphology may be part of the syndrome. It is also recognized that some women with the syndrome will have PCO morphology without clinical evidence of androgen excess, but will display evidence of ovarian dysfunction with irregular cycles. In this new schema, PCOS remains a diagnosis of exclusion with the need to rule out other disorders that mimic the PCOS phenotype (19).

Applying the recommended Rotterdam PCOS Diagnostic Criteria, the presence of two of the three criteria is sufficient to diagnosis PCOS: menstrual cycle anomalies (amenorrhea, oligomenorrhea), clinical and/or biochemical HA, and/or the ultrasound appearance of polycystic ovaries after all other diagnoses are ruled out. [2] This approach results in four phenotypes: (1) HA (clinical or biochemical) with ovarian dysfunction and PCO morphology, (2) HA (clinical or biochemical) with ovarian dysfunction, (3) HA (clinical or biochemical) with PCO morphology, (4) ovarian dysfunction and PCO morphology. This diagnostic approach for PCOS has been ratified by the Endocrine Society (2013) for adult women, but in adolescents the diagnosis should be based on persistent anovulation and clinical or biochemical HA. Other pathologies that can result in a PCOS phenotype include AOAH, adrenal or ovarian neoplasm, Cushing syndrome, hypo- or hypergonadotropic disorders, hyperprolactinemia, and thyroid disease (Fig. 35-4).

All other frequently encountered manifestations offer less consistent findings and therefore qualify only as minor diagnostic criteria for PCOS. They include elevated LH-to-FSH (follicle-stimulating hormone) ratio, IR, perimenarchal onset of hirsutism, and obesity.

Table 35-3 Revised Diagnostic Criteria of Polycystic Ovary Syndrome

1990 Criteria (both 1 and 2)
1. Chronic anovulation
2. Clinical and/or biochemical signs of hyperandrogenism and exclusion of other etiologies
Revised 2003 criteria (2 out of 3)
1. Oligoovulation or anovulation
2. Clinical and/or biochemical signs of hyperandrogenism
3. Polycystic ovaries and exclusion of other etiologies (congenital adrenal hyperplasia, androgen-secreting tumors, Cushing syndrome)

Clinical HA includes hirsutism, male pattern alopecia, and acne (19). Hirsutism occurs in approximately 70% of patients with PCOS in the United States and in only 10% to 20% of patients with PCOS in Japan (20,21). A likely explanation for this discrepancy is the genetically determined differences in skin 5α-reductase activity (22,23).

Nonclassic adrenal hyperplasia and PCOS may present with similar clinical features. It is important to measure the basal follicular phase 17-OHP level in all women presenting with hirsutism to exclude the presence of nonclassic congenital adrenal hyperplasia, regardless of the presence of polycystic ovaries or metabolic dysfunction (24).

The menstrual dysfunction in PCOS arises from anovulation or oligo-ovulation and ranges from amenorrhea to oligomenorrhea. Regular menses in the presence of anovulation in PCOS is uncommon, though one report found that among hyperandrogenic women with regular menstrual cycles, the rate of anovulation is 21% (25). **Classically, PCOS is lifelong and characterized by abnormal menses from puberty with acne and hirsutism arising in the teens. It may, however, arise in adulthood, concomitant with the emergence of obesity, presumably because this is accompanied by increasing hyperinsulinemia** (26).

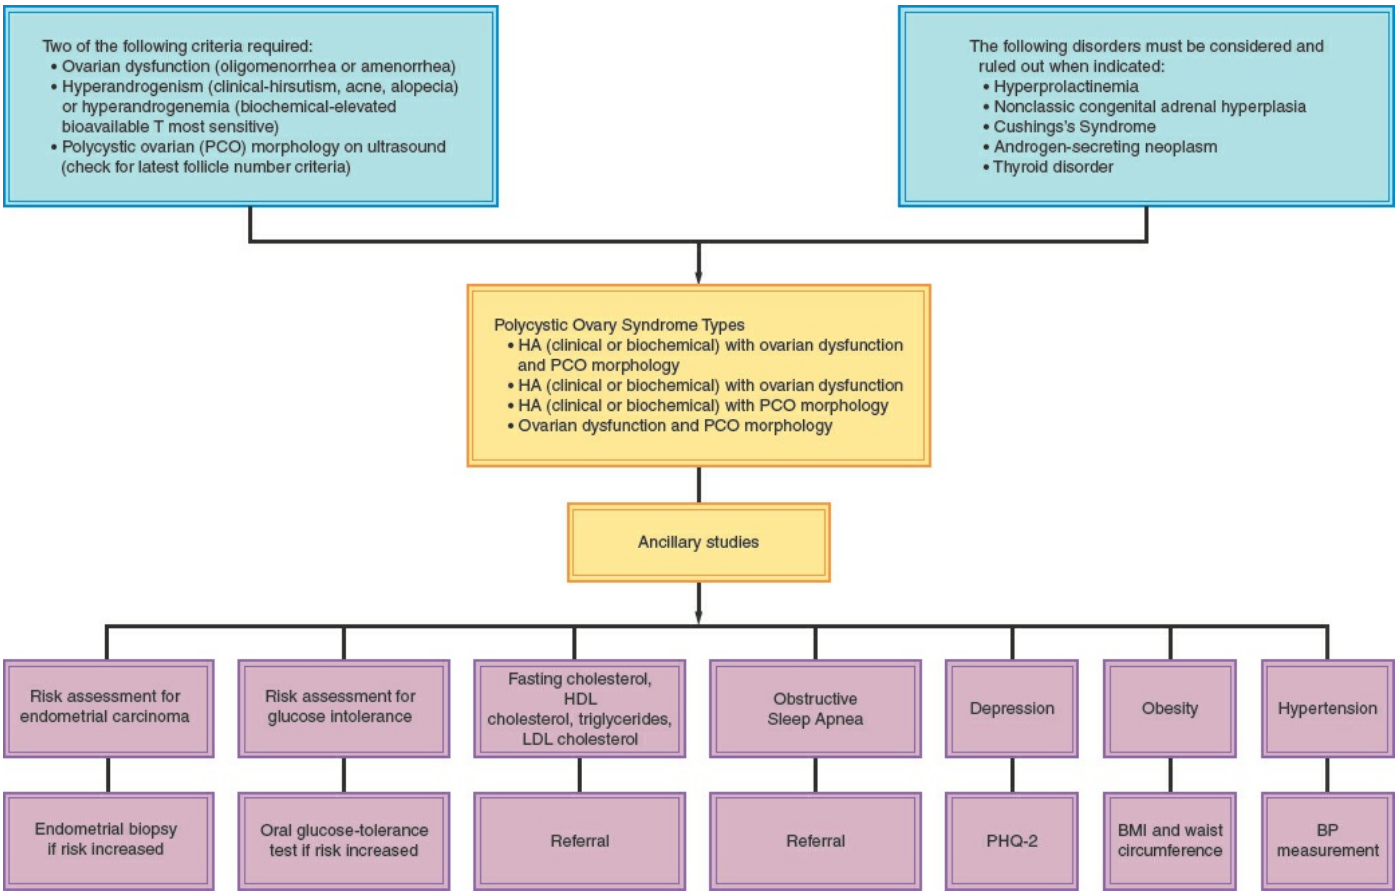

FIGURE 35-4 Diagnostic algorithm for polycystic ovary syndrome. (Modified with permission from

Rosenfield RL. Clinical practice. Hirsutism. *N Engl J Med* 2005;353:2578–2588.)

The sonographic criteria for PCOS morphology requires the presence of 20 or more follicles in either ovary measuring 2 to 9 mm in diameter and/or increased ovarian volume (>10 mL). A single ovary meeting these criteria is sufficient to affix the PCO morphology (27). The appearance of PCO on ultrasound scanning is common. Only a fraction of those with PCO appearance, however, have the clinical and/or endocrine features of PCOS. A PCO appearance is found in about 23% of women of reproductive age, while estimates of the incidence of PCOS vary between 5% and 10% (28). Polycystic appearing ovaries in women with PCOS were not associated with increased cardiovascular disease risk, and were independent of body mass index (BMI), age, and insulin levels (29). An English study demonstrated that without symptoms of PCOS, a PCO appearance alone is not associated with impaired fecundity or fertility (30). Other studies indicate that anti-mullerian hormone (AMH) is a reliable predictor of the small (2 to 9 mm) antral follicle count independent of PCOS or ovarian morphology (31).

Obesity occurs in more than 50% of patients with PCOS. The body fat is usually deposited centrally (android obesity), and a higher waist-to-hip ratio is associated with IR indicating an increased risk of diabetes mellitus and cardiovascular disease (32). Among women with PCOS, there is widespread variability in the degree of adiposity by geographic location and ethnicity. In studies in Spain, China, Italy, and the United States, the percentage of obese women with PCOS were 20%, 43%, 38%, and 69%, respectively (33).

Because increased adiposity, particularly abdominal, is associated with hyperandrogenemia and increased metabolic risk, it is recommended that PCOS patients have a BMI calculation and measurement of waist circumference.

Insulin resistance resulting in hyperinsulinemia is commonly exhibited in PCOS. Insulin resistance may eventually lead to the development of hyperglycemia and type 2 diabetes mellitus (34). About one-third of obese PCOS patients have impaired glucose tolerance (IGT), and 7.5% to 10% have type 2 diabetes mellitus (35). These rates are mildly increased even in nonobese women who have PCOS (10% IGT and 1.5% diabetes), compared with the general population of the United States (7.8% IGT and 1% diabetes) (36,37). **Because of the high risk of IGT and type 2 diabetes mellitus in PCOS, periodic screening of patients to detect early abnormalities in glucose tolerance is recommended (fasting and a 2-hour glucose level using a 75-g oral glucose load).**

Abnormal lipoproteins are common in PCOS and include elevated total cholesterol, triglycerides, and low-density lipoproteins (LDL) and low levels of high-density lipoproteins (HDL) and apoprotein A-I (32,38). According to one report, the most characteristic lipid alteration is decreased levels of $HDL_{2\alpha}$ (39).

Other observations in women with PCOS include impaired fibrinolysis, as shown by elevated circulating levels of plasminogen activator inhibitor (40), an increased incidence of hypertension over the years (which reaches 40% by perimenopause), a greater prevalence of atherosclerosis and cardiovascular disease, and an estimated 7-fold increased risk for myocardial infarction (38,40–43). It is recommended that adolescents and women with PCOS be screened for the following cardiovascular disease risk factors: family history of early cardiovascular disease, cigarette smoking, IGT/T2DM, hypertension, dyslipidemia, obstructive sleep apnea, and obesity (especially increased abdominal adiposity) and manage these when present **(Fig. 35-4)**.

Pathology

Macroscopically, ovaries in women with PCOS are two to five times the normal size. A cross section of the surface of the ovary discloses a white, thickened cortex with multiple cysts that are typically less than a centimeter in diameter. Microscopically, the superficial cortex is fibrotic and hypocellular and may contain prominent blood vessels. In addition to smaller atretic follicles, there is an increase in the number of follicles with luteinized theca interna. The stroma may contain luteinized stromal cells (44).

Pathophysiology and Laboratory Findings

The HA and anovulation that accompany PCOS may be caused by abnormalities in four endocrinologically active compartments: (i) the ovaries, (ii) the adrenal glands, (iii) the periphery (fat), and (iv) the hypothalamus–pituitary compartment **(Fig. 35-5)**.

In patients with PCOS, the ovarian compartment is the most consistent contributor of androgens. Dysregulation of CYP17, the androgen-forming enzyme in both the adrenals and the ovaries, may be one of the pathogenetic mechanisms underlying HA in PCOS (45). The ovarian stroma, theca, and granulosa contribute to ovarian HA and are stimulated by LH (46). This hormone relates to ovarian androgenic activity in PCOS in a number of ways.

1. Total and free testosterone levels correlate directly with LH levels (47).
2. The ovaries are more sensitive to gonadotropic stimulation, possibly as a result of CYP17 dysregulation (45).
3. Treatment with a gonadotropin-releasing hormone (GnRH) agonist effectively suppresses serum testosterone and androstenedione levels (48).
4. Larger doses of a GnRH agonist are required for androgen suppression than for endogenous gonadotropin-induced estrogen suppression (49).

The increased testosterone levels in patients with PCOS are considered ovarian in origin. The serum total testosterone levels are usually no more than twice the upper normal range (20 to 80 ng/dL). However, in ovarian hyperthecosis, values

may reach 200 ng/dL or more (50). The adrenal compartment plays a role in the development of PCOS. Although the hyperfunctioning CYP17 androgen-forming enzyme coexists in the ovaries and the adrenal glands, DHEAS is increased in only about 50% of patients with PCOS (51,52). The hyperresponsiveness of DHEAS to stimulation with ACTH, the onset of symptoms around puberty, and the observation of 17,20-lyase activation (one of the two CYP17 enzymes) are key events in adrenarche that led to the hypothesis that PCOS arises as an exaggeration of adrenarche (50).

FIGURE 35-5 Pathophysiologic characteristics of the polycystic ovary syndrome (PCOS). Insulin resistance results in a compensatory hyperinsulinemia, which stimulates ovarian androgen production in an ovary genetically predisposed to PCOS. Arrest of follicular development (*red "X"*) and anovulation could be caused by the abnormal secretion of gonadotropins such as follicle-stimulating hormone (FSH) or luteinizing hormone (LH) (perhaps induced by hyperinsulinemia), intraovarian androgen excess, direct effects of insulin, or a combination of these factors. Insulin resistance, in concert with genetic factors, may also lead to hyperglycemia and an adverse profile of cardiovascular risk factors. (Modified with permission from **Rosenfield RL**. Clinical practice. Hirsutism. *N Engl J Med* 2005;353:2578–2588.)

The peripheral compartment, defined as the skin and the adipose tissue, manifests its contribution to the development of PCOS in several ways.

1. The presence and activity of 5α-reductase in the skin largely determines the presence or absence of hirsutism (23,24).
2. Aromatase and 17β-hydroxysteroid dehydrogenase activities are increased in fat cells and peripheral aromatization is increased with increased body weight (53,54).
3. With obesity, the metabolism of estrogens, by way of reduced 2-hydroxylation and 17α-oxidation, is decreased and metabolism via estrogen active 16-hydroxyestrogens (estriol) is increased (55).
4. While E2 (estradiol) is at a follicular phase level in patients with PCOS, E1 (**estrone**) levels are increased as a result of peripheral aromatization of androstenedione (56).
5. A chronic hyperestrogenic state, with reversal of the E1-to-E2 ratio, results and is unopposed by progesterone.

The hypothalamic–pituitary compartment also participates in aspects critical to the development of PCOS.

1. An increase in LH pulse frequency relative to those in the normal follicular phase is the result of increased GnRH pulse frequency (57).
2. This increase in LH pulse frequency explains the frequent observation of an elevated LH and LH-to-FSH ratio.
3. FSH is not increased with LH, likely because of the combination of increased gonadotropin pulse frequency and the synergistic negative feedback of chronically elevated estrogen levels and normal follicular inhibin.
4. About 25% of patients with PCOS exhibit mildly elevated prolactin levels, which may result from abnormal estrogen feedback to the pituitary gland. In some patients with PCOS, *bromocriptine* has reduced LH levels and restored ovulatory function (58).

PCOS is a complex multigenetic disorder that results from the interaction between multiple genetic and environmental factors. **Genetic studies of PCOS reported allele sharing in large PCOS patient populations. Linkage studies focused on candidate**

genes, most likely to be involved in the pathogenesis of PCOS, reveal genes grouped into four categories: (i) IR-related genes, (ii) genes that interfere with the biosynthesis and the action of androgens, (iii) genes that encode inflammatory cytokines, and (iv) other candidate genes (59).

In PCOS genome-wide association studies (GWAS), there is evidence for candidate genes related to insulin signaling, FSH receptor, insulin receptor, sexual hormone function, type 2 diabetes (T2D), calcium signaling, interleukin-6, teleomerase activity, gamma-aminobutyric acid (GABA) A receptors, and endocytosis (1q22, 2p16.3, 2p21, 3q26.33, 4p12, 4q35.2, 8q24.2, 9q21.32, 9q33.3, 9q22.32, 11p13, 11q22.1, 12q13.2, 12q14.3, 16p13.3, 16q12.1, 19p13.3, 20q13.2) (60). GWAS in a European PCOS cohort has identified six susceptibility loci mapping to 11q22.1 (*YAP1*), 2p21 (*THADA*), 11p14.1 (*FSHB*), 2q34 (*ERBB4*), 12q21.2 (*KRR1*), and 5q31.1 (*RAD50*). The first four have been confirmed in Han Chinese (61).

Other linkage studies have identified the follistatin, *CYP11A*, *Calpain 10*, *IRS-1* and *IRS-2* regions and loci near the insulin receptor (19p13.3), *SHBG*, *TCF7L2*, and the insulin genes, as likely PCOS candidate genes (62–68). A polymorphic variant, *D19S884*, in *FBN3* was found to be associated with risk of PCOS (69). Using theca cells derived from women with PCOS elevated mRNA levels was noted for *CYP11A, 3BHSD2*, and *CYP17* genes with corresponding overproduction of testosterone, 17-α-hydroxyprogesterone, and progesterone. Despite the characteristically heightened steroidogenesis in POCS, the *STARB* gene was not overexpressed (62). Microarray data using theca cells from PCOS women did not identify any genes near the 19p13.3 locus that were differentially expressed; however, the mRNAs of several genes that map to 19p13.3, including the insulin receptor, p114-Rho-GEF, and several expressed sequence tags, were detected in both PCOS and normal theca cells. Those studies identified new factors that might impact theca cell steroidogenesis and function, including *cAMP-GEFII*, genes involved in all-transretinoic acid (atRA) synthesis signaling, genes that participate in the Wnt signal transduction pathway, and transcription factor GATA6. These findings suggest that a 19p13.3 locus or some other candidate gene may be a signal transduction gene that results in overexpression of a suite of genes downstream that may affect steroidogenic activity (70). Polymorphisms in major folliculogenesis genes, *GDF9*, *BMP15*, *AMH*, and *AMHR2*, are not associated with PCOS susceptibility (71).

Insulin Resistance

Patients with PCOS frequently exhibit IR and hyperinsulinemia. Insulin resistance and hyperinsulinemia participate in the ovarian steroidogenic dysfunction of PCOS. Insulin alters ovarian steroidogenesis independent of gonadotropin secretion in PCOS. Insulin and insulin-like growth factor I (IGF-I) receptors are present in the ovarian stromal cells. A specific defect in the early steps of insulin receptor–mediated signaling

(diminished autophosphorylation) was identified in 50% of women with PCOS (72).

Insulin has both direct and indirect roles in the pathogenesis of HA in PCOS. Insulin in collaboration with LH enhances the androgen production of theca cells. Insulin also inhibits the hepatic synthesis of SHBG, the main circulating protein that binds to testosterone, and thus increases the proportion of unbound or bioavailable testosterone (13).

The most common cause of IR and compensatory hyperinsulinemia is obesity, but despite its frequent occurrence in PCOS, obesity alone does not explain this important association (58). The IR associated with PCOS is not solely the result of HA based on the following:

1. Hyperinsulinemia is not a characteristic of HA in general but is uniquely associated with PCOS (73).
2. In obese women with PCOS, 30% to 45% have glucose intolerance or frank diabetes mellitus, whereas ovulatory hyperandrogenic women have normal insulin levels and glucose tolerance (73). It seems that the associations between PCOS and obesity on the action of insulin are synergistic.
3. Suppression of ovarian steroidogenesis in women with PCOS with long-acting GnRH analogs does not change insulin levels or IR (74).
4. Oophorectomy in patients with hyperthecosis accompanied by hyperinsulinemia and hyperandrogenemia does not change IR, despite a decrease in androgen levels (74,75).

Acanthosis nigricans is a reliable marker of IR in hirsute women. This thickened, pigmented, velvety skin lesion is most often found in the vulva and may be present on the axilla, over the nape of the neck, below the breast, and on the inner thigh (76). **The HAIR-AN syndrome consists of HA, IR, and acanthosis nigricans (AN)** (72,77). These patients often have high testosterone levels (>150 ng/dL), fasting insulin levels of greater than 25 µIU/mL (normal <20 to 24 µIU/mL), and maximal serum insulin responses to glucose load (75 g) exceeding 300 µIU/mL (normal is <160 µIU/m: at 2 hours postglucose load).

Screening Strategies for Diabetes, Insulin Resistance and Metabolic Syndrome

Professional societies collectively recommend that obese women with PCOS and nonobese PCOS patients with risk factors for IR, such as a family history of diabetes, should be screened for metabolic syndrome, including glucose intolerance with an Hgb A1c or oral glucose tolerance test (OGTT) (19). **The standard 2-hour OGTT (75 g) provides an assessment of the degrees of hyperinsulinemia and glucose tolerance and yields the highest amount of information for a reasonable cost and risk** (7). **While an HbA1c test alone provides a diagnosis in the setting of**

uncontrolled chronic hyperglycemia, utilizing an OGTT allows early detection and intervention to prevent complications.

Multiple other testing or screening schemas were proposed to assess the presence of hyperinsulinemia and IR. In one, the fasting glucose-to-insulin ratio is determined, and values less than 4.5 indicate IR. Using the 2-hour GTT with insulin levels, 10% of nonobese and 40% to 50% of obese PCOS women have IGT (2-hour glucose level ê140 but Ä199 mg/dL) or overt type 2 diabetes mellitus (any glucose level >200 mg/dL). Some research studies have utilized a peak insulin level of over 150 lIU/mL or a mean level of over 84 lIU/mL over the three blood draws of a 2-hour GTT as a criterion to diagnose hyperinsulinemia.

The documentation of hyperinsulinemia using either the glucose-to-insulin ratio or the 2-hour GTT with insulin is problematic. When compared with the gold standard measure for IR, the hyperinsulemic–euglycemic clamp, it shows that the glucose-to-insulin ratio does not always accurately portray IR. When hyperglycemia is present, a relative insulin secretion deficit is present. This deficient insulin secretion exacerbates the effects of IR and renders inaccurate the use of hyperinsulinemia as an index of IR. Thus, routine measurements of insulin levels may not be particularly useful.

Although detection of IR, per se, is not of practical importance to the diagnosis or management of PCOS, testing women with PCOS for glucose intolerance is of value because their risk of cardiovascular disease may correlate with this finding. An appropriate frequency for such screening depends on age, BMI, and waist circumference, all of which increase risk.

Interventions

Two-Hour Glucose Tolerance Test Normal Glucose Ranges (World Health Organization criteria, after 75-g glucose load)

- **Fasting: 64 to 128 mg/dL**
- **One hour: 120 to 170 mg/dL**
- **Two hours: 70 to 140 mg/dL**

Two-Hour Glucose Values for Impaired Glucose Tolerance and Type 2 Diabetes (World Health Organization criteria, after 75-g glucose load)

- **Normal (2-hour) <140 mg/dL**
- **Impaired (2-hour) = 140 to 199 mg/dL**
- **Type 2 diabetes mellitus (2-hour) = 200 mg/dL**

Abnormal glucose metabolism may be significantly improved with weight reduction, which may also reduce HA and restore ovulatory function (78). **In obese, insulin-resistant women, caloric restriction that results in weight reduction will reduce the**

severity of IR (a 40% decrease in insulin level with a 10-kg weight loss) (79). This decrease in insulin levels should result in a marked decrease in androgen production (a 35% decrease in testosterone levels with a 10-kg weight loss) (80). Exercise also reduces IR, independent from any associated weight loss, but data on the impact of exercise on the principal manifestations of PCOS are lacking.

In addition to addressing of the increased risk for diabetes, the clinician should recognize IR or hyperinsulinemia as a cluster syndrome called metabolic syndrome or dysmetabolic syndrome X. Recognition of the importance of IR or hyperinsulinemia as a risk factor for cardiovascular disease has led to diagnostic criteria for the metabolic syndrome. The more metabolic syndrome criteria present, the higher the level of IR and its downstream consequences. The presence of three of the following five criteria confirms the diagnosis, and an insulin-lowering agent and/or other interventions may be warranted (19).

Metabolic Syndrome Diagnostic Criteria

- **Female waist >35 in (88 cm)**
- **Triglycerides >150 mg/dL**
- **HDL <50 mg/dL**
- **Blood pressure >130/85 mm Hg**
- **Fasting glucose: 110 to 126 mg/dL**
- **Two-hour glucose from 75-g OGTT: 140 to 199 mg/dL**

Risk factors for metabolic syndrome include nonwhite race, sedentary lifestyle, BMI greater than 25, age over 40 years, cardiovascular disease, hypertension, PCOS, hyperandrogenemia, IR, HAIR-AN syndrome, nonalcoholic steatohepatitis (NASH), and a family history of type 2 diabetes mellitus, gestational diabetes, or IGT.

Long-Term Risks and Interventions

Comprehensive treatment of PCOS addresses reproductive, metabolic, and psychological features.

Metabolic Syndrome

A recent report by the Androgen Excess and PCOS Society concluded that **lifestyle management, either alone or combined with antiobesity pharmacologic and/or surgical treatments, should be used as the primary therapy in overweight and obese women with PCOS** (33). Lifestyle management of obesity in PCOS is multifactorial. Dietary management of obesity should focus on reducing body weight, maintaining a lower long-term body weight, and preventing weight gain. An initial weight loss of

greater than or equal to 5% to 10% is recommended. In obese and overweight women with PCOS, dietary interventions with a resultant weight reduction of more than 5% to less than 15% over the starting body weight is associated with a reduction in either total or free testosterone, adrenal androgens, and improvement in SHBG levels. Metabolic improvements in fasting insulin, glucose, glucose tolerance, total cholesterol, triglycerides, plasminogen activator inhibitor-1, and free fatty acids are reported. Clinically, hirsutism, menstrual function, and ovulation are all improved (33).

Structured exercise improves IR and offers significant benefits in PCOS. The incorporation of structured exercise, behavior modification, and stress management strategies as fundamental components of lifestyle management increases the success of the weight loss strategy **(Table 35-4)**.

Even though lifestyle management strategies should be used as the primary therapy in obese and overweight women with PCOS, they are difficult to maintain long term. Alternative approaches to the treatment of obesity include the use of pharmacologic agents, such as *orlistat*, *sibutramine*, and *rimonabant*, or bariatric surgery (33). The NIH clinical recommendations advise bariatric surgery when BMI is greater than 40 kg/m^2 or greater than 35 kg/m^2 in patients with a high-risk, obesity-related condition after failure of other treatments for weight control (33,81).

Table 35-4 Lifestyle Modification Principles Suggested for Obesity Management in Polycystic Ovary Syndrome (PCOS)

Guidelines for Dietary and Lifestyle Intervention in PCOS
1. Lifestyle modification is the first form of therapy, combining behavioral (reduction of psychosocial stressors), dietary, and exercise management
2. Reduced-energy diets (500–1,000 kcal/day reduction) are effective options for weight loss and can reduce body weight by 7–10% over a period of 6–12 months
3. Dietary plans should be nutritionally complete and appropriate for life stage and should aim for <30% of calories from fat, <10% of calories from saturated fat, with increased consumption of fiber, whole-grain breads and cereals, and fruit and vegetables
4. Alternative dietary options (increasing dietary protein, reducing glycemic index, reducing carbohydrate) may be successful for achieving and sustaining a reduced weight but more research is needed in PCOS specifically
5. The structure and support within a weight-management program is crucial and may be more important than the dietary composition. Individualization of the program, intensive follow-up and monitoring by a physician, and support from the physician, family, spouse, and peers will improve retention
6. Structured exercise is an important component of a weight-loss regime; aim for >30 min/day

Reprinted with permission from **Moran LJ, Pasquali R, Teede HJ, et al.** Treatment of obesity in polycystic ovary syndrome: a position statement of the Androgen Excess and Polycystic Ovary Syndrome Society. *Fertil Steril* 2009;92:1966–1982.

Dyslipidemia is one of the most common metabolic disorders seen in PCOS patients (up to 70% prevalence in a US PCOS population) (82). It is associated with IR and HA in combination with environmental (diet, physical, exercise) and genetic factors. Various abnormal patterns include decreased levels of HDL, elevated levels of triglycerides, decreased total and LDL levels, and altered LDL quality (83,84).

To assess cardiovascular risks and potentially prevent disease in patients with PCOS, multiple professional societies have recommended the following (84):

1. Waist circumference and BMI measurement at every visit, using the National Health and Nutrition Examination Survey method.
2. A complete lipid profile based on the American Heart Association guidelines **(Fig. 35-6)**. If the fasting serum lipid profile is normal, it should be reassessed every 2 years or sooner if weight gain occurs.
3. A 2-hour post-75-g oral glucose challenge measurement in PCOS women with a BMI greater than 30 kg/m^2, or alternatively in lean PCOS women with advanced age (40 years), personal history of gestational diabetes, or family history of type 2 diabetes. An HgbA1c test only provides information on impaired fasting blood glucose levels in the setting of uncontrolled chronic hyperglycemia.
4. Blood pressure measurement at each visit. The ideal blood pressure is 120/80 or lower. Prehypertension should be treated because blood pressure control has the largest benefit in reducing cardiovascular diseases.
5. Regular assessment for depression, anxiety, and quality of life.

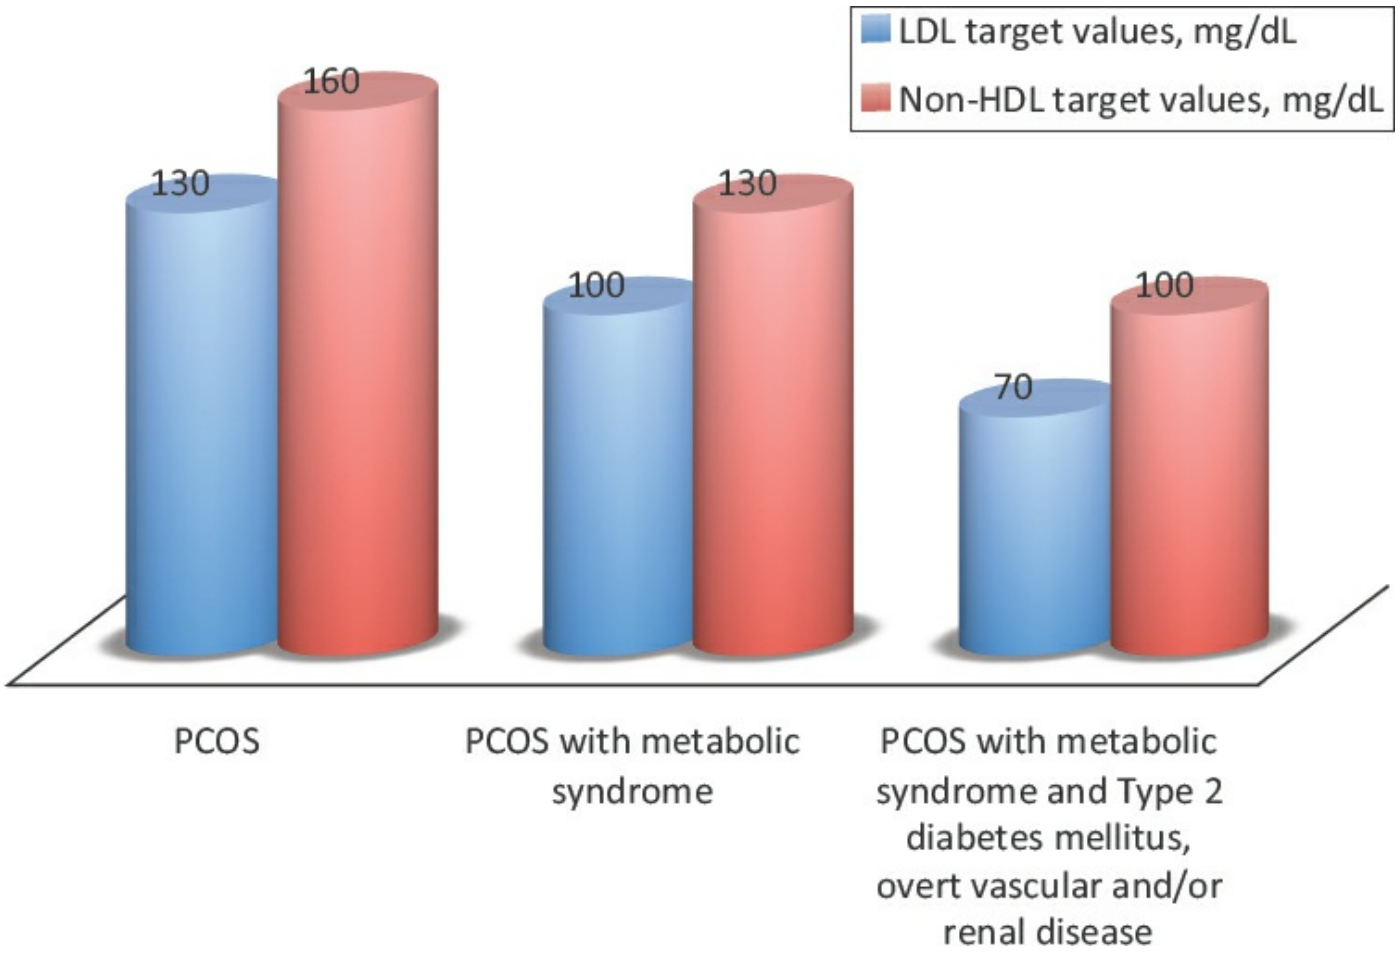

FIGURE 35-6 Lipid guidelines in PCOS to prevent cardiovascular disease risk (values in mg/dL). (Non-HDL = Total cholesterol − HDL, if TG < 400 mg/dL.) (Data for figure derived from **Wild RA, Carmina E, Diamanti-Kandarakis E, et al**. Assessment of cardiovascular risk and prevention of cardiovascular disease in women with the polycystic ovary syndrome: a consensus statement by the Androgen Excess and Polycystic Ovary Syndrome (AE-PCOS) Society. *J Clin Endocrinol Metab* 2010;95(5): 2038–2049.)

A significant proportion of the population and particularly the obese population have been noted to have inadequate vitamin D levels. Because vitamin D plays a role in many metabolic activities, assessment and supplementation when indicated can be considered.

25-Hydroxy Vitamin D Levels

- Deficient: 8 ng/mL or less (≤20 nmol/L);
- Insufficient: 8 to 20 ng/mL (20 to 50 nmol/L);
- Optimal: 20 to 60 ng/mL (50 to 150 nmol/L; 40 to 50 ng/mL is treatment goal);
- High: 60 to 90 ng/mL (150 to 225 nmol/L);
- Toxic: >90 ng/mL or greater (≥225 nmol/L).

Supplementation Facts

1. The body uses 3,000 to 5,000 IU D_3 per day.
2. In the absence of the sun, 600 IU of D_3 are required to maintain vitamin D levels.
3. D_2 is more rapidly metabolized and is less potent than D_3.
4. Patients receiving 50,000 IU of vitamin D_2 once a week for 8 weeks will usually correct a vitamin D deficiency, and this can be followed by giving 50,000 U of vitamin D_2 once every other week to maintain vitamin D sufficiency.
5. D_3 is more potent and appropriate dosing to correct levels is still under investigation but 600 IU/day is considered a safe intake for adults.

Cancer

In chronic anovulatory patients with PCOS, persistently elevated estrogen levels, which are uninterrupted by progesterone, increase the risk of endometrial carcinoma (85,86). **These endometrial cancers are usually well differentiated, stage I lesions with a cure rate of more than 90%** (see Chapter 37). Endometrial biopsy should be considered in PCOS patients, because they may occasionally harbor these cancers as early as the second decade of life. Abnormal bleeding, increasing weight, and age are factors that should lower the threshold for endometrial sampling. **Prevention of endometrial cancer is a core management goal for patients with PCOS.** If other dimensions of management do not induce regular ovulation (e.g., *clomiphene*, *letrazole*, *or gonadotropins*) or impose continuous progestation influence (e.g., OCs, pregnancy), regular secretory transformation and menstruation should be induced with periodic administration of a progestational agent. Even though the hyperestrogenic state is associated with an increased risk of breast cancer, studies examining the relationship between **PCOS** and **breast** cancer have not always identified a significantly increased risk (86–90). **The risk of ovarian cancer is increased 2-fold to 3-fold in women with PCOS** (86,91).

Depression and Mood Disorders

The clinical features of PCOS, such as infertility, acne, hirsutism, and obesity, promote psychological morbidity. Women with PCOS face challenges to their feminine identity that can lead to loss of self-esteem, anxiety, poor body image, and depression (92).

A study examining the prevalence of depression and other mood disorders in women with PCOS reported a significantly increased prevalence of depression (35% to 40%) when compared with controls (10.7%), after adjusting for BMI, and a family history of depression and/or infertility. Other mood disorders such as anxiety and eating disorders were common in women with PCOS (93). **The high prevalence of depression and other mental health disorders in women with PCOS suggests that assessment and treatment of mental health disorders should be included in the evaluation and management plan** (93). Lifestyle management improves quality of life and depression

in obese and overweight and women with PCOS (92). A simple two-item questionnaire can initiate the conversation (PHQ-2: Little interest or pleasure in doing things 0–3, Feeling down, depressed, or hopeless 0–3).

Treatment of Hyperandrogenism and PCOS

Treatment depends on a patient's goals. Some patients require hormonal contraception, whereas others desire ovulation induction. In all cases where there is significant ovulatory dysfunction, progestational interruption of the unopposed estrogen effects on the endometrium is necessary. This may be accomplished by periodic luteal function resulting from ovulation induction, progestational suppression via contraceptive formulations, or intermittent administration of progestational agents for endometrial or menstrual regulation. **Interruption of the steady state of HA and control of hirsutism usually can be accomplished simultaneously. Patients desiring pregnancy are an exception, and for them effective control of hirsutism may not be possible.** Treatment regimens for hirsutism are listed in Table 35-5. The induction of ovulation and treatment of infertility are discussed in Chapter 36.

Table 35-5 Medical Treatment of Hirsutism

Treatment Category	Specific Regimens
Weight loss	
Hormonal suppression	Oral contraceptives
	Medroxyprogesterone
	Gonadotropin-releasing hormone analogues
	Glucocorticoids
Steroidogenic enzyme inhibitors	Ketoconazole
5α-Reductase inhibitors	Finasteride
Antiandrogens	Spironolactone
	Cyproterone acetate
	Flutamide
Insulin sensitizer	Metformin
Mechanical	Temporary
	Permanent
	Electrolysis

	Laser hair removal

Weight Reduction

Weight reduction is the initial recommendation for patients with accompanying obesity because it promotes health, reduces insulin, SHBG, and androgen levels, and may restore ovulation either alone or combined with ovulation-induction agents (79). **Weight loss of as little as 5% to 7% over a 6-month period can reduce the bioavailable or calculated free testosterone level significantly and restore ovulation and fertility in more than 75% of women** (94). Exercise involving large muscle groups (i.e., thigh) reduces IR and can be an important component of nonpharmacologic, lifestyle-modifying management.

Oral Contraceptives

[3] Combination OCs decrease adrenal and ovarian androgen production and reduce hair growth in nearly two-thirds of hirsute patients (95–98). **Treatment with OCs offers the following benefits:**

1. The **progestin component suppresses LH**, resulting in diminished ovarian androgen production.
2. The **estrogen component increases hepatic production of SHBG**, resulting in decreased free testosterone concentration (99,100).
3. **Circulating androgen levels are reduced**, including those of DHEAS, which to some extent is independent of the effects of both LH and SHBG (32,101).
4. **Estrogens decrease conversion of testosterone to DHT** in the skin by inhibition of 5α-reductase.

When an OC is used to treat hirsutism, a balance must be maintained between the decrease in free testosterone levels and the intrinsic androgenicity of the progestin. Three progestin compounds that are present in OCs (*norgestrel*, *norethindrone*, and *norethindrone acetate*) are believed to be androgen dominant. The androgenic bioactivity of these steroids may be a factor of their shared structural similarity with 19-nortestosterone steroids (102). OCs containing the so-called new progestins (*desogestrel*, *gestodene*, *norgestimate*, and *drospirenone*) have minimized androgenic activity. However, there is limited evidence of clinically measurable differences in outcome resulting from the disparity of in vitro estimates of androgenic potency.

The use of OCs alone may be relatively ineffective (<10% success rate) in the treatment of hirsutism in women with PCOS, **and the OCs may exacerbate IR in these patients** (103,104). Therefore, effective protocols for pharmacologic management of significant hirsutism with OCs usually include coadministration of agents that impede

androgen action.

Medroxyprogesterone Acetate

Oral or intramuscular administration of *medroxyprogesterone acetate* (*MPA*) successfully treats hirsutism (105). It directly affects the hypothalamic–pituitary axis by decreasing GnRH production and the release of gonadotropins, thereby reducing testosterone and estrogen production by the ovary. Despite a decrease in SHBG, total and free androgen levels are decreased significantly (106). **The recommended oral dose for GnRH suppression is 20 to 40 mg daily in divided dosages or 150 mg given intramuscularly every 6 weeks to 3 months in the depot form.** Hair growth is reduced in up to 95% of patients (107). Side effects of the treatment include amenorrhea, bone mineral density loss, depression, fluid retention, headaches, hepatic dysfunction, and weight gain. MPA is not commonly used for hirsutism.

Gonadotropin-Releasing Hormone Agonists

Administration of GnRH agonists may allow the differentiation of androgen produced by adrenal sources from that of ovarian sources (49). GnRH agonists have been shown to suppress ovarian steroids to castrate levels in patients with PCOS (108). Treatment with *leuprolide acetate* given intramuscularly every 28 days decreases hirsutism and hair diameter in idiopathic hirsutism and hirsutism secondary to PCOS (109). Ovarian androgen levels are significantly and selectively suppressed. The addition of OC or estrogen replacement therapy to GnRH agonist treatment (add-back therapy) prevents bone loss and other side effects of menopause, such as hot flushes and genital atrophy. The hirsutism-reducing effect is retained (106,110). Suppression of hirsutism is not potentiated by the addition of estrogen replacement therapy to GnRH agonist treatment (111).

Glucocorticoids

Dexamethasone may be used to treat patients with PCOS who have either adrenal or mixed adrenal and ovarian HA. Doses of *dexamethasone* as low as 0.25 mg nightly or every other night are used initially to suppress DHEAS concentrations to less than 400 μg/dL. **Because *dexamethasone* has 40 times the glucocorticoid effect of cortisol, daily doses greater than 0.5 mg every evening should be avoided to prevent the risk of adrenal suppression and severe side effects that resemble Cushing syndrome.** To avoid oversuppression of the pituitary–adrenal axis, morning serum cortisol levels should be monitored intermittently (maintain at >2 μg/dL). Reduction in hair growth rate was reported, and significant improvement in acne associated with adrenal HA (112).

Ketoconazole

Ketoconazole inhibits the key steroidogenic cytochromes. Administered at a low dose

(200 mg per day), it can significantly reduce the levels of androstenedione, testosterone, and calculated free testosterone (113). It is rarely used for the chronic inhibition of androgen production in women with HA because of the serious risk of adrenocortical suppression and development of adrenal crisis (15).

Spironolactone

Spironolactone is a specific antagonist of aldosterone, which competitively binds to the aldosterone receptors in the distal tubular region of the kidney. It is an effective potassium-sparing diuretic that originally was used to treat hypertension. The effectiveness of *spironolactone* in the treatment of hirsutism is based on the following mechanisms:

1. Competitive inhibition of DHT at the intracellular receptor level (22).
2. Suppression of testosterone biosynthesis by a decrease in the CYP enzymes (114).
3. Increase in androgen catabolism (with increased peripheral conversion of testosterone to estrone).
4. Inhibition of skin 5α-reductase activity (22).

Although total and free testosterone levels are reduced significantly in patients with both PCOS and idiopathic hirsutism (HA with regular menses) after treatment with *spironolactone*, total and free testosterone levels in patients with PCOS remain higher than those with idiopathic hirsutism (HA with regular menses) (115). In both groups, SHBG levels are unaltered. The reduction in circulating androgen levels observed within a few days of *spironolactone* treatment partially accounts for the progressive regression of hirsutism.

At least a modest improvement in hirsutism can be anticipated in 70% to 80% of women using at least 100 mg of *spironolactone* per day for 6 months (116). *Spironolactone* reduces the daily linear growth rate of sexual hair, hair shaft diameters, and daily hair volume production (117). Combination therapy with spironolactone and OCs seems effective via their differing but synergistic activities (15,118).

The most common dose is 50 to 100 mg twice daily. Women treated with 200 mg per day show a greater reduction in hair shaft diameter than women receiving 100 mg per day (119). Maximal inhibition of hirsutism is noted between 3 and 6 months but continues for 12 months. Electrolysis can be recommended 9 to 12 months after the initiation of *spironolactone* for permanent hair removal.

The most common side effect of *spironolactone* is menstrual irregularity (usually metrorrhagia), which may occur in over 50% of patients with a dosage of 200 mg per day (119). Normal menses may resume with reduction of the dosage. Infrequently, other side effects such as mastodynia, urticaria, or scalp hair loss may occur. Nausea and fatigue can occur with high doses (116). Because spironolactone can increase serum

potassium levels, its use is not recommended in patients with renal insufficiency or hyperkalemia. Periodic monitoring of potassium and creatinine levels is suggested.

Return of normal menses in amenorrheic patients is reported in up to 60% of cases (115). Patients must be counseled to use contraception while taking *spironolactone* because it theoretically can feminize a male fetus.

Cyproterone Acetate

***Cyproterone acetate* is a synthetic progestin derived from 17-OHP, which has potent antiandrogenic properties.** The primary mechanism of *cyproterone acetate* is competitive inhibition of testosterone and DHT at the level of the androgen receptor (120). This agent induces hepatic enzymes and may increase the metabolic clearance rate of plasma androgens (121).

A European formulation of *ethinyl estradiol* with *cyproterone acetate* significantly reduces plasma testosterone and androstenedione levels, suppresses gonadotropins, and increases SHBG levels (122). *Cyproterone acetate* shows mild glucocorticoid activity (and may reduce DHEAS levels) (120,123). Administered in a reverse sequential regimen (*cyproterone acetate* 100 mg per day on days 5 to 15, and *ethinyl estradiol* 30 to 50 mg per day on cycle days 5 to 26), this cyclic schedule allows regular menstrual bleeding, provides excellent contraception, and is effective in the treatment of even severe hirsutism and acne (124).

Side effects of *cyproterone acetate* include fatigue, weight gain, decreased libido, irregular bleeding, nausea, and headaches. These symptoms occur less often when *ethinyl estradiol* is added. *Cyproterone acetate* administration is associated with liver tumors in beagles and is not approved by the U.S. Food and Drug Administration (FDA) for use in the United States.

Flutamide

Flutamide, a pure nonsteroidal antiandrogen, is approved for treatment of advanced prostate cancer. Its mechanism of action is inhibition of nuclear binding of androgens in target tissues. Although it has a weaker affinity to the androgen receptor than spironolactone or *cyproterone acetate*, larger doses (250 mg given two or three times daily) may compensate for the reduced potency. *Flutamide* is a weak inhibitor of testosterone biosynthesis.

In a single, 3-month study of *flutamide* alone, most patients demonstrated significant improvement in hirsutism with no change in androgen levels (125). Significant improvement in hirsutism with a significant drop in androstenedione, DHT, LH, and FSH levels was observed in an 8-month follow-up of *flutamide* and low-dose OCs in women who did not respond to OCs alone (126). The side effects of *flutamide* treatment combined with a low-dose OC included dry skin, hot flashes, increased appetite, headaches, fatigue, nausea, dizziness, decreased libido, liver toxicity, and breast

tenderness (127).

In hyperinsulinemic, hyperandrogenemic, nonobese PCOS adolescents on a combination of *metformin* (850 mg per day) and *flutamide* (62.5 mg per day), and the low-dose OC containing *drospirenone*, resulted in a more effective and more efficient reduction in total and abdominal fat excess than was demonstrated by those utilizing an OC with *gestodene* as the progestin (128). The combination of *ethinyl-drospirenone*, *metformin*, and *flutamide* is effective in reducing excess total fat, abdominal fat, and attenuating dysadipocytokinemia in young women with hyperinsulinemic PCOS. The use of the antiandrogen *flutamide* appeared to emphasize effects (129). Many patients taking *flutamide* (50% to 75%) report dry skin, blue-green discoloration of urine, and liver enzyme elevation. Liver toxicity or failure and death are rare but severe side effects of *flutamide* appear to be dose-related (130). The 2008 Endocrine Society clinical practice guidelines do not recommend using *flutamide* as first-line therapy for treating hirsutism. If it is used, the lowest effective dose should be given, and the patient's liver function should be monitored closely (4). *Flutamide* should not be used in women desiring pregnancy.

Finasteride

Finasteride is a specific inhibitor of type 2 5α-reductase enzyme activity, approved in the United States at a 5-mg dose for the treatment of benign prostatic hyperplasia, and at a 1-mg dose to treat male-pattern baldness. In a study in which *finasteride* (5 mg daily) was compared with *spironolactone* (100 mg daily), both drugs resulted in similar significant improvement in hirsutism, despite differing effects on androgen levels (131). Most of the improvement in hirsutism with *finasteride* occurred after 6 months of therapy with 7.5 mg of *finasteride* daily (132). The improvement in hirsutism in the presence of rising testosterone levels is convincing evidence that it is the binding of DHT, and not testosterone, to the androgen receptor that is responsible for hair growth. *Finasteride* does not prevent ovulation or cause menstrual irregularity. The increase in SHBG caused by OCs further decreases free testosterone levels; OCs in combination with *finasteride* are more effective in reducing hirsutism than *finasteride* alone. As with *spironolactone* and *flutamide*, *finasteride* could theoretically feminize a male fetus; therefore, these agents are used only with additional contraception.

Ovarian Wedge Resection

Bilateral ovarian wedge resection is associated with only a transient reduction in androstenedione levels and a prolonged minimal decrease in plasma testosterone (133,134). In patients with hirsutism and PCOS who had wedge resection, hair growth was reduced by approximately 16% (17,135). Although Stein and Leventhal's original report cited a pregnancy rate of 85% following wedge resection and maintenance of ovulatory cycles, subsequent reports show lower pregnancy rates and a concerning

incidence of periovarian adhesions (17,136). Instances of premature ovarian failure and infertility were reported (137).

Laparoscopic Electrocautery

Laparoscopic ovarian electrocautery is used as an alternative to wedge resection in patients with severe PCOS whose condition is resistant to *clomiphene citrate.* In one series, ovarian drilling was achieved laparoscopically with an insulated electrocautery needle, using 100-W cutting current to assist entry and 40-W coagulating current to treat each microcyst over 2 seconds (8-mm needle in ovary) (138). In each ovary, 10 to 15 punctures were created. This led to spontaneous ovulation in 73% of patients, with 72% conceiving within 2 years. Of those who had undergone a follow-up laparoscopy, 11 of 15 were adhesion free. To reduce adhesion formation, a technique that cauterized the ovary in only four points led to a similar pregnancy rate, with a miscarriage rate of 14% (139). Other laparoscopic techniques using laser instead of electrocautery for laparoscopic ovarian drilling were described (140). Most series report a decrease in androgen and LH concentrations and an increase in FSH concentrations (141,142). The beneficial endocrinologic effects of laparoscopic ovarian drilling and the improvement in hirsutism were sustained for up to 9 years in patients with PCOS (143). Unilateral diathermy results in bilateral ovarian activity (144). Further studies are anticipated to define candidates who may benefit most from such a procedure. **The risk of adhesion formation, reduction in AMH and alternative therapies should be discussed during informed consent** (145).

Physical Methods of Hair Removal

Depilatory creams remove hair only temporarily. They break down and dissolve hair by hydrolyzing disulfide bonds. Although depilatories can have a dramatic effect, many women cannot tolerate these irritative chemicals. The topical use of corticosteroid cream may prevent contact dermatitis. *Eflornithine hydrochloride* cream, also known as *difluoromethylornithine* (*DMFO*), irreversibly blocks ornithine decarboxylase (ODC), the enzyme in hair follicles that is important in regulating hair growth. It is effective in the treatment of unwanted facial hair (146). Noticeable results take about 6 to 8 weeks of therapy. Treatment must be continued while inhibition of hair growth is desired, and when the cream is discontinued, hair returns to pretreatment levels after about 8 weeks (4).

Shaving is effective and, contrary to common belief, it does not change the quality, quantity, or texture of hair. However, plucking, if done unevenly and repeatedly, may cause inflammation and damage to hair follicles and render them less amenable to electrolysis. Waxing is a grouped method of plucking in which hairs are plucked out from under the skin surface. The results of waxing last longer (up to 6 weeks) than shaving or depilatory creams (147).

Bleaching removes the hair pigment through the use of *hydrogen peroxide* (usually 6% strength), which is sometimes combined with *ammonia*. Although hair lightens and softens during oxidation, this method is frequently associated with hair discoloration or skin irritation and is not always effective (146).

Electrolysis and laser hair removal are the only permanent means recommended for hair removal. Under magnification, a trained technician destroys each hair follicle individually. When a needle is inserted into a hair follicle, galvanic current, electrocautery, or both used in combination (blend) destroy the hair follicle. After the needle is removed, a forceps is used to remove the hair. Hair regrowth ranges from 15% to 50%. Problems with electrolysis include pain, scarring, and pigmentation. Cost can also be an obstacle (148). Laser hair removal destroys the hair follicle through photoablation. These methods are most effective after medical therapy has arrested further growth.

Insulin Sensitizers

[4] Because hyperinsulinemia appears to play a role in PCOS-associated anovulation, treatment with insulin sensitizers may shift the endocrine balance toward ovulation and pregnancy, either alone or in combination with other treatment modalities.

Metformin (*Glucophage*) is an oral biguanide antihyperglycemic drug used extensively for non–insulin-dependent diabetes. *Metformin* is pregnancy category B drug with no known human teratogenic effect. It lowers blood glucose mainly by inhibiting hepatic glucose production and by enhancing peripheral glucose uptake. *Metformin* enhances insulin sensitivity at the postreceptor level and stimulates insulin-mediated glucose disposal (149).

Metformin has been used extensively to treat oligo-ovulatory infertility, IR, and HA in PCOS patients. *Metformin* has been used to treat PCOS oligo-ovulatory infertility either alone or in combination with dietary restriction, *clomiphene, letrozole*, or gonadotropins. In randomized control studies, *metformin* has been found to improve the odds of ovulation in women with PCOS when compared with placebo (150,151). **A large multicenter, randomized control trial in women with PCOS concluded that *clomiphene* is superior to *metformin* in achieving live births in infertile women with PCOS.** When ovulation was used as the **outcome, the combination of *metformin* and *clomiphene* was superior to either *clomiphene* alone or *metformin* alone** (152). *Metformin* alone compared with placebo increases the ovulation rate in women with PCOS. However, ovulation induction agents such as *clomiphene* or *letrozole* alone are much more effective in increasing ovulation, pregnancy, and live birth rates in women with PCOS than *metformin* alone. There is fair evidence that *metformin* alone does not increase rates of miscarriage when stopped at the initiation of pregnancy and insufficient evidence that *metformin* in combination with other agents used to induce

ovulation increases live birth rates but may improve ovulation rates in *clomiphene*- or *letrazole*-resistant cases (153). The combination of *metformin* and *letrazole* has been shown to be comparable to gonadotropins in pregnancy and live birth rates in *clomiphene*-resistant PCOS patients and superior to other interventions (154). Ovulation induction with *clomiphene* has been associated with a thinner endometrial lining compared with other agents like *letrozole* (155). A recent meta-analysis provided weak evidence that *letrozole* appears to improve live birth and pregnancy rates in subfertile women with anovulatory PCOS, compared with *clomiphene* (156). In women with PCOS, baseline serum AMH levels were higher in those who did not respond to ovulation induction and conversely lower among women who ovulated. Women with higher baseline AMH levels required higher doses of *clomiphene* or *letrozole* to achieve ovulation, suggesting that AMH levels may be a marker of ovarian resistance to ovulation induction (157).

The most common side effects are gastrointestinal, including nausea, vomiting, diarrhea, bloating, and flatulence. Because the drug caused fatal lactic acidosis in men with diabetes and renal insufficiency, **baseline renal function testing is suggested** (158). **The drug should not be given to women with elevated serum creatinine levels** (149).

Concepts regarding the role of obesity and IR or hyperinsulinemia in PCOS suggest that the primary intervention should be recommending and assisting with weight loss (5% to 10% of body weight). A percentage of PCOS patients will respond to weight loss alone with spontaneous ovulation. *Metformin* and lifestyle interventions has been associated with a lower BMI and improved menstruation in women with PCOS compared to lifestyle interventions and placebo over 6 months (159). **In those who do not respond to weight loss alone or who are unable to lose weight, the addition of an insulin sensitizer, after failing the ovulation induction agent alone, may promote ovulation without resorting to injectable gonadotropins.**

A prevailing concern over the increased incidence of spontaneous abortions in women with PCOS and the potential reduction afforded by insulin sensitizers suggests that insulin sensitizers may be beneficial in combination with gonadotropin therapy for ovulation induction or in vitro fertilization (160). Women with early pregnancy loss have a low level of IGF-binding protein-1 (IGFBP-1), and of circulating glycodelin, which has immunomodulatory effects protecting the developing fetus. Use of *metformin* increased levels of both factors, which might explain early findings suggesting that *metformin* use may reduce the high spontaneous abortion rates seen among women with PCOS (161).

A number of observational studies suggested that *metformin* reduces the risk of pregnancy loss (162,163). However, there are no adequately designed and sufficiently powered randomized control trials to address this issue. In the prospective randomized

PPCOS (Pregnancy and PCOS) trial, there was a concerning nonsignificant trend toward a greater rate of miscarriages in the *metformin* only group (162). This trend was not noted in other trials.

There are no conclusive data to support a beneficial effect of *metformin* on pregnancy loss, and the trend toward a higher miscarriage rate in the PPCOS trial, which used extended-release *metformin*, is of some concern (150,152).

The incidence of ovarian hyperstimulation syndrome is reduced with adjuvant *metformin* in PCOS patients at risk for severe ovarian hyperstimulation syndrome (164).

Cushing Syndrome

The adrenal cortex produces three classes of steroid hormones: glucocorticoids, mineralocorticoids, and sex steroids (androgen and estrogen precursors). Hyperfunction of the adrenal gland can produce clinical signs of increased activity of any or all of these hormones. Increased glucocorticoid action results in nitrogen wasting and a catabolic state. This causes muscle weakness, osteoporosis, atrophy of the skin with striae, nonhealing ulcerations and ecchymoses, reduced immune resistance that increases the risk of bacterial and fungal infections, and glucose intolerance resulting from enhanced gluconeogenesis and antagonism to insulin action.

Although most patients with Cushing syndrome gain weight, some lose it. Obesity is typically central, with characteristic redistribution of fat over the clavicles around the neck and on the trunk, abdomen, and cheeks. Cortisol excess may lead to insomnia, mood disturbances, depression, and even overt psychosis. With overproduction of sex steroid precursors, women may exhibit HA (hirsutism, acne, oligomenorrhea or amenorrhea, thinning of scalp hair). Masculinization is rare, and its presence suggests an autonomous adrenal origin, most often an adrenal malignancy. With overproduction of mineralocorticoids, patients may manifest arterial hypertension and hypokalemic alkalosis. The associated fluid retention may cause pedal edema (Table 35-6) (165).

Characteristic clinical laboratory findings associated with hypercortisolism are confined mainly to a complete blood count showing evidence of granulocytosis and reduced levels of lymphocytes and eosinophils. Increased urinary calcium secretion may be present.

Causes

The six recognized noniatrogenic causes of Cushing syndrome can be divided between those that are ACTH dependent and those that are ACTH independent (Table 35-7). The ACTH-dependent causes can result from ACTH secreted by pituitary adenomas or from an ectopic source. The hallmark of ACTH-dependent forms of Cushing syndrome is the presence of normal or high plasma ACTH

concentrations with increased cortisol levels. The adrenal glands are hyperplastic bilaterally. Pituitary ACTH-secreting adenoma, or Cushing disease, is the most common cause of endogenous Cushing syndrome (165). These pituitary adenomas are usually microadenomas (<10 mm in diameter) that may be as small as 1 mm. They behave as though they are resistant, to a variable degree, to the feedback effect of cortisol. Like the normal gland, these tumors secrete ACTH in a pulsatile fashion; unlike the normal gland, the diurnal pattern of cortisol secretion is lost. **Ectopic ACTH syndrome most often is caused by malignant tumors** (166). About one-half of these tumors are small-cell carcinomas of the lung (167). Other tumors include bronchial and thymic carcinomas, carcinoid tumors of the pancreas, and medullary carcinoma of the thyroid.

Ectopic corticotropin-releasing hormone (CRH) tumors are rare and include tumors such as bronchial carcinoids, medullary thyroid carcinoma, and metastatic prostatic carcinoma (167). The presence of an ectopic CRH-secreting tumor should be suspected in patients whose dynamic testing suggests pituitary ACTH-dependent disease but who have rapid disease progression and very high plasma ACTH levels.

The most common cause of ACTH-independent Cushing syndrome is exogenous or iatrogenic (i.e., supraphysiologic therapy with corticosteroids) or factitious (self-induced). Corticosteroids are used in pharmacologic quantities to treat a variety of diseases with an inflammatory component. Over time, such therapy will result in Cushing syndrome. When corticosteroids are taken by the patient but not prescribed by a physician, the diagnosis may be especially challenging. The diagnostic workup for Cushing syndrome focuses on the ability to suppress autonomous cortisol secretion and whether ACTH is elevated or suppressed. According to the Endocrine Society's clinical practice guidelines for the diagnosis of Cushing syndrome, the initial use of one test with high diagnostic accuracy (24-hour urinary free cortisol [UFC], late night salivary cortisol, 1 mg overnight or 2 mg 48-hour *dexamethasone* suppression test) is recommended. The 24-hour UFC should be used to diagnose Cushing syndrome in pregnant women and in patients with epilepsy, whereas the 1-mg overnight *dexamethasone* suppression test, rather than UFC, should be used for initial testing for Cushing syndrome in patients with severe renal failure and adrenal incidentaloma. The 2-mg 48-hour *dexamethasone* suppression test is the optimal test in conditions that are associated with overactivation of the hypothalamic–pituitary–adrenal (HPA) axis: depression, morbid obesity, alcoholism, and diabetes mellitus.

Table 35-6 Overlapping Conditions and Clinical Features of Cushing Syndrome

Symptoms	Signs	Overlapping Conditions
Features that best discriminate Cushing syndrome; most do not have a high sensitivity		

	Easy bruising	
	Facial plethora	
	Proximal myopathy (or proximal muscle weakness)	
	Striae (especially if reddish purple and >1 cm wide)	
	In children, weight gain with decreasing growth velocity	
Cushing syndrome features in the general population that are common and/or less discriminatory		
Depression	Dorsocervical fat pad ("buffalo hump")	Hypertension[a]
Fatigue	Facial fullness	Incidental adrenal mass
Weight gain	Obesity	Vertebral osteoporosis[a]
Back pain	Supraclavicular fullness	Polycystic ovary syndrome
Changes in appetite	Thin skin[a]	Type 2 diabetes[a]
Decreased concentration	Peripheral edema	Hypokalemia
Decreased libido	Acne	Kidney stones
Impaired memory (especially short term)	Hirsutism or female balding	Unusual infections
Insomnia	Poor skin healing	
Irritability		
Menstrual abnormalities		
In children, slow growth	In children, abnormal genital virilization	
	In children, short stature	
	In children, pseudoprecocious puberty or delayed puberty	

Features are listed in random order.

[a]Cushing syndrome is more likely if onset of the feature is at a younger age.

Table 35-7 Causes of Cushing Syndrome

Category	Cause	Relative Incidence

ACTH-dependent	Cushing Disease	60%
	Ectopic ACTH-secreting tumors	15%
	Ectopic CRH-secreting tumors	Rare
ACTH-independent	Adrenal cancer	15%
	Adrenal adenoma	10%
	Micronodular adrenal hyperplasia	Rare
	Iatrogenic/factitious	Common

ACTH-dependent Cushing syndrome may be caused by pituitary adenoma, basophil hyperplasia, nodular adrenal hyperplasia, or cyclic Cushing syndrome.
ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

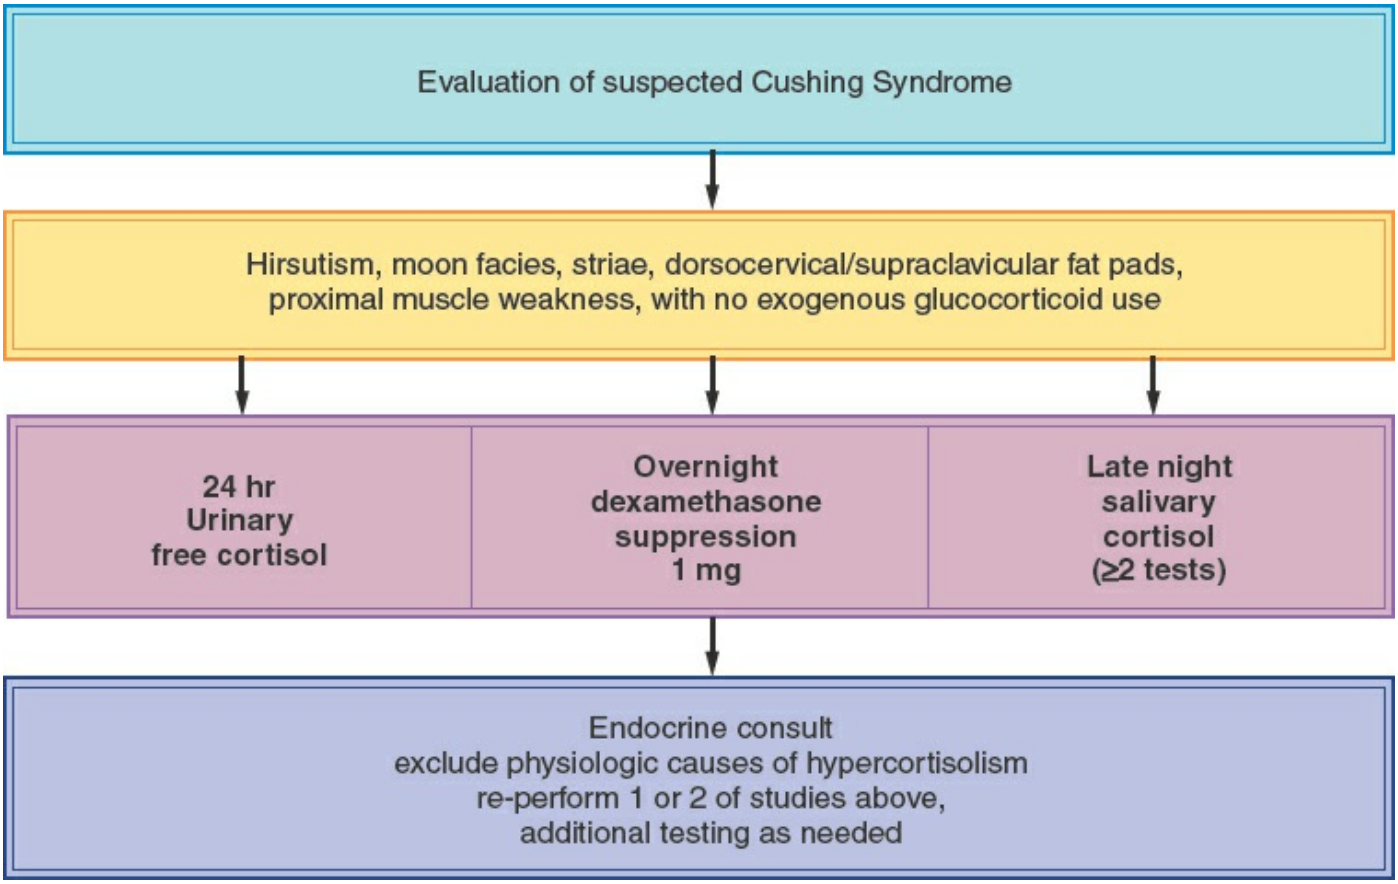

FIGURE 35-7 Algorithm for testing patients suspected of having Cushing syndrome (CS). Diagnostic criteria that suggest Cushing syndrome are a urinary free cortisol (UFC) greater than the normal range for the assay, serum cortisol greater than 1.8 μg/dL (50 nmol/L) after 1 mg dexamethasone (1 mg DST), and a late-night salivary cortisol greater than 145 ng/dL (4 nmol/L). (Based on recommendations from **Nieman LK, Biller BM, Findling JW, et al**. The diagnosis of Cushing's syndrome: an Endocrine Society Clinical Practice Guideline. *J Clin Endocrinol Metab* 2008;93:1526–1540.)

Patients with an abnormal result should see an endocrinologist and undergo a second test, either one of the above or, in some cases, a serum midnight cortisol or

dexamethasone CRH test. These guidelines are summarized in Figure 35-7 (165).

Treatment of ACTH-Independent Forms of Cushing Syndrome

[5] Excluding cases that are of iatrogenic or factitious etiology, ACTH-independent forms of Cushing syndrome are adrenal in origin. Adrenal cancers are usually very large by the time Cushing syndrome is manifest. This is because the tumors are relatively inefficient synthesizers of steroid hormones. Tumors are larger than 6 cm in diameter and are easily detectable by computed tomography (CT) scanning or magnetic resonance imaging (MRI). Adrenal cancers often produce steroids other than cortisol. Thus, when Cushing syndrome is accompanied by hirsutism or virilization in women or feminization in men, adrenal cancer should be suspected.

An adrenal tumor that appears large and irregular on radiologic imaging is suggestive of carcinoma. In these cases, a unilateral adrenalectomy through an abdominal exploratory approach is preferable. In most malignant tumors, complete resection is virtually impossible. However, a partial response to postoperative chemotherapy or radiation may be achieved. Most patients with malignancy die within 1 year. When administered immediately after surgery, *mitotane* (O,P-DDD, an adrenocorticolytic drug) may be of benefit in preventing or delaying recurrent disease (168). Manifestations of Cushing syndrome in these patients are controlled by adrenal enzyme inhibitors.

Adrenal adenomas are smaller than carcinomas and on average 3 cm in diameter. These tumors are usually unilateral and infrequently associated with other steroid-mediated syndromes. Micronodular adrenal disease is a disorder of children, adolescents, and young adults. The adrenal glands contain numerous small (>3 mm) nodules, which often are pigmented and secrete sufficient cortisol to suppress pituitary ACTH. This condition can be sporadic or familial.

Surgical removal of a neoplasm is the treatment of choice (169,170). If a unilateral, well-circumscribed adenoma is identified by MRI or CT scanning, the flank approach may be the most convenient. The cure rate following surgical removal of adrenal adenomas approaches 100%. Because normal function of the HPA axis is suppressed by autonomous cortisol production, cortisol replacement follows surgery and is titrated downward over several months, during which recovery of normal adrenal function is monitored.

Treatment of Cushing Disease

The main goals of treatment in ACTH-dependent Cushing syndrome are reversal of clinical features, normalization of biochemical changes with minimal morbidity, and long-term control without recurrence (166).

The treatment of choice for Cushing disease is transsphenoidal resection. The remission rate is approximately 70% to 90% and the recurrence rate is 5% to 10% at 5

years and 10% to 20% at 10 years in patients with microadenomas who undergo surgery by an experienced surgeon (171–175). Patients with macroadenoma have lower remission rates (<60%) and higher recurrence rates (12% to 45%) (176–178). Following surgery, transient diabetes insipidus and enduring compromise of anterior pituitary secretion of growth hormone, gonadotropins, and TSH are common (178,179).

Radiation Therapy

Fractionated external beam radiotherapy or stereotactic radiosurgery is used to treat patients with Cushing disease in whom transsphenoidal microsurgery was not successful or in patients who are poor surgical candidates. This therapy can achieve control of hypercortisolemia in approximately 50% to 60% of patients within 3 to 5 years (166,180,181). Hypopituitarism is the most common side effect of pituitary irradiation, and long-term follow-up is essential to detect relapse, which can occur after an initial response to radiotherapy.

High-voltage external pituitary radiation (4,200 to 4,500 cGy) is given at a rate not exceeding 200 cGy per day. Only 15% to 25% of adults show total improvement, but approximately 80% of children respond (179,182).

Medical Therapy

Mitotane can be used to induce medical adrenalectomy during or after pituitary radiation (168). The role of medical therapy is to prepare the severely ill patient for surgery and to maintain normal cortisol levels while a patient awaits the full effect of radiation. Occasionally, medical therapy is used for patients who respond to therapy with only partial remission. Adrenal enzyme inhibitors include *aminoglutethimide*, *metyrapone*, *trilostane*, and *etomidate*.

A combination of *aminoglutethimide* and *metyrapone* may cause a total adrenal enzyme block, requiring corticosteroid-replacement therapy. *Ketoconazole*, an FDA-approved antifungal agent, inhibits adrenal steroid biosynthesis at the side arm cleavage and 11β-hydroxylation steps. The dose of *ketoconazole* for adrenal suppression is 600 to 800 mg per day for 3 months to 1 year (183). *Ketoconazole* is effective for long-term control of hypercortisolism of either pituitary or adrenal origin.

Nelson syndrome results from adenomatous progression of ACTH-secreting cells in patients with Cushing syndrome treated with bilateral adrenalectomy. The macroadenoma that causes this syndrome produces sellar pressure symptoms of headaches, visual field disturbances, and ophthalmoplegia. Extremely high ACTH levels in Nelson syndrome are associated with severe hyperpigmentation (melanocyte-stimulating hormone activity). The treatment is surgical removal or radiation. The offending adenomatous tissue is often resistant to complete surgical removal (184). This syndrome reportedly complicates 10% to 50% of bilateral adrenalectomy cases. Measuring pituitary MRI and ACTH plasma levels at regular intervals after bilateral adrenalectomy will allow detection of the early progression of corticotroph tumors and

the possibility of cure by surgery, particularly with microadenomas (166). Nelson syndrome is less common today because bilateral adrenalectomy is less frequently used as initial treatment.

Congenital Adrenal Hyperplasia

[6] CAH is transmitted as an autosomal recessive disorder. Several adrenocortical enzymes necessary for cortisol biosynthesis may be affected. Failure to synthesize the fully functional enzyme has the following effects:

1. A relative decrease in cortisol production
2. A compensatory increase in ACTH levels
3. Hyperplasia of the zona reticularis of the adrenal cortex
4. An accumulation of the precursors of the affected enzyme in the bloodstream

21-Hydroxylase Deficiency

Deficiency of 21-hydroxylase is responsible for over 90% of all cases of adrenal hyperplasia as a result of adrenal synthetic enzyme deficiency. The disorder produces a spectrum of conditions; CAH, with or without salt wasting, and milder forms that are expressed as HA of pubertal onset (adult-onset adrenal hyperplasia, AOAH). Salt-wasting CAH, the most severe form, affects 75% of patients with congenital manifestations during the first 2 weeks of life and results in a life-threatening hypovolemic salt-wasting crisis, accompanied by hyponatremia, hyperkalemia, and acidosis. The salt-wasting form results from a severity of enzyme deficiency sufficient to result in ineffective aldosterone synthesis. With or without salt-wasting and newborn adrenal crisis, the condition is usually diagnosed earlier in affected female newborns than in males as genital virilization (e.g., clitoromegaly, labioscrotal fusion, and abnormal urethral course) is apparent at birth.

In simple virilizing CAH, affected patients are diagnosed as virilized newborn females or as rapidly growing masculinized boys at 3 to 7 years of age. Diagnosis is based on basal levels of the substrate for 21-hydroxylase, 17-OHP; in cases of congenital adrenal hyperplasia as a result of 21-hydroxylase deficiency and in milder forms of the disorder with manifestations later in life (acquired, late-onset, or adult-onset adrenal hyperplasia), diagnosis depends on basal and ACTH-stimulated levels of 17-OHP.

Patients with morning follicular phase 17-OHP levels of less than 300 ng/dL (10 nmol/L) are likely unaffected. When levels are greater than 300 ng/dL, but less than 10,000 ng/dL (300 nmol/L), ACTH testing should be performed to distinguish between 21-hydroxylase deficiency and other enzyme defects or to make the diagnosis in borderline cases. Levels greater than 10,000 ng/dL (300 nmol/L) are virtually

diagnostic of congenital adrenal hyperplasia.

Nonclassic Adult-Onset Congenital Adrenal Hyperplasia

The nonclassic type of 21-hydroxylase deficiency represents partial deficiency in 21-hydroxylation, which produces a late-onset, milder hyperandrogenemia. Its occurrence depends on some degree of functional deficit resulting from mutations affecting both alleles for the 21-hydroxylase enzyme. Heterozygote carriers for mutations in the 21-hydroxylase enzyme will demonstrate normal basal and modestly elevated stimulated levels of 17-OHP, but no abnormalities in circulating androgens. Some women with mild gene defects in both alleles demonstrate modest elevations in circulating 17-OHP concentrations, but no clinical symptoms or signs.

The hyperandrogenic symptoms of AOAH are mild and typically present at or after puberty. The three phenotypic varieties are as follows (185):

1. Those with ovulatory abnormalities and features consistent with PCOS (39%)
2. Those with hirsutism alone without oligomenorrhea (39%)
3. Those with elevated circulating androgens but without symptoms (cryptic) (22%)

Precocious puberty (PP) reveals late-onset congenital adrenal hyperplasia in 5% to 20% of cases that mainly are caused by nonclassic 21-hydroxylase deficiency.

Measurement of 17-OHP should be performed in patients presenting with PP, and a subsequent ACTH stimulation test is recommended if basal 17-OHP is greater than 200 ng/dL.

The need for screening patients with hirsutism for adult-onset adrenal hyperplasia depends on the patient population. The frequency of some form of the disorder varies by ethnicity and is estimated at 0.1% of the general population, 1% to 2% of Hispanics and Yugoslavs, and 3% to 4% of Ashkenazi Jews (186).

Genetics of 21-Hydroxylase Deficiency

1. The 21-hydroxylase gene is at 6p21.3 amid HLA B and HLA DR genes of the human leukocyte antigen (HLA).
2. The 21-hydroxylase gene is now termed *CYP21*. Its homolog is the pseudogene *CYP21P* (187).
3. Because *CYP21P* is a pseudogene, the lack of transcription renders it nonfunctional. The *CYP21* is the active gene.
4. The *CYP21* gene and the *CYP21P* pseudogene alternate with two genes called *C4B* and *C4A,* both of which encode for the fourth component (C4) of serum complement (187).
5. The close linkage between the 21-hydroxylase genes and HLA alleles has allowed the study of 21-hydroxylase inheritance patterns in families through blood HLA typing (e.g., linkage of HLA-B14 was found in Ashkenazi Jews, Hispanics, and

Italians) (188).

Prenatal Diagnosis and Treatment

Women with congenital and adult-onset forms of the disorder are at a significant risk for having affected infants, owing to the high frequency of 21-hydroxylase mutations in the general population. This presents an important rationale for screening hyperandrogenic women for this disorder when they anticipate childbearing. In families at risk for CAH and in instances where one partner expresses the congenital or adult-onset form of the disease, first-trimester prenatal screening using chorionic villus sampling is advocated (187). The fetal DNA is used for specific amplification of the *CYP21* gene using polymerase chain reaction (PCR) amplification (189). When the fetus is at risk for CAH, maternal *dexamethasone* treatment can suppress the fetal HPA axis and prevent genital virilization in affected females (190). The dose is 20 μg/kg in three divided doses administered as soon as pregnancy is recognized and no later than 9 weeks of gestation. This is done prior to performing chorionic villus sampling or amniocentesis in the second trimester. *Dexamethasone* crosses the placenta and suppresses ACTH in the fetus. If the fetus is determined to be an unaffected female or a male, treatment is discontinued. If the fetus is an affected female, *dexamethasone* therapy is continued.

The practice of prenatal *dexamethasone* treatment for women whose fetuses are at risk for CAH is controversial; seven of eight pregnancies will be treated with *dexamethasone* unnecessarily, albeit briefly, to prevent one case of ambiguous genitalia. The efficacy and safety of prenatal *dexamethasone* treatment is not established, and long-term follow-up data on the offspring of treated pregnancies are lacking (191).

Numerous studies in experimental animal models showed that prenatal *dexamethasone* exposure could impair somatic growth, brain development, and blood pressure regulation. A human study of 40 fetuses at risk for CAH who were treated prenatally with *dexamethasone* to prevent virilization of affected females reported long-term effects on neuropsychological functions and scholastic performance (190,192).

The 2010 Endocrine Society guidelines conclude that prenatal ***dexamethasone*** therapy should be pursued only through institutional review boards' approved protocols at centers capable of collecting sufficient outcome data (193).

11β-Hydroxylase Deficiency

In a small percentage of patients with CAH, hypertension, rather than mineralocorticoid deficiency, develops. The hypertension responds to corticosteroid replacement (194–197). Many of these patients have a deficiency in 11β-hydroxylase (195,196). In most populations, 11β-hydroxylase deficiency accounts for 5% to 8% of the cases of CAH, or 1 in 100,000 births (197). A much higher incidence, 1 in 5,000 to 7,000, was described

in Moroccan Jewish immigrants (197).

Two 11β-hydroxylase isoenzymes are responsible for cortisol and aldosterone synthesis, respectively, CYP11-B1 and CYP11-B2. They are encoded by two genes on the middle of the long arm of chromosome 8 (198–200).

Inability to synthesize a fully functional 11β-hydroxylase enzyme causes a decrease in cortisol production, a compensatory increase in ACTH secretion, and increased production of androstenedione, 11-deoxycortisol, 11-deoxycorticosterone, and DHEA. The diagnosis of 11β-hydroxylase-deficient late-onset adrenal hyperplasia is determined when 11-deoxycortisol levels are higher than 25 ng/mL 60 minutes after ACTH(1-24) stimulation (201).

Patients with 11β-hydroxylase deficiency may present with either a classic pattern of the disorder or symptoms of a mild deficiency. The severe classic form is found in about two-thirds of the patients with mild-to-moderate hypertension during the first years of life. In about one-third of the patients, it is associated with left ventricular hypertrophy, with or without retinopathy, and occasionally death is reported from cerebrovascular accident (194). Signs of androgen excess are common in the severe form and are similar to those seen in the 21-hydroxylase deficiency.

In the mild, nonclassic form, children have virilization or PP but not hypertension. Adult women seek treatment for postpubertal onset of hirsutism, acne, and amenorrhea.

3aβ-Hydroxysteroid Dehydrogenase Deficiency

Deficiency of 3β-HSD occurs with varying frequency in hirsute patients (202,203). The enzyme is found in the adrenal glands and ovaries (unlike 21- and 11-hydroxylase) and is responsible for transforming Δ-5 steroids into the corresponding Δ-4 compounds, a step integral to the synthesis of glucocorticoids, mineralocorticoids, testosterone, and estradiol. In severe forms, cortisol and mineralocorticoids are deficient. The clinical spectrum of 3β-HSD deficiency ranges from the classic salt wasting, hypogonadism, and ambiguous genitalia in males and females, to nonclassic hyperandrogenic symptoms in children and young women (204). In mild forms, elevated ACTH levels overcome these critical deficiencies, and the diagnosis of this disorder relies on the relationship of Δ-5 and Δ-4 steroids. A marked elevation of DHEA and DHEAS in the presence of normal, or mildly elevated, testosterone or androstenedione can suggest the initiation of a screening protocol for 3β-HSD deficiency using exogenous ACTH stimulation (202). Following intravenous administration of a 0.25-mg ACTH(1-24) bolus, within 60 minutes, 17-hydroxypregnenolone levels rise significantly in women with 3β-HSD deficiency, compared with normal women (2,276 ng/dL compared with normal of 1,050 ng/dL). The mean poststimulation ratio between 17-hydroxypregnenolone and 17-OHP is markedly elevated (mean ratio of 11 compared with 3.4 in normal controls and 0.4 in 21-hydroxylase deficiency). The rarity of this disorder indicates that routine screening of hyperandrogenic patients is not justified (202,203).

Treatment of Adult-Onset Congenital Adrenal Hyperplasia

Many patients with congenital AOAH do not need treatment. Glucocorticoid treatment should be avoided in asymptomatic patients with AOAH because the potential adverse effects of glucocorticoids probably outweigh any benefits (191,193).

Glucocorticoid therapy is recommended only to reduce HA for those with significant symptoms. *Dexamethasone* and antiandrogen drugs (both cross the placenta) should be used with caution and in conjunction with OCs in adolescent girls and young women with signs of virilization or irregular menses. When fertility is desired, ovulation induction might be necessary, and a glucocorticoid that does not cross the placenta (e.g., *prednisolone* or *prednisone*) should be used (190).

Many patients, those who are undiagnosed but actually have AOAH, are treated with therapies for ovarian HA and/or PCOS, with progestins for endometrial regulation, *clomiphene*, *letrozole*, or gonadotropins for ovulation induction, or progestins and antiandrogens for control of hirsutism. These therapies may be appropriate, as an alternative to glucocorticoid therapy, even when AOAH is recognized as the cause for the patient's symptoms.

Androgen-Secreting Ovarian and Adrenal Tumors

[7] Patients with severe hirsutism, virilization, or recent and rapidly progressing signs of androgen excess require careful investigation for the presence of an androgen-secreting neoplasm. The two most common sources of androgen-secreting tumors are the adrenal glands and the ovaries. To assess the symptoms, serum and urine tests for androgens and their metabolites should be obtained along with modern abdominal imaging techniques such as CT, MRI, and ultrasound scans (205). In prepubertal girls, virilizing tumors may cause signs of heterosexual PP in addition to hirsutism, acne, and virilization. In patients suspected of harboring an adrenal or ovarian tumor because of rapidly progressing or severe HA, the bioavailable testosterone level (free testosterone level above 6.85 pg/mL; 23.6 pmol/L), followed by an 11-desoxycortisol (above 7 ng/mL; 20.2 nmol/L), DHEAS (>3.6 µg/mL), and a 24-hour urinary cortisol (>45 µg per day) are the most sensitive and specific for the detection of an ACT-AS **(Table 35-2)**. A markedly elevated free testosterone level (2.5 times the upper normal range) is considered typical of an adrenal androgen-secreting tumor, while moderately elevated free testosterone levels are often ovarian in origin. A DHEAS level greater than 800 µg/dL is typical of an adrenal tumor. An adrenal tumor is unlikely when serum DHEAS and urinary 17-ketosteroid excretion measurements are in the normal basal range and the serum cortisol concentration is less than 3.3 µg/dL after *dexamethasone* administration (206). The results of other dynamic tests, especially testosterone suppression and stimulation, are unreliable (207).

A vaginal and abdominal ultrasonographic examination is the first step in the

evaluation of findings suggesting an ovarian neoplasm. Duplex Doppler scanning may increase the accuracy of tumor diagnosis and localization (208).

CT scanning can reveal tumors larger than 10 mm (1 cm) in the adrenal gland but may not help to distinguish among different types of solid tumors or benign incidental nodules (209). In the ovaries, CT scanning cannot help differentiate hormonally active from functional tumors (208,209).

MRI is comparable, if not superior, to CT scanning in detecting ovarian neoplasms, but is neither more sensitive than high-quality ultrasound nor more useful in clinical decision-making when ultrasound identifies a likely neoplasm. Nuclear medicine imaging of the abdomen and pelvis after injection with NP-59 ((131-iodine) 6-beta-iodomethyl-19-norcholesterol), preceded by adrenal and thyroid suppression, may facilitate tumor localization. In the rare circumstances when imaging fails to provide clear evidence for a neoplastic source of excess androgens, selective venous catheterization with measurement of site-specific androgen levels to identify an occult source of for androgen excess may be utilized (210). If all four vessels are catheterized transfemorally, selective venous catheterization allows direct localization of the tumor. Samples are obtained for hormonal analysis, with positive localization defined as a 5:1 testosterone gradient compared with lower vena cava values (211). Under such circumstances, specificity approaches 80%, but this rate should be weighed against the 5% rate of significant complications, such as adrenal hemorrhage and infarction, venous thrombosis, hematoma, and radiation exposure (212).

Androgen-Producing Ovarian Neoplasms

Ovarian neoplasms are the most frequent androgen-producing tumors. Granulosa cell tumors constitute 1% to 2% of all ovarian tumors and occur mostly in adult women (more frequently in postmenopausal than in premenopausal women; see Chapter 39). Usually associated with estrogen production, they are the most common functioning tumors in children and can lead to isosexual PP (213). Patients can present with vaginal bleeding caused by endometrial hyperplasia or endometrial cancer resulting from prolonged exposure to tumor-derived estrogen (214). Total abdominal hysterectomy and bilateral salpingo-oophorectomy are the treatments of choice. If fertility is desired, a more conservative approach involving unilateral salpingo-oophorectomy with careful staging can be performed in women with stage IA (the cancer does not extend outside the involved ovary and a concomitant uterine cancer is excluded) (214). The malignant potential of these lesions is variable. The 10-year survival rates vary from 60% to 90%, depending on the stage, tumor size, and histologic atypia (213).

Thecomas are rare and occur in older patients. In one study, only 11% were androgenic, even in the presence of steroid-type cells (luteinized thecomas) (213). They are unilateral in more than 90% of the cases and rarely malignant. A unilateral salpingo-

oophorectomy is adequate treatment (215).

Sclerosing stromal tumors are benign neoplasms that usually occur in patients younger than 30 years (213). A few cases with estrogenic or androgenic manifestations were reported.

Sertoli–Leydig cell tumors, previously classified as androblastoma or arrhenoblastoma, account for 11% of solid ovarian tumors. They contain various proportions of Sertoli cells, Leydig cells, and fibroblasts (213). Sertoli–Leydig cell tumors are the most common virilizing tumors in women of reproductive age; however, masculinization occurs in only one-third of patients. The tumor is bilateral in 1.5%. In 80% of cases, it is diagnosed at stage IA (213). Sertoli–Leydig cell tumors are frequently low-grade malignancies, and their prognosis is related to their degree of differentiation and stage of disease (216). Treatment with unilateral salpingo-oophorectomy is justified in patients with stage IA disease who desire fertility. Total abdominal hysterectomy, bilateral salpingo-oophorectomy, and adjuvant therapy are recommended for postmenopausal women who have advanced-stage disease.

Pure Sertoli cell tumors are usually unilateral. For a premenopausal woman with stage I disease, a unilateral salpingo-oophorectomy is the treatment of choice. Malignant tumors are rapidly fatal (217).

Gynandroblastomas are benign tumors with well-differentiated ovarian and testicular elements. A unilateral oophorectomy or salpingo-oophorectomy is sufficient treatment.

Sex cord tumors with annular tubules (SCTAT) are frequently associated with Peutz–Jeghers syndrome (gastrointestinal polyposis and mucocutaneous melanin pigmentation) (218). Their morphologic features range between those of the granulosa cell and Sertoli cell tumors.

While SCTAT with Peutz–Jeghers syndrome tends to be bilateral and benign, SCTAT without Peutz–Jeghers syndrome is almost always unilateral and malignant in one-fifth of cases (213).

Steroid Cell Tumors

According to Young and Scully, steroid cell tumors are composed entirely of steroid-secreting cells subclassified into stromal luteoma, Leydig cell tumors (hilar and nonhilar), and steroid cell tumors that are not otherwise specific (213). Virilization or hirsutism is encountered with three-fourths of Leydig cell tumors, with one-half of steroid cell tumors not otherwise specific, and with 12% of stromal luteomas.

Nonfunctioning Ovarian Tumors

Ovarian neoplasms that do not directly secrete androgens are occasionally associated with androgen excess, resulting from excess secretion by adjacent ovarian stroma, and include serous and mucinous cystadenomas, Brenner tumors, Krukenberg tumors, benign cystic teratomas, and dysgerminomas (219). Gonadoblastomas arising in the dysgenetic gonads of patients with a Y chromosome are rarely associated with androgen and

estrogen secretion (220,221).

Stromal Hyperplasia and Stromal Hyperthecosis

Stromal hyperplasia is a nonneoplastic proliferation of ovarian stromal cells. Stromal hyperthecosis is defined as the presence of luteinized stromal cells at a distance from the follicles (222). Stromal hyperplasia, which is typically seen in patients between 60 and 80 years of age, may be associated with HA, endometrial carcinoma, obesity, hypertension, and glucose intolerance (222,223). Hyperthecosis is also seen in a mild form in older patients. In patients of reproductive age, hyperthecosis may demonstrate severe clinical manifestations of virilization, obesity, and hypertension (224). Hyperinsulinemia and glucose intolerance may occur in up to 90% of patients with hyperthecosis and may play a role in the etiology of stromal luteinization and HA (76). Hyperthecosis is found in many patients with HAIR-AN syndrome.

In patients with hyperthecosis, levels of ovarian androgens, including testosterone, DHT, and androstenedione, are increased, usually in the male range. The predominant estrogen, as in PCOS, is estrone, which is derived from peripheral aromatization. The E1-to-E2 ratio is increased. Unlike in PCOS, gonadotropin levels are normal (225). Ovaries with stromal hyperthecosis have variable sonographic appearances (226).

Wedge resection for the treatment of mild hyperthecosis was successful and resulted in resumption of ovulation and a pregnancy (227). In cases of more severe hyperthecosis and high total testosterone levels, the ovulatory response to wedge resection is transient (225). In a study in which bilateral oophorectomy was used to control severe virilization, hypertension and glucose intolerance sometimes disappeared (228). When a GnRH agonist was used to treat patients with severe hyperthecosis, ovarian androgen production was dramatically suppressed (229).

Virilization During Pregnancy

Luteomas of pregnancy are frequently associated with maternal and fetal masculinization. This is not a true neoplasm but rather a reversible hyperplasia, which usually regresses postpartum. A review of the literature reveals a 30% incidence of maternal virilization and a 65% incidence of virilized female newborns in the presence of a pregnancy luteoma and maternal masculinization (230–232).

Other tumors causing virilization in pregnancy include (in descending order of frequency) Krukenberg tumors, mucinous cystic tumors, Brenner tumors, serous cystadenomas, endodermal sinus tumors, and dermoid cysts (213).

Virilizing Adrenal Neoplasms

The most common virilizing adrenal neoplasms are adrenal carcinomas. Adrenocortical

carcinomas are rare aggressive tumors that have a bimodal age incidence, with most cases presenting at ages 40 to 50 years (233). Virilization was reported in 20% to 30% of adults with functional adrenocortical carcinoma (234).

When these malignancies virilize, frequently they are associated with elevations in 11-deoxycortisol, cortisol, and DHEAS. These tumors are commonly large and often detectable on abdominal examination. Adrenal tumors that secrete androgens exclusively, whether benign or malignant, are extraordinarily rare (205,235). Modern imaging techniques, such as CT, ultrasonography, MRI, or venous sampling, are extremely useful for distinguishing between an ovarian and an adrenal tumor as a cause of virilization (233).

PROLACTIN DISORDERS

Prolactin was first identified as a product of the anterior pituitary, in 1933 (236). It is found in nearly every vertebrate species. Its presence in humans was long inferred by the association of the syndrome of amenorrhea and galactorrhea in the presence of pituitary macroadenomas, though it was not definitively identified as a human hormone until 1971. The specific activities of human prolactin (hPRL) were defined by the separation of its activity from growth hormone and subsequently by the development of radioimmunoassays (237–239). **Although the initiation and maintenance of lactation is the primary function of prolactin, many studies document roles for prolactin activity within and beyond the reproductive system.**

Prolactin Secretion

There are 199 amino acids within hPRL, with a molecular weight (MW) of 23,000 D **(Fig. 35-8)**. Although human growth hormone and placental lactogen have significant lactogenic activity, they have only a 16% and 13% amino acid sequence homology with prolactin, respectively. In the human genome, a single gene on chromosome 6 encodes prolactin. The prolactin gene (10 kb) has five exons and four introns, and its transcription is regulated in the pituitary by a proximal promotor region and in extrapituitary locations by a more upstream promotor (240).

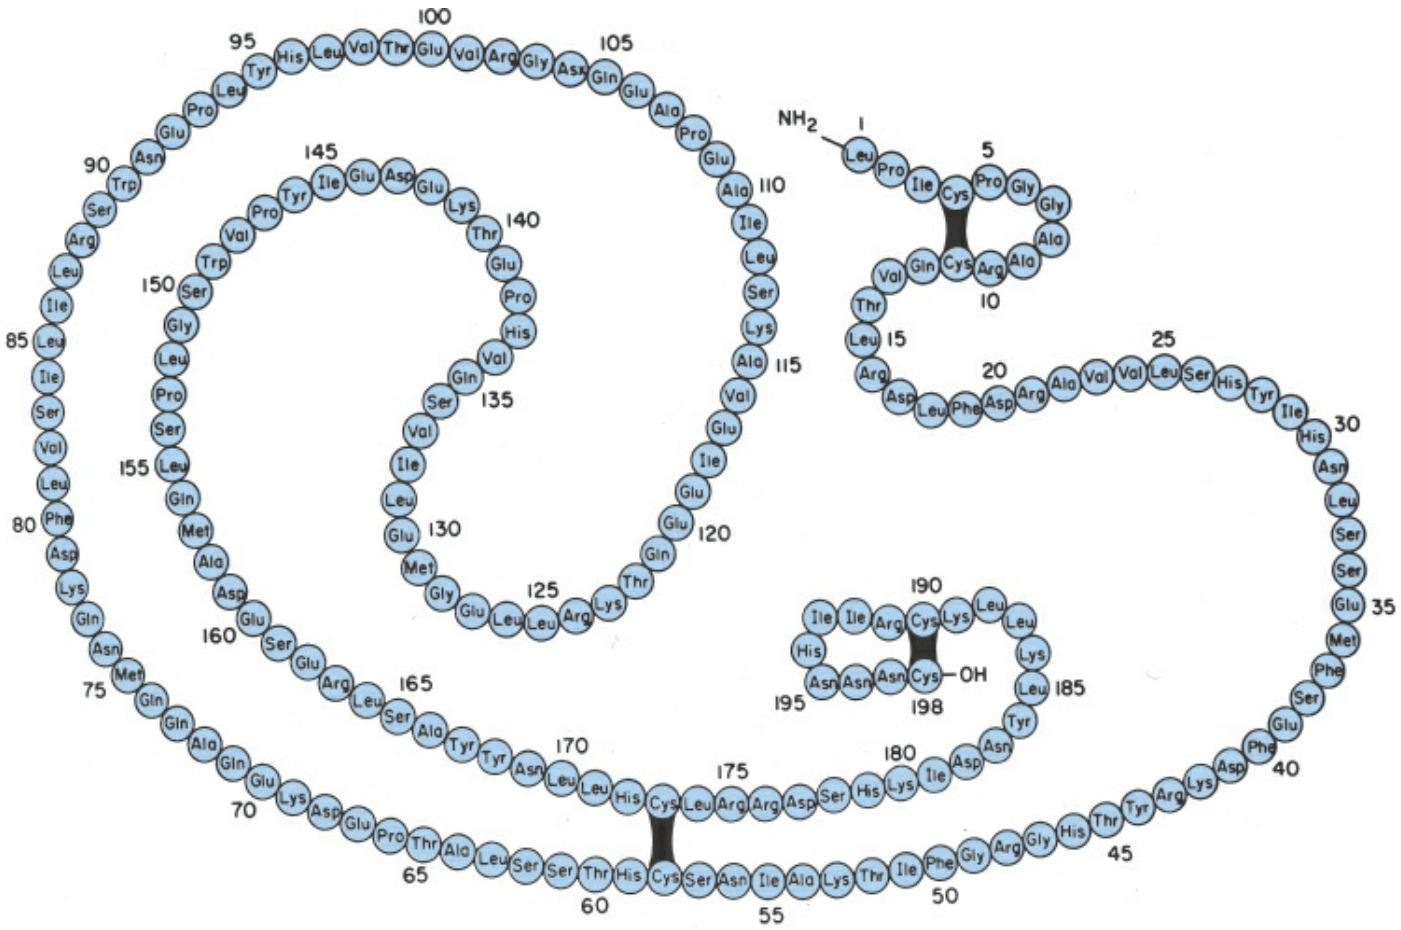

FIGURE 35-8 Amino acid sequence of prolactin. Three cysteine disulfide bands are located within the molecule. (With permission from **Bondy PK**. Rosenberg Leukocyte Esterase: Metabolic Control and Disease. 8th ed. Philadelphia, PA: WB Saunders; 1980.)

In the basal state, three forms are released: a monomer, a dimer, and a multimeric species, called little, big, and big-big prolactin, respectively (241–243). The two larger species can be degraded to the monomeric form by reducing disulfide bonds (244). The proportions of each of these prolactin species vary with physiologic, pathologic, and hormonal stimulation (244–247). The heterogeneity of secreted forms remains an active area of research. Studies indicate that little prolactin (MW 23,000 D) constitutes more than 50% of all combined prolactin production and is most responsive to extrapituitary stimulation or suppression (244,246,247). **Clinical assays for prolactin measure the little prolactin, and in all but extremely rare circumstances, these measures are sufficient to assess diseases of abnormal pituitary production of the hormone.** Prolactin, and its relatives, growth hormone and placental lactogen, do not require glycosylation for most of their primary activities, as is the case for the gonadotropins and TSH. Glycosylated forms are secreted, and glycosylation does affect the bioactivity and immunoreactivity of little prolactin (248–251). It appears that the glycosylated form is the predominant species secreted, but the most potent biologic form appears to be the 23,000-D nonglycosylated form of prolactin (250). Prolactin has over 300 known

biologic activities. Prolactin's most recognized activities include those associated with reproduction (lactation, luteal function, reproductive behavior) and homeostasis (immune responsivity, osmoregulation, and angiogenesis) (252). Despite these many activities, **the only recognized disorder associated with deficiency of prolactin secretion is the inability to lactate.**

To some degree, the physical heterogeneity of prolactin may explain the biologic heterogeneity of this hormone, and although this complicates the physiologic evaluation of prolactin's myriad effects, it is of little importance in the diagnosis and management of hyperprolactinemic states.

In contrast to other anterior pituitary hormones, which are controlled by hypothalamic-releasing factors, prolactin secretion is primarily under inhibitory control mediated by dopamine. **Multiple lines of evidence suggest that dopamine, which is secreted by the tuberoinfundibular dopaminergic neurons into the portal hypophyseal vessels, is the primary prolactin-inhibiting factor.** Dopamine receptors were found on pituitary lactotrophs, and treatment with dopamine or dopamine agonists suppresses prolactin secretion (253–259). The dopamine antagonist *metoclopramide* abolishes the pulsatility of prolactin release and increases serum prolactin levels (255,256,260). **Interference with dopamine transit from the hypothalamus to the pituitary by mass lesions, or blockade of the dopamine receptor as that occurs with antipsychotic and other medications, increases serum prolactin levels.** Thyrotropin-releasing hormone (TRH) causes prolactin release when present at supraphysiologic levels (as in primary hypothyroidism), but does not appear to play an important modulatory role in the normal physiologic regulation of prolactin secretion. GABA and other neurohormones and neurotransmitters also may function as prolactin-inhibiting factors (261–264). Several hypothalamic polypeptides that modulate prolactin-releasing activity are listed in Table 35-8. It appears that dopamine and TRH act as primary controlling neurohormones, while others (i.e., neuropeptide Y, galanin, and enkephalin) act as modulators. It is likely that under differing physiologic conditions (i.e., pregnancy, lactation, stress, aging), a modulator may become a principal regulator of hormone secretion.

The prolactin receptor is a member of the class 1 cytokine receptor superfamily and is encoded by a gene on chromosome 5 (265). Transcriptional regulation of the prolactin receptor is accomplished through three tissue-specific promoter regions: promoter I for the gonads, promoter II for the liver, and promoter III, a generic promoter that includes the mammary gland (266).

Hyperprolactinemia

Physiologic disturbances, pharmacologic agents, or markedly compromised renal function may cause elevations in prolactin levels, and transient elevations occur

with acute stress or painful stimuli. The most common cause of elevated prolactin levels is likely pharmacologic; most patients using antipsychotic medications and many other patients using agents with antidopaminergic properties will exhibit moderately elevated prolactin levels. Drug-related and physiologic conditions resulting in hyperprolactinemia do not always require direct intervention to normalize prolactin levels.

Table 35-8 Chemical Factors Modulating Prolactin Release and Conditions That Result in Hyperprolactinemia

Inhibitory factors
Dopamine
γ-Aminobutyric acid
Histidyl-proline diketopiperazine
Pyroglutamic acid
Somatostatin
Stimulatory factors
b-Endorphin
17b-Estradiol
Enkephalins
Gonadotropin-releasing hormone
Histamine
Serotonin

Estrogen therapy
Opiates
Reserpine
Sulpiride
Verapamil

Evaluation

Plasma levels of immunoreactive prolactin are 5 to 27 ng/mL throughout the normal menstrual cycle. Samples should not be drawn soon after the patient awakes or after procedures. Prolactin is secreted in a pulsatile fashion with a pulse frequency ranging from about 14 pulses per 24 hours in the late follicular phase to

about 9 pulses per 24 hours in the late luteal phase. There is also a diurnal variation, with the lowest levels occurring in midmorning. Levels rise 1 hour after the onset of sleep and continue to rise until peak values are reached between 5 and 7 am (267,268). The pulse amplitude of prolactin appears to increase from early to late follicular and luteal phases (269–271). Because of the variability of secretion and inherent limitations of radioimmunoassay, an elevated level should always be rechecked. This sample preferably is drawn midmorning and not after stress, previous venipuncture, breast stimulation, or physical examination, all of which transiently increase prolactin levels.

When prolactin levels are found to be elevated, hypothyroidism and medications should first be ruled out as a cause. Prolactin and TSH determinations are basic evaluations in anovulatory infertile women. Infertile men with hypogonadism also should be tested. Likewise, prolactin levels should be measured in the evaluation of amenorrhea, galactorrhea, hirsutism with amenorrhea, anovulatory bleeding, and delayed puberty **(Fig. 35-9)**.

In cases of asymptomatic, incidental hyperprolactinemia, the finding of a macroprolactin elevation will preclude further diagnostic workup and expense as big and big-big prolactin elevations are not associated with adenomas or recognized symptomatology (272).

Physical Signs of Hyperprolactinemia

[8] Elevations in prolactin may cause amenorrhea, galactorrhea, both, or neither. Amenorrhea without galactorrhea is associated with hyperprolactinemia in approximately 15% of women (273–275). The cessation of normal ovulatory processes resulting from elevated prolactin levels is primarily caused by the suppressive effects of prolactin, via hypothalamic mediation, on GnRH pulsatile release (254,273,274,276–284). In addition to causing a hypogonadotropic state, prolactin elevations may secondarily impair the mechanisms of ovulation by causing a reduction in granulosa cell number and FSH binding, inhibition of granulosa cell 17β-estradiol production by interfering with FSH action, and by causing inadequate luteinization and reduced luteal secretion of progesterone (285–290). Other etiologies for amenorrhea are detailed in Chapter 34.

Although isolated galactorrhea is considered indicative of hyperprolactinemia, prolactin levels are within the normal range in nearly 50% of such patients (291–293) **(Fig. 35-9)**. In these cases, whether caused by a prior transient episode of hyperprolactinemia or other unknown factors, the sensitivity of the breast to the lactotrophic stimulus engendered by normal prolactin levels is sufficient to result in galactorrhea. This situation is very similar to that observed in nursing mothers in whom milk secretion, once established, continues and even increases despite progressive normalization of prolactin levels. Repeat testing is occasionally helpful in detecting

hyperprolactinemia. **Approximately one-third of women with galactorrhea have normal menses. Conversely, hyperprolactinemia commonly occurs in the absence of galactorrhea (66%), which may result from inadequate estrogenic or progestational priming of the breast.**

[8] In patients with both galactorrhea and amenorrhea, approximately two-thirds will have hyperprolactinemia; in that group, approximately one-third will have a pituitary adenoma (294). In anovulatory women, 3% to 10% of women diagnosed with PCO disease have coexistent and usually modest hyperprolactinemia (295,296) **(Fig. 35-10)**.

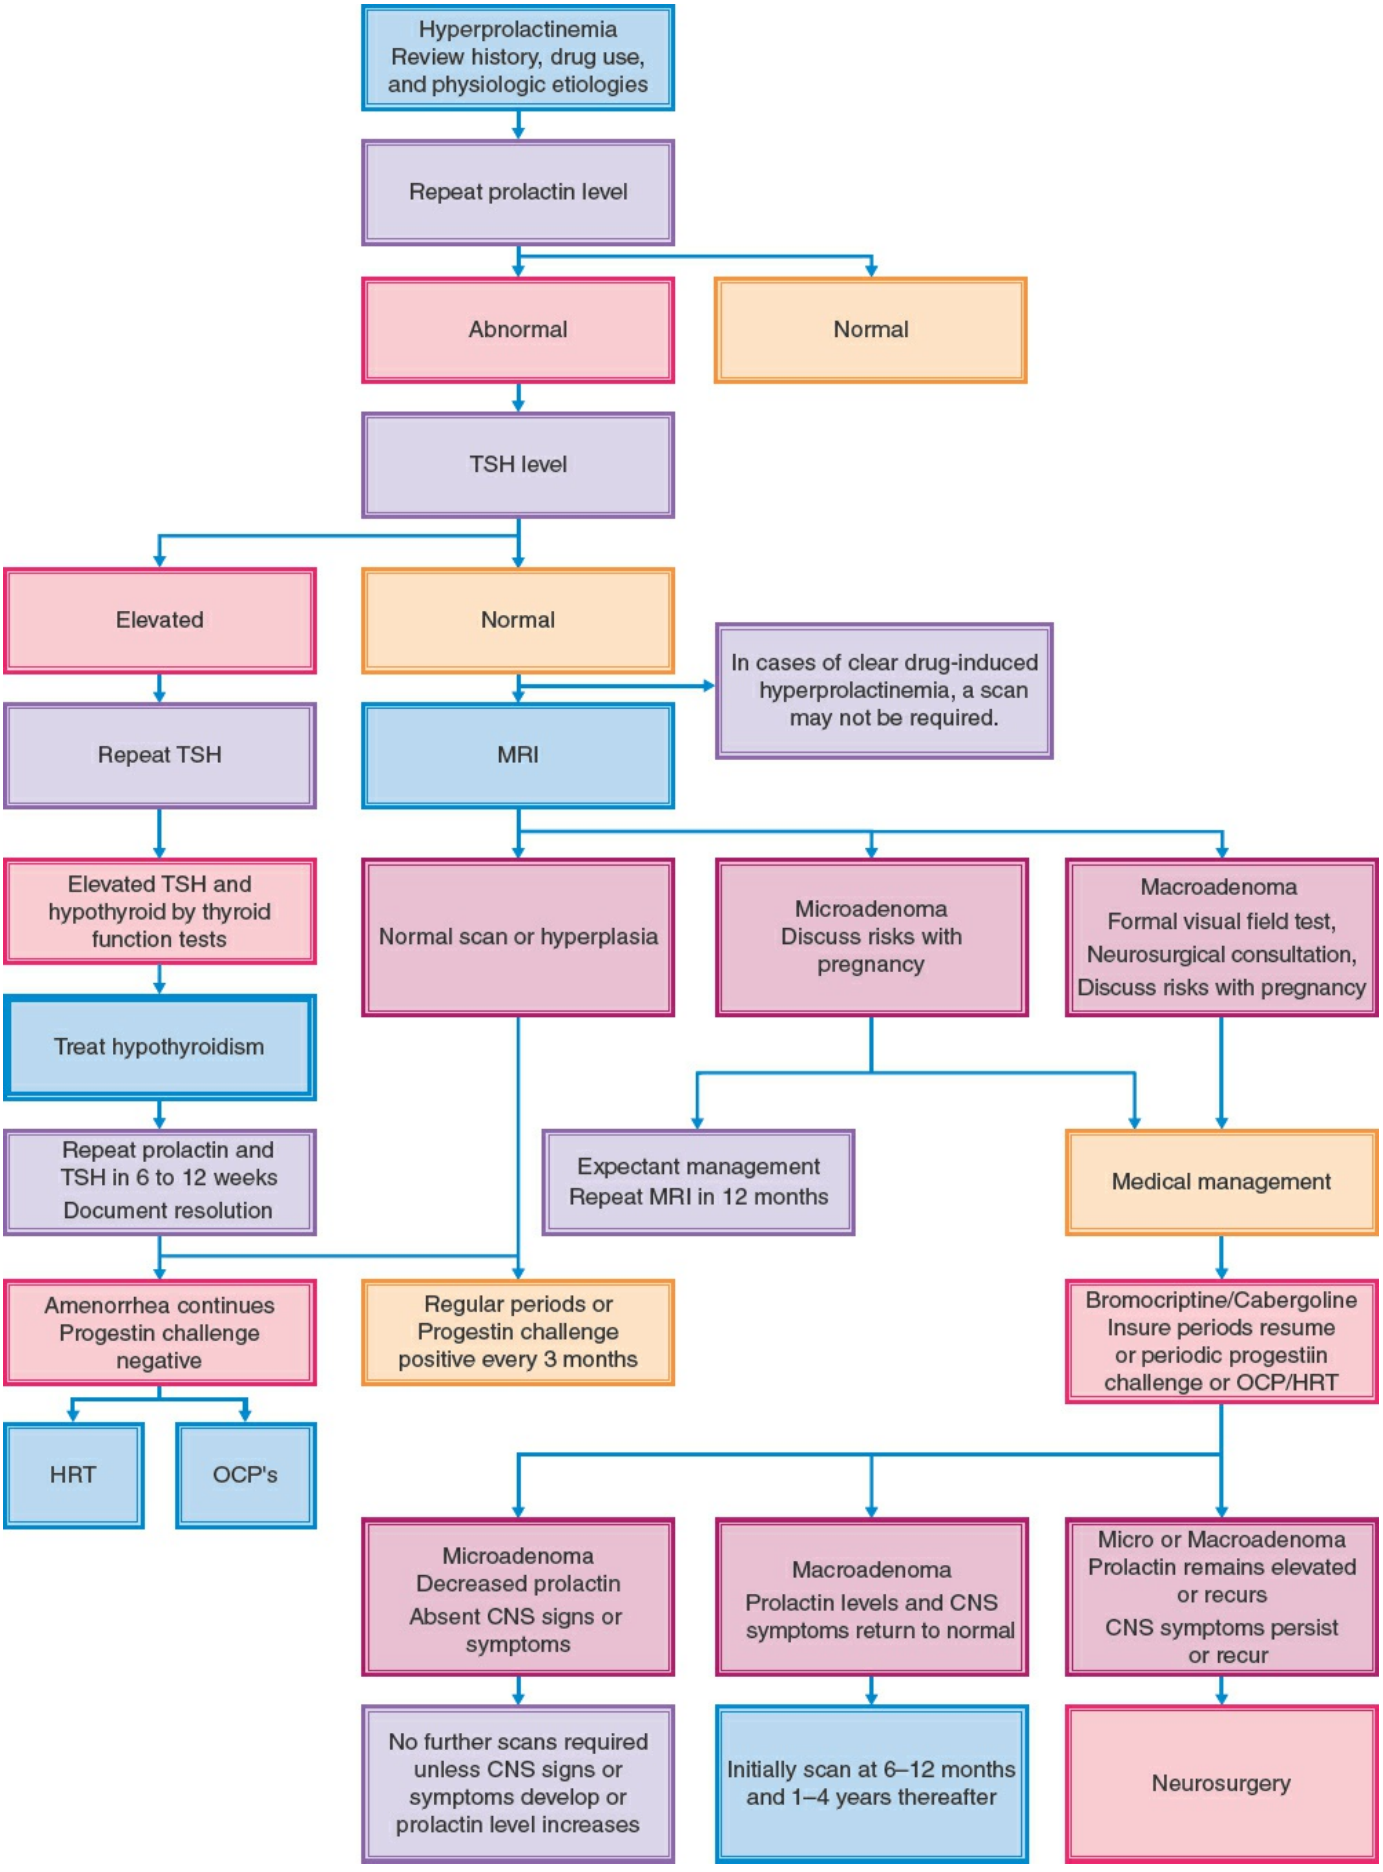
Prolactin and TSH levels should be measured in all patients with delayed puberty. Pituitary abnormalities, including craniopharyngiomas and adenomas, should be considered in all cases of delayed puberty accompanied by low levels of gonadotropins, regardless of whether prolactin levels are elevated. When prolactin-secreting pituitary adenomas are present, the condition of multiple endocrine neoplasia type 1 (MEN-1) syndrome (gastrinomas, insulinoma, parathyroid hyperplasia, and pituitary neoplasia) should be considered, although symptoms of pituitary adenoma are rarely the presenting symptom. Patients who have a pituitary adenoma and a family history of multiple adenomas warrant special attention (297). Prolactinomas are noted in approximately 20% of patients with MEN-1. The *MEN-1* gene is localized to chromosome 11q13 and appears to act as a constitutive tumor suppressor gene. An inactivating mutation results in development of the tumor. It is thought that prolactin-secreting pituitary adenomas that occur in patients with MEN-1 may be more aggressive than sporadic cases (298).

When an elevated prolactin level is documented and medications or hypothyroidism as the underlying cause is excluded, knowledge of neuroanatomy, imaging techniques, and their interpretation is essential to further evaluation (see Chapter 7). **Pituitary hyperprolactinemia is most often caused by a microadenoma or associated with normal imaging findings. These patients can be reassured that the probable course of their condition is benign. Macroadenomas or juxtasellar lesions are less common and require more complex evaluation and treatment, including surgery, radiation, or both.** Levels of TSH should be measured in all patients with hyperprolactinemia **(Fig. 35-9)**.

Imaging Techniques

In patients with larger microadenomas and macroadenomas, prolactin levels usually are higher than 100 ng/mL. However, levels lower than 100 ng/mL may be associated with smaller microadenomas, macroadenomas that produce a "stalk section" effect, and suprasellar tumors that may be missed on a "coned-down" view of the sella turcica. Modest elevations of prolactin can be associated with

microadenomas or macroadenomas, nonlactotroph pituitary tumors, and other central nervous system abnormalities. Imaging of the pituitary gland must be considered when otherwise unexplained and persistent prolactin elevation is present. **In patients with a clearly identifiable drug-induced or physiologic hyperprolactinemia, imaging is not necessary unless accompanied by symptoms suggesting a mass lesion (headache, visual field deficits).** MRI with gadolinium enhancement of the sella and pituitary gland appears to provide the best anatomic detail (299). The cumulative radiation dose from multiple CT scans may cause cataracts, and the "coned-down" views or tomograms of the sella are very insensitive and expose the patient to radiation. For patients with hyperprolactinemia who desire future fertility, MRI is indicated to differentiate a pituitary microadenoma from a macroadenoma and to identify other potential sellar-suprasellar masses. Although rare, when pregnancy-related complications of a pituitary adenoma occur, they occur more frequently in the presence of macroadenomas.



Hyperprolactinemia
Review history, drug use, and physiologic etiologies
Repeat prolactin level
Abnormal
Normal
TSH level
Elevated
Normal
In cases of clear drug-induced hyperprolactinemia, a scan may not be required.
Repeat TSH
MRI
Elevated TSH and hypothyroid by thyroid function tests
Normal scan or hyperplasia
Microadenoma
Discuss risks with pregnancy
Macroadenoma
Formal visual field test,
Neurosurgical consultation,
Discuss risks with pregnancy
Treat hypothyroidism
Repeat prolactin and TSH in 6 to 12 weeks
Document resolution
Expectant management
Repeat MRI in 12 months
Medical management
Amenorrhea continues
Progestin challenge negative
Regular periods or
Progestin challenge positive every 3 months
Bromocriptine/Cabergoline
Insure periods resume or periodic progestiin challenge or OCP/HRT
HRT
OCP's
Microadenoma
Decreased prolactin
Absent CNS signs or symptoms
Macroadenoma
Prolactin levels and CNS symptoms return to normal
Micro or Macroadenoma
Prolactin remains elevated or recurs
CNS symptoms persist or recur
No further scans required unless CNS signs or symptoms develop or prolactin level increases
Initially scan at 6–12 months and 1–4 years thereafter

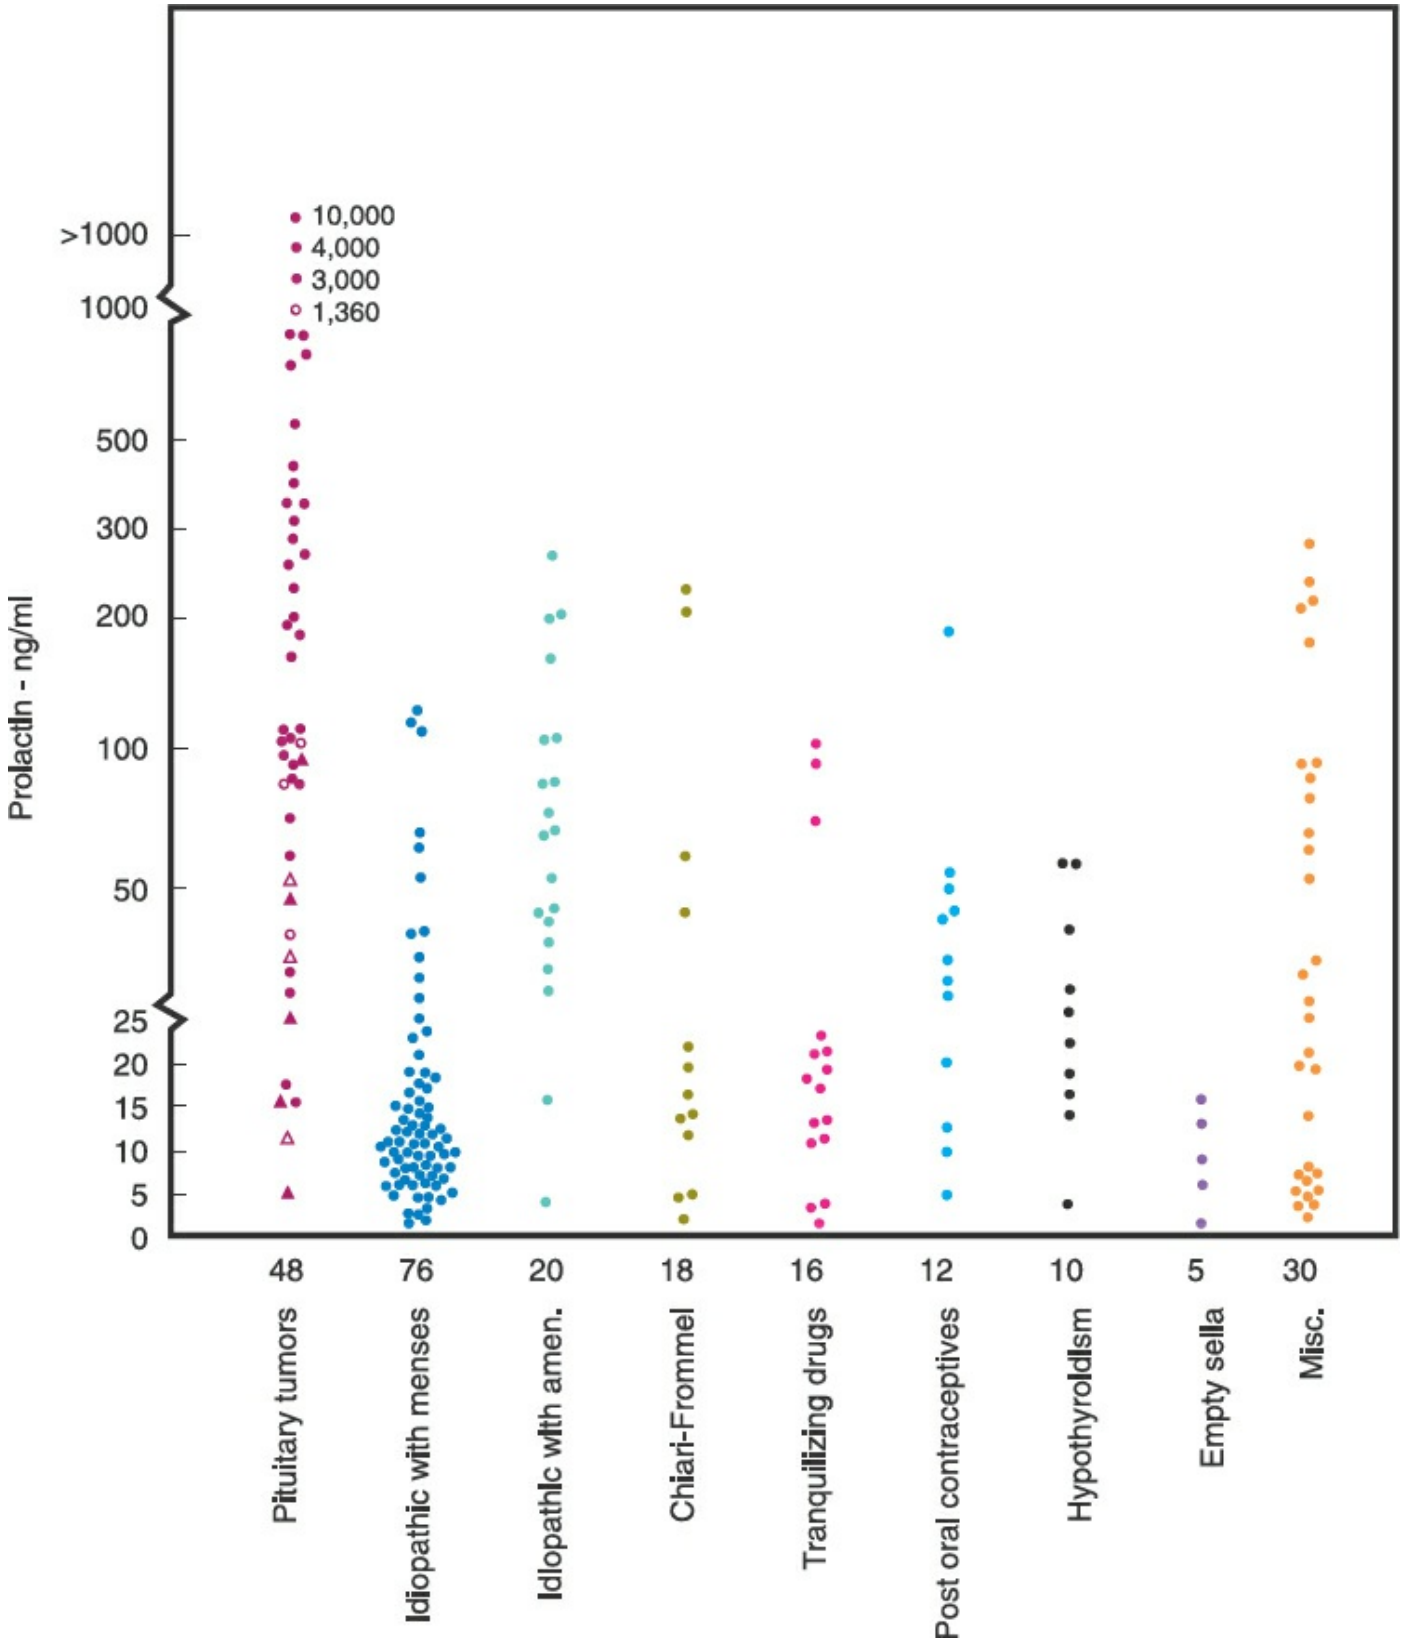

FIGURE 35-10 Prolactin levels in 235 patients with galactorrhea. Among patients with a tumor, open triangles denote associated acromegaly, and solid circles and solid triangles denote previous radiotherapy or surgical resection, respectively. (With permission from **Kleinberg DL, Noel GL, Frantz AG**. Galactorrhea: a study of 235 cases, including 48 with pituitary tumors. *N Engl J Med* 1977;296: 589–600.)

In over 90% of untreated women, microadenomas do not enlarge over a 4- to 6-year period. The argument that medical therapy will prevent a microadenoma from growing is false. While prolactin levels correlate with tumor size, both elevations and reductions in prolactin levels may occur without any change in tumor size. If during follow-up, the prolactin level rises significantly or central nervous system symptoms (headache, visual changes) are noted, repeat imaging may be indicated.

Hypothalamic Disorders

Dopamine was the first of many substances whose production was demonstrated in the arcuate nucleus. Dopamine-releasing neurons innervate the external zone of the median eminence. When released into the hypophyseal portal system, dopamine inhibits prolactin release in the anterior pituitary. **Lesions that disrupt dopamine release can result in hyperprolactinemia**. Such lesions may arise from the suprasellar area, pituitary gland, and infundibular stalk, as well as from adjacent bone, brain, cranial nerves, dura, leptomeninges, nasopharynx, and vessels. Numerous pathologic entities and physiologic conditions in the hypothalamic–pituitary region can disrupt dopamine release and cause hyperprolactinemia.

Pituitary Disorders

Microadenoma

In more than one-third of women with hyperprolactinemia, a radiologic abnormality consistent with a microadenoma (<1 cm) is found. Release of pituitary stem cell growth inhibition via activation or loss-of-function mutations results in cell cycle dysregulation and is critical to the development of pituitary microadenomas and macroadenomas. Microadenomas are monoclonal in origin. Genetic mutations are thought to release stem cell growth inhibition and result in autonomous anterior pituitary hormone production, secretion, and cell proliferation. Additional anatomic factors that may contribute to adenoma formation include reduced dopamine concentrations in the hypophyseal portal system and vascular isolation of the tumor, or both. Recently, the heparin-binding secretory-transforming (*HST*) gene has been noted in a variety of cancers and in prolactinomas (300). **Patients with microadenomas can be reassured of a probable benign course, and many of these lesions exhibit gradual spontaneous regression** (301,302).

Both microadenomas and macroadenomas are monoclonal in origin. Lactotoph adenomas are histologically granulated either sparsely or densely. The sparsely granulated lactotrope adenomas have trabecular, papillary, or solid patterns.

Calcification of these tumors may take the form of a psammoma body or a pituitary stone. Densely granulated lactotrope adenomas are strongly acidophilic tumors and appear to be more aggressive than sparsely granulated lactotrope adenomas. Unusual acidophil stem cell adenomas can be associated with hyperprolactinemia, with some clinical or biochemical evidence of growth hormone excess.

Microadenomas rarely progress to macroadenomas. Six large series of patients with microadenomas reveal that, with no treatment, the risk for progression of microadenoma to a macroadenoma is only 7% (303). Treatments include expectant, medical, or, rarely, surgical therapy. All affected women should be advised to notify their physicians of chronic headaches, visual disturbances (particularly tunnel vision consistent with bitemporal hemianopsia), and extraocular muscle palsies. Formal visual field testing is rarely helpful, unless imaging suggests compression of the optic nerves.

Autopsy and radiographic series reveal that 14.4% to 22.5% of the US population harbor microadenomas, and approximately 25% to 40% stain positively for prolactin (304). Clinically significant pituitary tumors requiring some type of intervention affect only 14 per 100,000 individuals (304).

Expectant Management

In women who do not desire fertility, expectant management can be used for microadenomas and hyperprolactinemia without an adenoma while menstrual function remains intact. Hyperprolactinemia-induced estrogen deficiency, rather than prolactin itself, is the major factor in the development of osteopenia (305). Therefore, **estrogen replacement with typical hormone replacement regimens or hormonal contraceptives is indicated for patients with amenorrhea or irregular menses. Patients with drug-induced hyperprolactinemia can be managed expectantly with attention to the risks of osteoporosis. In the absence of symptoms of pituitary enlargement, imaging may be repeated in 12 months, and if prolactin levels remain stable, less frequently thereafter, to assess further growth of the microadenoma**.

Medical Treatment

Ergot alkaloids are the mainstay of therapy. In 1985, bromocriptine was approved for use in the United States to treat hyperprolactinemia caused by a pituitary adenoma. These agents act as strong dopamine agonists, thus decreasing prolactin levels. Effects on prolactin levels occur within hours, and lesion size may decrease within 1 or 2 weeks. Bromocriptine decreases prolactin synthesis, DNA synthesis, cell multiplication, and overall size of prolactinomas. Bromocriptine treatment results in normal prolactin blood levels or return of ovulatory menses in 80% to 90% of patients.

Because ergot alkaloids, like *bromocriptine*, are excreted via the biliary tree, caution is required when using it in the presence of liver disease. The major adverse effects include nausea, headaches, hypotension, dizziness, fatigue and drowsiness, vomiting,

headaches, nasal congestion, and constipation. **Many patients tolerate *bromocriptine* when the dose is increased gradually, by 1.25 mg (one-half tablet) daily each week until prolactin levels are normal or a dose of 2.5 mg twice daily is reached. A proposed regimen is as follows: one-half tablet every evening (1.25 mg) for 1 week, one-half tablet morning and evening (1.25 mg) during the second week, one-half tablet in the morning (1.25 mg) and a full tablet every evening (2.5 mg) during the third week, and one tablet every morning and every evening during the fourth week and thereafter (2.5 mg twice a day).** The lowest dose that maintains the prolactin level in the normal range is continued (1.25 mg twice daily often is sufficient to normalize prolactin levels in individuals with levels less than 100 ng/mL). Pharmacokinetic studies show peak serum levels occur 3 hours after an oral dose, with a nadir at 7 hours. Because little detectable *bromocriptine* is in the serum by 11 to 14 hours, twice-a-day administration is required. Prolactin levels can be checked soon (6 to 24 hours) after the last dose.

One rare adverse effect of *bromocriptine* is a psychotic reaction. Symptoms include auditory hallucinations, delusional ideas, and changes in mood that quickly resolve after discontinuation of the drug (306).

Many investigators report no difference in fibrosis, calcification, prolactin immunoreactivity, or the surgical success in patients pretreated with *bromocriptine* compared with those not receiving *bromocriptine* (303).

An alternative to oral administration is the vaginal administration of *bromocriptine* tablets, which is well tolerated, and actually results in increased pharmacokinetic measures (307). *Cabergoline*, another ergot alkaloid, has a very long half-life and can be given orally twice per week. Its long duration of action is attributable to slow elimination by pituitary tumor tissue, high-affinity binding to pituitary dopamine receptors, and extensive enterohepatic recirculation.

Cabergoline, which appears to be as effective as *bromocriptine* in lowering prolactin levels and in reducing tumor size, has substantially fewer adverse effects than *bromocriptine*. Very rarely, patients experience nausea and vomiting or dizziness with *cabergoline*; they may be treated with intravaginal *cabergoline* as with *bromocriptine.* A gradually increasing dosage helps avoid the side effects of nausea, vomiting, and dizziness. *Cabergoline* at 0.25 mg twice per week is usually adequate for hyperprolactinemia with values less than 100 ng/mL. If required to normalize prolactin levels, the dosage can be increased by 0.25 mg per dose on a weekly basis to a maximum of 1 mg twice weekly.

Recent studies reveal an increased risk of cardiac valve regurgitation in patients with Parkinson disease who were treated with high doses of *cabergoline* or *pergolide* but not with *bromocriptine* (308,309). Higher doses and a longer duration of therapy were associated with a higher risk of valvulopathy. It is postulated that 5HT2b-receptor

stimulation leads to fibromyoblast proliferation (310). A recent cross-sectional study showed a higher rate of asymptomatic tricuspid regurgitation among *cabergoline*-treated patients compared with untreated patients with newly diagnosed prolactinomas and normal controls (311,312).

The demonstrated relative safety of *bromocriptine* in reproductive-aged women and during more than 2,500 pregnancies suggests *bromocriptine* is the first choice for hyperprolactinemia and micro- and macroadenomas (313).

When *bromocriptine* or *cabergoline* cannot be used, other medications such as *pergolide* or *metergoline* may be used. In patients with a microadenoma who are receiving *bromocriptine* therapy, a repeat MRI scan may be performed 6 to 12 months after prolactin levels are normal, if indicated. Normal prolactin levels and resumption of menses should not be considered absolute proof of tumor response to treatment. Further MRI scans should be performed if new symptoms appear.

Discontinuation of *bromocriptine* therapy after 2 to 3 years may be attempted in a select group of patients who have maintained normoprolactinemia while on therapy (314,315). In a retrospective series of 131 patients treated with *bromocriptine* for a median of 47 months, normoprolactinemia was sustained in 21% at a median follow-up of 44 months after treatment discontinuation (315). Discontinuation of *cabergoline* therapy was successful in patients treated for 3 to 4 years who maintained normoprolactinemia (316). In *cabergoline* discontinuers who met stringent inclusion criteria, a recurrence rate of 64% was noted (317). A meta-analysis involving 743 patients noted sustained normoprolactinemia in only a minority of patients (21%) after discontinuation. Patients with 2 years or more of therapy before discontinuation and no demonstrable tumor visible on MRI had the highest chance of persistent normoprolactinemia (318). Recurrence rates are higher for macroadenomas (as compared to microadenomas or hyperprolactinemia without adenoma) after cessation of either *bromocriptine* or *cabergoline*, warranting a close follow-up with serum prolactin and MRI after cessation of therapy. In patients with macroadenomas, withdrawal of therapy should proceed with caution, as rapid tumor re-expansion may occur.

Macroadenomas

Macroadenomas are pituitary tumors that are larger than 1 cm in size. *Bromocriptine* is the best initial and potentially long-term treatment option, but transsphenoidal surgery may be required. High-dose *cabergoline* therapy was used in *bromocriptine*-resistant or -intolerant macroadenoma patients successfully; however, cautions remain regarding the development of cardiac valve abnormalities (319).

Evaluation for pituitary hormone deficiencies may be indicated. Symptoms of macroadenoma enlargement include severe headaches, visual field changes, and, rarely, diabetes insipidus and blindness. After prolactin has reached normal levels following ergot alkaloid treatment, a repeat MRI is indicated within 6 months to document

shrinkage or stabilization of the size of the macroadenoma. This examination may be performed earlier if new symptoms develop or if there is no improvement in previously noted symptoms. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment, particularly with a macroadenoma.

Medical Treatment

Treatment with *bromocriptine* decreases prolactin levels and the size of macroadenomas; nearly one-half show a 50% reduction in size, and another one-fourth show a 33% reduction after 6 months of therapy. Because tumor regrowth occurs in more than 60% of cases after discontinuation of *bromocriptine* therapy, long-term therapy is usually required.

After stabilization of tumor size is documented, the MRI scan is repeated 6–12 months later and, if stable, yearly for several years. This examination may be performed earlier if new symptoms develop or if there is no improvement in symptoms. Serum prolactin levels are measured every 6 months. Because tumors may enlarge despite normalized prolactin values, a reevaluation of symptoms at regular intervals (6 months) is prudent. Normalized prolactin levels or resumption of menses should not be taken as absolute proof of tumor response to treatment (318,320).

Surgical Intervention

Tumors that are unresponsive to *bromocriptine* or that cause persistent visual field loss require surgical intervention. Some neurosurgeons have noted that a short (2- to 6-week) preoperative course of *bromocriptine* increases the efficacy of surgery in patients with larger adenomas (303). Despite surgical resection, recurrence of hyperprolactinemia and tumor growth is common. Complications of surgery include cerebral carotid artery injury, diabetes insipidus, meningitis, nasal septal perforation, partial or panhypopituitarism, spinal fluid rhinorrhea, and third nerve palsy. Periodic MRI scanning after surgery is indicated, particularly in patients with recurrent hyperprolactinemia.

Metabolic Dysfunction and Hyperprolactinemia

Occasionally, patients with hypothyroidism exhibit hyperprolactinemia with remarkable pituitary enlargement caused by thyrotroph hyperplasia. These patients respond to thyroid replacement therapy with reduction in pituitary enlargement and normalization of prolactin levels (321).

Hyperprolactinemia occurs in 20% to 75% of women with chronic renal failure. Prolactin levels are not normalized through hemodialysis but are normalized after transplantation (322–324). Occasionally, women with hyperandrogenemia also have hyperprolactinemia. Elevated prolactin levels may alter adrenal function by enhancing the release of adrenal androgens such as DHEAS (325).

Drug-Induced Hyperprolactinemia

Numerous drugs interfere with dopamine secretion and can be responsible for hyperprolactinemia and its attendant symptoms (Table 35-8). If medication can be discontinued, resolution of hyperprolactinemia is uniformly prompt. If not, endocrine management should be directed at estrogen replacement and normalization of menses for those with disturbed or absent ovulation. Treatment with dopamine agonists may be utilized if ovulation is desired and the drug-inducing hyperprolactinemia cannot be discontinued.

Use of Estrogen in Hyperprolactinemia

In rodents, pituitary prolactin-secreting adenomas occur with high-dose estrogen administration (326). Elevated levels of estrogen, as found in pregnancy, are responsible for hypertrophy and hyperplasia of lactotrophic cells and account for the progressive increase in prolactin levels in normal pregnancy. The increase in prolactin during pregnancy is physiologic and reversible; adenomas are not fostered by the hyperestrogemia of pregnancy. Pregnancy may have a favorable influence on preexisting prolactinomas (327,328). Estrogen administration is not associated with clinical, biochemical, or radiologic evidence of growth of pituitary microadenomas or the progression of idiopathic hyperprolactinemia to an adenoma status (329–332). **For these reasons, estrogen replacement or OC use is appropriate for hypoestrogenic patients with hyperprolactinemia secondary to microadenoma or hyperplasia.**

Monitoring Pituitary Adenomas During Pregnancy

Prolactin-secreting microadenomas rarely create complications during pregnancy. Monitoring of patients with serial gross visual field examinations and funduscopic examination is recommended. If persistent headaches, visual field deficits, or visual or funduscopic changes occur, MRI scanning is advisable. **Because serum prolactin levels progressively rise throughout pregnancy, prolactin measurements are rarely of value.**

For those women who become pregnant while taking bromocriptine to treat a return of spontaneous ovulations, discontinuation of bromocriptine is recommended. This does not preclude subsequent use of *bromocriptine* during the pregnancy to treat symptoms (visual field defects, headaches) that arise from further enlargement of the microadenoma (313,333–335). *Bromocriptine* did not exhibit teratogenicity in animals, and observational data do not suggest harm to pregnancy or fetus in humans.

Pregnant women with previous transsphenoidal surgery for microadenomas or macroadenomas may be monitored with monthly Goldman perimetry visual field testing. Periodic MRI scanning may be necessary in women with symptoms or visual changes. **Breastfeeding is not contraindicated in the presence of microadenomas or**

macroadenomas (313,333–335). The use of *bromocriptine* and presumably other dopaminergic agents that may cause blood pressure elevation during the postpartum period is contraindicated (336–340).

THYROID DISORDERS

Thyroid disorders are 10 times more common in women than men. Approximately 1% of the female population of the United States will develop overt hypothyroidism (341). Even prior to the discovery of the long-acting thyroid stimulator (LATS) in women with Graves disease in 1956, numerous investigations demonstrated a link between these autoimmune thyroid disorders and reproductive physiology and pathology (342).

Thyroid Hormones

Iodide is a critical component of the class of hormones known as thyronines, among which the most important are triiodothyronine (T_3) and thyroxine (T_4). Iodide obtained from dietary sources is actively transported into the thyroid follicular cell for the synthesis of these hormones. The sodium–iodide symporter (NIS) is a key molecule in thyroid function. It allows the accumulation of iodide from the circulation into the thyrocyte against an electrochemical gradient. The NIS requires energy that is supplied by Na-K ATPase, and iodine uptake is stimulated by TSH or thyrotropin. The enzyme thyroid peroxidase (TPO) then oxidizes iodide near the cell-colloid surface and incorporates it into tyrosyl residues within the thyroglobulin molecule, which results in the formation of monoiodotyrosine (MIT) and diiodotyrosine (DIT). T_3 and T_4, formed by secondary coupling of MIT and DIT, are catalyzed by TPO. The membrane-bound, heme-containing oligomer, TPO, is localized in the rough endoplasmic reticulum, Golgi vesicles, lateral and apical vesicles, and on the follicular cell surface. Thyroglobulin, the major protein formed in the thyroid gland, has an iodine content of 0.1% to 1.1% by weight. About 33% of the iodine is present in thyroglobulin in the form of T_3 and T_4, and the remainder is present in MIT and DIT or found as unbound iodine. Thyroglobulin provides a storage capacity capable of maintaining a euthyroid state for nearly 2 months without the formation of new thyroid hormones. The thyroid antimicrosomal antibodies found in patients with autoimmune thyroid disease (ATD) are directed against the TPO enzyme (343,344).

TSH regulates thyroidal iodine metabolism by activation of adenylate cyclase. This facilitates endocytosis as a component of iodide uptake, digestion of thyroglobulin-containing colloid, and the release of thyroid hormones T_4, T_3, and reverse T_3. T_4 is released from the thyroid at 40 to 100 times the concentration of T_3. The concentration of reverse T_3, which has no intrinsic thyroid activity, is 30% to 50% of T_3 and 1% of T_4 concentration. Of thyroid hormones released, 70% are bound by circulating thyroid-binding globulin (TBG). T_4 is present in higher concentrations in the circulating storage pool and has a slower turnover rate than T_3. Approximately 30% of T_4 is converted to

T_3 in the periphery. Reverse T_3 participates in regulation of the conversion of T_4 to T_3. T_3 is the primary physiologically functional thyroid hormone at the cellular level. T_3 binds the nuclear receptor with 10 times the affinity of T_4. Thyroid hormone effects on cells include increased oxygen consumption, heat production, and metabolism of fats, proteins, and carbohydrates. Systemically, thyroid hormone activity is responsible for the basal metabolic rate. It balances fuel efficiency with performance. Hyperthyroid states result in excessive fuel consumption with marginal performance, while hypothyroidism reduces both fuel consumption and performance.

Iodide Metabolism

Normal function of the thyroid gland is dependent on iodine. The World Health Organization recommends 150 µg of iodine per day in women of reproductive age and 250 µg per day is recommended during pregnancy and nursing. Adequate iodination of household salt is defined as salt containing 15 to 40 mg of iodine per kilogram of salt (345).

Optimal iodine intake to prevent disease lies within a relatively narrow range around the recommended daily consumption. Extreme iodine deficiency states are associated with cretinism, goiter, and hypothyroidism, while iodine sufficiency is associated with ATD and reduced remission rates in Graves disease (346).

Risk Factors for Autoimmune Thyroid Disorders

Environmental factors associated with the occurrence of ATDs include pollutants (plasticizers, polychlorinated biphenyls) and exposure to infections such as *Yersinia enterocolitica*, coxsackie B, *Helicobacter pylori*, and hepatitis C (347,348). For reasons not entirely known, women experience a 5- to 10-fold increased incidence of ATD (349). This difference is postulated to be the result of differences in sex steroid hormone levels, differences in environmental exposures, innate differences in female and male immune systems, and inherent chromosomal differences in the sexes (350,351). The immunoglobulins produced against the thyroid are polyclonal, and the multiple combinations of various antibodies consolidate to create the clinical spectrum of ATDs that may affect health and reproductive function.

Evaluation

Thyroid Function

Measurements of free serum T_4 and T_3 are complicated by the low levels of free hormone in systemic circulation, with only 0.02% to 0.03% of T_4 and 0.2% to 0.3% of T_3 circulating in the unbound state (351). Of the T_4 and T_3 in circulation, approximately 70% to 75% is bound to TBG, 10% to 15% attached to prealbumin, 10% to 15% bound

to albumin, and a minor fraction (<5%) is bound to lipoprotein (352,353). Total thyroid measurements are dependent on levels of TBG, which are variable and affected by many conditions such as pregnancy, OC pill use, estrogen therapy, hepatitis, and genetic abnormalities of TBG. Thus, **assays for the measurement of free T_4 and T_3 are more clinically relevant than measuring total thyroid hormone levels.**

There are many different laboratory techniques to measure estimated free serum T_4 and T_3. These methods invariably measure a portion of free hormone that is dissociated from the in vivo protein-bound moiety. This is of little clinical significance assuming the same proportions are measured for all assays and considered in the calibration of the assay (354). The T_3 resin uptake (T_3 RU) test is an example of one laboratory method used to estimate free T_4 in the serum. The T_3 RU determines the fractional binding of radiolabeled T_3, which is added to a serum sample in the presence of a resin that competes with TBG for T_3 binding. The binding capacity of TBG in the sample is inversely proportional to the amount of labeled T_3 bound to the artificial resin. Therefore, a low T_3 RU indicates high TBG T_3 receptor site availability and implies high circulating TBG levels.

The free T_4 index (FTI) is obtained by multiplying the serum T_4 concentration by the T3 RU percentage, yielding an indirect estimate of the levels of free T_4:

$$T_3 \text{ RU\%} \times T_4 \text{ total} = \text{free } T_4 \text{ index.}$$

A high T_3 RU percentage indicates reduced TBG receptor site availability and high FTI and thus hyperthyroidism, whereas a low T_3 RU percentage is a result of increased TBG receptor site binding and thus hypothyroidism. Equilibrium dialysis and ultrafiltration techniques may be used to determine the free T_4 directly. Free T_4 and T_3 may also be determined by radioimmunoassay. Most available laboratory methods used for determining estimations of free T_4 are able to correct for moderate variations in serum TBG but are prone to error in the setting of large variations of serum TBG, when endogenous T_4 antibodies are present, and in the setting of inherent albumin abnormalities (352).

[9] Because most disorders of hyperthyroidism and hypothyroidism are related to dysfunction of the thyroid gland and TSH levels are sensitive to excessive or deficient levels of circulating thyroid hormone, TSH levels are used to screen for these disorders. Thyrotropin or TSH sandwich immunoassays are extremely sensitive and capable of differentiating low-normal from pathologic or iatrogenically subnormal values and elevations. TSH measurements provide the best way to screen for thyroid dysfunction and accurately predict thyroid hormone dysfunction in about 80% of cases (355). Reference values for TSH are traditionally based on the central 95% of values for healthy individuals, and some controversy exists regarding the upper limit of normal.

Values in the upper limit of normal may predict future thyroid disease (354,356). In a longitudinal study, women with positive thyroid antibodies (TPOAbs or TgAbs), the prevalence of hypothyroidism at follow-up was 12.0% (3.0% to 21.0%; 95% CI) when baseline TSH was 2.5 mU/L or less, 55.2% (37.1% to 73.3%) for TSH between 2.5 and 4.0 mU/L, and 85.7% (74.1% to 97.3%) for TSH above 4.0 mU/L (357). Physicians ordering thyrotropin values should be aware of their limitations in the setting of acute illness, central hypothyroidism, and the presence of heterophile antibodies and TSH autoantibodies. In the setting of heterophile antibodies or TSH autoantibodies, TSH values will be falsely elevated (354). In cases of central hypothyroidism, decreased sialylation of TSH results in a longer half-life and a reduction in bioactivity (358,359). TSH levels may be elevated or normal when the patient remains clinically hypothyroid in states of central hypothyroidism, and successful treatment is often associated with low or undetectable TSH levels.

Immunologic Abnormalities

Many antigen–antibody reactions affecting the thyroid gland can be detected. Antibodies to TgAb, the TSH receptor (TSHRAb), TPOAb, the NIS (NISAb), and to thyroid hormone were identified and implicated in ATD states (360). A number of recognized thyroid autoantigens are listed in **Table 35-9**. Antibody production to thyroglobulin depends on a breach in normal immune surveillance (361,362). The prevalence of thyroid autoantibodies in various autoimmune thyroid disorders is shown in **Table 35-10**.

Table 35-9 Thyroid Autoantigens

Antigen	Location	Function
Thyroglobulin (Tg)	Thyroid	Thyroid hormone storage
Thyroid peroxidase (TPO) (microsomal antigen)	Thyroid	Transduction of signal from TSH
TSH receptor (TSHR)	Thyroid, lymphocytes, fibroblasts, adipocytes (including retro-orbital), and cancers	Transduction of signal from TSH
Na^+/I^- symporter (NIS)	Thyroid, breast, salivary or lacrimal gland, gastric or colonic mucosa, thymus, pancreas	ATP-driven uptake of I^- along with Na^+

TSH, thyroid-stimulating hormone; ATP, adenosine triphosphate.

Table 35-10 Prevalence of Thyroid Autoantibodies in Autoimmune Thyroid Disorders

	Hypothyroid		
Antibody	**General**	**Autoimmune**	**Graves**

	Population	Thyroiditis	Disease
Antithyroglobulin (TgAb)	3%	35–60%	12–30%
Antimicrosomal thyroid peroxidase (TPOAb)	10–15%	80–99%	45–80%
Anti-TSH receptor (TSHRAb)	1–2%	6–60%	70–100%
Anti-Na/I symporter (NISAb)	0%	25%	20%

TSH, thyroid-stimulating hormone.

Antithyroglobulin antibodies are predominantly in the noncomplement fixing, polyclonal, immunoglobulin-G (IgG) class. Antithyroglobulin antibodies are found in 35% to 60% of patients with hypothyroid autoimmune thyroiditis, 12% to 30% of patients with Graves disease, and 3% of the general population (363–365). Antithyroglobulin antibodies are associated with acute thyroiditis, nontoxic goiter, and thyroid cancer (360).

Previously referred to as antimicrosomal antibodies, TPO antibodies are directed against TPO and are found in Hashimoto thyroiditis, Graves disease, and postpartum thyroiditis. The antibodies produced are characteristically cytotoxic, complement-fixing IgG antibodies. In patients with thyroid autoantibodies, 99% will have positive anti-TPO antibodies, whereas only 36% will have positive antithyroglobulin antibodies, making anti-TPO a more sensitive test for ATD (365). Anti-TPO antibodies are present in 80% to 99% of patients with hypothyroid autoimmune thyroiditis, 45% to 80% of patients with Graves disease, and 10% to 15% of the general population (364–366). These antibodies can cause artifact in the measurement of thyroid hormone levels. Antithyroid peroxidase (anti-TPO) antibodies are used clinically in the diagnosis of Graves disease, the diagnosis of chronic autoimmune thyroiditis, in conjunction with TSH testing as a means to predict future hypothyroidism in subclinical hypothyroidism, and to assist in the diagnosis of autoimmune thyroiditis in euthyroid patients with goiter or nodules (360).

Another group of antibodies important in ATD bind the TSH receptor (TSHR). The TSHR belongs to the family of G-protein–coupled receptors. TSHRAb are pathogenic and capable of activating (TSI) or blocking (TBI) TSHR functions. TBIs are detectable in two varieties: those that block TSH binding and those that block prereceptor and postreceptor processes. Several investigators have detected such blocking antibodies in patients with primary hypothyroidism and atrophic thyroid glands (367,368). The nomenclature and detection assay of TSHRAb are listed in Table 35-11. Anti-TSH receptor antibodies were reported in 6% to 60% of patients with hypothyroid autoimmune thyroiditis, 70% to 100% of patients with Graves disease, and 1% to 2% of the general population (369–373). Untreated Graves disease patients tested with third-generation immunometric assays are uniformly positive (374). TSHRAb are classified

as binding inhibitory immunoglobulins by competitive binding assays (TBII); and in functional assays: stimulating (TSI)—which possesses capacity to increase cyclic adenosine monophosphate (cAMP) production; blocking (TBI)—which possesses the capacity to reduce TSH effects; and, neutral (TNI)—with no effect on TSH binding or alteration of cAMP levels. A number of competitive and functional assays are available to determine the levels of each antibody type, which, in toto, correlate with severity of disease, extraglandular signs, risk of fetal effects, and chances for remission and recurrence. TSHRAb are used clinically to distinguish postpartum thyroiditis from Graves disease, to predict the risk of fetal and neonatal thyrotoxicosis in women with prior ablative treatment or current thionamide therapy in the setting of Graves disease, and in the diagnosis of euthyroid Graves opthalmopathy (360). These assays will increasingly optimize individual patient testing and treatment (375).

Table 35-11 Nomenclature of Anti-TSH Receptor Antibodies

Abbreviation	Term	Assay Used	Refers To
LATS	Long-acting thyroid stimulator	In vivo assay of stimulation of mouse thyroid	Original description of serum molecule able to stimulate mouse thyroid; no longer used
TSHRAb, TRAb	TSHR antibodies	Competitive and functional assays described below	All antibodies recognizing the TSH receptor (includes TBII (competitive) and TSI, TBI, and TNI (competative) based on assay method)
TBII	TSHR-binding inhibitory immunoglobulin	Competitive binding assays with TSH	Antibodies able to compete with TSH for TSH receptor binding irrespective of biologic activity
TSI (also TSAb)	TSHR-stimulating immunoglobulins	Competitive and functional bioassays of TSH receptor activation	Antibodies able to block TSH receptor binding, induce cAMP production, and nonclassical signaling cascades
TBI (also TSBAb, TSHBAb)	TSHR stimulation-blocking antibodies	Functional bioassays of TSH receptor activation	Antibodies able to block TSH receptor binding, induce cAMP production with ± effects on nonclassical cascades
TNI	TSHR nonbinding immunoglobulin	Binding and functional assays	No TSH binding, no effect on cAMP levels, and variable effects on nonclassical cascades

TSH, thyroid-stimulating hormone.

Antibodies to the NIS are prevalent in a number of thyroid conditions. Anti-NISAbs were detected in 24% of patients with Hashimoto disease and 22% of patients with Graves disease (376). Anti-NISAbs are used experimentally (360).

Autoimmune Thyroid Disease

The most common thyroid abnormalities in women, autoimmune thyroid disorders, represent the combined effects of the multiple thyroid autoantibodies (377). The various antigen–antibody reactions result in the wide clinical spectrum of these disorders. Transplacental transmission of some of these immunoglobulins may affect thyroid function in the fetus. The presence of autoimmune thyroid disorders, particularly Graves disease, is associated with other autoimmune conditions: Hashimoto thyroiditis, Addison disease, ovarian failure, rheumatoid arthritis, Sjögren syndrome, diabetes mellitus (type 1), vitiligo, pernicious anemia, myasthenia gravis, and idiopathic thrombocytopenic purpura. Other factors that are associated with the development of autoimmune thyroid disorders include low birth weight, iodine excess and deficiency, selenium deficiency, parity, OC pill use, reproductive age span, fetal microchimerism, stress, seasonal variation, allergy, smoking, radiation damage to the thyroid, and viral and bacterial infections (378).

Recommendations for Testing and Treatment

Overt and subclinical hypothyroidism are defined as an elevated TSH with a low T_4 and an elevated TSH and normal T_4, respectively, using appropriate patient ranges (nonpregnant and pregnant). A number of professional organizations published various recommendations for thyroid function assessment via a TSH in women. Because of the long interval from development of disease to diagnosis, the nonspecific nature of symptoms, and the potential adverse neonatal and maternal outcomes associated with untreated hypothyroidism in pregnancy, the American Association of Clinical Endocrinologists (AACE) recommended screening women prior to conceiving or at the first prenatal appointment (379,380). The AACE recommended screening for the presence of hypothyroidism in patients with type 1 diabetes mellitus (3-fold increased risk of postpartum thyroid dysfunction and 33% prevalence overall) and patients taking lithium therapy (35% prevalence), and consideration of testing in patients presenting with infertility (>12% prevalence) or depression (10% to 12% prevalence), as these populations are at an increased risk of hypothyroidism (380). **A screening TSH was recommended in women starting at the age of 50 because of the increased prevalence of hypothyroidism in this population** (381). Thyroid function testing at 6-month intervals was recommended for patients taking *amiodarone*, as hyperthyroidism or hypothyroidism occurs in 14% to 18% of these patients (380). Any woman with a history of postpartum thyroiditis should be offered annual surveillance of thyroid function, as 50% of these patients will develop hypothyroidism within 7 years of diagnosis (382). Because there is a high prevalence of hypothyroidism in women with Turner and Down syndromes, an annual check of thyroid function is recommended for these patients (383,384).

Alternatively, the Endocrine Society's clinical practice guidelines regarding the management of thyroid dysfunction during pregnancy and postpartum recommends targeted screening for the following individuals: history of thyroid disorder, family history of thyroid disease, goiter, thyroid autoantibodies, clinical signs or symptoms of thyroid disease, autoimmune disorders, infertility, head and/or neck radiation, and preterm delivery (385). The American Congress of Obstetricians and Gynecologists accepted these recommendations for TSH testing (386). Because of the (i) potentially significant neurologic effects on the fetus and other adverse pregnancy events, (ii) physiologic rise in TBG and the hCG like activity of TSH in pregnancy, and (iii) potential for the targeted screening groups to have overt or subclinical hypothyroidism defined by the reference ranges for pregnancy (TSH <2.5, 3.1, and 3.5 mU/L for the first, second, and third trimesters, respectively), targeted maternal testing for hypothyroidism is encouraged. The targeted screening protocol allows that 30% of subclinical hypothyroidism cases may be missed. According to these recommendations, preconceptionally diagnosed hypothyroid women (overt or subclinical) should have their T_4 dosage adjusted such that the TSH value is less than 2.5 mU/L before pregnancy. The T_4 dosage in women already on replacement will routinely require a dose escalation (30% to 50%) at 4 to 6 weeks gestation in order to maintain a TSH value less than 2.5 mU/L. Pregnant women with overt hypothyroidism should be normalized as rapidly as possible to maintain TSH at less than 2.5 and 3 mU/L in the first, second, and third trimesters, respectively. Euthyroid women with thyroid autoantibodies are at risk of hypothyroidism and should have TSH screening in each trimester. After delivery, hypothyroid women need a reduction in T_4 dosage used during pregnancy. Because subclinical hypothyroidism is associated with adverse outcomes for the mother and the fetus, T_4 replacement is recommended. The American Thyroid Association (ATA) has recommended an alternative approach that states that therapy may be considered for TPO antibody-positive women with TSH concentrations greater than 2.5 mU/L. Treatment is also recommended for TPO antibody-negative women with TSH concentrations greater than 4 mU/L. The ATA does not recommend *levothyroxine* therapy for TPO antibody-negative women with a TSH less than 4.0 mU/L (387).

Hashimoto Thyroiditis

Hashimoto thyroiditis, or chronic lymphocytic thyroiditis, was first described in 1912 by Dr. Hakaru Hashimoto. Hashimoto thyroiditis can manifest as hyperthyroidism, hypothyroidism, euthyroid goiter, or diffuse goiter. High levels of antimicrosomal and antithyroglobulin antibody are usually present, and TSHRAb may also be present (365,388,389). Hashimoto thyroiditis is characterized by a direct T-cell attack on the thyroid gland, leading to thyroiditis and subsequent exposure of thyroid antigens (TPO and thyroglobulin) against which antibodies are produced. Thyroglobulin antibodies (TgAbs) and thyroid peroxidase antibodies (TPOAbs) are commonly associated with a

destructive pattern and are considered diagnostic for this disease. In any iodine-sufficient population, however, the prevalence of TPOAbs and TgAbs is much higher than that of clinical disease, amounting to approximately 15% to 25%, with the highest prevalence found in females and increasing with age. Typically, glandular hypertrophy is found, but atrophic forms are also present. Three classic types of autoimmune injury are found in Hashimoto thyroiditis: (i) complement-mediated cytotoxicity, (ii) antibody-dependent cell-mediated cytotoxicity, and (iii) stimulation or blockade of hormone receptors, which results in hypo- or hyperfunction or growth (Fig. 35-11).

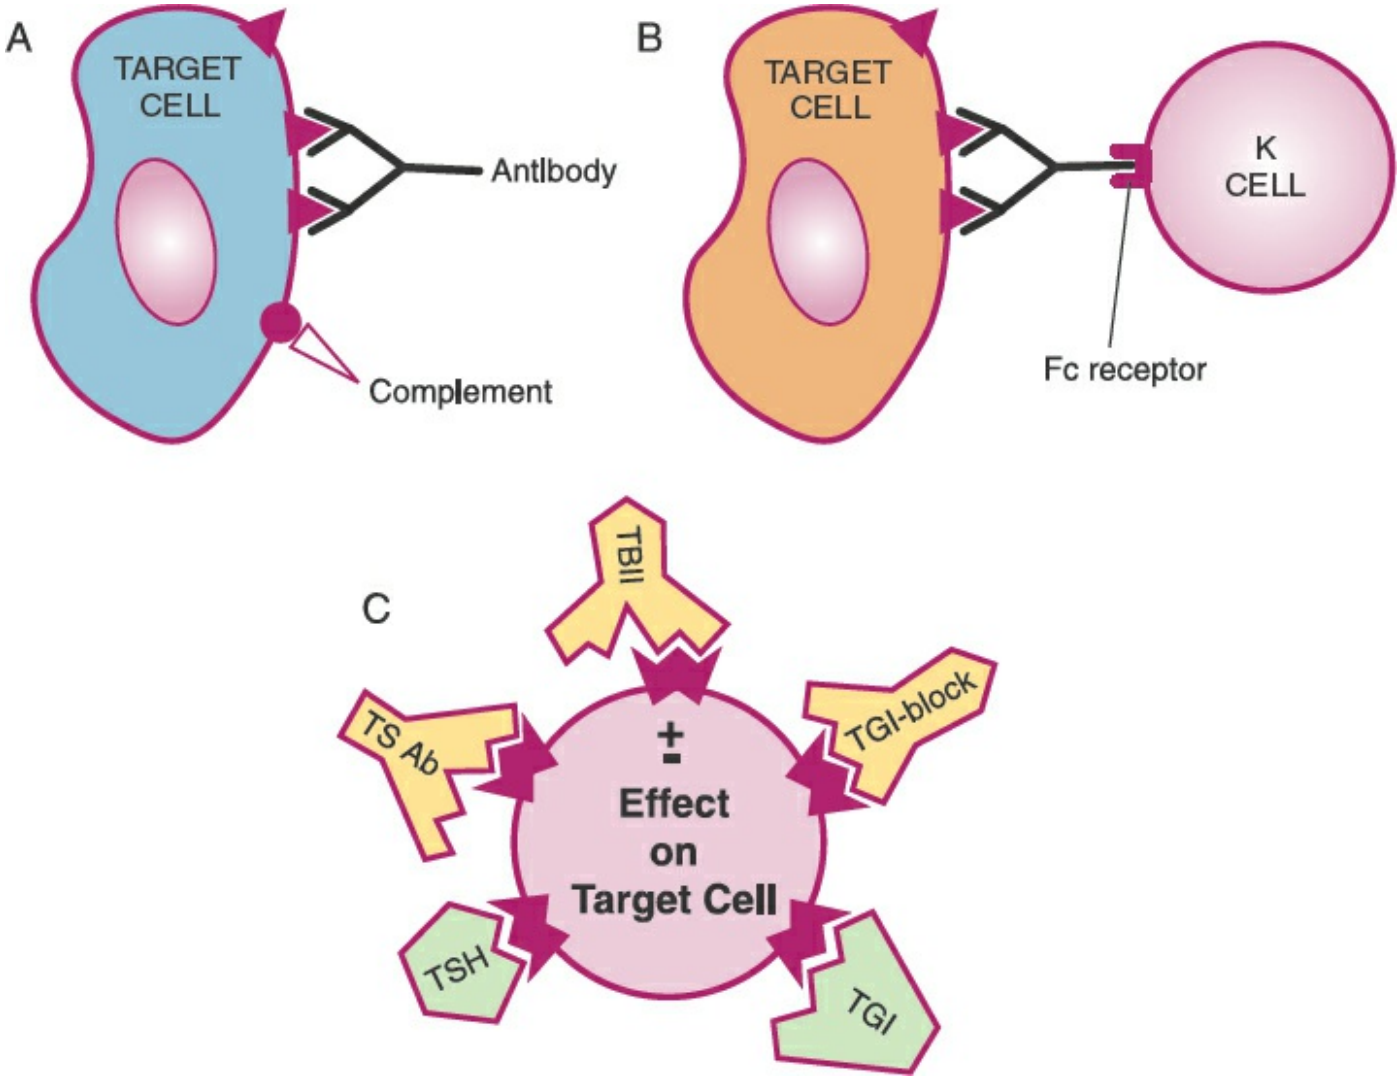

FIGURE 35-11 Types of autoimmune injury found in Hashimoto thyroiditis. **A:** Complement-mediated cytotoxicity, which can be abolished by inactivating the complement system. **B:** Antibody-dependent cell-mediated cytotoxicity (ADCC) function through killer T cells, monocytes, and natural killer cells that have immunoglobulin G fragment receptors. **C:** Stimulation of blockade of hormone receptors leading to hyperfunction or hypofunction or growth, depending on the types of immunoglobulins acting on the target cell. TBII, TSH-binding inhibitor immunoglobulin; TGI, thyroid growth–promoting immunoglobulin; TSAb, thyroid-stimulating antibodies; TSH, thyroid-stimulating hormone. (From IMMUNOLOGICAL OBSTETRICS, edited by W.B. Coulam et al. Copyright © 1992 by W.W. Norton & Company Inc. Used by permission of W. W. Norton & Company, Inc.)

The histologic picture of Hashimoto thyroiditis includes cellular hyperplasia, disruption of follicular cells, and infiltration of the gland by lymphocytes, monocytes, and plasma cells. Occasionally, adjacent lymphadenopathy may be noted. Some epithelial cells are enlarged and demonstrate oxyphilic changes in the cytoplasm (Askanazy cells or Hürthle cells, which are not specific to this disorder). The interstitial cells show fibrosis and lymphocytic infiltration. Graves disease and Hashimoto thyroiditis may cause very similar histologic findings manifested by a similar mechanism of injury.

Clinical Characteristics and Diagnosis of Hashimoto Thyroiditis

Patients with Hashimoto thyroiditis may present with typical symptoms of hypothyroidism or may be relatively asymptomatic. Patients often present with a goiter, which can involve the parietal lobe. At later stages of the disease, hypothyroidism can be found without a goiter. Notable clinical manifestations associated with Hashimoto thyroiditis include fatigue, weight gain, hyperlipidemia, dry hair, dry skin, cold intolerance, depression, menstrual irregularities, bradycardia, and or memory impairment. Hashitoxicosis, the hyperthyroid manifestation of Hashimoto thyroiditis, may occur after a hypothyroid state and development into a euthyroid or hyperthyroid state and is thought to be the result of development of TSH-stimulating antibodies (TSI) associated with Graves disease (380). This variant is estimated to occur in 4% to 8% of patients with Hashimoto thyroiditis. In the setting of Hashitoxicosis, the patient requires frequent follow-up and the potential for adjustments in thyroid supplementation. These patients often become hypothyroid during the course of treatment.

In many cases, an elevated serum TSH is detected during routine screening. Elevated serum anti-TPO antibodies confirm the diagnosis, and free T_4 and T_3 document overt or subclinical hypothyroidism. The sedimentation rate may be elevated, depending on the course of the disease at the time of recognition. Other causes of hypothyroidism should be considered, as listed in **Table 35-12**. Progression from subclinical to clinically overt hypothyroidism is reported to vary from 3% to 20%, with a higher risk noted in patients with goiter or thyroid antibodies (341,390). Treatment of subclinical hypothyroidism is somewhat controversial, but clinical studies suggested treatment of subclinical hypothyroidism is associated with a reduction in neurobehavioral abnormalities, a reduction in cardiovascular risk factors, and an improvement in lipid profile (391,392).

Hashimoto thyroiditis is one of the most frequent autoimmune diseases and has been reported to be associated with gastric disorders in 10% to 40% of patients. About 40% of patients with autoimmune gastritis also present with Hashimoto thyroiditis. Chronic autoimmune gastritis (CAG) is characterized by the partial or complete disappearance of parietal cells leading to impairment of hydrochloric acid and intrinsic factor production. The patients develop hypochlorhydria-dependent iron-

deficient anemia, leading to pernicious anemia, and severe gastric atrophy. This entity is known as polyglandular autoimmune syndrome (393).

Table 35-12 Potential Causes of Hypothyroidism

Primary
Congenital absence of thyroid gland
External thyroid gland radiation
Familial disorders and thyroxine synthesis
Hashimoto thyroiditis
Iodine-131 ablation for Graves disease
Ingestion of antithyroid drugs
Iodine deficiency
Idiopathic myxedema (autoimmune)
Surgical removal of thyroid gland
Secondary
Hypothalamic thyrotropin-releasing hormone deficiency
Pituitary or hypothalamic tumors or disease

Treatment

Thyroxine replacement is initiated in patients with clinically overt hypothyroidism or subclinical hypothyroidism with a goiter. Regression of gland size usually does not occur, but treatment often prevents further growth of the thyroid gland. Treatment is recommended for patients with subclinical hypothyroidism in the setting of a TSH greater than 10 mIU/L on repeat measurements, pregnant patients, a strong habit of tobacco use, signs or symptoms associated with thyroid failure, or patients with severe hyperlipidemia (394). All pregnant patients with an elevated TSH level should be treated with *levothyroxine*. Treatment does not slow progression of the disease. The initial dosage of *levothyroxine* may be as little as 12.5 µg per day up to a full replacement dose. The mean replacement dosage of *levothyroxine* is 1.6 µg/kg of body weight per day, although the dosage varies greatly between patients (380). Aluminum hydroxide (antacids), cholestyramine, iron, calcium, and sucralfate may interfere with absorption. *Rifampin* and *sertraline hydrochloride* may accelerate the metabolism of *levothyroxine*. The half-life of *levothyroxine* is nearly 7 days; therefore, nearly 6 weeks of treatment are necessary before the effects of a dosage change can be evaluated.

Hypothyroidism appears to be associated with decreased fertility resulting from

disruption in ovulation, and thyroid autoimmune disease is associated with an increased risk of pregnancy loss with or without overt thyroid dysfunction (395). A meta-analysis of case–control and longitudinal studies performed since 1990 reveals a possible association between miscarriage and thyroid antibodies with an odds ratio of 2.73 (95% CI 2.20 to 3.40). This association may be explained by a heightened autoimmune state affecting the fetal allograft or a slightly higher age of women with antibodies compared with those without antibodies (0.7 ± 1 year, $p < 0.001$) (396). Studies suggest that early subclinical hypothyroidism may be associated with menorrhagia (397).

Severe primary hypothyroidism is associated with menstrual irregularities in 23% of women, with oligomenorrhea being the most common (396). Reproductive dysfunction in hypothyroidism may be caused by a decrease in the binding activity of SHBG, resulting in increased estradiol and free testosterone as well as from hyperprolactinemia (396). The increase in prolactin levels is the result of enhanced sensitivity of the prolactin-secreting cells to TRH (with elevated TRH seen in primary hypothyroidism) and defective dopamine turnover resulting in hyperprolactinemia (398–401). Hyperprolactinemia-induced luteal phase defects are associated with less severe forms of hypothyroidism (402,403). Replacement therapy appears to reverse the hyperprolactinemia and correct ovulatory defects (404,405).

Combined thyroxine and triiodothyronine therapy is no more effective than thyroxine therapy alone, and patients with hypothyroidism should be treated with thyroxine alone (406). Treatment should target normalizing TSH values, and a daily dose of 0.012 mg up to a full replacement dose of *levothyroxine* (1.6 μg/kg of body weight per day) may be required with dosage dependent on the patient's weight, age, cardiac status, and duration and severity of hypothyroidism (380).

Graves Disease

Graves disease, characterized by exophthalmos, goiter, and hyperthyroidism, was first identified as an association of findings in 1835. A heritable specific defect in immunosurveillance by suppressor T lymphocytes is believed to result in the development of a helper T-cell population that reacts to multiple epitopes of the thyrotropin receptor. This activity induces a B-cell–mediated response, resulting in the clinical features of Graves disease (403). The TSHRAb bind to conformational epitopes in the extracellular domain of the thyrotropin receptor and are uniformly detected in patients with untreated Graves disease (404). Thus, Graves disease is primarily caused by a T-cell abnormality, but the hyperthyroidism associated with the disease is caused by the production of the pathognomonic thyrotropin receptor autoantibodies (TRAbs) produced by B cells.

Graves disease is a complex autoimmune disorder in which several genetic susceptibility loci and environmental factors are likely to play a role in the development of the disease. Human leukocyte antigen and polymorphisms in the

cytotoxic T-lymphocyte antigen 4 (*CTLA-4*) gene were established as susceptibility loci; however, the magnitude of their contributions seems to vary among patient populations and study groups. Additional loci are likely to be identified by a combination of genome-wide linkage analyses and allelic association analyses of candidate genes. The rate of concordance for Graves disease is only 20% in monozygotic twins and even lower in dizygotic twins, consistent with a multifactorial inheritance pattern highly influenced by environmental factors. Linkage analysis identified loci on chromosomes 14q31, 20q11.2, and Xq21 that are associated with susceptibility to Graves disease (407).

Clinical Characteristics and Diagnosis

The classic triad in **Graves disease** consists of exophthalmos, goiter, and hyperthyroidism. The symptoms associated with Graves disease include frequent bowel movements, heat intolerance, irritability, nervousness, heart palpitations, impaired fertility, vision changes, sleep disturbances, tremor, weight loss, and lower extremity swelling. Physical findings may include lid lag, nontender thyroid enlargement (two to four times normal), onycholysis, dependent lower extremity edema, palmar erythema, proptosis, staring gaze, and thick skin. A cervical venous bruit and tachycardia may be noted. The tachycardia does not respond to increased vagal tone produced with a Valsalva maneuver. Severe cases may demonstrate acropachy, chemosis, clubbing, dermopathy, exophthalmos with ophthalmoplegia, follicular conjunctivitis, pretibial myxedema, and vision loss.

Approximately 40% of patients with new onset of Graves disease and many of those previously treated have elevated T_3 and normal T_4 levels. Abnormal T_4 or T_3 results are often caused by protein binding changes rather than altered thyroid function; therefore, assessment of free T_4 and free T_3 is indicated in conjunction with TSH. In Graves disease, the TSH levels are suppressed, and levels may remain undetectable for some time even after the initiation of treatment. Thyroid autoantibodies, including TSI, may be useful during pregnancy to more accurately predict fetal risk of thyrotoxicosis (380). Autonomously functioning, benign thyroid neoplasms that exhibit a similar clinical picture include toxic adenomas and toxic multinodular goiter. A radioactive iodine uptake thyroid scan may help differentiate these two conditions from Graves disease. Rare conditions resulting in thyrotoxicosis include metastatic thyroid carcinoma causing thyrotoxicosis, amiodarone-induced thyrotoxicosis, iodine-induced thyrotoxicosis, postpartum thyroiditis, a TSH-secreting pituitary adenoma, an hCG-secreting choriocarcinoma, struma ovarii, and “de Quervan’s” or subacute thyroiditis (408). Factitious ingestion of thyroxine or desiccated thyroid should be considered in patients with eating disorders. Patients with thyrotoxicosis factitia demonstrate elevated T_3 and T_4, suppressed TSH, and a low serum thyroglobulin level, whereas other causes of thyroiditis and thyrotoxicosis demonstrate high levels of thyroglobulin. **Potential**

causes of hyperthyroidism are listed in Table 35-13.

Treatment

Iodine-131 Ablation

Treatment of women with hyperthyroidism of an autoimmune origin presents unique challenges to the physician who must consider the patient's needs and her reproductive plans. Because the drugs used to treat this disorder have potentially harmful effects on the fetus, special attention must be given to the use of contraception and the potential for pregnancy.

Table 35-13 Potential Causes of Hyperthyroidism

Factitious hyperthyroidism
Graves disease
Metastatic follicular cancer
Pituitary hyperthyroidism
Postpartum thyroiditis
Silent hyperthyroidism (low radioiodine uptake)
Struma ovarii
Subacute thyroiditis
Toxic multinodular goiter
Toxic nodule
Tumors secreting human chorionic gonadotropin (molar pregnancy, choriocarcinoma)

A single dose of radioactive iodine-131 is an effective cure in about 80% of cases and is the definitive treatment in nonpregnant women. Any woman of childbearing age should be tested for pregnancy before undergoing diagnostic or therapeutic administration of iodine. Ablation of a second-trimester fetal thyroid gland and congenital hypothyroidism (cretinism) from treatment during the first trimester were reported (409). Nuclear medicine professionals provide expertise in the administration of the radioactive isotope, and because the effect of the radioactive iodine is not immediate, the endocrinologist continues to provide suppressive medical treatment for 6 to 12 weeks after administration of iodine while the patient remains hyperthyroid. As early as 2 to 3 months after treatment, patients may become hypothyroid and should be supplemented with thyroxine as indicated by serum levels of free thyroid hormone levels (380). TSH testing is not sensitive for predicting thyroid function during this time as changes in TSH lag 2 weeks to several months behind thyroid function changes (380).

Failure to respond to iodine 6 months after treatment may require a repeat treatment with radioactive iodine (408). Postablative hypothyroidism develops in 50% of patients within the first year after iodine therapy and in more than 2% of patients per year thereafter.

A higher rate of miscarriage was noted in women treated with iodine therapy in the year preceding therapy, but there is no reported increase in the rate of stillbirths, preterm birth, low birth weight, congenital malformation, or death after therapy (410). Many thyroidologists and nuclear medicine specialists are willing to allow pregnancy earlier than 1 year after therapy if patients receive replacement therapy with *levothyroxine*.

Thyroid-Stimulating Receptor Antibody in Graves Disease

The level of TSHRAb of the TBII class grossly parallels the degree of hyperthyroidism as assessed by the serum levels of thyroid hormones and total thyroid volume. Studies suggest that the combination of a small goiter volume (<40 mL) and a low TBII level (<30 U/L) results in a 45% chance of remission during the 5 years after completion of a 12- to 24-month course of antithyroid drug therapy (411). In contrast, the overall rate of relapse exceeded 70% in patients with a large goiter volume (>70 mL) and a higher TBII level (>30 U/L). The subgroup of patients with larger goiters and higher TBII levels had less than a 10% chance to remain in remission in the 5 years after treatment. Although it is not necessary for the diagnosis of Graves disease, except in some cases of multinodular goiter, a TSHRAb measurement may be a useful marker of disease severity. Used in combination with other clinical factors, it may contribute to initial decisions regarding treatment. See Table 35-11 for a review of the nomenclature and assay methods for TSHRAb.

Measurements of TSHRAb (TBII category) during treatment with antithyroid drugs are predictive of subsequent outcome. In one series, 73% of TBII-negative patients had remission compared with only 28% of TBII-positive patients who achieved remission after 12 months of antithyroid drug therapy (412). The duration of a course of antithyroid drug therapy may be modified according to the TSHRAb status. In patients whose TSHRAb status became negative and antithyroid drug therapy was discontinued, the relapse rate was 41% compared with a rate of 92% for those patients who remained TSHRAb positive (413). Regardless of the rapidity of the disappearance of TSHRAb, it does seem that antithyroid drug therapy should be maintained for 9 to 12 months to minimize the risk of relapse. TSHRAb status appears to determine, in an inverse relationship, the reduction in thyroid volume after radioactive iodine therapy.

Third-generation TSHRAb assays have been developed, and their utility in evaluation and treatment monitoring is being evaluated. Some patients with Graves disease have or will develop antineutrophil cytoplasmic antibodies (ANCA) after treatment, which may be associated with small-vessel vasculitides, such as Wegener

granulomatosis and microscopic polyangiitis. Smoking appears to be an independent risk factor for relapse after medical therapy and should be considered when planning treatment.

Antithyroid Drugs

Antithyroid drugs of the thioamide class include *propylthiouracil* (*PTU*) and *methimazole*. Low doses of either agent block the secondary coupling reactions that form T_3 and T_4 from MIT and DIT. At higher doses, they also block iodination of tyrosyl residues in thyroglobulin. *PTU* additionally blocks the peripheral conversion of T_4 to T_3. Approximately one-third of patients treated by this approach alone go into remission and become euthyroid (411).

In 2009, the FDA published a warning on the use of *PTU* because of 32 reported cases of serious liver injury associated with its use (414,415). The average daily dose associated with liver failure was 300 mg, and liver failure was reported to occur anywhere from 6 days to 450 days after initiation of therapy (416). Traditionally, *PTU* was the drug of choice to treat hyperthyroidism for the duration of pregnancy because it less readily crosses the placenta, and *methimazole* was associated with an increased risk of choanal atresia and aplasia cutis (417–420). **Because of the case reports of *PTU*-related liver failure and the increased risk of birth defects associated with *methimazole* use during embryogenesis, the FDA and the Endocrine Society recommend *PTU* never be used as first-line medical treatment of hyperthyroidism for nonpregnant patients. It is recommended that its use be limited to pregnant women during the first trimester, situations where surgery or radioactive iodine treatment are contraindicated, and individuals who have developed a toxic reaction to *methimazole*** (414,416). The FDA recommends monitoring patients closely for signs and symptoms of liver injury while taking *PTU*. If liver injury is suspected, *PTU* should be promptly discontinued (414). The ATA recommends an initial dose of 100 to 600 mg per day in three divided doses with a goal to maintain T_4 in the upper limit of normal using the lowest possible dose. Minor reactions such as pruritus affect 3% to 5% of patients treated with thionamide therapy, and antihistamines may eliminate symptoms and allow continued use. Agranulocytosis is a rare and potentially fatal complication of *PTU* and *methimazole* therapy, developing in 0.2% of women treated, and it mandates immediate discontinuation of the drug (417). Agranulocytosis most commonly presents with fever and a sore throat followed by sepsis; the occurrence of fever, sore throat, or a viral-like syndrome should prompt an urgent evaluation.

***Methimazole* is the first-line drug for the treatment of hyperthyroidism, except in the first trimester of pregnancy, as it has been shown to be more effective than *PTU* at controlling severe hyperthyroidism and is associated with higher adherence rates and less toxicity** (421). The ATA recommends initial daily doses of 10 to 40 mg

per day in a single dose. Like treatment with *PTU*, the goal is to maintain a free T_4 level in the upper limits of normal using the lowest possible dose. Free T_4 levels show improvement 4 weeks after therapy, and TSH levels take 6 to 8 weeks to normalize (417). *Methimazole* use in pregnancy is associated with an 18-fold risk of fetal choanal atresia compared with the general population (95% CI 3 to 121) (422). Congenital aplasia cutis was associated with maternal use of *methimazole* during pregnancy; however, it is not known whether the risk (0.03%) is greater than that seen in the general population (423).

Studies suggest a potential role for an intrathyroid *dexamethasone* injection to prevent relapse (424). Other medical therapies include iodide and lithium, both of which reduce thyroid hormone release and inhibit the organification of iodine. Iodide leads to the secondary coupling of T_3 and T_4. Iodide inhibition of thyroid metabolism is only transient, and complete escape from inhibition occurs within 1 to 2 weeks of iodide therapy, making this useful only for acute management of severe thyrotoxicosis (408). *Lithium* may be used when *thionamide* therapy is contraindicated or in combination with *PTU* or *methimazole* (408). To avoid toxicity during treatment, serum lithium levels should be monitored. *Lithium* has been associated with fetal Ebstein anomaly, and iodide has been associated with congenital goiter; these medications should not be used in pregnant women and should be used with caution in women of reproductive age. Because of the complications related to medical therapy of hyperthyroidism, women desiring pregnancy should be counseled to strongly consider surgical treatment or radioactive iodine treatment prior to pregnancy (416).

Breastfeeding and Use of Anti-Thyroid Drugs

Studies have shown that only limited quantities of *PTU* and *methimazole* are secreted in milk, and therefore the neonatal exposure to ATD is minimal and clinically insignificant. Furthermore, a few studies, albeit small scale, have shown normal TFTs and no increased risk of malformations in neonates whose mothers received methimazole in pregnancy (425).

Surgery

Thyroidectomy was used for the treatment of Graves disease but is now rarely used unless there is a suspicion for coexisting thyroid malignancy (380). Potential candidates for surgical intervention include pregnant women refusing or not tolerating antithyroid medical therapy, pediatric patients presenting with Graves disease, or patients who refuse radioactive iodine therapy. Surgery is the most rapid and consistent method of achieving a euthyroid state in Graves disease and avoids the possible long-term risks of radioactive iodine. Surgical intervention may be considered in severe Graves ophthalmopathy. Patients should be rendered euthyroid before a thyroidectomy. The risks of surgery include postoperative hypoparathyroidism, recurrent laryngeal nerve

paralysis, routine anesthetic and surgical risks, hypothyroidism, and failure to relieve thyrotoxicosis.

β-Blockers

Propranolol occasionally is used with or without concurrent antithyroid medications before radioactive iodine or surgery to provide relief of symptoms. Larger and more frequent doses may be required because of a relative resistance to β-adrenergic antagonists in the setting of hyperthyroidism.

Thyroid Storm

Thyroid storm is an acute, life-threatening exacerbation of hyperthyroidism and should be treated as a medical emergency in an intensive care unit setting. Symptoms include tachycardia, tremor, diarrhea, vomiting, fever, dehydration, and altered mental status that may proceed to coma. Patients with poorly controlled hyperthyroidism are most susceptible. Beta-blocker agents, glucocorticoids, *PTU* (the action of which includes inhibition of T_4–T_3 conversion), and iodides are all key elements of therapy.

Hyperthyroidism in Gestational Trophoblastic Disease and Hyperemesis Gravidarum

Because of the weak TSH-like activity of hCG, conditions with high levels of hCG, such as molar pregnancy, may be associated with biochemical and clinical hyperthyroidism. Symptoms regress with removal of the abnormal trophoblastic tissue and resolution of elevated levels of hCG. In a similar fashion, **when hyperemesis gravidarum is associated with high levels of hCG, mild biochemical and clinical features of hyperthyroidism may be seen** (426,427). Gestational trophoblastic disease is reviewed in Chapter 41.

Thyroid Function in Pregnancy

Physicians should be aware of the changes in thyroid physiology during pregnancy. Pregnancy is associated with reversible changes in thyroid physiology that should be noted before diagnosing thyroid abnormalities (see **Fig. 35-12** for pregnancy-associated changes in TBG, total T_4, hCG, TSH, and free T_4) (417). Women with a history of hypothyroidism often require increased thyroxine replacement (25% to 50%) during pregnancy, and patients should have thyroid function tests performed at the first prenatal visit and during each trimester thereafter. Evidence suggests that optimal fetal and infant neurodevelopmental outcomes may require careful titration of replacement thyroxine that meets the frequently increased requirements of pregnancy (428,429). Postpartum, women should return to their prepregnancy dosage of *levothyroxine* and have a follow-up TSH checked 6 weeks postpartum.

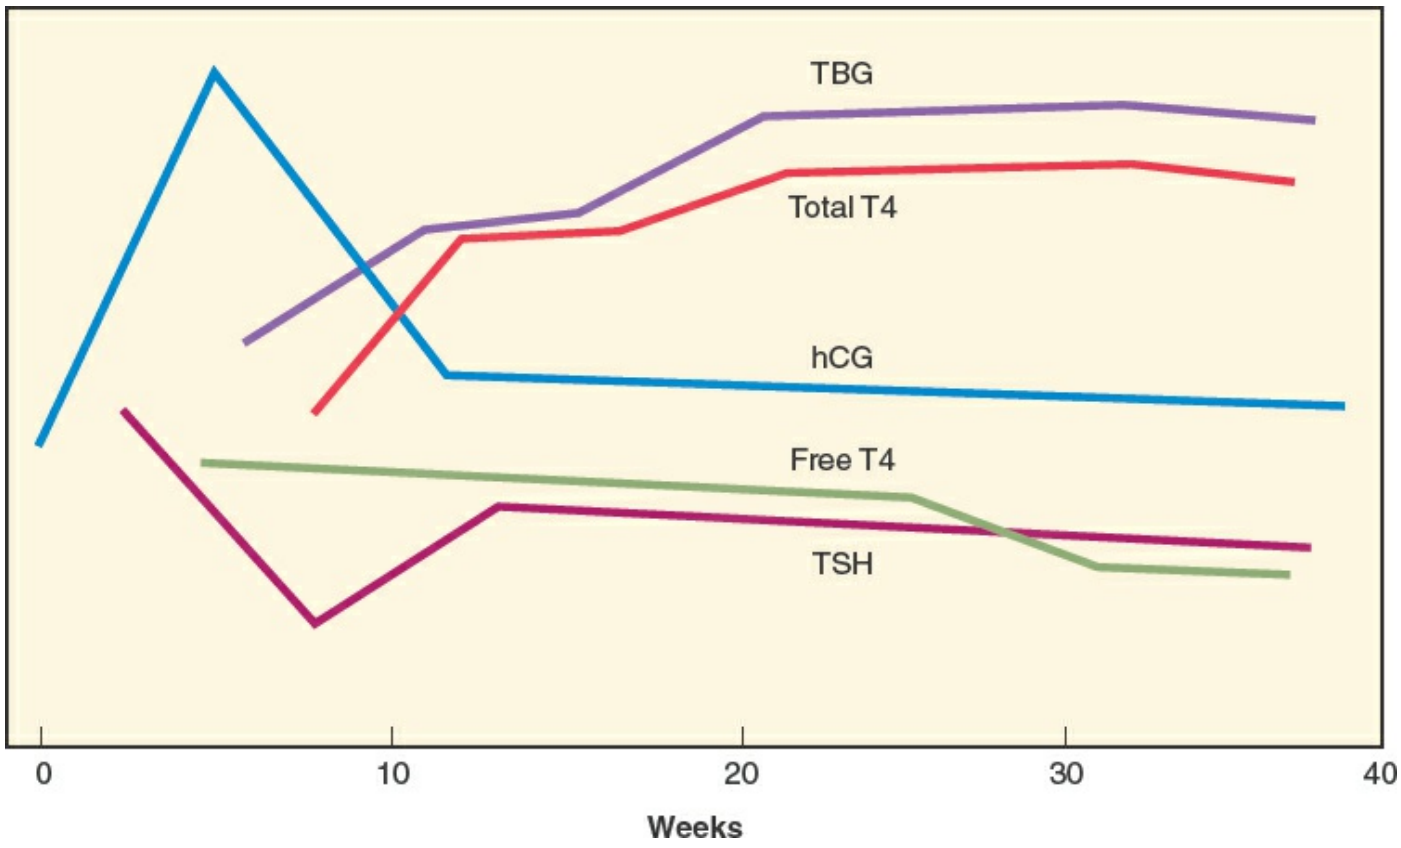

FIGURE 35-12 Pregnancy-associated changes in TSH relative to hCG and free T_4 in relation to TBG. Relative serum concentration changes throughout pregnancy highlighting a fall in TSH associated with an increase in hCG early in pregnancy and a fall in free T_4 as TBG levels rise during pregnancy. hCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone; TBG, thyroid-binding globulin total T_4, total thyroxine; free T_4, free thyroxine. (Based on data from **Brent GA**. Maternal thyroid function: interpretation of thyroid function tests in pregnancy. *Clin Obstet Gynecol* 1997;40:3–15.)

Reproductive Effects of Hyperthyroidism

High levels of TSAb (TSI) in women with Graves disease are associated with fetal–neonatal hyperthyroidism (430,431). Despite both the inhibition and elevation of gonadotropins seen in thyrotoxicosis, most women remain ovulatory and fertile (401,432). Severe thyrotoxicosis can result in weight loss, menstrual cycle irregularities, and amenorrhea. An increased risk of spontaneous abortion is noted in women with thyrotoxicosis. An increased incidence of congenital anomalies, particularly choanal atresia and possibly aplasia cutis, can occur in the offspring of women treated with *methimazole* (418,419,422).

Autoimmune hyperthyroid Graves disease may improve spontaneously, in which case antithyroid drug therapy may be reduced or stopped. TSHRAb production may persist for several years after radioactive iodine therapy or radical surgical treatment for hyperthyroid Graves disease. In this circumstance, there is a risk of exposing a fetus to TSHRAb. Fetal–neonatal hyperthyroidism is observed in 2% to 10% of pregnancies occurring in mothers with a current or previous diagnosis of Graves disease, secondary

to the transplacental passage of maternal TSHRAb. This is a serious condition with a 16% neonatal mortality rate and a risk of intrauterine fetal death, stillbirth, and skeletal developmental abnormalities, such as craniosynostosis. Caution against overtreatment with antithyroid medication is warranted, as these medications may cross the placenta in sufficient quantities to induce fetal goiter. Guidelines for TSHRAb testing during pregnancy in women with previously treated Graves disease are found in Table 35-14. Fetal goiters and the associated fetal hypo- or hyperthyroid status were diagnosed accurately in mothers with Graves disease using a combination of fetal ultrasonography of the thyroid with Doppler, fetal heart rate monitoring, bone maturation, and maternal TSHRAb and antithyroid drug status (433).

Postpartum Thyroid Dysfunction

Postpartum thyroid dysfunction is much more common than recognized; it is often difficult to diagnose because its symptoms appear 1 to 8 months postpartum and are often confused with postpartum depression and difficulties adjusting to the demands of the neonate and infant. Postpartum thyroiditis appears to be caused by the combination of a rebounding immune system in the postpartum state and the presence of thyroid autoantibodies. Histologically, lymphocytic infiltration and inflammation are found and anti-TPO antibodies are often present (434,435). The following are criteria for the diagnosis of postpartum thyroiditis: (i) no history of thyroid hormonal abnormalities either before or during pregnancy, (ii) documented abnormal TSH level (either depressed or elevated) during the first year postpartum, and (iii) absence of a positive TSH-receptor antibody titer (Graves disease) or a toxic nodule. A number of studies describe clinical and biochemical evidence of postpartum thyroid dysfunction in 5% to 10% of new mothers (436,437).

Table 35-14 Guidelines for TSHRAb Testing During Pregnancy With Previously Treated Graves Disease

1. In the woman with antecedent Graves disease in remission after ATD treatment, the risk for fetal–neonatal hyperthyroidism is negligible, and systematic measurement of TSHRAb is not necessary. Thyroid function should be evaluated during pregnancy to detect an unlikely but possible recurrence. In that case, TSHRAb assay is mandatory
2. In the woman with antecedent Graves disease previously treated with radioiodine or thyroidectomy and regardless of the current thyroid status (euthyroidism with or without thyroxine substitution), TSHRAb should be measured early in pregnancy to evaluate the risk for fetal hyperthyroidism. If the TSHRAb level is high, careful monitoring of the fetus is mandatory for the early detection of signs of thyroid overstimulation (tachycardia, impaired growth rate, oligohydramnios, goiter). Cardiac echography and measurement of circulatory velocity may be confirmatory. Ultrasonographic measurements of the fetal thyroid have been defined from 20 weeks gestational age but require a well-trained operator, and thyroid visibility may be hindered because of fetal head position. Color Doppler ultrasonography is helpful in evaluating thyroid hypervascularization. Because of the potential risks of fetal–neonatal hyperthyroid cardiac insufficiency and the inability to measure the degree of hyperthyroidism in the mother because of previous thyroid ablation, it may be appropriate to consider direct diagnosis in the fetus. Fetal blood sampling through cordocentesis is feasible as early as 25–

27 weeks gestation with less than 1% adverse effects (fetal bleeding, bradycardia, infection, spontaneous abortion, in utero death) when performed by experienced clinicians. ATD administration to the mother may be considered to treat the fetal hyperthyroidism

3. In the woman with concurrent hyperthyroid Graves disease, regardless of whether it has preceded the onset of pregnancy, ATD treatment should be monitored and adjusted to keep free T_4 in the high-normal range to prevent fetal hypothyroidism and minimize toxicity associated with higher doses of these medications. TSHRAb should be measured at the beginning of the last trimester, especially if the required ATD dosage is high. If the TSHRAb assay is negative or the level low, fetal–neonatal hyperthyroidism is rare. If antibody levels are high (TBII ≥40 U/L or TSAb ≥300%), evaluation of the fetus for hyperthyroidism is required. In this condition, there is usually a fair correlation between maternal and fetal thyroid function such that monitoring the ATD dosage according to the mother's thyroid status is appropriate for the fetus. In some cases in which a high dose of ATD >20 mg/d of methimazole or >300 mg/d of PTU is necessary, there is a risk of goitrous hypothyroidism in the fetus, which might be indistinguishable from goitrous Graves disease. The correct diagnosis relies on the assay of fetal thyroid hormones and TSH, which allows for optimal treatment

4. In any woman who has previously given birth to a newborn with hyperthyroidism, a TSHRAb assay should be performed early in the course of pregnancy

TSHRAb, thyroid-stimulating hormone receptor antibodies; ATD, autoimmune thyroid disease; T_4, thyroxine; TBII, TSH-binding inhibitory immunoglobulin; TSAb, thyroid-stimulating antibody; PTU, propylthiouracil.

Clinical Characteristics and Diagnosis

Postpartum thyroiditis usually begins with a transient hyperthyroid phase between 6 weeks and 6 months postpartum followed by a hypothyroid phase. Only one-fourth of the cases follow this classic clinical picture, and more than one-third have either hyperthyroidism or hypothyroidism alone. Individuals with type 1 diabetes have a 3-fold increased risk of developing postpartum thyroiditis. Women with a history of postpartum thyroiditis in a previous pregnancy have nearly a 70% chance of recurrence in a subsequent pregnancy. Additional risk factors include a family history of thyroid disorders and TPOAb positivity (438). Although psychotic episodes are rare, postpartum thyroid dysfunction should be considered in all women with postpartum psychosis. The thyrotoxic phase may be subclinical and overlooked, particularly in areas where iodine intake is low (439). Unlike patients with Graves disease, those with the hyperthyroidism caused by postpartum thyroiditis have a low level of radioactive isotope uptake. Women with a history of postpartum thyroiditis should be followed closely as they have a 20% risk of permanent hypothyroidism immediately following the onset of thyroiditis, up to a 60% risk of permanent hypothyroidism over the next 5 to 10 years, and up to a 70% risk of postpartum thyroiditis in future pregnancies (440,441).

The absence of thyroid tenderness, pain, fever, elevated sedimentation rate, and leukocytosis helps to rule out subacute thyroiditis (de Quervain thyroiditis). Evaluation of TSH, T_4, T_3, T_3 RU, and antimicrosomal antibody titer confirms the diagnosis.

Treatment

Most patients are diagnosed during the hypothyroid phase and require 6 to 12 months of thyroxine replacement if they are symptomatic (382). Because approximately 60% of women develop permanent hypothyroidism, TSH should be evaluated following discontinuation of replacement therapy.

Rarely, patients are diagnosed during the hyperthyroid phase (442). Antithyroid medications are not routinely used for these women. *Propranolol* may be used for relief of symptoms but should be used with appropriate counseling in nursing mothers.

Antithyroid Antibodies and Disorders of Reproduction

Women who have antithyroid autoantibodies before and after conception appear to be at an increased risk for spontaneous abortion (443,444). Non-organ–specific antibody production and pregnancy loss are documented in cases of antiphospholipid abnormalities (445). The concurrent presence of organ-specific thyroid antibodies and non-organ–specific autoantibody production is not uncommon (445–447). In cases of recurrent pregnancy loss, thyroid autoantibodies may serve as peripheral markers of abnormal T-cell function and further implicate an immune component as the cause of reproductive failure. The clinical implications of these findings in the management of patients with recurrent pregnancy loss are not known. Recurrent pregnancy loss is covered in Chapter 33.

Thyroid Nodules

Thyroid nodules are a common finding on physical examination and are demonstrated by high-frequency ultrasonography in over two-thirds of patients (448). Occasionally such nodules are functional, and clinical and laboratory evaluation should be applied to distinguish these nodules from nonfunctional nodules, which are occasionally malignant. For nonfunctional "cold" nodules, fine-needle biopsy and aspiration are required to rule out malignancy. In the case of indeterminate aspirates, 2% to 20% are malignant; therefore, surgical biopsy is often indicated (449). Molecular diagnosis screening of the *BRAF* mutation improves the diagnosis of cancer on fine-needle aspiration (450).

Turner Syndrome and Down Syndrome

Patients with Turner syndrome (and other forms of hypergonadotropic hypogonadism associated with abnormalities of the second sex chromosome) exhibit a high prevalence of autoimmune thyroid disorders. Approximately 50% of adult patients with Turner syndrome have anti-TPO and antithyroglobulin (anti-TG) autoantibodies. Of these patients, approximately 30% will develop subclinical or clinical hypothyroidism. The disorder is indistinguishable from Hashimoto thyroiditis. A susceptibility locus for Graves disease is noted on chromosome X (451). Because of the increased risk of ATD, it is recommended that women with Turner syndrome are screened with yearly TSH testing starting at the age of 4 (452).

Down syndrome, caused by an extra chromosome 21, is characterized by an atypical

body habitus, mental retardation, cardiac malformations, an increased risk of leukemia, and a reduced life expectancy. The extra chromosome is almost always of maternal origin. Autoimmune thyroid disorders are more common in patients with Down syndrome than in the general population. The gene for autoimmune polyglandular syndrome I (*APECED*) has been mapped to chromosome 21 and is thought to be a transcription factor involved in immune regulation (AIRE). This gene may play a role in the development of ATD in these patients (453). Hashimoto thyroiditis is the most common type of thyroid disease in individuals with Down syndrome. Hypothyroidism develops in as many as 50% of patients older than age 40 with Down syndrome. These clinical syndromes and other evidence suggest part of the genetic susceptibility to Hashimoto thyroiditis may reside on chromosomes X and 21. Because of the increased frequency of hypothyroidism associated with Down syndrome, it is recommended to screen individuals at 6 months, 12 months, and then annually thereafter (384).

KEY POINTS

The physician's initial encounter with an infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. Factors from either or both partners may contribute to difficulties in conceiving. Therefore, it is important to understand male and female reproductive physiology and consider all possible diagnoses before pursuing invasive treatment.

1 The main causes of infertility include male factor, decreased ovarian reserve, ovulatory disorders (ovulatory factor), tubal injury, blockage, or paratubal adhesions (including endometriosis with evidence of tubal or peritoneal adhesions), uterine factors, systemic conditions (including infections or chronic diseases such as obesity, autoimmune conditions, or chronic renal failure), cervical and

immunologic factors, and unexplained factors (including endometriosis with no evidence of tubal or peritoneal adhesions).

2 Basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and documentation of tubal patency. Ovarian reserve screening is often performed.

3 Male factor is the only cause of infertility in 20% of infertile couples, but it may be a contributing factor in as many as 50% of cases. Within this category are same sex female couples desiring to conceive; they would not necessarily be considered traditionally infertile, but they would need donor sperm. Treatment of reversible anatomic, endocrine or infectious causes of subfertility, such as varicocele repair, cessation of suppressive medications or toxic behaviors, and treatment of sexually transmitted diseases and thyroid disorders, may be efficacious. Intrauterine insemination (IUI) is the best studied and most widely practiced of all the insemination techniques. Intracytoplasmic sperm injection (ICSI) has allowed couples with male factor infertility to achieve assisted reproductive technology (ART) pregnancy outcomes that are comparable with those of couples with nonmale factor infertility using conventional in vitro fertilization (IVF) treatment.

4 An association between the age of the woman and reduced fertility has been well-documented. The decline in fecundability begins in the early 30s and accelerates during the late 30s and early 40s. Chemotherapeutics may hasten loss of ovarian reserve and may prompt fertility preservation counseling. Similar counseling should be undertaken for male cancer patients.

5 Disorders of ovulation account for about 30% to 40% of all cases of female infertility. These disorders are generally among the most easily diagnosed and most treatable causes of infertility.

6 The most common cause of oligo-ovulation and anovulation—both in the general population and among women presenting with infertility—is polycystic ovarian syndrome (PCOS).

7 Tubal and peritoneal factors account for 30% to 40% of cases of female infertility. Cervical factor is estimated to be a cause of infertility in no more than 5% of infertile couples. Uterine pathologies contribute to infertility in as many as 15% of couples seeking treatment. Leiomyomas have not been shown to be a direct cause of infertility. If the evaluation is negative (i.e., unexplained) then superovulation with IUI may be considered, though with less success than ART.

8 ART techniques include gametes from autologous or third-party sources, IVF, ICSI using ejaculated or surgically retrieved sperm that is either fresh or cryopreserved, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), oocyte and embryo cryopreservation, and use of gestational carriers. Because of improved success rates associated with IVF embryo transfer, the performance of GIFT and ZIFT has declined dramatically. Embryo screening using morphokinetic methods, PGD, and PGS are also utilized.

9 Multiple gestation, especially higher-order multiple gestation, is a serious complication of infertility treatment and has tremendous medical, psychological, social, and financial implications.

10 Other complications of ART can occur, but stress is the most common reason for patients to discontinue fertility therapy. Improved protocols can minimize ovarian hyperstimulation syndrome (OHSS) risks, and recent studies have not shown an increased risk for breast, uterine, or ovarian cancer secondary to medications used for superovulation in the treatment of infertility. Although concerns have been raised about congenital abnormalities in offspring, absolute risk seems to be low.

11 Information on the Society for Assisted Reproductive Technology (SART) and registered ART clinics are accessible by the public at https://www.sartcorsonline.com/rptCSR_PublicMultYear.aspx?reportingYear=2015. The Centers for Disease Control (CDC) by law collects ART data and this is publicly available at ftp://ftp.cdc.gov/pub/Publications/art/ART-2015-Clinic-Report-Full.pdf#page=4.

Assessing the scope of infertility is hampered in part by the lack of standardized definitions (1). Infertility is variably defined as no pregnancy with unprotected intercourse for 1 year (2) or 2 years (1). This condition may be further classified as

primary infertility, **in which no previous pregnancies have occurred, and** ***secondary infertility,*** **in which a prior pregnancy, although not necessarily a live birth, has occurred** (3). **About 90% of couples should conceive within 12 months of unprotected intercourse** (4). **The term subfertility is often used interchangeably with infertility** (5). **Fecundability refers variously to the probability of pregnancy per cycle or to the number of cycles to achieve a pregnancy** (6). **Fecundity refers to the probability of achieving a live birth** (7). **The diagnosis of impaired fecundity has been proposed to include couples with ê36 months without conception or physical inability or difficulty in having a child** (7).

EPIDEMIOLOGY

The prevalence of infertility in the United States has been variously estimated from 7.4% (8) **to 15.5%** (9) **depending on the methodologic approach used.** However, utilization of infertility services in the United States remains low at 17% or 6.9 million women aged 25 to 44 from 2006 to 2010 with higher utilization noted among women age ≥30, non-Hispanic Whites, and higher socioeconomic strata (10).

INITIAL ASSESSMENT

The physician's initial encounter with an infertile couple is the most important one because it sets the tone for subsequent evaluation and treatment. **It cannot be overemphasized that in partnered patients, infertility is a problem of the couple.** The presence of the partner, beginning with the initial evaluation, involves him or her in the therapeutic process. **[1]** This essential involvement demonstrates the physician's receptivity to the partner's needs and those of the patient, allowing both members of the couple an opportunity to ask questions and voice any concerns.

[2] **The physician should obtain a complete medical, surgical, and urologic/gynecologic history from both partners.** Specifically, information regarding menstrual cycle regularity, pelvic pain, and previous pregnancy outcomes is important. Risk factors for infertility, such as a history of pelvic inflammatory disease (PID) or pelvic surgery, should be reviewed. A history of intrauterine exposure to diethylstilbestrol (DES) is significant. In addition, a review of systems relevant to pituitary, adrenal, and thyroid function is useful. Questions regarding galactorrhea, hirsutism, and changes in weight are particularly relevant. A directed history, including developmental defects such as undescended testes, past genital surgery, infections (including mumps orchitis), previous genital trauma, and medications should be obtained from the male partner. A history of occupational exposures that might affect the reproductive function of either partner is important, as is information about coital

frequency, dyspareunia, and sexual dysfunction. Finally, information should be obtained on any family history of infertility, premature ovarian failure, congenital physical or intellectual impairments, and hereditary conditions relevant to preconception planning, such as cystic fibrosis, thalassemia, and Tay–Sachs disease.

[1] The initial interview provides the physician with the opportunity to assess the emotional impact of infertility on the couple. It gives the physician a chance to emphasize the emotional support available to the couple as they proceed with the diagnostic evaluation and suggested treatments. In most cases, referral to a trained social worker or psychologist may be beneficial.

The physical examination of the woman should be thorough, with attention given to height, weight, body habitus, hair distribution, thyroid gland, and pelvic examination. Referral of the male partner to a urologist for examination often is beneficial if historic information or subsequent evaluation suggests an abnormality. This initial encounter provides an opportunity to outline the general causes of infertility and discuss subsequent diagnostic and treatment plans (**Figs. 30-1** to **30-3**).

[3] The basic investigations that should be performed before starting any infertility treatment are semen analysis, confirmation of ovulation, and documentation of tubal patency (**Figs. 36-1** **to** **36-3**). If a patient with severe systemic illness such as renal failure, liver failure, or cancer wishes to conceive, careful preconception assessment and counseling is advisable because the risks of fertility treatment and pregnancy can be substantial.

CAUSES OF INFERTILITY

The main causes of infertility include:

1. **Male factor**
2. **Decreased ovarian reserve**
3. **Ovulatory factor**
4. **Tubal factor**
5. **Uterine factor**
6. **Pelvic factor**
7. **Unexplained**

The relative prevalence of the different causes of infertility varies widely among patient populations (Table 36-1). Worldwide, male factor accounts for 51.2% (11) and tubal blockage for 25% to 35% (12) of infertility and subfertility (conception after attempting for 1 year). In Europe, ovulatory dysfunction accounts for 21% to 32%, male factor 19% to 57%, tubal factor 14% to 26%, unexplained 8% to 30%, endometriosis 4% to 6%, and combined male and female factors 34.4% of infertility (13–15). **[4]**

Male factor is the only cause of infertility in about 20% of infertile couples, but it may be a contributing factor in as many as 50% of cases (15–17). Very few couples have absolute infertility, which can result from congenital or acquired irreversible loss of functional gametes in either partner or the absence of reproductive structures in either partner. **[2]** Spontaneous conception is less likely to occur with age >42, infertility duration >4 years, severe endometriosis, or severe tubal disorder (18), so patients with those features should be strongly encouraged to consider treatment rather than expectant management.

Impact of Lifestyle on Fertility

[2] Women with class II obesity particularly when partnered with similarly obese men experience longer time to pregnancy compared to normal-weight couples, and female obesity is associated with lower pregnancy rates with IVF compared to normal-weight women (21–23). Potential etiologies for obesity-associated infertility include disrupted hypothalamic–pituitary–ovary axis, diminished fertilization rate, and impaired

endometrial gene receptivity. In mildly obese body mass index (BMI) <35 kg/m^2 women randomized to weight loss of ~20 pounds versus no weight loss, IVF live birth rates did not significantly differ, but spontaneously conceived live birth rates were higher in the weight-loss group (24). Obese men have higher rates of hypogonadotropic hypogonadism and sperm DNA or mitochondrial damage compared to normal-weight men (25,26). Substance (drug and alcohol) use in men is discussed in "Male Factor." A survey of 12,800 women in the United States undergoing IVF revealed that nearly a quarter of them consumed alcohol, 7% smoked, and two-thirds used caffeine during treatment (27). Studies report that compared to nonsmokers, maternal and paternal tobacco smokers have lower live birth rates with intercourse (28), lower pregnancy rates using donor IUI (29) and partner IUI (30), and higher rates of IVF cycle cancellation prior to oocyte retrieval even among female former smokers (31). Reassuringly, maternal low to moderate daily intake of alcohol (<12 g) and caffeine (<200 mg) in the 1 year prior to ART did not impact ART outcomes (32).

[2] TABLE 36-1 Causes of Infertility

Relative Prevalence of the Etiologies of Infertility (%)	
Male factor	17–28
Both male and female factors	8–39
Female factor	33–40
Unexplained infertility	8–28
Approximate Prevalence of the Causes of Infertility in the Female (%)	
Ovulatory dysfunction	21–36
Tubal or peritoneal factor	16–28
Miscellaneous causes	9–12
Prevalence of etiologies of infertility (1,15,19,20)	

Male Factor

The concept of a global decline in sperm counts is controversial (33,34). A decline in sperm density has been observed in the United States, Europe, and Australia, while decreased motility and semen volume have been reported in India (33). Given that decreases in sperm parameters have been noted in fertile men (35) and in U.S. sperm donors (36), the clinical relevance for fecundability is unknown. However, one simulation model has suggested that if sperm concentrations decline by 21% to 47%, fecundability would decrease by 7% to 15% (37).

Physiology

Spermatogenesis

The male reproductive tract consists of the testis, epididymis, vas deferens, prostate, seminal vesicles, ejaculatory duct, bulbourethral glands, and urethra. **Gonadotropin-responsive cells in the testes include Leydig cells (the site of androgen synthesis) and Sertoli cells, which line the seminiferous tubules (the site of spermatogenesis)** (38). **The [1] pituitary gland secretes luteinizing hormone (LH), which stimulates the synthesis and secretion of testosterone by the Leydig cells, and follicle-stimulating hormone (FSH), which acts with testosterone on the Sertoli cells to stimulate spermatogenesis (38).** In [1] humans, a new cohort of spermatogonia enter the maturation process every 16 days, and the development from spermatogonia stem cells to the mature sperm cells takes about 75 days (39). Spermatogonia undergo mitotic division to give rise to spermatocytes (38). These diploid spermatocytes subsequently undergo meiosis to produce haploid spermatids, which contain 23 (rather than 46) chromosomes (38). Maturation of spermatids is called spermiogenesis and involves condensation of the nucleus, formation of the flagellum, and the formation of the acrosome (a structure derived from the Golgi complex covering the tip or head of the sperm nucleus) (40). The resultant spermatozoa are released into the seminiferous tubule lumen and enter the epididymis, where they continue to mature and become progressively more motile during the 2 to 6 days that is required to traverse this tortuous structure and reach the vas deferens (41).

Sperm Transport

[1] During ejaculation, mature spermatozoa are released from the vas deferens along with fluid from the prostate, seminal vesicles, and bulbourethral glands (42). The released semen is a gelatinous mixture of spermatozoa and seminal plasma; however, this thins out 20 to 30 minutes after ejaculation. This process, called liquefaction, is the direct result of proteolytic enzymes within the prostatic fluid (42). **[1] Following ejaculation, the released spermatozoa must undergo capacitation to become competent to fertilize the oocyte** (43). Capacitation occurs within the cervical mucus and involves removal of inhibitory mediators such as cholesterol from the sperm surface, tyrosine phosphorylation, and calcium ion influx, all of which allow the sperm to recognize additional fertilization cues during travel through the female reproductive tract (43). After the sperm reach the tubal isthmus they are slowly released into the ampulla, further reducing the number of sperm that reach the oocyte (43). Sperm transport from the posterior vaginal fornix to the fallopian tubes occurs within 2 minutes during the follicular phase of the menstrual cycle (44).

Fertilization

[1] As the capacitated sperm near and pass through cumulus cells surrounding the

oocyte, hydrolytic enzymes are released from the acrosome via exocytosis in a process called the acrosome reaction (43). Capacitation and the acrosome reaction can be induced in vitro (40,43). Following the acrosome reaction, the sperm binds to and penetrates the zona pellucida (the extracellular coat surrounding the oocyte). This allows fusion of the sperm with the plasma membrane of the oocyte, an event that promotes changes in the oocyte that prevent entry by additional sperm (43). **As the first sperm penetrates, cortical granules are released (the cortical reaction) from the oocyte into the perivitelline space. This stops the oocyte's zona pellucida from binding new sperm and inhibits penetration by previously bound sperm, further reducing the possibility of polyspermy** (45).

Recreational, Iatrogenic, and Environmental Male Reproductive Toxins

Decreased sperm concentration and motility have been noted in areas of the United States with heavy agriculture and pesticide use (35), but occupational exposures have not been linked to infertility (46). **[4] Alcoholism negatively affects all semen analysis parameters** (47,48) **and either smoked** (48,49) **or chewed tobacco** (50) **is associated with decreased sperm density and motility.** Compared to nonusers, marijuana used greater than once per week was associated with diminished sperm concentration and count by nearly 30% (51). Concurrent use of other illicit substances such as cocaine further decreased sperm quantity and negatively impacted motility (51). Certain medications may reduce sperm numbers or function or may cause ejaculatory dysfunction (Table 36-2). **Vaginal lubricants such as Astroglide, KY Jelly, saliva, and olive oil inhibit sperm motility in vitro, while no adverse effects are seen with hydroxethyl cellulose (Pre-Seed), mineral oil, or canola oil** (44). **[4]** However, Astroglide and KY do not appear to affect fecundability in noninfertile couples engaging in procreative intercourse (52).

[1] TABLE 36-2 Drugs that Can Impair Male Fertility

Impaired spermatogenesis—sulfasalazine, methotrexate, nitrofurantoin, colchicine, chemotherapy
Pituitary suppression—testosterone injections, gonadotrophin-releasing hormone analogs
Antiandrogenic effects—cimetidine, spironolactone
Ejaculation failure—a blockers, antidepressants, phenothiazines
Erectile dysfunction—b blockers, thiazide diuretics, metoclopramide
Drugs of misuse—anabolic steroids, cannabis, heroin, cocaine

Semen Analysis

[3] The basic semen analysis measures semen volume, sperm concentration, sperm motility, and sperm morphology (42). Recently revised, the normal values suggested by the World Health Organization (WHO) in 2010 are listed with the previously published guidelines in Table 36-3 (42,53). Both criteria were developed using fertile men whose semen parameters were in the lowest 5th centile of the group studied, but values above the reference ranges do not guarantee male fertility. Because infertile men were not used to develop the criteria, values below the cutoffs may not necessarily indicate infertility (42). However, significant deviations from the reference limits are generally classified as male factor infertility (17). Given regional differences between laboratories and in semen quality, laboratories are encouraged to develop their own reference ranges (42). Typically, semen is assessed manually, but computer-aided sperm analysis (CASA) may be used (42). Limitations of CASA include a lack of standardization among instruments, an inability to differentiate intact from nonintact sperm, possible bias from artifacts during preparation, and a paucity of studies on fertility outcomes in large populations (42).

Abstinence

[3] Previous recommendations for prolonged abstinence time up to 7 days (42) **have little supporting evidence, and likely there is benefit to shorter abstinence duration regardless of baseline parameters. [1]** The epididymis stores the equivalent of three ejaculations (41), and therefore short abstinence is unlikely to significantly deplete sperm quantity in most men. A retrospective United States study of 1939 oligozoospermic subfertile men found that >2 days abstinence was associated with more samples with >20 M total motile counts and higher ejaculate volume but no statistically significant impact on concentration, motility, or morphology (54). With >5 days of abstinence, oligozoospermic men had reduced total motile sperm count and normal morphology (55). Although longer abstinence >2 days in normozoospermic men increased sperm concentration and total count, it was globally detrimental with respect to lower ejaculate volume, total and progressive motility, viability, and tail morphology (54). With prolonged abstinence >10 days, even normozoospermic men will have reduced total motile sperm count and reduced proportions of sperm with normal morphology (55), as sperm overflow into the urethra and are flushed out into the urine (42). Prolonged epididymal storage with heightened oxidative stress negatively affects quality in terms of elevated sperm DNA fragmentation (54), and may explain the improved pregnancy rates associated with shortening abstinence times to ≤2 days prior to specimen collection for intrauterine insemination (IUI) (56).

[3] TABLE 36-3 Semen Analysis Terminology and Normal Values

Terminology (42)	
Normozoospermia	All semen parameters normal

Oligozoospermia	Reduced sperm numbers Mild to moderate: 5–20 million/mL Severe: <5 million/mL
Asthenozoospermia	Reduced sperm motility
Teratozoospermia	Increased abnormal forms of sperm
Oligoasthenoteratozoospermia	Sperm variables all subnormal
Azoospermia	No sperm in semen
Aspermia (anejaculation)	No ejaculate (ejaculation failure)
Leucocytospermia	Increased white cells in semen
Necrozoospermia	All sperm are nonviable or nonmotile

Normal Semen Analysis—World Health Organization (42)		
	1992 Guidelines	**2010 Guidelines**
Volume	>2 mL	≥1.5 mL
Sperm concentration	>20 million/mL	≥15 million/mL
Sperm motility	>50% progressive or >25% rapidly progressive	≥32% progressive
Morphology (strict criteria)	>15% normal forms	≥4% normal forms
White blood cells	<1 million/mL	<1 million/mL
Immunobead or mixed antiglobulin reaction test	<10% coated with antibodies	<50%

Terminology from **Hirsh A.** Male infertility. *BMJ* 2003;327:669–672, with permission.

Specimen Collection

The specimen should be obtained by masturbation and collected in a clean container kept at ambient temperature (42). **[3]** The patient should report any loss of the specimen, particularly the first portion of the ejaculate, which contains the highest sperm concentration (42). Collection may be performed either at home or in a private room near the laboratory (42). The sample should be taken to the laboratory within one-half to one hour of collection to prevent dehydration and degradation (42). **If masturbation into a container is not possible, condoms specially designed for semen analysis should be used rather than latex condoms which are toxic to sperm** (42). **Intercourse to collect the sample is discouraged because of contamination risk** (42).

[3] Even when the specimen is obtained under optimal circumstances, interpretation of the results of the semen analysis is complicated by variability within the same individual and overlap in infertile and fertile reference semen parameters (42). Semen parameters may vary widely from one man to another and among men with proven fertility (42). **In many circumstances, several specimens are necessary to verify an abnormality** (42).

Sperm Volume and pH

The lower limit of normal semen volume is ê1.5 mL and the pH should be ê7.2 (42). These parameters are affected mainly by the balance between the acidic secretions of the prostate gland and the alkaline fluid from the seminal vesicles (42). Low volume along with pH <7 suggests obstruction of the ejaculatory ducts or absence of the vas deferens (42). **[3]** Difficulties with collection, retrograde ejaculation, or androgen deficiency can contribute to low volume (42). Consider further workup with urine voided immediately after ejaculation in patients with documented low semen volume <1 mL, after verifying with the man that no spill occurred during collection (17). Calculate the total sperm in the urine divided by the (total sperm in urine plus total sperm in ejaculate) multiplied by 100. A value >7.1% to 8.3% will be found in patients with partial retrograde ejaculation (57).

High volumes >5 mL suggest inflammation of the accessory glands (42).

Sperm Concentration

Sperm concentration or density is defined as the number of sperm per milliliter in the total ejaculate (42). **[3] The normal lower limit is ê 15 million/mL, revised from ê 20 million/mL (42,53).** Only intact sperm are counted in determining sperm concentration (42). Fifteen percent to 20% of infertile men are azoospermic (no sperm) and 10% have a density of <1 million/mL (42,58).

Sperm Motility and Viability

Sperm motility is the percentage of progressively and total (progressive plus nonprogressive) motile sperm in the ejaculate (42). **[3] The normal lower limit is ê 32%, which was revised from ê 50% (42,53). Viability should be at least 58% (42).** Progressive motility refers to movement either linearly or in a large circle regardless of speed. Nonprogressive motility describes sperm that display only small movements/twitching or no movement at all (immotile) (42). Assessments of speed of progression, either rapid or slow, have been removed from the revised guidelines as a result of difficulty in unbiased measurement of this parameter (42). A reduction in sperm motility is referred to as asthenozoospermia (42). Leukocytes can impair sperm motility through oxidative stress (42). When many immotile sperm are present or when progressive motility is <40% viability studies should be performed (42). Viable immotile sperm may have flagellar defects while the presence of nonviable immotile

sperm (necrozoospermia) suggests epididymal pathology (42). **[3]** Viable sperm have intact plasma membranes, which will not stain (dye exclusion) but will swell in hypoosmotic solutions (hypoosmotic swelling test) (42). Sperm motility *in-vitro* is decreased in the presence of women's serum neutrophils, which release extracellular "traps" that enmesh sperm in filaments elaborated by these inflammatory cells.

Sperm Morphology

Morphology testing assesses anatomic malformations of the sperm. **[3] The lower limit for normal morphology is ê 4% using strict criteria, a change from previous guidelines using a more lenient assessment and a cutoff of ê 30% (42,53).** Assessment of sperm morphology involves fixing and staining a portion of the specimen (42). The strict Tygerberg criteria were introduced by Kruger et al. in 1986 to assess sperm morphology (42,59,60). Using this system, the entire spermatozoon—including the head, midpiece, and tail—is assessed, and even mild abnormalities in head forms are classified as abnormal (42). Most sperm from normal men exhibit minor abnormalities when subjected to Tygerberg standards (42). An abnormality of sperm morphology is known as teratozoospermia, and these sperm have poor fertilizing potential and may have abnormal DNA (42). Low strict sperm morphology <9% was a better discriminator for infertility than either count or motility in a large cross sectional multicenter study (61). A disadvantage to any morphology assessment is that reproducibility may be hampered by the subjective nature of the assessment (42).

Round Cells, Bacteria, and Leukocytes

[3] Round cells include immature germ cells and leukocytes (42). The prevalence of round cells in a large IVF cohort was 5.4%, of which 73% were found to be immature germ cells (62). Immature germ cell elevation is associated with lower sperm concentration and normal morphology, compromised sperm DNA integrity, lower fertilization, and higher pregnancy loss rates with Intracytoplasmic sperm injection (ICSI) (62), while leukocytes (predominantly neutrophils) are associated with inflammation (42). Leukocytes can be distinguished by positive peroxidase staining, and normal leukocyte concentrations should be <1 million/mL (42). However, the prognostic significance of leukocytes in the semen is controversial; even low levels can be associated with reactive oxygen species and sperm DNA damage, but their presence has inconsistent effects on IVF/ICSI outcomes (42,62–64). Bacteriospermia prevalence among infertile men is ~50%, with detection rates likely affected by semen collection technique and specific test parameters, and prevalence is not necessarily associated with leukocytospermia; it may represent asymptomatic colonization without an inflammatory response (62,65). The most common pathogens associated with bacteriospermia are *Chlamydia trachomatis* (41.4%), *Ureaplasma urealyticum* (15.5%), and *Mycoplasma hominis* (10.3%), with *M. hominis* and *U. urealyticum* having higher prevalence in men with leukocytospermia compared to those without (65).

Antisperm Antibodies

Antisperm antibodies are often associated with sperm agglutination, may be present in seminal plasma, on sperm surfaces and in maternal serum, and risk factors include history of ductal obstruction, prior genital infection, testicular trauma, and prior vasectomy reversal (17). Using the immunobead test, washed spermatozoa are exposed and assessed for binding to labeled beads (42). In the mixed agglutination reaction, human red blood cells sensitized with human IgG are mixed with partner's semen (42). Spermatozoa that are coated with antibodies form mixed agglutinates with the red blood cells (42).**[3]** Antisperm antibody testing is limited by the lack of specific antibody binding, which is important because only a subset of antibodies is thought to have cytotoxic or agglutinating effects (66). Although the presence of antisperm antibodies has typically been managed with ICSI, it is uncertain whether that treatment is beneficial (66), and antibody testing would not be indicated if ICSI were a priori planned (17).

Postcoital Testing

[3] The purpose of the postcoital test, in which the cervical mucus is microscopically examined shortly after intercourse during the periovulatory cycle phase, is to assess the effect of cervical mucus on sperm viability and function (2). The test is considered positive if one or more progressively moving sperm per high power field is observed, negative if no sperm or only nonprogressive or immotile sperm are seen (3). However, its prognostic value and impact on management are limited by poor specificity, poor reproducibility, or controversial interpretation of the results (2). Nevertheless, a large recent study of infertile couples with <3 years of infertility from the Netherlands found that a positive postcoital test was associated with improved spontaneous pregnancy rates compared to negative test results, while a negative postcoital test was associated with improved IUI and IVF pregnancy rates compared to positive test results (3).

Sperm DNA Integrity

[3] Sperm DNA fragmentation has been associated with impaired pregnancy rates during IVF and is associated with an elevated risk of miscarriage, perhaps related to paternal age with its associated increase in double strand DNA damage (67). Sperm DNA fragmentation does not appear to correlate with blastocyst aneuploidy in a small study (68). Sperm chromatin structure assays, terminal deoxynucleotidyl transferase–mediated deoxyuridine triphosphate nick end labeling (TUNEL) assays, sperm chromatin dispersion tests, and single gel electrophoresis assays have varying thresholds for DNA damage diagnosis and varying positive predictive values (PPVs) for pregnancy with assisted reproduction; TUNEL assay results have the best correlation (67). These tests reflect the aggregate sperm DNA integrity of a heterogeneous sperm population rather than an individual fertilizing sperm, which limits the utility of this testing in the context of fertility treatment (67). **[3]** Nonetheless it may add etiologic information particularly in otherwise unexplained cases, and may prompt

recommendations for reducing sperm DNA damage with interventions such as antioxidant supplementation (67).

Epigenetic Sperm DNA Assessment

Epigenetics is the next frontier in sperm functional biology assessment, and epigenetic changes may be acquired transgenerationally or from conditions such as obesity (69). In couples with unexplained infertility, poor embryo development during IVF and men with abnormal semen analysis parameters, the sperm exhibit genome-wide alterations in genome packaging (i.e., histone modifications) and DNA methylation using chip microarrays as compared to those from fertile men (70,71). Assessment is available with the Episona test, but similar limitations as with the sperm integrity assays exist, including lack of applicability to the individual fertilizing sperm, and uncertainty as to treatments. In the case of obesity, weight loss may ameliorate epigenetic sperm changes through remodeling (69).

Differential Diagnosis of Male Factor

An underlying etiology for male factor was found using diagnostics in two-thirds of infertile men (72). Table 36-4 lists the differential diagnoses for male factor infertility (73). Several groups have attempted to assess the distribution of male infertility diagnoses; two such distributions are shown in Table 36-5 (74,75). The first is the result of a WHO study of 7,057 men with complete diagnoses based on the WHO standard investigation of the infertile couple (74). The figures include data from cases in which the male partner was normal and the presumed cause of the couple's infertility was a female factor. The second distribution is the result of a study of 425 subfertile male patients (74). Although the two studies represent different populations (one is from a study of couples, the other from a urologic practice) and differ in their distribution of male infertility diagnoses, idiopathic male factor and varicocele predominate. Other anatomic and endocrine causes occur less frequently. Particularly among men with oligozoospermia, 75% of cases were idiopathic (16). Factors which definitively lead to male infertility include secondary hypogonadism, genetic causes, seminal tract obstruction, oncologic disease therapies, and severe sexual dysfunction, while plausible causative factors include congenital urogenital anomalies and acquired testicular damage (unilateral cryptorchidism, testis cancer, and orchitis) (16). **[2]** Although not considered as primary etiologies for male factor infertility, varicocele, leukocytospermia, obesity, and uncontrolled chronic disease are more prevalent in infertile compared to fertile men (16). Same sex female couples or single women without a male partner who desire pregnancy may be considered as part of this category.

Male Age

[2] Men have reportedly fathered children into their 90s, but pregnancy rates are decreased with paternal age ê 40 to 45 and particularly ê age 50 (76). Increasing

paternal age is associated with a higher frequency of disomic sex chromosomes and structural chromosomal abnormalities in the sperm (76). With respect to the offspring, paternal age confers higher rates of autosomal dominant diseases such as achondroplasia and craniosynostosis and somewhat higher rates of trisomy 21 (76). In mice, offspring of older fathers have decreased survival (77). Increased paternal age is associated with recurrent pregnancy loss (78). Psychiatric conditions such as schizophrenia have been associated with increased paternal age, but this may reflect trends of men with psychiatric conditions to delay fathering children until later ages rather than *de-novo* genetic mutations (79).

Treatment of Male Factor Not due to Azoospermia

Medical treatment of reversible infectious or endocrine causes of male subfertility, such as sexually transmitted diseases and thyroid disorders, tends to be efficacious (80). Although injections of exogenous FSH have been reported to improve pregnancy rates, the benefit is less clear for clomiphene citrate, an estrogen antagonist at the hypothalamus and pituitary that promotes gonadotropin release (80). **[4] Exogenous testosterone is not recommended in the treatment of male subfertility because of negative feedback inhibition at the pituitary that results in reduced intratesticular testosterone and decreased spermatogenesis** (81). The prevalence of men receiving prescribed testosterone replacement therapy is 7% to 9%, of whom one-third have normal or supraphysiologic testosterone levels prior to treatment and half do not receive appropriate follow-up (81,82). Antioxidant food supplements have been evaluated (80). **[4]** Glutathione, carnitine, and vitamin E do not appear to affect semen parameters, but administration of zinc and folic acid were associated with improved sperm concentration and morphology (83). The diagnosis and treatment of azoospermia (no sperm on semen analysis) will be discussed separately from other forms of male factor infertility.

Varicocele Repair

A varicocele is an abnormal dilation of the veins within the spermatic cord (16). Clinically palpable varicoceles are present in 13.5% of men who recently fathered a pregnancy and 31% of men with otherwise idiopathic oligozoospermia (16). The pathophysiologic effects of a varicocele appear to be mediated by an associated rise in testicular temperature, reflux of toxic metabolites from the left adrenal or renal veins, or higher reactive oxygen species (84,85). **[4] While treatment is associated with improved semen parameters in some studies, it is not clear whether varicocele repair improves fertility** (84,86,87). Treatment via surgery or percutaneous embolization is typically considered if the varicocele is palpable and the semen analysis is abnormal, and may allow some couples to use IUI instead of in vitro fertilization (IVF) (88) and improve IVF outcomes in the setting of oligozoo or

azoospermia (89). Complications of treatment include infection, varicocele persistence, recurrence, and hydrocele formation (84).

[4] TABLE 36-5 Frequency of Some Etiologies in Male Factor Infertility

Cause	Percentage	Cause	Percentage
No demonstrable cause	48.5	Varicocele	37.4
Idiopathic abnormal semen	26.4	Idiopathic	25.4
Varicocele	12.3	Testicular failure	9.4
Infectious factors	6.6	Obstruction	6.1
Immunologic factors	3.1	Cryptorchidism	6.1
Other acquired factors	2.6	Low semen volume	4.7
Congenital factors	2.1	Semen agglutination	3.1
Sexual factors	1.7	Semen viscosity	1.9
Endocrine disturbances	0.6	Other	5.9
Total	**103.9[a]**		**100**

[a]More than 100% because of multiple factors.

Artificial Insemination

Artificial insemination has mainly been used to treat unexplained infertility (usually combined with superovulation) and male factor infertility (including same sex female couples). **[4] All artificial insemination procedures involve the placement of whole semen or processed sperm into the female reproductive tract, which permits sperm–ovum interaction in the absence of intercourse.** The placement of whole semen into the vagina as a mode of fertility treatment is now rarely performed except in cases of severe coital dysfunction. All the common forms of artificial insemination involve processed sperm obtained from the male partner or a donor. Many techniques for artificial insemination have been described, but only intracervical (ICI) and IUI have been routinely employed.

Insemination Processing

During and after intercourse, seminal fluid usually is prevented from reaching the intrauterine cavity and intra-abdominal space by the cervical barrier. **[4] The**

introduction of seminal fluid past this barrier may be associated with pelvic infection and severe uterine cramping or anaphylactoid reactions, possibly mediated by seminal factors such as prostaglandins (90). Thus, protocols for processing whole semen include the washing of specimens to remove seminal factors and to isolate pure sperm (90). Additional processing may include centrifugation through density gradients, sperm migration protocols, and differential adherence procedures (90). Finally, phosphodiesterase inhibitors, such as pentoxiphylline, have been used during semen processing to enhance sperm motility, fertilization capacity, and acrosome reactivity for IVF procedures (83,91).

Intrauterine Insemination

IUI is the best studied and most widely practiced of all the insemination techniques. It involves placement of approximately 0.3 to 0.5 mL of washed, processed, and concentrated sperm into the intrauterine cavity by transcervical catheterization (90). **[4]** Patients should remain immobile for approximately 15 minutes following the procedure (92). It is difficult to identify an optimal protocol or definitively determine pregnancy rates with IUI because of patient and protocol heterogeneity, with multifactorial influences on pregnancy rates including couple age, fertility diagnosis, stimulation type, and insemination timing relative to ovulation (93). **Ideally, the partner's total motile sperm count in the IUI specimen should be ê5 million** (94–96) **or ê10 million** (97), **although a French study found similar pregnancy rates with all values ê1 million** (98). Pregnancy rates with semen meeting those thresholds have been reported to be 10.5% per cycle (97) and 38% after 4 to 6 cycles (96). Delivery rates (17% vs. 8%) are higher when ≥2 follicles ≥15 mm are present as compared to 1 follicle, particularly when GnRH antagonists are employed (98). Although teratozoospermia using older criteria has been associated with IUI failure (94), low strict normal morphology of 2% to 4% has not been found to be predictive of IUI failure as compared to morphology >4% in two recent retrospective studies (99,100), but effects of more severe teratozoospermia on IUI outcomes remain nebulous. No benefit has been found with respect to double IUI versus single IUI during a single cycle (101). The technique of fallopian tube sperm perfusion (FSP) has been proposed to improve IUI pregnancy rates, whereby the washed sperm is instilled slowly over several minutes through an inflated balloon catheter to prevent reflux, but has not been found in a large randomized trial (102) or in a 2013 Cochrane systematic review (103) to be associated with improved pregnancy rates. Unexplained infertility and IUI will be discussed separately later in this chapter.

Timing of IUI

IUI typically is performed 24 hours following the LH surge (104). However, given data that ovulation can occur much later than this, it is not surprising that no differences in

pregnancy rates were found when IUI was performed between 24 and 60 hours following the LH surge (105). IUI pregnancy rates doubled when human chorionic gonadotropin (hCG) trigger was used instead of natural LH surge (98). **[4]** Although timing of IUI is typically performed 36 hours following hCG administration to coincide with follicle rupture, no significant differences in pregnancy or live birth rates are seen whether IUI is performed at 24 or 36 hours following the hCG trigger (106).

Donor IUI

For men with azoospermia, couples with significant male factor infertility who do not desire ART, and women without a male partner who are seeking pregnancy, therapeutic donor insemination offers an effective option (107). In earlier prospective randomized or crossover trials, IUI was shown to be superior to ICI for donor insemination (108). The success rates with ICI are lower than those with IUI, particularly when using frozen sperm (90,108–110). Women receiving donor sperm because of same sex partnership or being single had natural cycle IUI ongoing pregnancy rates that were similar to ICI at 10% per cycle and 40% cumulative over six treatment cycles (111). Lesbian women who achieved a live birth required a (mean ± SD) 3 ± 1.1 donor IUI cycles to conceive (112). **[4]** In patients younger than 30 years of age who have no other infertility factors, delivery rates approach 90% after 12 cycles of IUI treatment with frozen sperm (113), so patients who do not conceive within 6 to 12 months should be assessed for female factors and encouraged to terminate treatment or proceed with alternative forms of therapy. The concomitant use of clomiphene citrate or human menopausal gonadotropin (hMG) for controlled ovarian hyperstimulation (COH) did not result in higher fecundity rates in these patients (113). **[4] Psychological counseling should be offered because of the potential repercussions of using donor gametes** (107). Higher pregnancy rates have been demonstrated when donor IUI is performed 1 day after natural cycle serum LH rise (20%) compared to those randomized to 2 days postrise (11%) (114).

Donor Sperm Screening

Although the use of fresh donor semen is associated with higher pregnancy rates than the use of frozen specimens (115,116), both the Centers for Disease Control and Prevention (CDC) and the American Society for Reproductive Medicine recommend the use of frozen samples (107). **This recommendation stems from the increasing incidence of human immunodeficiency virus (HIV) infection in the general population and the lag time between HIV infection and seroconversion** (107). Semen donors are screened for HIV infection, hepatitis B, hepatitis C, syphilis, gonorrhea, chlamydia, and cytomegalovirus infections, all of which may be transmitted through semen (107). All cryopreserved samples are quarantined for 6 months, and the donor is retested for HIV before clinical use of the specimen (107). Donors are likewise questioned about any family history of genetically transmitted disorders, including both mendelian (e.g., hemophilia, Tay–Sachs disease, thalassemia, cystic fibrosis, congenital adrenal

hyperplasia, Huntington disease) and polygenic/multifactorial conditions (e.g., mental retardation, diabetes, heart malformation, spina bifida) (107). **[1]** Those with a positive family history of these conditions are eliminated as donor candidates (107).

Intracytoplasmic Sperm Injection

ICSI in the United States has been utilized for 93% of ART cycles for male factor infertility to achieve pregnancy outcomes that are comparable with those of couples with nonmale factor infertility using conventional IVF treatment (117). **[9]** The technique involves direct injection of a live sperm into the oocyte, thereby theoretically bypassing limitations imposed by sperm motility and defects in capacitation, the acrosome reaction, and/or sperm binding the zona pellucida (117). This microsurgical procedure involves stripping the aspirated cumulus complex of all surrounding granulosa cells, inserting a single viable sperm into the cytoplasm (ooplasm) of the oocyte that optimally is metaphase II (117) though less mature oocytes may still be considered for injection (118). ICSI should be offered if the semen analysis shows <2 million motile sperm, <5% motility, or if surgically recovered sperm is used (58), though there is wide latitude for utility depending on use of semen normal value thresholds (119). **[9]** Higher pregnancy rates have been noted with fresh when compared to frozen specimens and with ejaculated when compared to surgically retrieved sperm (58). **Success rates are affected by the age of the female partner and oocyte quality** (58). **[9]Nonmale factor indications for ICSI are contentious** (120) **but are utilized in 66.9% of United States ART cases** (117) **and with much higher frequency worldwide, and include teratozoospermia** (121), **unexplained infertility, previous fertilization failure with conventional IVF, diminished ovarian reserve, fertility preservation, and the fertilization of oocytes before preimplantation genetic diagnosis (PGD)** (117).

Risks of ICSI

Oocyte degeneration following ICSI is a relatively common occurrence with rates ranging from 5% to 19% (122). Prior reports have not supported the idea that oocyte degeneration is a function of technician skill; though, it is suggested that inherent oocyte quality, ovarian stimulation itself, unexpected random technical problems, or mechanical removal of cumulus and corona cells may contribute to this phenomenon (122). **While accumulated data indicate that there is an overall increased risk of congenital abnormalities with ART, ICSI does not appear to be associated with a higher risk compared to conventional IVF** (123). **[11]** The prevalence of sex chromosome abnormalities and translocation appears to be slightly higher with ICSI versus IVF; however, it is unclear whether these relate to the ICSI procedure or inherent gamete defects, as men with abnormal semen parameters have higher rates of sperm aneuploidy (124). There may be an increased risk of imprinting disorders with ICSI

(125). Although prior studies have not found an association with impaired intellectual or motor development among ICSI children, one study reported a higher incidence of autism when ICSI was used compared with IVF (126). **In the setting of specific genetic abnormalities such as Y chromosome microdeletions, abnormal karyotypes, cystic fibrosis mutations or congenital absence of the vas deferens, genetic counseling should be offered to address the possible risk of infertility or other abnormalities in the offspring** (124).

Azoospermia: Classification and Treatment

[4] Azoospermia describes the absence of spermatozoa in the ejaculate and is found in 1% of all men (127) **and up to 15% to 20% of infertile men** (58,127). Causes are categorized into pretesticular (nonobstructive), testicular (nonobstructive), and posttesticular (includes obstructive and nonobstructive) etiologies, but in some cases the condition is idiopathic (58).

Pretesticular Azoospermia

Pretesticular azoospermia from organic causes is relatively rare and results from gonadotropin deficiency, which leads to loss of spermatogenesis (58,127,128). The physician should perform a full endocrine history that includes information on puberty and growth and check for low serum levels of LH, FSH, and testosterone (58,127,128). Prolactin levels and pituitary imaging are indicated in cases of hypogonadotropic hypogonadism (58). **[4] Hormonal treatment includes pulsatile GnRH, hCG, and exogenous gonadotropins** (58,127,128). The best predictors of good response are postpubertal onset of gonadotropin deficiency and testicular volume >8 mL (58). **Iatrogenic azoospermia commonly results from medical testosterone use.** Treatment includes discontinuation of exogenous testosterone and recovery therapy with medications such as clomiphene citrate, hCG, and/or follicle stimulating hormone (FSH) with frequent follow-up semen analyses and endocrine labs (81). Azoospermia recovers to a median concentration of 6.5 million/mL 4.5 months following cessation of testosterone use; full recovery of sperm quantity was more likely in those men who used testosterone for less than 1 year, while those use who used it for several years were unlikely to recover (81).

Testicular Azoospermia

Gonadal failure is the hallmark of testicular azoospermia. Causes of this condition may be genetic, acquired (e.g., radiation therapy, chemotherapy, testicular torsion, varicocele, or mumps orchitis), or developmental (e.g., testicular maldescent) (58,127,128). Testicular atrophy is often present (58,127,128). Because of the low chance of obtaining sperm, testicular biopsy is generally not recommended with hypergonadotropic hypogonadism (elevated levels of LH and FSH with low serum

levels of testosterone) and consideration should be given to using donor sperm (58,127,128). Diagnostic testicular biopsies may be indicated in the setting of normal hormonal testing (58,127,128). If sperm are present in diagnostic testing, consideration can be given to using surgically retrieved spermatozoa for ICSI (58,127,128). If no sperm are present, consideration can be given to correcting acquired conditions such as varicocele, which may restore sperm to the ejaculate to permit ICSI or spontaneous pregnancy (129,130). **[4] Chromosomal abnormalities by peripheral karyotype testing are present in about 7% of infertile, 5% of oligospermic, and 10% to 15% of azoospermic men** (131). Sex chromosome aneuploidies such as Klinefelter syndrome (47,XXY) encompass two-thirds of these infertility-associated chromosome abnormalities (131). Microdeletions in the Y chromosome have been identified in 10% to 20% of men with idiopathic azoospermia or severe oligospermia with concentration <5 million/mL **(Table 36-6)** (131). These microdeletions can be transmitted to the male offspring, who may suffer from infertility (131). Therefore, screening for genetic causes is indicated in nonacquired cases of testicular azoospermia so that genetic counseling can be provided before treatment (124). The two most commonly implicated candidate gene families are the RNA-binding motif (*RBM*) and the "deleted in azoospermia" (*DAZ*) families, but microdeletions at various loci on the Y chromosome have been described (131,132). For example, microdeletions in Yq11.23 can occur in one or more of three regions: *AZFa* (proximal), *AZFb* (central), and *AZFc* (distal) (131).

[4] TABLE 36-6 Genetics and Male Infertility

Clinical Diagnosis	Genetic Tests	Most Common Defects	Incidence (%)
Congenital bilateral absence of vas deferens (CBAVD)	Cystic fibrosis (CFTR gene)	ΔF508, R117H	66
Nonobstructive azoospermia	Karyotype	47, XXY AZFa, AZFb[a], AZFc	15–30 10–15
Severe (<5 M/mL) oligozoospermia	Karyotype Translocation Y chromosome microdeletions	47, XXY Partial AZFb, AZFc	1–2 0.2–0.4 7–10

[a]AZFb the most severe (DAZ gene—deleted in azoospermia) causes the most severe defects of spermatogenesis; AZFc causes the mildest defects of spermatogenesis

CFTR, cystic fibrosis transmembrane conductance regulator; AZF, azoospermia factor.

Posttesticular Azoospermia

Posttesticular or obstructive etiologies are associated with normal gonadotropin and testosterone levels and are present in up to 40% of azoospermic men (58,127).

Ejaculatory dysfunction is associated with oligospermia or aspermia but rarely azoospermia (127). **[4] Obstructive causes include congenital absence or obstruction of the vas deferens or ejaculatory ducts, acquired obstruction of these ducts, or ductal dysfunction, including retrograde ejaculation** (58,127). In the congenital bilateral absence of the vas deferens (CBAVD) or hypogonadism, men with low-volume ejaculate should have a postejaculatory urinalysis to check for retrograde ejaculation, which is associated with diabetics and surgery to the bladder or prostate (58,128). Sperm may be isolated from the neutralized urine of men with retrograde ejaculation and processed for insemination or for ART (42). Transrectal ultrasound (US) may be of use to diagnose ejaculatory duct obstruction or unilateral vasal agenesis (to demonstrate contralateral atresia) but is generally not needed for CBAVD (127). **[3] Renal imaging is necessary when either unilateral or bilateral vasal absence is diagnosed as a result of the 10% to 25% incidence of renal agenesis** (127). Most men with CBAVD will also have seminal vesicle agenesis, so they will almost all have low semen volume, pH, and low fructose (127). Spermatogenesis can be expected to be normal in CBAVD, so diagnostic biopsy is generally not indicated (133). In some cases, testicular biopsy may be indicated to differentiate between testicular and posttesticular causes (127). At least two-thirds of men with CBAVD have mutations of the cystic fibrosis transmembrane conductance regulator *(CFTR)*gene (127). **[3] However, because many CFTR mutations are undetectable, CBAVD patients should be assumed to have a mutation and thus testing of the female partner's carrier status should be performed** (127).

Vasectomy Reversal and Treatment of Obstructive Azoospermia

Vasectomy can be reversed effectively using microsurgical vasovasostomy or vasoepididymostomy. The latter technique can be used for epidydimal obstructions (134). Patency and subsequent pregnancy rates after vasectomy reversal approach are 100% and 80% respectively (135). Pregnancy typically occurs within 24 months of reversal (135). **[4] Rates of patency and pregnancy vary inversely with the length of time from vasectomy, particularly for reversal procedures performed after ê15 years** (134,135). Although 60% of reversal patients develop antisperm antibodies, these do not appear to affect fecundability (135). Following surgery, periodic semen analyses can identify reobstruction, which can range from 3% to 21% depending on which segments were anastomosed (135). For those patients with azoospermia 6 months after reversal, the procedure is considered a failure and testicular sperm aspiration with ICSI could be considered (135). However, repeat vasovasostomy is associated with patency rates of 75% and pregnancy rates of 43% (135).

Surgical Sperm Recovery for Intracytoplasmic Sperm Injection

Among the many surgical methods for sperm recovery, the most widely described are

microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), testicular sperm extraction (TESE), and percutaneous testicular sperm fine-needle aspiration (TESA, also called fine needle aspiration, or FNA) (133). Both MESA and TESE are open surgical procedures performed with an operating microscope and general or regional anesthesia, whereas the percutaneous procedures need only local anesthesia (133). The optimal method for surgical sperm recovery has not been determined and certainly varies based on patient history (133). **[9]** Hematoma risk appears to be low regardless of method (133). Testicular atrophy is a rare complication of TESE and TESA even when biopsies are obtained from multiple testicular sites (133).

With obstructive azoospermia, pregnancy rates using sperm retrieval and ICSI are 24% to 64% and outcomes using either frozen thawed or fresh sperm are comparable (133). Because MESA allows for diagnosis and possible reconstruction of ductal pathology and usually yields very large numbers of sperm, sperm cryopreservation and avoidance of repeat surgery may be possible (133). If repeat sperm retrievals are needed, the minimum interval between procedures is 3 to 6 months to allow for adequate healing (134). Surgical sperm retrieval in the setting of nonobstructive azoospermia is addressed in the "Testicular Azoospermia" section.

Female Age and Decreased Ovarian Reserve

Decreased Fecundability and Diminished Ovarian Reserve

Most women will experience an age-related decline in fecundability that is physiologic rather than pathologic. **[9]** **This decline begins in the early 30s and accelerates during the late 30s and early 40s, reflecting declines in oocyte quantity and quality, commonly referred to as ovarian reserve** (136). Attribution of age-related decline of fecundability to ovarian reserve is supported by research findings among women using a wide range of methods to conceive, including natural conception, donor sperm through IUI for male factor infertility, use of donor egg in IVF, and age-related declines in IVF success rates when using a woman's own eggs. Among populations that do not practice contraception, fertility peaks at age 20, declines somewhat at age 32, steeply declines after the age of 37, and is rare after age 45 (136). Female partners of azoospermic husbands who received donor IUI had cumulative pregnancy rates over 12 cycles of 74% (age <31 years), 62% (age 31 to 35), and 54% (age >35) (137). Chronologic aging of the endometrium does not seem to play an appreciable role in reduced fertility, given the excellent (~40% to 60%, depending on whether frozen oocytes were utilized) live birth rates using donor oocytes regardless of recipient age (138,139). These examples of reproductive aging relate to the decline of the stock of primordial follicles, established early in fetal life, to near zero at menopause (140). **[5]** "Diminished ovarian reserve" has been variously defined based on age, biochemical parameters, sonography,

poor follicular response to ovarian stimulation, and number of oocytes retrieved during IVF (141). The prevalence of diminished ovarian reserve diagnoses in a U.S. IVF cohort increased to 26% in 2011, but the diagnosis has not consistently predicted IVF or pregnancy outcomes (141). Etiologies attributed to prematurely diminished ovarian reserve include iatrogenic (i.e., cytotoxic agents, radiation, and surgical removal of reproductive tissues), pelvic endometriosis or adhesions, immunologic, and genetic factors. **[5]** Although premature ovarian failure/menopause prior to age 40 has been associated with an increased number of premutation-level trinucleotide repeat lengths in the ***FMR1*** gene, a similar increase has not been consistently confirmed in premenopausal diminished ovarian reserve women (142,143).

Spontaneous Pregnancy Loss

[5] Reproductive aging is associated with abnormalities in the oocyte meiotic spindles that lead to chromosome alignment errors and increase rates of conceptus aneuploidies, particularly trisomies (136). This serves to increase the risk for spontaneous pregnancy loss and thereby decrease live birth rates in older women (136,144). A large study based on the Danish national registry estimated the rates of clinically recognized spontaneous pregnancy loss for various age groups to be 13.3% (12 to 19 years), 11.1% (20 to 24 years), 11.9% (25 to 29 years), 15.0% (30 to 34 years), 24.6% (35 to 39 years), 51.0% (40 to 44 years), and 93.4% (>45 years) (145). Using sensitive hCG assays in women during their reproductive years, 22% of all pregnancies were found to be lost before they could be clinically diagnosed (146).

Ovarian Reserve

[1] Ovarian reserve refers to the size of the nongrowing, or resting, primordial follicle population in the ovaries. This ovarian reserve, in turn, presumably determines the number of growing follicles and the "quality" or reproductive potential of their oocytes (144). Although ovarian reserve and fecundability decrease with aging, they may not be consistently reflected by a woman's chronologic age because ovarian reserve does not decline at the same pace at a given age for all women. The prognostic value of anti-mullerian hormone (AMH) levels and antral follicle count (AFC) among IVF patients, independent of age, has established them as standard ovarian reserve tests (147–150).

Serum Anti-Mullerian Hormone

AMH is produced by the granulosa cells of preantral and small antral follicles (151,152). The serum level of AMH in women with normal cycles declines with age (151) and becomes undetectable after menopause (153). **[3] Unlike other serum markers, AMH can be measured at any time in the menstrual cycle** (153) **and levels are best interpreted using age-specific reference ranges** (154). Evolving assay platforms from Diagnostic Systems Laboratories to Beckman Coulter AMH Generation

II (154), modifications to the generation II assay protocol (155) and further use of automated platforms (156) limits interpretation of serial AMH results. In women engaging in procreative intercourse without a history of infertility, AMH level does not correlate with monthly fecundability regardless of age at least in the short term (6 to 12 months) (6,157). **[5]** Anti-mullerian hormone was found to be a good predictor of both excessive (>3.5 ng/mL) and poor (<1 ng/mL) IVF stimulation response and is strongly correlated to the AFC (152,153,158).

Antral Follicle Count

Using transvaginal US in the early follicular phase, all 2 to 10 mm ovarian follicles are counted and the total for both ovaries is called the basal AFC (140). The AFC correlates very well with chronologic age in normal fertile women and appears to reflect what remains of the primordial follicular pool (140). Decreases in AFC with age are gradual rather than sudden (159). **[3] A total AFC <4 is predictive of poor response and higher cancellation rates with IVF** (160,161).

With the use of machine learning, IVF success prediction models using AMH and/or AFC can be used together with age and other clinical factors such as BMI, reproductive history, and clinical infertility diagnoses, to provide highly accurate IVF live birth probabilities. **[3]** For example, the use of AMH and/or AFC reclassified over 60% of patients to have higher IVF live birth probabilities and over 10% of patients found to have lower probabilities compared to the age-control model (150). Some providers use other ovarian reserve tests in addition to AMH and AFC.

Serum Day 3 FSH

[5] As women age, FSH physiologically rises in the early follicular phase (cycle day 3), with levels of 5.74 IU/L at ages 35 to 39 and 14.34 IU/L at ages 45 to 59 (162). In a study of 181,536 IVF cycles in the United States, a basal FSH ≥12 constituted the 90th centile of the dataset and was selected as the threshold for elevated level (141). Higher levels are seen after unilateral oophorectomy (162). In women in their 40s, levels >20 IU/L are predictive of menopause (162). Because the incidence of abnormal values is lower in younger women, testing is typically performed for women aged 35 or older (162). In subfertile women with an FSH ≥8 IU/L, spontaneous pregnancy rates decrease by 7% per unit of FSH increase, with a 40% reduction at 15 IU/L and 58% at 20 IU/L (163). FSH levels vary widely by assay, laboratory, and population (164). Basal FSH ≥12 mIU/mL has a PPV of 30.9% when used alone and 48% when combined with female age ≥40 years for predicting cycle cancellation for poor response or fewer than four oocytes obtained at retrieval, such that IVF therapy should not necessarily be withheld from patients diagnosed with diminished ovarian reserve (141). Compared to women with normal levels, elevated basal serum (>10 mIU/mL) did not affect monthly fecundability in women aged 30 to 44 without a history of infertility attempting to conceive spontaneously, regardless of age (157).

Basal Estradiol Level

Basal day 3 FSH is often combined with estradiol (E2) testing. E2 levels on day 3 reflect follicular growth rather than the number of antral follicles (151). Elevations in FSH and decreases in inhibin B (see below) that accompany aging result in advanced follicular growth at the end of the preceding luteal phase. In response, early follicular E2 levels are typically higher in older women and in women with advanced reproductive aging (140).

Clomiphene Citrate Challenge Test

Clomiphene citrate is thought to have antiestrogenic effects on the hypothalamic–pituitary axis, resulting in a decrease in E2-mediated suppression of FSH production by the pituitary (165). **The clomiphene citrate challenge test (CCCT) involves the measurement of serum FSH and E2 on day 3 of the menstrual cycle, and again on day 10 after administration of clomiphene citrate (100 mg orally each day) from days 5 to 9** (165). **[3]** The CCCT has been reported to be more sensitive than basal FSH alone in identifying poor response to exogenous gonadotropins, but others report that the predictive values of the tests do not differ substantially (164,165).

Serum Inhibin B

Serum inhibin B is secreted by ovarian granulosa cells starting at the preantral follicle stage and therefore reflects the size of the growing follicular cohort (152). Reduced inhibin B levels are seen with aging even in normal fertile women (151). Inhibin B alone has poor predictive value for ovarian response (152,164) but improves the predictive value when added to the CCCT (165). Unlike basal testing, levels of inhibin B measured on the 5th day of ovarian stimulation were predictive of live birth following IVF/ICSI (166).

Options for Diminished Ovarian Reserve

[5] Treatments of diminished ovarian reserve include autologous IVF, use of donor oocytes or embryos, and adoption. Multiple stimulation protocols have been proposed for autologous IVF in poor responders including judicious use of gonadotropins with LH activity, estrogen pretreatment, use of GnRH antagonists during and prior to ovarian stimulation, microdose flare GnRH agonists, and selective estrogen receptor modulators such as clomiphene and letrozole along with gonadotropin injections (167,168). All have varying degrees of success, but counseling for diminished ovarian reserve patients in whom donor gametes are not of interest must include disclosure that per-cycle pregnancy rates are low, particularly in older women (169), such that multiple IVF cycles may be necessary and the prognosis may be poor or futile. However, isolated case reports of success do provide some hope in this regard (170,171), so it may be appropriate to offer autologous therapy to motivated, well-counseled patients.

Adjuncts During Autologous IVF

[5] Adjunctive autologous IVF therapies include androgens such as DHEA and testosterone, growth hormone, Coenzyme Q-10 (CoQ10), vitamin D, and omega-3 fatty acids. Pretreatment of women with diminished ovarian reserve for 2 to 5 months with dehydroepiandrosterone (DHEA; 25 mg three times daily) has been described to improve oocyte yield and pregnancy rates with IVF in case series (172–174). Putative mechanisms for this action include increasing serum concentrations of insulin-like growth factor 1 (IGF-1), which may potentiate gonadotropic effects on the follicle, and providing the ovary with additional prohormone for additional ovarian steroidogenesis (174). Pretreatment with DHEA led to higher ovarian volumes and AFCs in women with premature ovarian insufficiency (175), however some prospective cohort and randomized trials have not found statistically significant improvements for stimulation parameters or pregnancy rates in poor (176,177) or normal responders (178). A similar rationale has prompted the use of transdermal testosterone 10 to 12.5 mg for 14 to 28 days pretreatment or during stimulation with varied results in terms of number of oocytes retrieved and pregnancy rate (179,180). A Cochrane review of 17 randomized controlled trials found moderate quality evidence of live birth benefit for DHEA and testosterone in poor responders (181).

Growth hormone, by enhancing the granulosa cell response to gonadotropins through increases in local IGF-1 production, has been found to improve pregnancy and live birth rates for poor responders in some meta-analyses including the Cochrane database (182–184). Suggested dosing for growth hormone is 2.5 mg subcutaneously from day 6 of stimulation to day of trigger (182). The cost of growth hormone may be prohibitive for some patients; it is generally not covered by insurance for off-label use, and such use may be restricted by the 1990 Anabolic Steroids Control Act (185).

Nutritional supplementation may provide important adjunctive benefits. CoQ10 is found in higher concentrations in follicular fluid of oocytes that produce good quality embryos by morphokinetic assessment and pregnancies (186). Oocytes and early embryos obtain energy solely from CoQ10-mediated mitochondrial oxidative phosphorylation which allows proper oocyte maturation and fertilization, but aging diminishes CoQ10 production mitochondrial oxidative phosphorylation (187). These changes can be reversed by CoQ10 supplementation in mice and humans (188). Women randomized to 600 mg of daily CoQ10 for 2 months prior and during their IVF cycle had a nonstatistically significant increase in good quality embryos and embryo euploidy compared to the placebo group (187). Omega-3 fatty acids such as those found in fish oil extends reproductive lifespan in murine models, and this may be through effects on the pituitary. Normal-weight reproductively healthy women taking 4 g of eicosapentaenoic acid and docosahexaenoic acid daily for 4 weeks had reduced baseline and GnRH-stimulated serum FSH levels (189). Vitamin D deficiency has been inconsistently associated with AMH levels and AFC, so it is difficult to derive clinical recommendations for vitamin D supplementation solely for the indication of diminished

ovarian reserve (190). Supplementation for vitamin D deficient patients has produced inconsistent outcomes with respect to pregnancy rates in the context of IVF (191,192).

Ovulatory Factor

[6] Ovulatory factor accounts for 30% to 40% of all cases of female infertility (193). Initial diagnoses among women with ovulatory factor infertility may include anovulation (complete absence of ovulation) or oligo-ovulation (infrequent ovulation). **[1]** Menstrual history may be suggestive if oligomenorrhea, amenorrhea, polymenorrhea, or dysfunctional uterine bleeding are present (193). Menstrual dysfunction is present in 18% to 20% of the general population (194). **Figure 36-4** shows the fluctuations of E2, progesterone, FSH, and LH in a normal, 28-day ovulatory cycle. **The normal length of the menstrual cycle in reproductive-age women varies from 21 to 35 days, with a mean of 27 to 29 days** (195). Most of the variability in cycle length occurs during the follicular phase (196) but the luteal phase, often considered to be fixed at 14 days, can range from 7 to 19 days (197). **[1]** Even women with regular monthly menses may have anovulation (194), although the presence of moliminal symptoms such as premenstrual breast swelling, bloating, and mood changes are much more suggestive of ovulatory cycles (194). **[3]** In women with absent or infrequent ovulation, serum FSH, prolactin, and thyroid-stimulating hormone (TSH) testing should be performed (193).

Methods to Document Ovulation

The "Fertile Window"

[1] The fertile window is the 6-day interval ending on the day of ovulation, and does not extend past ovulation (44,196). Sperm can survive for up to 6 days in well-estrogenized cervical mucus, but the egg may be fertilizable for less than a day (196). Daily intercourse during this window may increase the probability of conception (44,196). **[1]** The average woman is fertile between days 10 and 17 of the menstrual cycle, but many women can conceive outside of this range (197). **[4]** Therefore, if timed intercourse (TI) is too cumbersome, intercourse two to three times weekly throughout the menstrual cycle will likely result in at least some of those occasions falling within the fertile window (198). Duration of abstinence prior to the fertile window has not been established, although one author suggests 5 days (196).

Basal Body Temperature

This inexpensive method involves daily recording of oral or rectal temperature using a basal body temperature (BBT) thermometer before the patient arises, eats, or drinks (199). The secretion of progesterone following ovulation causes a temperature increase of about 0.5° to 1°F over the baseline temperature of 97° to 98.8°F that is typically recorded during the follicular phase of the menstrual cycle (199). Ovulation is assumed

after 3 consecutive days of raised temperatures (199). Charting of daily BBTs produces a characteristic biphasic pattern in women with ovulatory cycles (199). [1] **Limitations to BBT include its inability to prospectively predict ovulation and its frequent false negative results** (200). Smoking and irregular sleep patterns can interfere with accurate BBT testing (199).

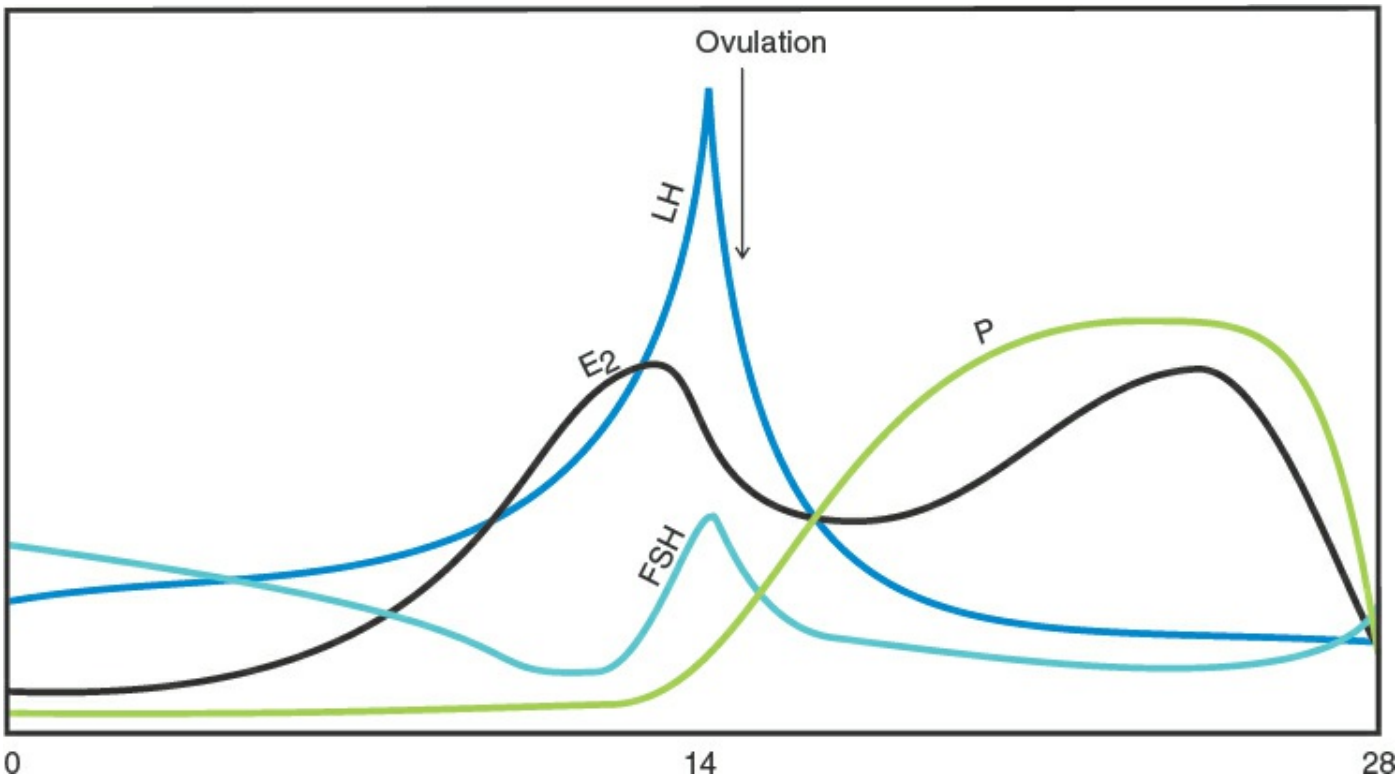

FIGURE 36-4 Relative hormonal fluctuations in a normal, ovulatory, 28-day menstrual cycle.

Cervical Mucus

During the fertile window, cervical secretions at the vaginal introitus are slippery and clear, while secretions at other times of the menstrual cycle are dry and sticky (44,199). [1] The volume of cervical mucus peaks 2 to 3 days prior to ovulation, thus identifying higher day-specific probabilities of conception (44).

Luteinizing Hormone Monitoring

At a mean time of 2 hours following the peak of the serum LH surge, urinary LH can be detected (201). Commercially available kits for documenting the LH surge are generally accurate, quick, convenient, and relatively inexpensive enzyme-linked immunosorbent assays (ELISA) that use 35 to 50 mIU/mL as their threshold for detection (201,202). **When the LH surge is detected, ovulation may occur within the next 48 hours** (44,201,202). The positive predictive and negative predictive values for these kits have been described to be 92% (201) and 95% (203), respectively. Because the duration of the surge may be <12 hours, twice daily testing may increase detection rates (202).

However, the 2 days of highest probability of conception are the day of and the day prior to the LH surge, so this may lead to abstaining from intercourse during a potentially fertile time (196). False positive rates occur in 7% of cycles (44,204), which may reflect urinary clearance of unsustained premature LH surges (200). **[1]** The tests cannot be used in patients with irregular cycles (196).

Midluteal Serum Progesterone

When used to document ovulation, serum progesterone measurement should coincide with peak progesterone secretion in the midluteal phase (typically on days 21 to 23 of an ideal 28-day cycle or 7 days following the LH surge) (193). **The lower limit of progesterone levels in the luteal phase varies among laboratories, but a level above 3 ng/mL (10 nmol/L) typically confirms ovulation** (193). **Interpretation of isolated luteal phase measurements of serum progesterone is complicated by the frequent pulses that characterize the secretion of this hormone** (193). **[1]** Although ovulatory levels are often considerably higher than 3 ng/mL, low midluteal serum levels of progesterone are not necessarily diagnostic of anovulation (193).

Ultrasound Monitoring

Ovulation is characterized by a decrease in the size of a monitored ovarian follicle and by the appearance of fluid in the cul-de-sac using transvaginal US (193). **[6]** **Follicles reach a preovulatory diameter of 17 to 19 mm in spontaneous cycles or 19 to 25 mm for clomiphene-induced cycles** (205,206). A combination of LH testing and US can be used, with LH kit testing starting when the US-measured follicle size reaches 14 mm (200). Ten percent of the cycles of normally fertile women may have a luteinized unruptured follicle, whereby progesterone is released and the luteal phase progresses normally without visible signs of follicle rupture when daily USs are performed from cycle days 10 to 20 (207). This incidence is increased to 25% in women with unexplained infertility (207). **Because of the inconvenience and expense of serial measurements, US monitoring should be reserved for patients who fail less expensive methods for detecting ovulation or for certain types of ovulation induction** (193).

Polycystic Ovarian Syndrome

[7] The most common cause of oligo-ovulation and anovulation—in the general population and among women presenting with infertility—is PCOS (208). The diagnosis of PCOS is determined by exclusion of other medical conditions such as pregnancy, hypothalamic–pituitary disorders, or other causes of hyperandrogenism, for example, androgen-secreting tumors or nonclassical congenital adrenal hyperplasia *and* the presence of two of the following conditions (209):

- **Oligo-ovulation or anovulation (manifested as oligomenorrhea or**

amenorrhea)

- **Hyperandrogenemia (elevated levels of circulating androgens) or hyperandrogenism (clinical manifestations of androgen excess)**
- **Polycystic ovaries detected by US**

Documentation of elevated serum LH: FSH ratios and hyperinsulinemia are not required for either diagnosis or treatment of PCOS (208,209). Patients with PCOS should be counseled and screened regarding potential metabolic disease and obstetric complications prior to fertility treatment (208).

Ovulation Induction in Women With Polycystic Ovarian Syndrome

Despite the use of similar medications, the indications and goals of ovulation induction should be distinguished from those of superovulation. The goal of ovulation induction refers to the therapeutic restoration of the release of one egg per cycle in a woman who either has not been ovulating regularly or has not been ovulating at all (205). **In contrast, the explicit goal of superovulation for women with unexplained infertility is to cause more than one egg to be ovulated, thereby increasing the probability of conception** (205). **Overall, 60% to 85% of women with PCOS will ovulate when treated with clomid or letrozole. [6] Of the women who ovulate, 15% to 20% will be pregnant per cycle and 50% will be pregnant by 6 months of treatment** (210–212).

Weight Loss

Obesity in PCOS patients is associated with poor infertility treatment outcomes (208,213–215), although the impact on pregnancy loss rates is less clear (208,213,216). **[7] Given that even a 5% weight loss may improve pregnancy rates, weight loss should be encouraged in all overweight and obese infertility patients** (208). In general, lifestyle modification is the first-line therapy, followed by pharmacologic treatment and weight-loss surgery (208). Lifestyle recommendations include a decrease in daily caloric consumption by 500 kcal and regular physical exercise, although the optimal regimen for the latter is unknown (208,217). Weight-loss interventions should be undertaken prior to attempting conception in patients with excess body weight (208).

Ovulation Induction Agent Pharmacology (Clomiphene Citrate [Clomid, Serophene], Letrozole [Femara], Anastrozole [Arimidex])

Clomiphene citrate is a weak synthetic estrogen that mimics the activity of an estrogen antagonist when given at typical pharmacologic doses for the induction of ovulation (205). It is cleared through the liver and excreted into the stool, with 85% clearance in 6 days (205). **[7] A functional hypothalamic–pituitary–ovarian axis is usually required for appropriate clomiphene citrate action** (205). More specifically, clomiphene citrate is thought to bind and block estrogen receptors in the hypothalamus

for prolonged periods, thereby decreasing the normal ovarian–hypothalamic estrogen feedback loop (205). This blockade increases GnRH pulsatility, leading to increased pituitary secretion of gonadotropins which promote ovarian follicular development (205). Letrozole and anastrozole are potent, reversible nonsteroidal aromatase inhibitors that have been used off-label for the treatment of patients with anovulatory infertility since 2001 (218). Letrozole is administered orally and cleared by the liver with a shorter half-life (48 hours) than clomiphene citrate (2 weeks). By reducing ovarian E2 secretion, letrozole disrupts E2's negative feedback effect on pituitary gonadotropin release. The consequent rise in FSH promotes ovarian follicular development.

Ovulation Induction Outcomes

Ovulation induction is first-line treatment for anovulatory infertility (219). Over the course of 6 months, clomiphene is associated with 49% ovulation, 23.9% pregnancy, and 22.5% live birth rates in women with anovulatory infertility (213). **[7]** **Clomiphene effectiveness is decreased by obesity, increased age, and hyperandrogenic states** (213,220,221). Side effects of clomiphene citrate include vasomotor flushes, mood swings, breast tenderness, pelvic discomfort, and nausea (205). In a minority of individuals, the antiestrogenic effects of clomiphene citrate at the level of the endometrium or the cervix may have adverse effects on fertility (205). In the presence of visual abnormalities, clomiphene citrate should be discontinued promptly (205). Multiple gestation rates with clomiphene citrate are approximately 8%, most of which are twins (205). Though historically clomiphene citrate has been the drug of choice for the treatment of women with PCOS-associated anovulation, current evidence suggests that letrozole results in higher ovulation and live birth rates compared with clomiphene, particularly for obese (BMI >30) women. In a multicenter trial of 750 women with PCOS-associated infertility randomizing to letrozole (2.5 mg) or clomiphene citrate (50 mg) from cycle day 3 to 7 for up to five cycles, the cumulative live birth rate was significantly higher in the letrozole arm (27.5% vs. 19.1%; RR 1.44, 95% CI 1.10–1.87) (222). Twin pregnancy rates were similar in the letrozole (3.4%) and clomiphene (7.4%) groups (222). A subsequent meta-analysis of six trials comparing clomiphene and letrozole for ovulation induction in anovulatory women with PCOS observed higher live birth rates with letrozole (OR 1.79; 95% CI 1.38–2.31) (223). Side effects with letrozole include dizziness and fatigue. **[7]** Although concerns have been raised regarding possible associations between fetal congenital anomalies and the use of aromatase inhibitors, no such increase was observed when letrozole was compared to clomiphene (224).

Ovulation Induction Dosing

Letrozole is supplied in 2.5 mg tablets, and the typical starting dose is 2.5 mg per day. Clomiphene citrate drug is supplied in 50 mg tablets; the usual starting dosage is 50

mg/day, but patients who are very sensitive may respond to 12.5 to 25 mg/day (205). Either agent is typically begun within the first 5 days after the onset of a spontaneous or progesterone-induced menses and is continued for 5 days (i.e., treatment on days 3 to 7 or 5 to 9 of the menstrual cycle) (205). Prior to initiating letrozole, patients should be counseled that ovulation induction represents an off-label use of the drug. Given the pregnancy category X designation of both clomiphene and letrozole, care should be taken to ensure that the patient is not pregnant prior to administration of these agents. If ovulation does not occur at the initial dosage of 2.5 mg letrozole or 50 mg *clomiphene citrate,* the dosage is increased in each subsequent cycle by 2.5 mg or 50 mg per day, respectively (205). **Seventy-four percent of women will ovulate with 100 mg/day** (205), **the maximum dose approved by the U.S. Food and Drug Administration** (209). However, some patients need higher doses, which have been safely given up to 250 mg/day (205). A stair-step method increases the dose within a single cycle without intervening menses if no follicular response is documented by US 4 to 5 days after the last dose (225). **[7]** Ovulation induction treatment should be limited to six ovulatory cycles or 12 total cycles (205,226,227).

Monitoring Ovulation Induction Therapy

If preovulation monitoring is not performed, patients should be instructed to have intercourse every 2 to 3 days following the last day of therapy and check serum progesterone weekly × 5 weeks before inducing a withdrawal bleed or increasing the dose of the ovulation induction agent (213). **Although no clear advantage has been demonstrated for any ovulation monitoring technique, regular contact should be maintained with patients to review response to therapy** (205). The urinary LH surge may be detected 5 to 12 days after treatment is completed (205). When clomiphene or letrozole is given on cycle days 5 to 9, the surge typically occurs on cycle days 16 to 17 and can be confirmed by midluteal serum progesterone testing 7 days later (205). With US monitoring, treatment should be withheld if large cysts are seen on baseline testing (205). Following ovulation induction use, follicles typically reach a preovulatory diameter of 19 to 25 mm by US, but may be as large as 30 mm (205,206). **[7]** A combination of LH testing and US can be used, with LH kits starting when the largest US-measured follicle reaches 14 mm in diameter (200).

Human Chorionic Gonadotropin

If a dominant follicle develops, but there is no spontaneous LH surge, hCG can be used to induce final follicular maturation (205), with ovulation occurring approximately 40 hours following administration (228). **Although administration of hCG at mid-cycle does not** appear to improve conception chances in most infertility patients using clomiphene citrate (104,229,230), **it may be useful for patients with known ovulatory dysfunction** (229) **or for IUI.** **[7]** The medication may be derived from urine (5,000 to

10,000 international units intramuscularly) or manufactured with recombinant technology (250 µg subcutaneously, equivalent to 5,000 to 6,000 IU urinary) (228).

Insulin Sensitizers

Insulin resistance contributes to the pathogenesis of PCOS. Metformin is an oral biguanide that is approved for the treatment of noninsulin-dependent diabetes and has been used in PCOS to increase the frequency of spontaneous ovulation (231). Metformin acts by several mechanisms, including inhibition of gluconeogenesis in the liver and increasing the uptake of glucose in the periphery (231). **Although the literature is conflicting, larger studies have suggested that the live birth rate with metformin alone (7.2%) is lower than that achieved with clomiphene, and overall the combination does not confer additional benefit over clomiphene alone** (213,232). Subgroups of patients including those who are obese may benefit from combination therapy, however (220,233). Though prepregnancy use of metformin does not appear to reduce miscarriage rate, there is insufficient evidence to recommend metformin use during pregnancy to reduce the risk of miscarriage (234). Risks of metformin include gastrointestinal upset and rare lactic acidosis, so it should be avoided in settings of hepatic/renal dysfunction and prior to surgery or use of contrast radiologic dye (231). Reported effective doses include 500 mg three times daily (231), 850 mg twice daily (231), and 1,000 mg twice daily (213). The medication is best tolerated when started at the lowest dose and increased gradually. Extended release formulations are associated with less gastrointestinal upset (213). **Because regular ovulation may not occur with metformin alone, patients may need medications to induce withdrawal bleeding to reduce the risk of continued anovulation and endometrial hyperplasia** (208). **[7] The use of thiazolidinediones, including the PPAR-f agonists, *rosiglitazone* and *pioglitazone*, for ovulation induction in PCOS patients has become less widespread as a result of their association with weight gain and, in the case of *rosiglitazone*, increased cardiovascular risk** (208).

Dexamethasone

Adjunctive oral dexamethasone may improve ovulation rates in patients resistant to clomiphene alone (219). These improvements have been reported even in the absence of adrenal hyperandrogenemia (235,236), so the mechanism of action remains unclear. Dose regimens have included 0.5 mg × 5 days starting on day of clomiphene (237), 0.5 mg × 6 weeks prior to starting clomiphene (238), and 2 mg × 10 days starting on day of clomiphene (235,236).

Oral Contraceptive Pretreatment

[7] Administration of oral contraceptives (OCs) × 2 months prior to beginning a cycle of clomiphene may improve ovulation and pregnancy rates in clomiphene-resistant patients, perhaps by improving a pre-existing hyperandrogenic environment (219,239).

Gonadotropin Therapy

Anovulatory PCOS patients who fail to ovulate or conceive with oral agents may be considered for ovulation induction with exogenous gonadotropin injections (240). For women with clomiphene-resistant PCOS, treatment with gonadotropins results in ovulation rates of 43% to 83% and pregnancy rates of 21% to 29% (241–243). Evening medication administration allows for morning monitoring and mid-day decision-making. Monitoring involves serum E2 levels and transvaginal US measurements of follicle development. Typical protocols monitor at baseline, 4 to 5 days after treatment initiation, and every 1 to 3 days until follicular maturation. Expected follicle growth is 1 to 2 mm daily after achieving 10 mm diameter (240). **Given the goal of promoting growth of a single mature follicle, low initial gonadotropin doses of 37.5 to 75 international units (IU)/day are generally recommended, with increases in doses by 50% of the previous dose after 7 days if no follicle >10 mm is observed** (208,240). Typical treatment duration is 7 to 12 days, but some patients require longer medication regimens for adequate stimulation (240). The maximum required gonadotropin dose seldom exceeds 225 IU per day (240). Ovulation triggering with hCG is recommended for gonadotropin cycles and is used when 1 to 2 follicles are 16 to 18 mm diameter and the E2 level per dominant follicle is 150 to 300 pg/mL (240). Ovulation is expected 24 to 48 hours after the hCG trigger. GnRH agonists such as leuprolide (500-µg subcutaneously) can be used to trigger ovulation to minimize risks associated with ovarian hyperstimulation syndrome, but require progesterone supplementation following administration (240). Intercourse should be recommended within 24 to 48 hours of ovulation triggering or IUI 24 to 36 hours after triggering (240). Testing for pregnancy is performed within 15 to 16 days after ovulation triggering and the cycle reviewed if pregnancy testing is negative. **[7]** Gonadotropin dosage in future cycles should be altered if the prior response was inadequate or excessive.

Gonadotropin Preparations

Several gonadotropin preparations are available. hMG is derived from human urine and includes approximately equivalent FSH and LH (derived from hCG) activity of 75 IU each (228). Formulations of hMG and FSH can be administered either subcutaneously or intramuscularly (228). FSH-only preparations may be derived either from urine or via recombinant methods, and are packaged either as lyophilized powder or premixed liquid cartridges/pens (228). Except for highly purified urinary FSH, which has an FSH activity of 82.5 IU per ampule, all other products contain 75 IU of gonadotropin when supplied in ampules (228). **All preparations of FSH are highly purified, with minimal to no batch to batch variation and a high level of safety regardless of the derived source** (228). Despite being differentially marketed as follitropin alpha and beta, these recombinant FSH preparations still contain combinations of 1 alpha and 1 beta glycoprotein chain. Rather, they differ in their posttranslational modifications and

processes for purification (228). [7] For PCOS patients, FSH alone appears to be sufficient in the gonadotropin preparation, although hMG is not harmful (Table 36-7) (240). Contraindications to gonadotropin therapy are listed in Table 36-8.

Gonadotropin Outcomes

Cumulative live birth rates are similar when gonadotropins are compared to clomiphene for ovulation induction when the goal is monofollicular ovulation and a maximum of six ovulatory cycles is similarly recommended (208). [7] **When compared to other anovulatory patients, PCOS patients using gonadotropins are at higher risk for multiple gestations (36%), ovarian hyperstimulation syndrome (4.6%), and cycle cancellation (10%) as a result of their high numbers of baseline antral follicles** (208,212,240). Cancellation should be strongly considered in patients who reach E2 levels of 1,000 to 2,500 pg/mL, have ≥3 follicles ≥16 mm, or ≥2 follicles ≥16 mm plus ≥2 follicles ≥14 mm (208). Sequential use of gonadotropins and either clomiphene or aromatase inhibitors has been associated with lower gonadotropin requirements and lower cancellation rates and treatment duration without compromising pregnancy rates. The addition of aromatase inhibitors is associated with a lower number of dominant follicles and lower maximum E2 levels (244–246).

[8] TABLE 36-7 Relative and Absolute Contraindications of Gonadotropins for the Treatment of Infertility in Women

Trade Name	Name of Compound	Source	Amount of FSH per Ampule	Amount of LH Activity per Ampule	Route of Administration
Menopur (Ferring Pharmaceuticals, Inc.)	Menotropin urinary hMG	Highly purified	75 IU	75 IU (from ~10 units HCG)	SC
Follistim (Merck)	Follitropin	Recombinant FSH beta	75 IU[a]	None	SC
Gonal-F (EMD Serono)	Follitropin	Recombinant FSH alpha	75 IU[a]	None	SC

[a]Also available in pen formulation.

FSH, follicle-stimulating hormone; LH, luteinizing hormone; hMG, human menopausal gonadotropin; IM, intramuscularly; SC, subcutaneously; N/A, not applicable.

Surgical Treatment

For clomiphene resistant patients, surgical ovarian drilling has been performed as an alternative to the outdated ovarian wedge resection to decrease ovarian androgen-producing tissue and to promote ovulation without the risk of multiple pregnancy seen with gonadotropin administration (208,247). Drilling 3 to 15 puncture sites per ovary is typically performed via laparoscopy using electrocautery/diathermy (248–251) or laser (252–254), although transvaginal US-guided (255,256) and vaginal hydrolaparoscopy (257) procedures have been reported. Successful drilling has been performed with the harmonic scalpel (252). Within 12 months after ovarian drilling, cumulative ovulation, clinical pregnancy, and live birth rates are 52%, 26% to 48%, and 13% to 32%, respectively (247). **These outcomes are similar to those using gonadotropins, but**

ovarian drilling carries a lower multiple gestation rate (247). Outcomes are not significantly different when diathermy versus laser are used for drilling (247), but they are compromised with patient age >35 years or basal FSH >10 mIU/mL (249). **[7]** The risks of ovarian drilling include surgical complications, adhesions, recurrence of anovulation, and a theoretical risk of ovarian failure (247,258).

[8] TABLE 36-8 Relative and Absolute Contraindications of Gonadotropins for the Treatment of Infertility in Women

1. Primary ovarian failure with elevated follicle-stimulating hormone levels
2. Uncontrolled thyroid and adrenal dysfunction
3. An organic intracranial lesion such as a pituitary tumor
4. Undiagnosed abnormal uterine bleeding
5. Ovarian cysts or enlargement not caused by polycystic ovary syndrome
6. Prior hypersensitivity to the particular gonadotropin
7. Sex hormone–dependent tumors of the reproductive tract and accessory organs
8. Pregnancy

Ovulation Induction for Other Anovulatory Disorders

Hyperprolactinemia

Hyperprolactinemia can be associated with oligomenorrhea or amenorrhea and should be evaluated with a pituitary MRI to exclude macroadenoma or other intracranial pathology (259). **[6] Dopamine agonists are first-line agents in symptomatic patients with hyperprolactinemia to restore ovulation** (259). Bromocriptine normalizes prolactin levels and induces ovulation in 80% to 90% of patients (260). It is taken two to three times daily, and most patients will respond to a total dose <7.5 mg daily (260). Side effects can be significant and include nausea, vomiting, postural hypotension, and headache (260). For this reason, bromocriptine is begun with a low dose of 1.25 mg (half of a 2.5-mg tablet) daily with food in evenings and prolactin level can be repeated 2 weeks later to adjust the dose as appropriate (261). The 1.25-mg dose may be adequate for those with prolactin level <50 ng/mL, while those <100 ng/mL may need 2.5 mg daily (261). In patients unable to tolerate oral administration, bromocriptine has been used vaginally 5 mg daily (262). Cabergoline has similarly high efficacy and the advantage of a 0.25 mg twice-weekly dosing schedule and fewer side effects (260). **[6]** In a review of over 700 cases of cabergoline use at the time of conception, the risk of miscarriage and malformations was no higher than the baseline rate in the general

population (263).

Hypogonadotropic Hypogonadism

[6] Anovulation in the presence of low serum LH, FSH, and E2 levels defines hypogonadotropic hypogonadism and reflects dysfunction within the hypothalamic–pituitary axis (259). Causes of hypogonadotropic hypogonadism, including craniopharyngiomas, pituitary adenomas, arteriovenous malformations, or other central space-occupying lesions, should be excluded using magnetic resonance imaging (259). Stress, extreme weight loss, anorexia, excessive exercise, and low BMI are all associated with functional hypothalamic suppression, so good nutrition and optimal body weight should be encouraged to restore ovulation (259,264). Leptin is a hormone produced by peripheral adipocytes that reflects energy stores and is deficient in women with diet or exercise-induced amenorrhea (265). Exogenous leptin has been reported to restore ovulation in these women (265,266). **Other conditions of hypothalamic dysfunction, such as congenital hypothalamic failure (Kallmann syndrome), can be treated using pulsatile GnRH therapy or gonadotropins. In these patients, FSH and LH should be administered** (259,267). Pulsatile GnRH agonist therapy (25 ng/kg every 60 to 90 minutes) simulates normal physiology and offers some advantages over gonadotropin injections, including fewer multiple gestations and less ovarian hyperstimulation syndrome (OHSS) while maintaining excellent pregnancy rates (267).

Hypothyroidism

The prevalence of hypothyroidism among mid-reproductive aged women is 2% to 4% and is mostly caused by autoimmune factors (268). Menstrual abnormalities, including those from anovulation, are present in 23% to 68% of overtly hypothyroid women and can be corrected with levothyroxine replacement (268). **The presence of antithyroid antibodies (even if euthyroid) are associated with increased rates spontaneous pregnancy loss and lower live birth rates** (269). However, among euthyroid Chinese women with elevated thyroid peroxidase antibodies, levothyroxine supplementation 25 to 50 mcg daily did not affect miscarriage or live birth rates with IVF in a 2017 randomized trial (270). **[2]** In any case, because even very mild or subclinical hypothyroidism can have adverse effects on fetal brain development and subsequent intelligence quotient, it is prudent to screen and treat women with thyroid hormone abnormalities before commencing infertility treatment (268).

Tubal Factor

Tubal factor accounts for 25% to 35% of infertility (12). Noninfectious causes for tubal factor include tubal endometriosis, salpingitis isthmica nodosa, tubal polyps, tubal spasm, and intratubal mucous debris (12). **[8] The incidence of tubal infertility has been reported to be 8%, 19.5%, and 40% after one, two, and three episodes of**

PID, respectively (271). Live birth rates are negatively affected by the severity of a single episode of PID (272). *C. trachomatis* and *Neisseria gonorrhoeae* are common pathogens associated with PID and infertility (273). *M. hominis* and *U. urealyticum* have been implicated in PID but their contribution to infertility is less clear (273). Many patients with documented tubal damage have no history of PID and are presumed to have had subclinical chlamydial infections (274,275).

Hysterosalpingography

Hysterosalpingography (HSG) is performed after menses but prior to ovulation between cycle days 7 and 12 to avoid potential pregnancy and take advantage of the thinner proliferative phase endometrium (276). The patient is typically premedicated 30 to 60 minutes prior to the procedure with ibuprofen or related medication (276). Lidocaine injected intracervically may provide further pain relief (277). With the patient in the dorsal lithotomy position, **either a metal cannula or a balloon catheter is inserted through the cervix and past the internal cervical os. [3] Contrast dye is injected under fluoroscopy to visualize the uterine cavity, fallopian tube architecture, and tubal patency** (276,278). Certain disease processes, such as salpingitis isthmica nodosa, have a characteristic appearance on HSG, with honeycombing as a result of contrast-filled diverticular projections (279). Compared to laparoscopy, HSG has a sensitivity and specificity of 65% and 83% for the diagnosis of tubal patency (280). By flushing inspissated mucus and debris, the HSG procedure may have therapeutic value, particularly with use of oil-based contrast. A large multicenter RCT that randomized 1,119 women to oil- or water-based contrast found a significantly higher live birth rate after use of oil-based contrast at HSG (38% vs. 28%; RR 1.38, 95% CI 1.17–1.64) (281).

Hysterosalpingography Risks

Although use of oil-based contrast is thought to carry potential risk of intravasation-associated oil embolism, this complication has not been observed in large prospective studies (282). Patients should be screened for and pretreated with glucocorticoids if iodine allergy is found (278). The risk of PID after HSG is 0.3% to 3.1% overall but is >10% in the setting of hydrosalpinges (283,284). **Therefore, HSG should be avoided in the setting of known hydrosalpinges and/or current or suspected PID** (276,284). The role of routine antibiotic prophylaxis for HSG is controversial (285), but in high-risk patients doxycycline could be considered. Recommended dosing is 100 mg twice daily, beginning the day before HSG and continuing for 3 to 5 days. If prophylaxis is not used and hydrosalpinges are noted on examination, postprocedure doxycycline treatment is recommended. Other rare complications of HSG include vascular intravasation, cervical laceration, uterine perforation, hemorrhage, vasovagal reactions, severe pain, and allergic response to the contrast dye (276).

Sonohysterography

Many infertility practices routinely use sonohysterography to assess tubal patency because it can be performed in a typical fertility clinic and involves no ionizing radiation exposure for patient or staff. **[3]** This advantage over HSG is at least partially offset by an inability to accurately define tubal architecture when performed using standard 2D approaches. The use of contrast media during sonohysterography is preferred to improve accuracy in documenting fallopian tubal patency, but these contrast agents are not available in the United States. As a substitute, the use of agitated saline (air-saline) during sonohysterography provides good negative predictive value when compared to HSG or laparoscopy (286). Large studies comparing the sensitivity and specificity of sonohysterography and HSG in the detection of tubal occlusion are not available.

Chlamydia Serology

Chlamydia antibody testing appears to have comparable sensitivity and specificity to HSG, but does not localize pathology and testing has no therapeutic benefit (279). It has been proposed that positive serologies in the setting of normal HSG should still prompt laparoscopy to rule out peritubal adhesions (275).

Laparoscopy

[3] Laparoscopy is considered the gold standard for diagnosing tubal and peritoneal disease (287). It allows visualization of all pelvic organs and permits detection and potential concurrent treatment of intramural and subserosal uterine fibroids, peritubal and periovarian adhesions, and endometriosis (287). Abnormal findings on HSG can be validated by direct visualization on laparoscopy using chromopertubation, which involves the transcervical installation of a dye such as indigo carmine to directly visualize tubal patency and fimbrial architecture (287). **[3] Even laparoscopy has been reported to have a false positive rate of 11% for proximal tubal occlusion when resected tubal segments are examined pathologically** (288).

Other Diagnostic Modalities

Falloposcopy is used in conjunction with hysteroscopy and allows direct fiberoptic visualization of tubal ostia and intratubal architecture for identification of tubal ostial spasm, abnormal tubal mucosal patterns, and even intraluminal debris causing tubal obstruction (288,289). Instrumentation availability and technical complications, including tubal perforation, limit its routine use (289).

Treatment of Tubal Factor Infertility

[8] As success rates for ART continue to improve, the indications for surgical approaches in the treatment of tubal infertility have become increasingly limited (290). Surgery can be effective in several situations and may be the optimal approach in some

patients.

Proximal Tubal Occlusion

Proximal tubal catheterization and cannulation performed either via HSG or hysteroscopy can restore tubal patency in up to 85% of obstructions, although the reocclusion rate approaches 30% (12). **The best candidates for proximal tubal catheterization/cannulation have suspected muscle spasm, stromal edema, amorphous debris, mucosal agglutination, or viscous secretions, while nonresponders include those with luminal fibrosis, failed tubal reanastomosis, fibroids, congenital atresia, or tuberculosis** (12). Occlusion caused by salpingitis isthmica nodosa, endometriosis, synechiae, salpingitis, and cornual polyps will only occasionally respond to catheterization/cannulation (12). Catheterization involves passage of a soft catheter into the tubal ostia, while cannulation passes a guidewire through the ostia and injects contrast media or colored dye (12,279). Tubal perforation, typically minor, occurs in 1.9% to 11% of cases (12,279,288). **Catheterization under fluoroscopy during HSG is referred to as selective salpingography** (291). **Visualization of patency with the hysteroscopic approach can be accomplished using laparoscopy** (12) **or US** (288). Ongoing pregnancy rates following proximal tubal catheterization/cannulation are 12% to 44% regardless of hysteroscopic or HSG approach (12). If occlusion persists or recurs, IVF is usually recommended. Microsurgical tubocornual anastomosis is an option with small studies reporting pregnancy rates of up to 68% (12). This procedure is typically performed via laparotomy and involves excision of the tubal isthmus, followed by reimplantation of the residual tube into a new opening made through the uterine cornua (279).

Distal Tubal Occlusion (Excluding Sterilization or Hydrosalpinx)

[8] Distal tubal disease and occlusion are causal in 85% of all tubal infertility and can be secondary to a variety of inflammatory conditions including infection, endometriosis, or prior abdominal or pelvic surgery (279,292). Patients younger than 35 years of age with mild distal tubal disease, normal tubal mucosa, and absent or minimal pelvic adhesions are the best candidates for corrective microsurgery (292). IVF should be considered for older patients or those with diminished ovarian reserve, combined proximal and distal tubal disease, severe pelvic adhesions, tubal damage that is not amenable to reconstruction, or additional infertility factors (292,293). Fimbrioplasty involves lysis of fimbrial adhesions or dilation of fimbrial phimosis, whereas salpingostomy (also known as salpingoneostomy) involves the creation of a new tubal opening in an occluded fallopian tube (292). In well-selected patients, pregnancy rates are reported to be 32% to 42.2%, 54.6% to 60%, 30% to 34.6%, and 55.9% for adhesiolysis, fimbrioplasty, salpingostomy, and nonsterilization-related anastomosis, respectively (279,292). **As a group, these procedures are associated**

with a 7.9% rate of subsequent ectopic pregnancy (292).

Sterilization Reversal

Twenty percent of women express regret following sterilization, and 1% to 5% of those will request reversal (294), **often as a result of a change in marital status** (293). The technique for sterilization reversal involves microsurgical dissection of the occluded ends of the fallopian tube followed by a layered reapposition of the proximal and distal tubal segments (293). Surgical approaches include minilaparotomy, laparoscopy (293), and robotic-assisted laparoscopy (294). Pregnancy rates following microsurgical tubal reanastomosis for sterilization reversal are 55% to 81%, with most pregnancies occurring within 18 months of surgery (293). Ectopic pregnancy rates following the procedure are generally <10% but may approach 18% (292,295). **The main predictors of success are age <35 years** (293,295), **isthmic–isthmic or ampulo-ampullar anastomosis** (295), **final anastomosed tubal length >4 cm** (293), **and less destructive sterilization methods such as rings or clips** (293,295). Unlike vasectomy reversal, the length of time between fallopian tubal sterilization and reversal does not seem to affect outcome (293). **[8]** IVF should be considered ***in lieu*** of sterilization reversal for older patients or those with diminished ovarian reserve, severe pelvic adhesions, additional infertility factors or prior unsuccessful reanastomosis (292,293).

Hydrosalpinx

Distal occlusion may lead to fluid buildup in the fallopian tube causing a hydrosalpinx (279). Hydrosalpinx fluid impedes embryo development and implantation (279). A meta-analysis of 14 studies and 1,004 patients with hydrosalpinges concluded that IVF pregnancy rates were significantly lower in the presence of hydrosalpinges (296). **[9] Salpingectomy for hydrosalpinx prior to IVF significantly improves both pregnancy and live birth rates when compared to IVF performed with the fallopian tubes *in situ*** (297,298), **although laparoscopic tubal occlusion appears to be a reasonable alternative** (299). There is significantly less outcome data on the use of transvaginal needle drainage and salpingostomy for treatment of hydrosalpinges prior to IVF (279).

Uterine Factors

[8] Pathologies within the uterine cavity are the sole cause of infertility in as many as 15% of couples seeking treatment (300) **and are diagnosed in >50% of infertile patients** (300). Therefore, the evaluation of the couple with infertility should consistently include an assessment of the endometrial cavity. Uterine cavity abnormalities include endometrial polyps, endometrial hyperplasia, submucous myomas, intrauterine synechiae, and congenital uterine anomalies (301).

Diagnostic Imaging for Uterine Pathology

Hysteroscopy

[3] Hysteroscopy is considered the gold standard for uterine cavity evaluation because it permits direct visualization (300–302). The procedure involves insertion of an endoscope through the cervical canal into the uterine cavity and instillation of distention media to facilitate visualization (300–302). **Diagnostic hysteroscopy may be performed in the office using a small-diameter hysteroscope and saline distention, often without need for anesthesia** (301). To optimize visualization of the endometrial cavity and avoid performing the procedure during early pregnancy, hysteroscopy is typically scheduled during the early- to mid-follicular phase of the cycle (300). Disadvantages to the procedure include poor visualization when uterine bleeding is present and the inability to evaluate structures outside the uterine cavity, including those in the myometrium and adnexa (300). Office hysteroscopy is reported to have 72% sensitivity for cavity abnormalities when compared to operative hysteroscopy using general anesthesia (300).

Hysterosalpingogram

Insofar as it allows assessment of tubal and uterine pathology, HSG ("Tubal Factors") is a reasonable initial imaging technique to use in the basic infertility evaluation (301). Hysterosalpingogram shows the general configuration of the uterine cavity and indicates endometrial lesions as filling defects or irregularities of the uterine **[3]** wall (301). **Excessive contrast may lead to false negative findings** (301), **which may account for the 50% sensitivity of HSG compared to hysteroscopy for endometrial polyps** (302). Inability to discriminate air bubbles, mucous, and debris from true intracavitary pathology may account for HSG's high false positive rate when compared with hysteroscopy (301,302). Other drawbacks include patient discomfort, use of iodinated contrast, and radiation exposure (301).

Transvaginal Ultrasound

Compared to hysteroscopy, standard 2D transvaginal US has a 75% PPV and 96.5% negative predictive value for intracavitary polyps but a 0% PPV for intrauterine adhesions (302). Similar to HSG, it has a sensitivity of 44% for uterine malformations (302).

Sonohysterography

Saline infusion sonography (SIS), synonymous with sonohysterography, involves the transcervical instillation of saline, often via a balloon catheter, during transvaginal US to distend the uterine cavity and delineate the endometrium (303). As with office hysteroscopy and HSG, SIS is performed during the follicular phase of the cycle and anesthesia is typically not required (303). Endometrial polyps appear as hyperechogenic pedunculated lesions, submucous fibroids have mixed echogenicity, and adhesions contain densely echogenic and cystic areas (303). **Compared to**

hysteroscopy, SIS has 100% sensitivity, specificity, positive and negative predictive values for uterine polyps (302). As a result of the smaller volume of distention media used, SIS is generally better-tolerated than HSG or hysteroscopy (300,303). Another advantage of SIS is the ability to evaluate the adnexa, and the myometrium for fibroids or adenomyosis. When combined with 3D technology, SIS is particularly good at assessing the overall uterine contour and delineating congenital anomalies such as septate uteri (303). Standard SIS has a somewhat lower sensitivity of 77.8% in detecting uterine congenital anomalies when compared to hysteroscopy, but this is higher than 2D transvaginal US or HSG (302). **[3]** Hysterosalpingogram and SIS perform similarly for intrauterine adhesions, each having approximately 50% PPV and >90% negative predictive value (302).

Magnetic Resonance Imaging (MRI)

Although transvaginal US, HSG, SIS, and hysteroscopy may suggest congenital uterine anomalies, pelvic MRI is considered the gold standard for imaging and is particularly useful for diagnosing rudimentary uterine horns (304). Pelvic MRI has the best sensitivity and specificity for intramural and submucous myomas compared to pathologic examination (305), and is especially useful for large or multiple fibroids (306). **[3]** MRI has been suggested as a tool to differentiate fibroids from adenomyosis, but routine use over US is not recommended (306,307).

Congenital Anomalies of the Uterus

Congenital uterine anomalies occur in 3% to 4% of women. This increases to 5% to 10% in women with early pregnancy loss and up to 25% in those with second and third trimester pregnancy losses (304). During female embryonic development the paired paramesonephric or mullerian ducts elongate toward each other and fuse in the midline. This is followed by resorption of the intervening septum to form the upper vagina, cervix, uterus, and fallopian tubes by week 20 of gestation (308). Failure of any of these steps leads to absent uterine development or development of unicornuate, bicornuate, arcuate, didelphys, or septate uteri (308). **Because of the proximity of the paramesonephric ducts to the urinary system, renal anomalies often coexist with mullerian anomalies. Appropriate urologic imaging should be performed whenever a mullerian anomaly is diagnosed** (304,308). **[2] Uterine anomalies are more closely associated with pregnancy wastage and poor obstetric outcomes than infertility, as the prevalence of congenital uterine defects is generally similar among fertile and infertile women** (304). The exception to this is mullerian agenesis. Patients with mullerian agenesis can have genetically related children only through use of IVF and a gestational carrier (304). The arcuate uterus is the mildest congenital uterine anomaly and typically live birth rates are comparable to those in women with normal uteri (304). **Surgical uterine repair to improve obstetric outcomes remains controversial for**

most anomalies. [8] However, rudimentary uterine horns require removal on diagnosis and hysteroscopic metroplasty of the septate uteri significantly reduces the rates of pregnancy loss, but not infertility (304,309). The number of reproductive-age patients presenting with *in utero* exposure to DES is declining rapidly and will continue to decline, as the substance was banned in 1971 (304). Women whose mothers were exposed to DES have higher rates of uterine malformations (e.g., T-shaped uterus) and associated obstetric complications (304).

Acquired Abnormalities of the Uterus

Leiomyomas

Leiomyomas, also called myomas or fibroids, are benign monoclonal uterine myometrial tumors that affect 25% to 45% of all reproductive-age women; this number is even higher in African Americans (310). The mechanisms by which fibroids cause infertility are unknown, but may involve altered uterine contractility, impaired gamete transport, or endometrial dysfunction (311). Among women with infertility and uterine leiomyomas, pregnancy rates are primarily affected by leiomyoma location (305,311). **[8] Subserosal fibroids do not appear to affect fertility or obstetric outcomes, while cavity-distorting intramural, noncavity-distorting >5 cm, and submucosal myomas are associated with lower implantation and live birth rates** (305,311,312).

Myomectomy

In women desiring fertility who require treatment for fibroids, myomectomy is the preferred approach and uterine artery embolization is relatively contraindicated (311). **Removal of cavity-distorting intramural and submucous myomas is generally recommended prior to proceeding with infertility treatment** (305,311). **[8] The utility of surgical removal of noncavity-distorting intramural fibroids is unknown** (305,311,312). Myomectomy can be performed hysteroscopically (306), via laparotomy (310,313), laparoscopically (alone [310,314], with robotic assistance [313,314]), or vaginally (315). Hysteroscopic removal is generally preferred for small submucous fibroids (306), while use of the other methods generally depends on patient preference, operator skill, or the presence of other pelvic pathologies (310,313,314). The utility of pretreatment with GnRH agonists prior to surgery is debatable. GnRH agonists may shrink larger fibroids (5 to 6 cm) enough to allow hysteroscopic resection (306) and may decrease the risk of intraoperative blood loss and postoperative anemia (310). **Fluid overload and uterine perforation are the most common complications of hysteroscopic myomectomy** (306), **while bleeding and adjacent organ injury are more often associated with alternative approaches** (310). Fibroids that are located low on the uterus and posteriorly are less amenable to laparoscopic resection (310). Transmyometrial approaches raise concern for uterine rupture during pregnancy, although this risk appears to be very low (310).

Endometrial Polyps

The incidence of asymptomatic endometrial polyps among women with infertility has been reported to range from 6% to 8% (316,317) but may be as high as 32% (318). Risk factors for polyp development include obesity, unopposed estrogen exposure, and polycystic ovary syndrome (319). The mechanisms by which endometrial polyps may impair fertility are incompletely described, but may relate to disordered endometrial receptivity (319). One report localized 32% of endometrial polyps in infertile women to the posterior uterine wall, indicated that 40.3% of patients had multiple polyps, and stated a 6.9% hyperplasia rate (320). Polypectomy is generally performed via curettage, blind avulsion, or hysteroscopic removal (318). **[8] Although the efficacy of polypectomy prior to infertility treatment has not been clearly established** (318), **a prospective randomized trial showed a 2.1-fold higher rate of pregnancy among women who underwent the procedure prior to IUI** (321). Higher pregnancy rates have been noted for polyps removed from the uterotubal junction when compared to those removed from other locations (320). Smaller nonrandomized studies provide conflicting data on the negative fertility effects of polyps <1.5 to 2 cm (320,322,323).

Intrauterine Synechiae or Asherman Syndrome

Severe trauma to the basalis layer of the endometrium with subsequent tissue bridge formation leads to intrauterine synechiae or Asherman syndrome (324). Symptoms of severe disease include amenorrhea, menstrual irregularities, spontaneous abortion, and recurrent pregnancy loss (324). **[1] The causes of intrauterine adhesions are often iatrogenic, with patients typically reporting intraoperative or postoperative complications of uterine evacuations for incomplete pregnancy loss, pregnancy termination, or postpartum hemorrhage** [1] (324). Myomectomy, hysterotomy, diagnostic curettage, cesarean section, tuberculosis, caustic abortifacients, and uterine packing are less common causes in Western countries (324). In developing countries, Asherman syndrome caused by genital tuberculosis is quite common (325). **Hysteroscopic resection of synechiae is the preferred treatment to restore fertility in women with Asherman syndrome. Patients with genital tuberculosis have a very poor prognosis** (324–326). Postoperative prevention of adhesion reformation disease may involve estrogen therapy alone × 1 month or in combination with intraoperative placement of an intrauterine device (such as a small Malecot catheter or pediatric Foley catheter) for 1 to 2 weeks (324,326). There is no standard regimen for estrogen therapy, but oral conjugated estrogens 2.5 mg daily overlapping with progestin (324) or E2 valerate 2-mg injections daily (326) have been suggested.

Luteal Phase Defect and Progesterone Supplementation

Mechanisms

The luteal phase is normally characterized by progesterone secretion by the corpus

luteum and appropriate endometrial secretory transformation that allow for embryonic implantation in the endometrium and support of early pregnancy for the first 7 to 8 weeks of gestation (327,328). **Luteal phase deficiency (LPD) is a condition in which endogenous progesterone is not sufficient to maintain a functional secretory endometrium during the implantation window** (329,330) **and is thought to account for 4% of infertility** (329). Proposed mechanisms for LPD include inadequate production of progesterone following ovulation (331), improper GnRH pulsatility causing insufficient gonadotropin production during the LH surge (329,330), and inadequate endometrial responsivity to progesterone (329). **Assisted reproductive technologies (ARTs) or gonadotropin ovulation induction medications may induce iatrogenic LPD via disruption of granulosa cells from follicular aspiration and suppression of endogenous LH secretion through a combination of supraphysiologic E2 levels and GnRH agonist/antagonist therapy** (328,331).

Diagnosis

Diagnostic criteria for LPD have been variably defined, but have included a low mid-luteal phase serum progesterone level, a BBT rise lasting less than 11 days, and a shortened luteal phase of less than 14 days (332). Unfortunately, the characteristic pulsatile secretion of progesterone during the luteal phase of the menstrual cycle combines with wide temporal variations (even within a 60- to 90-minute time span) to make interpretation of mid-luteal progesterone levels difficult (327). **Similar rates of shortened luteal phase are found in fertile and infertile women and there is significant variability of luteal phase length from cycle to cycle in an individual woman** (330). **The notion of a universal optimal duration of progesterone to achieve embryo implantation has been questioned** (333). **[1] There is significant interobserver variability in pathologic interpretation of endometrial biopsies from infertile women** (334) **and out-of-phase biopsy results poorly discriminate between fertile and infertile women** (335).

Treatment

[8] Progesterone therapy is considered standard practice during ART cycles, but is more controversial during non-ART fertility treatments (336,337). When used, progesterone supplementation can be administered via oral, vaginal, or intramuscular routes, with highest serum levels associated with daily 50- to 100-mg intramuscular progesterone (336,337). Most products are delivered in oil, and caution should be used to ascertain the presence of sesame or peanut allergies. Vaginal micronized progesterone, 200 to 600 mg daily in divided doses, is associated with the highest endometrial concentrations of progesterone. The side effects of this delivery route can include vaginal discharge and irritation. Other vaginal preparations include a once-daily gel and a 100-mg insert that is given two to three times daily. As a result of erratic

absorption and decreased bioavailability, oral micronized progesterone is less effective for progesterone supplementation (336). **There remains no consensus regarding the superiority of vaginal versus intramuscular administration.** When hCG is used for trigger, hCG levels peak at the time of egg retrieval, followed by a rise in serum progesterone levels that peak 5 days postretrieval and then decline (336). There are no differences in pregnancy or live birth rates when progesterone is initiated on the same day following retrieval versus 1 day after retrieval (338). A systematic 2015 review indicated lower pregnancy rates when progesterone support was administered prior to hCG-triggered egg retrieval or delayed until 6 days postretrieval, and suggested an initiation window for intramuscular progesterone of postegg retrieval day 0 to day 3 postretrieval (336). This initiation window is consistent with descriptions of luteal phase support during GnRH-agonist–triggered cycles (339). Because of the more rapid endometrial advancement compared to intramuscular route, delayed vaginal progesterone administration until 48 hours postretrieval has been advocated, but better-quality randomized trials are needed before drawing definitive conclusions (336). **[9]** Though the optimum duration of supplementation has not been determined, progesterone is typically continued until 8 to 10 weeks of gestation (336,337). Intravaginal luteal phase supplemental progesterone may increase pregnancy rates in women with PCOS treated with letrozole (340). **[8]** A 2017 systematic review and meta-analysis indicated a benefit for unexplained infertility using primarily vaginal progesterone initiated 0 to 2 days post-IUI in cycles using clomiphene alone or with gonadotropins with 1 live birth for every 11 patients treated (337).

Pelvic Factor

Endometriosis

Endometriosis affects 6% to 10% reproductive age women (341) but is present in 25% to 50% women with unexplained infertility (287). **[8]** It is characterized by the presence of endometrial glands and stroma located outside of the uterine cavity and is found primarily on the peritoneum, ovaries, and rectovaginal septum (341). Fecundability rates in affected patients are estimated at 2% to 10% per month (342). Possible mechanisms for infertility among women with endometriosis include anatomic distortion from adhesions or fibrosis and the impact of chronic inflammation on gametes, embryos, tubal fimbria, and eutopic endometrium (341,342). Laparoscopic visualization and histologic confirmation of biopsied lesion(s) remains the gold standard for the diagnosis of endometriosis. **[8]** The disease is staged laparoscopically according to the Revised American Society for Reproductive Medicine's classification, with stage III to IV (moderate-severe) characterized by ovarian endometriomas, dense tubal or ovarian adhesions, and/or cul-de-sac obliteration (341). Vaginal US has excellent specificity for endometriomas and other deep disease (343). It is unclear whether the mere presence of

endometriosis negatively affects IVF outcomes. Endometriosis patients have similar rates of embryonic aneuploidy (344) and live birth with ARTs (345,346) as compared to unaffected patients. **[9]** However, more severe disease (stages III and IV) and previous endometriosis surgery are associated with fewer oocytes retrieved and reduced pregnancy/live birth rates (by 30% to 40%) compared to patients without endometriosis (345,346).

Endometriosis Infertility

Management

Hormonal suppression of endometriosis typically has minimal benefit for endometriosis-related infertility (341,347). For minimal to mild disease, laparoscopic ablation appears to significantly improve pregnancy rates when compared to diagnostic laparoscopy alone as evidenced by a large randomized trial reporting 31% (treated) versus 17% (untreated) pregnancy rates (348,349). A subsequent meta-analysis supported the effectiveness of laparoscopic treatment in stages I to II endometriosis-associated infertility (341,342,350,351). **[8]** **Number needed to treat analysis suggests that eight laparoscopies involving treatment of mild or minimal endometriosis would need to be performed for each pregnancy gained.** A Cochrane review found moderate evidence in favor of particularly excisional laparoscopic treatment of minimal-mild endometriosis for spontaneous pregnancy in the 9 to 12 months postoperatively (183,347). Although removal of endometriomas may be indicated prior to IVF, when they would interfere with oocyte retrieval (349), endometrioma resection during IVF/ICSI treatment is associated with decreased ovarian function in up to 13% of cases (352,353), reduced quantity of dominant follicles, and fewer retrieved oocytes compared to unoperated patients in a meta-analysis of 2,649 IVF cycles (354). Furthermore, 40% of endometriomas recur postoperatively (349). **[8]** Therefore, IVF is considered a reasonable first-line therapy for endometriosis-associated infertility because of the short time to pregnancy and avoidance of surgery (290). Sclerotherapy, whereby the endometrioma is drained via transvaginal puncture and a sclerotic agent such as ethanol is instilled into the cyst cavity, was associated with higher numbers of retrieved oocytes and similar pregnancy rates as compared to laparoscopic management, in a meta-analysis of 18 studies, and may be an alternative to surgery (345).

Adhesions

Adhesions may result from sharp, mechanical, or thermal injury, infection, radiation, ischemia, desiccation, abrasion, or foreign body reaction (355). Adhesiolysis improves pregnancy rates by 12% at 1 year and by 29% at 2 years in infertile women with adnexal adhesions (355). Use of adhesion barriers reduces adhesion formation following laparoscopy and laparotomy, but there is no consistent evidence for

improvement in pregnancy rates (355,356).

Unexplained Infertility

Thirty percent of couples are diagnosed with unexplained infertility, in which the basic infertility evaluation reveals normal semen parameters, evidence of ovulation, patent fallopian tubes, and no other obvious cause of infertility (357). **Patients with unexplained infertility may feel reassured that even after 12 months of attempting, 20% will conceive in the following 12 months and over 50% in the following 36 months** (4). In couples with good prognostic factors of female age <30, <24 months of infertility, and a previous pregnancy in the same partnership (4), unexplained infertility may merely reflect the lower extreme of normal fertility (357). It is likely that technology is limited in terms of diagnosing all causes for infertility (357). **[2]** The utility of evaluations other than basic testing in an infertile couple has yet to be proven (358).

Proposed Mechanisms for Unexplained Infertility

Luteinized Unruptured Follicle Syndrome

This condition involves luteinization of a follicle that has failed to rupture and release its oocyte, leading to a normal menstrual cycle but infertility (207). It is thought to occur in up to 25% of patients with unexplained infertility, more than twice the incidence in fertile women (207). The diagnosis may justify the use of IVF whereby follicles are aspirated and oocytes are retrieved and fertilized in vitro.

Immunologic Factors

The impact of the immune system on reproductive function is an area of intense study and debate. Among the potential immune causes of reproductive failure are imbalances in the T-lymphocyte population. By increasing the secretion of anti-inflammatory T_H2 cytokines and inhibiting the secretion of proinflammatory T_H1 cytokines, progesterone shifts the balance to T_H2 dominance to support embryo implantation and early pregnancy (359). The absence of a reliable screening test for T_H1:T_H2 balance has handicapped studies designed to influence the balance toward improved outcomes. Although serum antiphospholipid antibodies and antithyroid antibodies are more prevalent among patients with unexplained infertility than among fertile women (360), the presence of antiphospholipid antibodies has not been found to adversely affect IVF outcomes, so screening is discouraged (361). Furthermore, a randomized double-blinded placebo controlled trial found no difference in *in vitro* fertilization-embryo transfer (IVF-ET) live birth rate with administration of heparin 5,000 units SC and aspirin 100 mg daily in patients with detectable antiphospholipid antibodies (362). The relationship of thyroid antibodies and reproductive outcomes are discussed in the

Ovulatory Factor section.

Unexplained infertility has been associated with antisperm antibodies (363), described further in the Male Factor section. Uterine natural killer cells (UNKs) account for over 70% of leukocytes in the secretory endometrium and appear to play a primary role in regulating early placentation (364). UNKs express specialized cell surface receptors known as killer cell immunoglobulin receptors (KIRs), encoded by highly polymorphic genes classically divided into inhibitory (KIR A) and activating (KIR B) haplotypes (365). The ligand for KIRs is the highly polymorphic HLA-C molecule expressed by extravillous trophoblast cells. In a study of 668 euploid single embryo transfers with annotation of maternal KIR and embryonic HLA-C haplotypes, maternal KIR haplotype was found to influence the risk of pregnancy loss and the HLA-C ligands modified the risk (366). High-risk combinations such as KIR A/homozygous C2 resulted in a 51% increase in the risk of pregnancy loss with euploid embryo transfer (366). **[2]** These studies support a potential role for immune factors contributing to unsuccessful implantation and pregnancy.

Infection

C. trachomatis and related clinical and subclinical infections have been discussed in the "Tubal Factor" section. No consistent associations have been reported between chlamydial species, *M. hominis* and unexplained infertility in men or women (275,367,368). *U. urealyticum* and *Mycoplasma genitalium* may be of more concern (369). Prophylactic doxycycline (100 mg twice daily for 4 weeks) given to infertile couples improved pregnancy rates only among couples in whom the male partner cleared ureaplasma infections (370). Antimicrobial prophylaxis is often given for ART, but it is not clear the extent to which clearance of these organisms improves pregnancy rates (369,371). Chronic endometritis is an inflammatory condition characterized by the presence of plasma cells in the endometrium found in 56.8% of patients with unexplained infertility, 57.6% of patients with repeat implantation failure, and 42.3% of women with endometriosis (372–374). A significantly higher rate of spontaneous pregnancies and live births were observed in patients successfully treated with antibiotics as compared to patients with persistent endometritis after antibiotics (374). **[8]** Although the uterine cavity has classically been designated to be sterile, different bacterial communities have been detected that appear to influence implantation following IVF embryo transfer (375).

Undiagnosed Pelvic Pathology

[8] Following a negative infertility workup, laparoscopy has been proposed to evaluate for peritubal adhesions that may distort tubo-ovarian relationships and endometriosis (376,377) but there is a lack of consensus as to the frequency of these abnormalities and many practitioners will forego laparoscopy ***in lieu*** of empiric fertility treatment in such patients. In young patients, laparoscopy may be cost-effective compared to fertility

therapy (378).

Occult Male or Oocyte Factors

[2] Occult male factor, such as impaired sperm DNA integrity (see Male Factor), despite normal semen analysis and oocyte factors, such as premature zona hardening, mitochondrial dysfunction, and/or aberrant spindle formation have been suggested as putative mechanisms for unexplained infertility (379).

Treatment of Unexplained Infertility

Historically, unexplained infertility was often treated with superovulation using clomiphene, letrozole, or gonadotropins in a stepwise approach, combined with IUI (e.g., CC/IUI, letrozole/IUI, and FSH/IUI), followed by ART. However, a randomized clinical trial (the FASTT trial) showed that for patients aged 21 to 39, CC/IUI and FSH/IUI were inferior compared to IVF based on their lower ongoing pregnancy rates (CC/IUI 7.6%, FSH/IUI 9.8%, and IVF 30.7%), a shorter time-to-pregnancy period and higher costs (380). These results are consistent to those reported by Guzick et al. in which the per-cycle pregnancy rates are 9% for gonadotropins/IUI, 4% for superovulation, or 5% for IUI alone (381). **Meta-analysis of 1,159 participants with unexplained infertility involving seven randomized controlled trials of CC alone or CC/IUI indicated no improvement in pregnancy or live birth rates when compared to no treatment or placebo** (227). Another review of over 3,000 patients showed that CC or CC/IUI or TI were similar to expectant management (382). Therefore, CC/IUI or FSH/IUI is not the treatment of choice for unexplained infertility (383,384). Similarly, in the Forty and Over Treatment Trial (FORT-T trial), patients aged 38 to 42 were found to have higher live birth rates from IVF than from CC/IUI or FSH/IUI (385). **[9]** **Despite research findings supporting the use of IVF as first-line treatment for unexplained infertility, superovulation/IUI treatments have continued to be widely used,** presumably because they are less expensive than IVF on a per-cycle basis and in some countries, superovulation/IUI may be much more accessible than IVF. (Risks with clomiphene, letrozole, and non-ART gonadotropins, and gonadotropin preparations, are discussed in the "Ovulatory Factor" section.)

ART options for unexplained infertility include conventional IVF, split IVF/ICSI, and ICSI, depending on whether the patient and her provider accept the risk of failed fertilization. The use of ICSI or splitting sibling oocytes between IVF and ICSI has been proposed as an approach to unexplained infertility patients to diagnose and treat underlying occult male or oocyte factors (379,386). **While ICSI is often suggested or recommended to patients with unexplained infertility to minimize the occurrence of failed fertilization caused by occult male or oocyte factors** (379,386), **IVF and ICSI have comparable pregnancy or live birth rates in patients with unexplained infertility** (386,387).

For young couples with unexplained infertility, especially those with a desire to have more than one child, diagnostic laparoscopy may be a good option for the evaluation and possible treatment of endometriosis (378,388).

Superovulation (Controlled Ovarian Hyperstimulation) with IUI

Unlike ovulation induction, in which the goal is to stimulate the release of a single oocyte in anovulatory women, the explicit goal of superovulation (for non-ART or ART purposes) is to cause more than one egg to be ovulated, thereby increasing the probability of conception in women with unexplained infertility (205). **[8] In most superovulation protocols, a baseline scan is performed on day 2 of the menstrual cycle to assess AFC and the presence or absence of ovarian cysts. Baseline estrogen and progesterone levels are typically obtained on this day** (389). **Starting daily doses in superovulation cycles are higher for clomiphene (100 mg × 5 days) and gonadotropins (150 to 300 IU daily) than those used for ovulation induction** (152,381,389). **Superovulation with clomiphene is otherwise conducted as described above for ovulation induction. When gonadotropins are used in normal responders with unexplained infertility, FSH doses of 225 IU and 300 IU lead to similar outcomes with IVF** (152). The maximal gonadotropin dosage is typically 450 IU per day because higher dosages do not increase ovarian response (389). **In most superovulation protocols, gonadotropins are started on day 2 or 3 of menses** (381,389,390). **The starting dose of gonadotropins is maintained each day until cycle day 6 or 7 (stimulation day 4 or 5), when the serum E2 level and transvaginal US are first measured to document ovarian response** (152,381,390). **Gonadotropin dosage is increased by 50 to 100 IU per day every 2 to 4 days until a response is evident** (391). **E2 levels typically double every 48 hours, with follicle growth of 1.7 mm daily after 10-mm diameter is reached** (392). **Triggering of ovulation typically occurs when at least 2 follicles have reached an average diameter of ê17 to 18 mm and the endometrial thickness is ê8 mm** (152,381,390,393–395). **For non-ART cycles,** patients should receive counseling about the risk of high-order multiple gestation and offered the option for **cancellation** for **E2 levels 1,000 to 2,500 pg/mL, for ê3 follicles ê16 mm, or for ê2 follicles ê16 mm plus ê2 follicles ê14 mm** (208). **In a randomized trial, previously untreated couples with unexplained infertility** had similar cumulative live birth rates using three cycles of gonadotropin/IUI compared to a single cycle of IVF (5).

Cost-Effectiveness

According to computerized decision-tree modeling, laparoscopy followed by expectant management for unexplained infertility may be cost-effective when compared to no intervention, non-ART treatment, or IVF (378). Given that 15 gonadotropin/IUI cycles are needed to produce one additional pregnancy when compared to ICI alone (357), IVF

seems a reasonable option. **[8]** In Massachusetts, where insurance companies are required to cover infertility treatment, the cost-effectiveness of IVF in the treatment of unexplained infertility was determined (380). Couples were randomized to accelerated treatment with three cycles of clomiphene citrate/IUI followed by up to six cycles of IVF if no pregnancy occurred (n = 256) versus conventional treatment with clomiphene/IUI × 3 cycles, then injectable gonadotropins/IUI × three cycles, then IVF × six cycles (n = 247) (380). Median time to pregnancy was 8 months in the accelerated versus 11 months in the conventional treatment groups. The authors used an average cost per cycle with clomiphene/IUI of $500, with gonadotropin/IUI of $2,500, and assuming IVF costs were <$17,749/cycle. They reported that the accelerated treatment protocol resulted in a savings of $2,624 per couple and lowered the per delivery charges by $9,856 compared to conventional treatment regimens (380). **The study concluded that couples with unexplained infertility who have not achieved pregnancy after three cycles of clomiphene/IUI should proceed directly to IVF** (380).

Assisted Reproductive Technologies (ART) Process

Process of ART

ARTs include IVF, ICSI, gamete intrafallopian transfer (GIFT), zygote intrafallopian transfer (ZIFT), cryopreserved embryo transfers, and the use of donor oocytes (396). Because of improved success rates associated with IVF embryo transfer, the performance of GIFT and ZIFT has declined in the United States (396), so this review will focus primarily on IVF and ICSI. **Both processes involve the following:**

- **Prevention of a premature LH surge**
- **Follicle growth**
- **Pretreatment**
- **Adjunctive medications**
- **Oocyte maturation/ovulation triggering**
- **Oocyte retrieval**
- **Luteal support**
- **Fertilization by IVF or ICSI**
- **In vitro embryo culture**
- **Transfer of fresh embryos**
- **Cryopreservation surplus embryos**
- **First trimester pregnancy monitoring**

Baseline Ovarian Cysts

[9] Prior to beginning therapy, a baseline US may be performed on cycle day 2 or 3

during menses (or following GnRH agonist suppression) to confirm an optimally thin (<4 mm) endometrium and quiescent ovaries. With clomiphene citrate cycles, the presence of ovarian cysts on a baseline scan was associated with decreased rates of ovulation but not of pregnancy, although cyst size was not predictive of response (397). Ovarian cysts on baseline evaluation have been associated with decreased pregnancy rates in ovulation induction cycles employing gonadotropins (398). In IVF patients, **functional (estrogen-producing) cysts are seen in 9.3% of women following GnRH agonist suppression** (399). Although nonfunctional ovarian cysts up to 5.3 cm did not affect IVF outcomes (400), functional ovarian cysts (mean diameter 2 cm and baseline E2 180 pg/mL) have been associated with increased gonadotropin requirements (dosing and duration), higher cancellation rates, fewer retrieved oocytes, poorer embryo quality, and lower pregnancy rates per cycle (9.6% vs. 29.7% in cyst-free cycles) (399). Ovarian cysts >20 mm that are seen on the baseline scan tend to resolve spontaneously within 1 to 2 months and OC administration does not appear to hasten their resolution (401). However, OC or progesterone/progestin pretreatment prior to GnRH agonist cycles is associated with decreased risk of cyst formation (402,403). Functional cyst aspiration prior to gonadotropin stimulation, which is commonly performed to expedite initiation of treatment, did not improve IVF outcomes in one large study (399). US-guided transvaginal cyst aspiration prior to IVF stimulation led to similar pregnancy outcomes as use of antagonist for cyst resolution though prestimulation antagonist was associated with slightly longer duration and dose of stimulation (404).

Prevention of Premature Luteinizing Hormone Surge

LH Surge and Premature Luteinization

[9] Without GnRH agonist or antagonist suppression **(Fig. 36-5)**, LH surges occur in IVF cycles as a result of high E2 levels in the early follicular phase. This, in turn, results in a lower oocyte yield and reduced pregnancy rates (405). **Spontaneous ovulation prior to oocyte retrieval is reported to occur in 16% of nonsuppressed IVF cycles** (406). The premature LH rise typically occurs after 5 to 7 days of stimulation (405). **[9] In contrast, premature luteinization is a somewhat misleading term that refers to a rise in serum progesterone (cutoffs vary from 0.8 to 2 ng/mL) observed on the day of hCG administration and occurs in the setting of low LH levels secondary to gonadotropin-suppressive medications** (407). The incidence of premature luteinization has been estimated at 6% to 7% when the progesterone cut-off level is set at >1.5 ng/mL (408), but it may be as high as 35% (407). Mechanisms underlying premature luteinization may include: incomplete pituitary desensitization, increased granulosa cell receptor sensitivity to LH secondary to aggressive COH or innately poor responders, and/or the presence of multiple follicles each producing a normal amount of progesterone consistent with the late follicular phase (407,408). Although the literature on this subject remains inconsistent, the negative effects of

premature luteinization (409), have been attributed to endometrial advancement rather than oocyte or embryo dysfunction (407,408). Methods proposed to address premature luteinization have included earlier triggering with hCG, less aggressive stimulation protocols, cryopreservation of embryos (freeze all) (408) and administration of the antiprogestin mifepristone at the time of hCG (410).

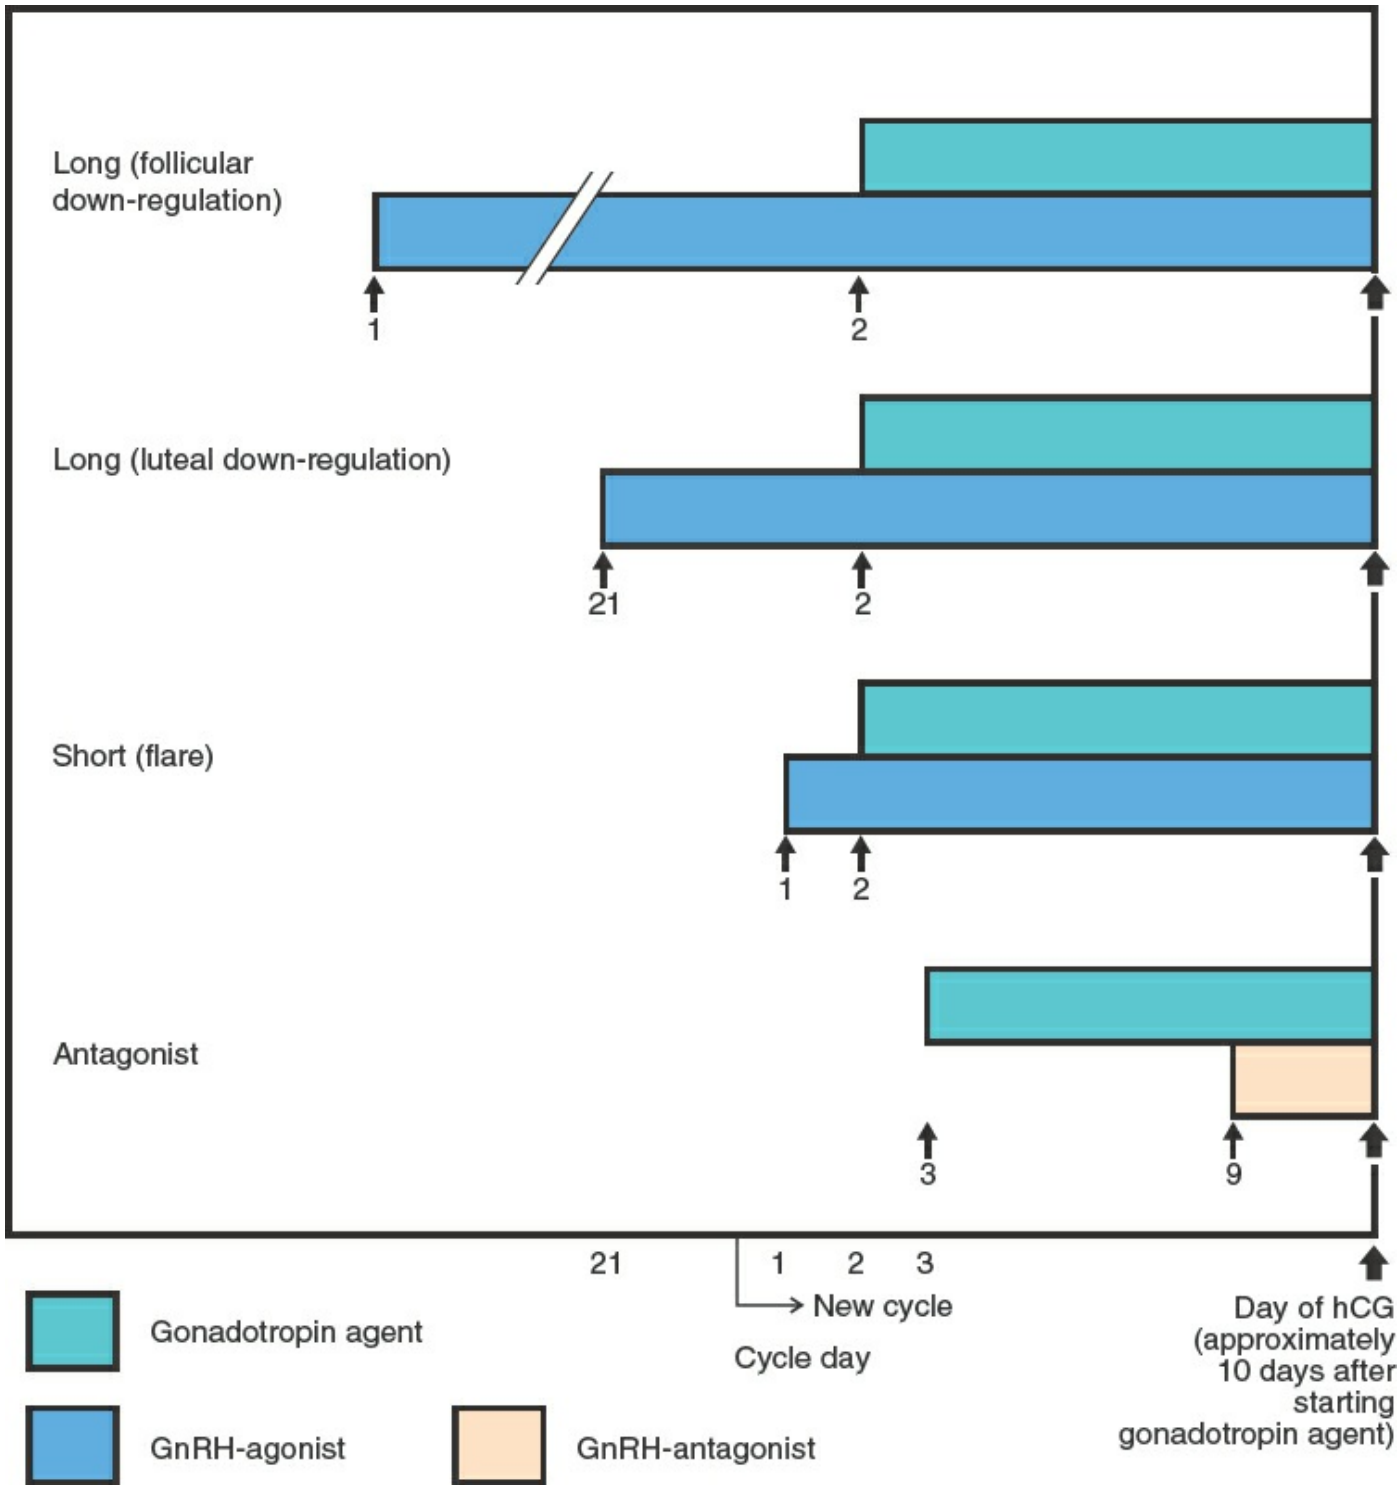

FIGURE 36-5 In vitro fertilization protocols using gonadotropin-releasing hormone (GnRH) agonist or antagonist with gonadotropins in controlled ovarian hyperstimulation. hCG, human chorionic gonadotropin.

GnRH Agonists

Native GnRH is rapidly degraded in the circulation (411). Commercial preparations of GnRH agonists consist of decapeptides similar to GnRH but for modification at two amino acid residues, which increase the half-life and receptor binding affinities (411). **Over the course of 10 to 14 days, agonists initially bind to and upregulate pituitary GnRH receptor activity, leading to a "flare response" of increased gonadotropin secretion. [9] This is followed by receptor desensitization (depleted gonadotropin pools along with rapid uncoupling of the GnRH receptor from its regulatory protein and loss of signal transduction) which suppresses circulating levels of pituitary gonadotropins and, with high doses and prolonged use, eventually decreases GnRH receptor numbers** (389,405,411–413). Therefore, prolonged use of GnRH agonists induces a menopause-like state characterized by low E2 levels and accompanied by common side effects such as hot flashes and moodiness (389). The flare effect may cause ovarian cyst formation as described in the "Unexplained Infertility" section of this chapter (389). GnRH agonists are commercially available for either depot or daily use and can be administered intranasally (buserelin and nafarelin) or by intramuscular or subcutaneous injection (leuprolide, triptorelin, or buserelin). Intranasal preparations have lower absorption rates when compared to injectable agonists and are associated with milder suppression (414). Typical starting daily doses of leuprolide are 1 mg, 0.5 mg, or 25 mcg (microdose) (412).

GnRH Agonist Protocols

Some of the more commonly used ART medications and protocols are summarized in Figure 36-5 and Table 36-7. [9] In the "long protocol," a GnRH agonist is started in the luteal phase (day 21) of the previous cycle. This diminishes the GnRH agonists flare effect and suppresses endogenous FSH and dominant follicle selection to promote synchronous follicular growth (405). **After 10 to 14 days of GnRH agonist administration, a pelvic US and E2 level are used to confirm suppression and gonadotropin stimulation begins. The GnRH agonist is continued (the dose may be halved or unchanged) throughout the cycle until the hCG trigger** (405,412).**Mean serum progesterone levels on the day of hCG administration using the long protocol are reportedly 0.84 ng/mL** (408). **[9] The long protocol provides for better oocyte yields and pregnancy rates in normal responders when compared with shorter protocols that use later administration or early cessation of agonists** (405). **Shorter protocols using lower GnRH agonist doses have been advocated for poor responders in whom excessive suppression may be undesirable, perhaps because of direct negative effects of the agonist on the ovary** (412). **Long protocols, particularly those using single-dose depot rather than daily GnRH agonist formulations** (415), **are associated with higher gonadotropin dose and**

duration, which themselves have been associated with lower pregnancy rates (416,417). Alternatively, GnRH microdose flare protocols have been developed that may improve oocyte yield in poor responders. Microdose flare regimens involve pretreatment with 14 to 21 days of combination OCs. Four days following the cessation of the OC pills, a microdose (25-mcg leuprolide) of agonist is added in the early follicular phase to take advantage of the agonist flare effect. Gonadotropin stimulation is initiated 1 to 2 days later while continuing the agonist (412).

GnRH Antagonists

GnRH antagonists (cetrorelix and ganirelix) were developed by modifying the GnRH decapeptide at six positions. They compete with endogenous GnRH for binding to pituitary GnRH receptors (411). **[9] Because they have no agonistic activity, GnRH antagonists lead to almost immediate suppression of FSH and LH and do not require the additional time for pituitary downregulation that characterizes the GnRH agonists** (411). With prolonged use, GnRH antagonists downregulate GnRH receptors (411). The only delivery method available for GnRH antagonist is subcutaneous injection, although orally active agents are in development (413). GnRH antagonists can be given as 0.25 mg daily doses or as a single 3-mg dose with no differences in outcomes (413). The time between daily injections should not exceed 30 hours (389). With single-dose regimens, avoidance of multiple injections is attractive but additional small doses starting 4 days after initial dose are required in 10% of cycles (413). **Use of GnRH antagonists in ART protocols is typically begun on days 4 to 7 of stimulation. [9] This timing balances the risk for premature LH surges with the need for initiation of endogenous FSH-mediated follicular recruitment and endogenous E2 production prior to administration** (389,405,413).

GnRH Antagonists Fixed Versus Flexible Protocols

Several GnRH antagonist protocols have been developed for use in ART cycles. **Fixed protocols involve starting the antagonist on days 4, 5, 6, or 7 of stimulation regardless of follicular response** (389,395,405,413). Flexible protocols were developed to reduce gonadotropin stimulation dose and duration (405). **In flexible protocols, varying thresholds have been described for antagonist initiation. [9] These include addition of the antagonist when the leading follicle has reached 12 to 16 mm in average diameter or when the E2 level has risen above 600 pg/mL** (390,394,405,412,413). When flexible protocols are used, pregnancy rates are similar when antagonist is initiated on days 4 or 5 of stimulation but drop significantly when antagonist is initiated after day 6. This suggests that rapid follicular growth may be more important in preventing LH surges and improving pregnancy rates than the day the antagonist is initiated (390). Fixed initiation of a GnRH antagonist on day 6 of

stimulation has been associated with higher pregnancy rates when compared to flexible protocols in one meta-analysis involving four randomized trials, however **the true superiority of one approach over the other remains to be defined** (390,412,413). **Diminished E2 levels can be expected following GnRH antagonist administration, but this does [9] not appear to affect follicular growth** (395). **Dose increases in exogenous FSH** (389,412) **or LH** (412,413) **do not appear to be necessary.**

GnRH Agonists Compared With Antagonists

Because there is no pituitary desensitization period required when GnRH antagonists are used in ART, cycles can begin more quickly than those that employ GnRH agonists (389). **Antagonists are associated with lower duration of stimulation, lower stimulation dose, and reduced rates of ovarian hyperstimulation syndrome** (418). **Antagonists are often used in the absence of pretreatment with OCPs. Initiation of antagonist cycles relies on the start of spontaneous menses often making scheduling easier for GnRH agonist cycles** (419). **Study and protocol heterogeneity make it difficult to detect consistent differences in IVF pregnancy outcomes after GnRH agonist and [9] antagonist cycles** (418,420). **A Cochrane review of 27 randomized controlled trials indicated that, while the number of good quality transferred embryos produced are similar, clinical pregnancy rates are higher by 4.7% in agonist compared to antagonist cycles. They concluded that for every 21 couples, 1 additional pregnancy would be gained by using a GnRH agonist protocol** (418). **The number of oocytes retrieved and the live birth rates also favored agonist usage** (418).

Follicular Growth and Stimulation Protocols

Follicular Recruitment

Primordial follicles are 0.03 mm in size and reach the point of ovulation only after 150 days (five menstrual cycles) during which they grow into preantral (primary and secondary follicles), early antral, small antral, and large antral follicles (421,422). The resting follicle pool includes primordial and preantral follicles (421). Resting follicles continuously enter either growth or apoptotic phases from birth until menopause, a process which is gonadotropin independent (421). After 90 days, activated resting follicles contain a fluid-filled antrum, marking their responsiveness to gonadotropins and are referred to as early antral follicles of 0.2- to 0.5-mm size (421,423). Over the next 70 days these early antral follicles grow into 2 mm small antral follicles, with this slow pace of growth mediated by AMH (421). Small antral follicles size 2 to 5 mm, which are recruitable and gonadotropin dependent, begin to slowly enlarge in the late luteal phase of the cycle preceding ovulation while concurrently LH-induced theca cell androgen production increases (421,424). In the early follicular phase during the menses of a natural cycle, the follicle that will ultimately become dominant has a

diameter of 5 to 8 mm (425). Growth of the follicle to 10 mm indicates selection, with the next largest follicle typically 8 mm (424,425). When the antral follicle grows beyond 10 mm, follicular AMH decreases and FSH induces the appearance of LH receptors on the granulosa cells (414). **[1]** At that point, somewhat contrary to the 2-cell-2-gonadotropin model, LH can exert FSH-like actions on the granulosa cell, including stimulation of aromatase with associated intrafollicular decreasing androgen and increasing E2 levels (414,421). **With complete absence of endogenous LH, such as that seen with hypothalamic hypogonadism, exogenous FSH produces fewer preovulatory follicles, inadequate E2, lower ovulation rates, and thinner endometrium when compared to ovaries stimulated with agonist downregulation and exogenous hMG (FSH and LH)** (414). **[6]** Therefore, in the setting of normal hypothalamic function, it seems likely that even with suppressive therapy, enough endogenous LH is present to synergize with exogenous FSH to provide adequate stimulation for recruitment (414).

Follicular Waves and Timing of Stimulation

The above referenced 2 to 5 mm small antral follicles develop synchronously, cyclically, in cohorts, or "waves," during each menstrual cycle (423). The emergence of a wave is detectable ultrasonographically when the lead follicle reaches 4 to 6 mm, which occurs in association with at least two follicles reaching ≥6 mm (423). The wave is considered major (ovulatory) when over the next ~2 days the lead follicle is ≥10 mm and exceeds other follicles by ≥2 mm, while in minor (anovulatory) waves the largest follicle is <10 mm and is similar size to other follicles (423,425,426). In major waves of unstimulated cycles, the nonovulated follicles become atretic, while in minor waves all follicles in the cohort become atretic (426). The majority of unstimulated human menstrual cycles have two waves of follicular development (423,425). In two-wave cycles, the first wave is minor and has been variously described to occur the day before ovulation (423,425) or the day after ovulation (426), with progesterone elevations facilitating follicle atresia (426). **[1]** The second wave (in two-wave cycles) is major and occurs 14 to 15 days after ovulation (or the day after menses onset) (423,425,426). Of the 32% of menstrual cycles with three waves, most of those involved two minor waves occurring the day of ovulation and 12 to 13 days after ovulation (or 1 day prior to menses onset) and one major wave occurring 17 days after ovulation (or 6 days after menses onset) (423,425). However, 19% of the three-wave cycles had three major waves occurring at each of the same time points (425). For simplification, day 1 of menses (if onset occurred in evening then day 1 is considered to be the next day) will likely correspond to the emergence of the ovulatory wave in women with two waves, while day 1 of menses will correspond to emergence of an anovulatory wave in women with three waves (423).

Synchronization of Follicle Growth

A small randomized trial in 2012 found women who began stimulation on cycle day 1 of spontaneous menses had two additional follicles ≥15 mm at time of trigger compared to the group starting stimulation on cycle day 4; nonsignificant trends favoring the day 1 start were observed for cycle cancellation rates, number of total and mature oocytes retrieved (423). **[9]** During the hormone-free interval on combination OC pills, the dominant follicles emerged at the 4 to 5 mm diameter ~3 to 5 days after pill cessation (427) providing support for the practice of starting gonadotropin stimulation at this time. **These findings are intriguing and suggest a path toward greater synchrony during stimulation.** Based upon findings in cows, one group hypothesized that in women, aspirating the dominant follicle at ~ menstrual cycle day 6 to 7 should induce emergence of a new wave 2 days later at which point gonadotropin stimulation can begin to precisely synchronize the follicle cohort (426). Pharmacologic induction of wave emergence has been proposed to include high-dose E2 (i.e., a single 8-mg E2V injection) followed immediately by 5 days of progesterone 100 mg daily given at any time of the cycle to induce luteolysis and suppress FSH to regress the dominant follicle (426). Upon cessation of the progesterone, a new wave should begin with serum FSH surge at which point gonadotropin stimulation can start; the authors suggest that OCs would not affect wave dynamics but a citation is not given (426).

Monitoring and Timing of Trigger

Monitoring during ART is helpful to detect the synchronous growth of dominant follicles, though practitioners vary in specific monitoring elements. **[9]** Survey respondents of consistently high-performing United States IVF clinics all used both E2 and US follicle size for stimulation monitoring, and 40% to 50% additionally measured progesterone and LH during the stimulation, with monitoring performed four to six times during the stimulation (428); however, a Cochrane study in 2014 found that US monitoring alone without serum testing may be reasonable for monitoring (429).

In one report, women who were predicted to be normal responders using 225 to 300 IU of FSH required 11 days of stimulation, had 11 to 13 follicles ≥15 mm on the day of hCG trigger, had a peak E2 level of approximately 2,100 pg/mL, and had 10 to 11 oocytes retrieved, of which 82% to 83% were mature (152). **[9]** The optimal level of E2 at the time of hCG administration is between 70 and 140 pg/mL per oocyte or follicle (393). Oocytes have been recovered from follicles with US mean diameters between 13 and 24 mm corresponding to fluid volumes of >1 mL and ≤7 mL, with optimal recovery rates for 3 mL (430). In a worldwide survey of IVF practices, of which 18% were in the United States, the majority administered trigger when 2 to 3 lead follicles (81% of respondents) reached an US mean diameter of 16 to 20 mm (92% of respondents) (431). High-performing United States IVF clinics administer trigger after a mean of 9 to 10 days of stimulation, when at least two lead follicles reach mean diameter ≥18 mm, with that study reporting a range of 17 mm to >20 mm (428). See the

"Superovulation" section of "Unexplained Infertility" for additional information on gonadotropin stimulation.

Follicle Stimulating Hormone Versus Human Menopausal Gonadotropin

Concern has been raised that exogenous LH might be needed to address the sudden decrease in endogenous LH that is associated with GnRH antagonist use and the possible excess endogenous LH suppression in long GnRH agonist protocols (414). In a 2010 survey of high-performing United States clinics none chose an FSH-only protocol for young normal responders (428). An analysis of >21,000 IVF/ICSI cycles that used antagonist suppression performed in 15 Latin American countries found hMG and LH protocols were associated with fewer oocytes retrieved, while pregnancy and live birth rates as compared to FSH-only protocols were not statistically significantly different (432). **[9]** This suggests that less expensive **FSH-only protocols may be reasonable in unselected women** (432). The authors did acknowledge, however, that the hMG and LH treated women were older and had higher rates of ovarian insufficiency than the FSH-only patients (432), so **individualizing protocols given extremes of age and ovarian response is appropriate.** In support of individualized protocols is a study showing hMG in women with elevated AMH >5.2 ng/mL is associated in agonist and antagonist protocols with fewer instances of retrieving >15 oocytes and higher fresh transfer live birth rates as compared to FSH only, although OHSS rates were similar (433). Higher androgen and lower progesterone levels on the day of hCG trigger are observed when hMG is used for stimulation rather than FSH alone, indicating a more favorable endocrine profile with hMG (433,434). The ratio of LH to FSH must be evaluated cumulatively over the entire stimulation rather than just at the beginning, as there appears to be a "sweet spot" of 0.3 to 0.6 for the lowest risk of serum progesterone premature elevation ≥1.5 ng/mL (434).

Stimulation Dose and Optimal Number of Retrieved Oocytes

Concerns have been raised about premature luteinization and lower pregnancy rates with higher-dose FSH stimulation protocols (408); each additional 100 IU of gonadotropins has been associated with a 2% lower rate of clinical pregnancy and live birth (416), and 300 units daily FSH did not increase number of retrieved oocytes or live birth rate compared to 225 units in a randomized controlled trial of "normal responders" (435). A possible explanation stems from comparative evaluations of unstimulated cycles in which the dominant follicle contains higher follicular E2, androgen, AMH, and LH concentrations compared to those measured in stimulated dominant follicles and may indicate follicle quality is inversely proportional to quantity (436,437). Therefore reduced-dose stimulation to obtain <8 or ≤4 oocytes using clomiphene citrate 50 to 100 mg for either 5 days or more extended durations through the day of trigger along with gonadotropin doses of 75 to 150 units ranging from a few days to longer duration have been described (437–439). A meta-analysis of >300

minimal stimulation cycles found that a median of five oocytes retrieved was optimal for pregnancy and live birth rates (417). These protocols are less expensive and multiple cycles may be noninferior in terms of live birth rates to higher-dose protocols (440).

Higher-stimulation doses are understood to be a function of patient characteristics (genetically determined ovarian sensitivity to gonadotropins or age-related aneuploidy) rather than exerting a direct adverse effect on IVF outcome and a more nuanced portrait of different ovarian reserve categories is needed in order to draw conclusions between dose and outcome (441). **[9] Other publications provide compelling support for protocols that regardless of responder status aim for increased retrieved oocytes in a single retrieval cycle and has led some to disavow previous rationales for minimal stimulation** (437,442). Sixty percent of high-performing United States IVF centers in 2010 reported that for a young normal responder with healthy BMI they would use a relatively high-starting gonadotropin dose of 300 units per day (428). There appears to be no benefit of exceeding a total daily gonadotropin dose of 450 IU in any patient (389). A previous trial indicating no benefit with higher gonadotropin doses was notable for nonsignificant trends to higher age, higher BMI, lower AMH, and lower antral count in the high FSH dose compared to the lower-dose group (435). A randomized trial of minimal stimulation versus conventional higher-dose stimulation in 564 first cycles with women age <39 found that while minimal stimulation was associated with 49% cumulative (over 6 months) live birth rates, the conventional stimulation live birth rates were significantly higher at 63% (439). In fresh oocyte donor cycles, recipient live birth rates were maximized when >10 oocytes were retrieved (443); each 3.4 mature (M2) oocytes were associated with 1 euploid embryo (444). Among oocyte donors, embryo aneuploidy rates increased with decreased ovarian sensitivity (i.e., gonadotropin doses per oocyte increased) but increased overall gonadotropin doses were not associated with aneuploidy (444). In autologous cycles 15 to 20 oocytes was optimal for fresh transfer live birth (445,446). **[9]** Higher numbers of oocytes 15 to 25 were associated with more usable blastocysts and >1 live birth from a single autologous IVF cycle and each additional oocyte was associated with an 8% increase in the chance for >1 live births (446). The likelihood of a single autologous retrieval leading to live birth over subsequent fresh and frozen/thaw transfers was highest with >15 retrieved oocytes in a randomized trial of >1,000 women allocated to either antagonist or long agonist suppression (447). A second retrospective paper reporting on >1,000 women who underwent a single retrieval cycle similarly found that >15 oocytes retrieved was associated with the highest cumulative live birth rates with single embryo transfer compared with fewer numbers of oocytes (448). In >400,000 autologous IVF cycles, increased number of oocytes >10 were associated with a 3% lower miscarriage rate compared to cycles with <4 oocytes even after adjusting for age (449). In poor responders of mean age 38 with AFC 5 to 6 and AMH

0.7 ng/mL, those randomized to high gonadotropin doses had nearly 10% lower cycle cancellation rates, 8% lower rates of no oocytes retrieved, two additional mature oocytes retrieved (4.8 vs. 2.7), more embryos available for transfer (2.7 vs. 1.8), and a nonsignificant trend to higher pregnancy rate per initiated cycle (438). Oocyte donors in whom ≥17 oocytes were obtained had 2 to 3 additional euploid embryos per retrieval cycle compared to cycles with <17 oocytes, and aneuploidy rate did not increase with gonadotropin dose (444). **Although minimal stimulation protocols by design are simpler with less up-front medication and freezing services which may contribute to cost, these should be weighed against the advantages of protocols that aim for safely maximizing per-cycle live birth efficiency** (442). Caution should be exercised when deciding whether to prolong stimulation duration to obtain additional embryos when trigger-day serum progesterone levels are >1.49 or >2 ng/mL as these thresholds correlate respectively with fewer morphologically top-quality blastocyst or day 3 embryos.

Pretreatment

[9] Combined OCs are commonly taken for 14 to 28 days prior to GnRH analogs to ease cycle scheduling (419), **synchronize follicular development** (450), **further prevent LH surges** (450), **reduce the incidence of ovarian cysts** (450), **and reduce cancellation rates caused by hyperstimulation** (451). Patients can begin OCs anytime between days 1 and 5 of menses (450). For antagonist cycles, COH begins 2 to 5 days after OCs (irrespective of menses) (419). During long GnRH agonist protocols, the agonist overlaps the final 5 days of OC use, followed by initiation of COH on the second or third day of withdrawal bleeding (402,451). Microdose flare protocols involve pretreatment with 14 to 21 days of OC, followed 4 days later by a microdose of agonist. COH typically starts 1 to 2 days later (412). **The progestins norethindrone acetate 10 mg orally daily, medroxyprogesterone acetate 10 mg orally daily, or a single intramuscular dose of progesterone (not specified) can be used in place of an OC in ART cycles. Recommended duration and the timing of treatment initiation vary widely. A duration of 5 to 20 days and initiation anytime between days 1 and 19 of menses have been reported** (450). Four mg of daily micronized 17β E2 or E2 valerate, has been used *in lieu* of OCs in ART cycles, with initiation between cycle days 15 and 21 and a duration of 10 to 15 days (450). OC pretreatment for antagonist cycles has been shown to increase the duration and number of medication doses during stimulation. There is "moderate quality" evidence from a recent Cochrane review for reduced ongoing pregnancy and live birth rates with a possible improvement in pregnancy loss rates (403). However, OC pretreatment during GnRH agonist cycles is associated with higher pregnancy rates than those in cycles without pretreatment (402). Progestin and E2 pretreatment do not conclusively affect live birth rates in either agonist or antagonist cycles (403). They may be useful to synchronize stimulated follicle

growth (see “Follicular Growth and Stimulation Protocols”).

Adjunctive Medications

Prenatal vitamins should be given to all infertility patients beginning at least 1 month prior to initiation of infertility treatment. Low-dose aspirin 80 to 100 mg daily commencing at downregulation and given for variable durations (up to 13 weeks gestation or if recurrent loss to 38 weeks) is commonly used during IVF regimens to improve ovarian stimulation response and endometrial implantation. In some recurrent loss patients low-dose aspirin is given in conjunction with heparin (452). A 2016 Cochrane review of “low to moderate quality” RCT evidence comprising >2,600 patients found no evidence of benefit for routine IVF use in terms of pregnancy, miscarriage, or live birth (453). Aspirin use confers a fourfold increased risk (50% vs. 13.6% in nonusers) of first trimester subchorionic hemorrhage in non-IVF and IVF pregnancies, which was not observed with heparin use (452). These findings prompted the authors to discontinue the use of aspirin in routine infertility and IVF patients, reserving it for antiphospholipid syndrome and recurrent loss patients. They will discontinue the aspirin if subchorionic bleeding is detected (452). Glucocorticoids given to women during the peri-implantation period may improve pregnancy rates in women undergoing IVF (rather than ICSI). A Cochrane study found this result of marginal statistical significance and did not observe improvement in terms of pregnancy or live birth rates for glucocorticoids given to an overall sample of 1,800 patients. More study is needed before recommendations to specific subgroups (i.e., autoantibodies, unexplained infertility, or recurrent implantation failure [RIF]) (454). In 2015 one group discontinued their routine use of oral doses of methylprednisolone (16 mg daily) and doxycycline (100 mg twice daily) for 4 days commencing either on the day of oocyte retrieval or 4 days prior to frozen ET, because they did not find that these medications statistically beneficial in terms of pregnancy, miscarriage, or live birth rates regardless of whether ICSI and assisted hatching were performed (455). Metformin may limit OHSS in PCOS patients (456). An updated Cochrane review found that metformin improved clinical pregnancy rates with IVF, but showed no conclusive benefit for live birth rates (457).

Physiology of Oocyte Maturation

Prior to maturation, oocytes are arrested in the prophase stage of meiosis I, also known as the germinal vesicle stage (458,459). Meiosis I oocytes must reach at least the early antral follicle stage to respond to FSH and be competent to resume meiosis (460). *In vivo*, LH receptors on the follicle are induced by FSH during later stages of follicular development (460). Therefore, only fully grown oocytes respond to the LH surge *in vivo* to begin the cytoplasmic and nuclear maturation that are required for developmental progression toward the metaphase stage of meiosis II. At this point, the developmentally competent oocyte will extrude the first polar body, the oocyte–cumulus complex will

detach from the ovarian wall (461), ovulation will occur, and fertilization is possible (458–460).

Trigger During ART Cycles

Because spontaneous LH surges occur inconsistently during non-ART gonadotropin cycles and are suppressed in ART cycles, hCG has been used to trigger ovulation. In combination with its long half-life, the homology between hCG and LH (identical α subunits) permits cross-reactivity with the LH receptor and induction of final oocyte maturation and ovulation (462). **[9]** hCG is derived from urine (5,000 to 10,000 IU intramuscularly) or through recombinant technology (250 µg subcutaneously, equivalent to 5,000 to 6,000 IU of intramuscular urinary product) (228). The half-life of hCG is 2.32 days, compared to 1 to 5 hours for LH (462). **Ovulation is typically triggered when at least 2 follicles are ê17 to 18 mm in average diameter (but <24 mm) and the endometrial thickness is ê8 mm** (152,381,390,393–395,463). Similar clinical outcomes have been noted when 5,000 IU or 10,000 IU of urine-derived hCG (464) and urinary or recombinant preparations (463,465) are used for triggering. If there is concern for OHSS, GnRH agonists can substitute for hCG to trigger ovulation in antagonist protocols.

Oocyte Retrieval

Oocyte retrieval is performed via transvaginal US–guided needle puncture into each follicle and aspiration of follicular fluid. Either general anesthesia or intravenous conscious sedation may be used (466). Prophylactic antibiotics such as ceftriaxone are recommended at the time of retrieval (467). The vaginal prep can be performed either with sterile saline alone or with povidone-iodine and vigorous saline flushing (468,469). **The highest oocyte yield is obtained when oocyte retrieval is performed 36 to 37 hours after the hCG injection** (463). Earlier retrieval (35 hours) is associated with a much lower oocyte yield, and later retrieval risks ovulation. Spontaneous follicular rupture appears to occur at a mean of 38.3 hours following hCG administration (463).

Luteal Support

The rationale and regimens for luteal phase support with progesterone are discussed in the "Uterine Factor" section. Luteal phase E2 supplementation is not necessary for fresh embryo transfers unless GnRH agonist trigger is utilized (339,470,471). In the case of GnRH agonist trigger, E2 0.1-mg patches starting 1-day postretrieval coadministered with intramuscular progesterone has been proposed to offset corpus luteum dysfunction (339). **[9]** Luteal support with low-dose hCG 1,000 to 1,500 units given at egg retrieval and again up to 5 days postretrieval has been used successfully (339).

Fertilization by IVF or ICSI

Following semen collection and sperm processing (described in the "Male Factor" section), sperm are incubated in media for 3 to 4 hours to promote sperm capacitation and the acrosome reaction. Before fertilization, retrieved oocytes are cultured in media. Conventional IVF involves insemination concentrations of 100,000 to 800,000 motile sperm/mL per oocyte with each oocyte in a small droplet of media under oil (11,472,473). **[9]** For every three cycles done for severe male factor, the use of ICSI prevents one case of fertilization failure when compared to conventional IVF (11). The indications for, procedure, and risks of ICSI are discussed under "Male Factor."

In Vitro Embryo Culture

Embryo Development

Initial embryo development is typically assessed 15 to 20 hours after insemination or ICSI, when fertilization is characterized by the presence of two pronuclei and the extrusion of the second polar body (11,473,474). **[9]** Embryos are examined again for cleavage after 24 to 30 hours of culture (11). The first embryo cleavage occurs approximately 21 hours after fertilization, and subsequent divisions occur every 12 to 15 hours up to the 8-cell stage on the 3rd day of embryo development (475). Compaction to form the 16-cell morula occurs on the 4th day of embryo development,

and differentiation of the inner cell mass and trophectoderm to form a blastocyst (containing a fluid-filled area called a blastocoel) is completed by the 5th to 6th days (476,477).

Culture Environment

Prior to compaction, while the embryo is under genetic control of the oocyte, it uses a pyruvate-based metabolism. It requires at least a few amino acids, and prefers a relatively oxygenated environment (though much lower than atmospheric oxygen) similar to that found in the fallopian tube (475,478). **After compaction, glucose and amino acid needs increase, the embryonic genome is activated, and metabolism requires a very low oxygen environment similar to that found in the uterus** (475,478). Supplementation of culture media with hyaluron and albumin is beneficial in the postcompaction period (475). Culture media systems are classified as either single or sequential. Single culture media was developed to provide all the necessary nutrients required (day 1 through day 5/6) in a single media formulation, reducing stress on the embryo by keeping a stable environment and allowing any embryo-generated autocrine/paracrine factors to remain (479). Single culture media uses stable dipeptide glutamine to avoid toxic ammonium buildup from the breakdown of amino acids (479). Sequential culture media systems were designed to mimic the changing metabolic and nutritional requirements of the developing embryo by culturing embryos in media designed for the cleavage-stage embryo (days 1 to 3) and on day 3 switching to culture media designed to support blastocyst development. **Although both culture systems have advantages, there is insufficient evidence to recommend one over the other, particularly as to whether any benefit of increased blastocyst development translates into improved pregnancy or live birth rates** (479).

Extended Culture to Blastocyst

Although precompaction human embryos can survive when placed in the uterus, the uterine cavity is a nonphysiologic location for them and there is greater uterine pulsatility during this period that may cause the embryos to be expelled (480). **Therefore, the blastocyst stage represents a more physiologic time for embryo transfer** (480). Because nearly 60% of morphologically normal cleavage embryos, but only 30% of blastocysts, are chromosomally abnormal, extended culture allows for better selection of embryos with improved quality (480,481). Notably, if a patient is a carrier of a balanced translocation, nearly 80% of cleavage embryos and 60% of blastocysts may be chromosomally abnormal (482). The euploidy rate of blastocysts is higher with completed development by postretrieval day 5 compared to day 6 or day 7.

Blastocyst Versus Cleavage Transfer Outcomes

Comparisons involving equal numbers of transferred embryos demonstrate that fresh blastocyst transfer is associated with up to 10% higher pregnancy rate and up

to 13% higher live birth rate than cleavage-stage transfer, which can be helpful information if considering elective single embryo transfer. Drawbacks to extended culture include the small possibility that no embryos will survive to fresh blastocyst transfer and a 23% reduction in women having additional embryos for cryopreservation. However, ovarian reserve with AMH >1 ng/mL strongly positively influences the presence of supernumerary blastocysts available for cryopreservation. Monozygotic twinning rates may be higher with blastocyst culture, although this has not been a consistent finding.

Criteria for Extended Culture

There are no established guidelines or criteria that determine when to utilize extended culture (483). Varying suggestions include: maternal age ≤42 with ≥ five 2-pronuclear (2PN) stage embryos on postretrieval day 1; maternal age of ≤40 and ≥ three good-quality day 3 embryos having 4 to 10 cells with <15% fragmentation; maternal age of ≤41 to 42 and ≥ four good-quality day 3 embryos having 4 to 10 cells with <15% fragmentation; and age <37 with ≥4 morphologically good embryos on day 3 or ≥4 embryos with 6 cells and <10% fragmentation (474,476,483).

Embryo Transfer

Embryo Morphology

[9] Embryo morphology guides the choice of embryo for transfer. Pronuclear embryos are assessed by their distribution and number of nucleoli, the position of the second polar body relative to the first, and cleavage rates (abnormal rates are too fast, too slow, or arrested) (477). Preferred cleavage-stage embryos have a normal developmental pattern characterized by early cleavage on day 1, 4 cells on day 2, and 8 cells on day 3. Embryo fragmentation should be ≤10%, the blastomere size should be regular and there should be no multinucleation (474). The Gardner and Schoolcraft system for scoring blastocysts uses a scale from 1 (worst) to 6 (best), with grades 1 to 3 indicating growth of the blastocele until it completely fills the embryo. Grade 4 blastocysts are expanded with a larger blastocele volume and a thinning zona pellucida. The trophectoderm in a grade 5 blastocyst is starting to hatch though the zona and the grade 6 blastocyst has completely escaped or hatched from the zona (473). The inner cell mass is graded A–C based on tightness and cellularity (A is best), and the trophectoderm is assessed from A–C based upon cohesiveness and cellularity (A is best) (473). Conventional embryo morphology grading remains the most common methodology in choosing embryos to transfer but it has limitations. In order to assess development and morphology of embryos, handling of the embryos and removing them from the controlled environment of the incubator is required. This exposure leads to differences in oxygen levels, temperature and pH which may have adverse effects on the development of the embryos (484). Understandably conventional morphology

assessment is limited to specific points in time to avoid repeated exposure to the atmospheric environment (484). Time-lapse imaging has been developed by installing a camera in the incubator allowing for continuous undisturbed evaluation of the embryos. In addition to the ability to assess morphology at multiple time points, morphokinetic monitoring, which assesses the rate at which embryos reach developmental events, can be accomplished with time-lapse imaging. Prior results of randomized studies comparing clinical outcomes of time-lapse monitoring versus conventional morphology have been mixed (484–486). Although there appears to be a potential benefit in the application of time-lapse imaging, more high-quality, well-designed randomized control trials need to be performed before any definitive conclusions can be drawn (484–486).

Number of Embryos to Transfer

Multiple gestation pregnancies increase complications for mothers and fetuses, so guidelines have been developed to minimize this adverse outcome (487). **[10] Single embryo transfer should be the standard if an embryo is euploid regardless of the age of the patient or stage of the embryo** (487). Single embryo transfer is recommended for patients <age 38 undergoing a fresh cycle, if they have had a prior live birth or there is an expectation that at least one high-quality embryo will be available for cryopreservation (487). Patients < age 38 undergoing frozen embryo transfer (FET) should have a single embryo transferred if vitrified blastocysts are available, if it is the patient's first FET, or if the patient had a previous live birth (487). In all other cases, transfer of embryos should be limited to two embryos in women under the age of 35. In older women, the maximum number of transferred cleavage-stage embryos should be: 3 in women aged 35 to 37, 4 in women aged 38 to 40, and 5 in women >40 years of age (487). Because of their high implantation potential, no more than three blastocysts should be transferred to any woman regardless of her age (487). **[10]** Limits on the number of embryos transferred when the embryos were created from donor oocytes should be based on the age of the donor, rather than the recipient (487).

Transfer Procedure

[9] The goal of transcervical embryo transfer is to atraumatically deliver the embryos to an optimal intrauterine location for implantation. Prior to performing the embryo transfer the cervix and vagina are cleansed using media or saline. The utility of removing remaining cervical mucus appears to be beneficial in improving live birth and clinical pregnancy rates (488). Embryo transfer can be accomplished using a number of transcervical techniques. Direct transfer is performed by loading the transfer catheter with embryo(s) and transferring immediately without a trial transfer. Trial transfer permits assessment of the cervical canal prior to performing the actual transfer. Trial transfer can be combined with an afterload technique if the trial transfer is difficult. The outer sheath of the trial transfer catheter is left in place while removing the inner catheter and a new inner transfer catheter loaded with the embryo(s) is threaded through

the trial catheter sheath into the uterus. Afterload technique can be planned and utilized intentionally without a trial transfer. Transabdominal US should be utilized to assess the endometrial cavity and other pelvic structures prior to and during the transfer to assure deposit of the embryo(s) in the upper or middle area of the uterine cavity but no closer than 1 cm from the fundus (488). **[9] Implantation is more likely when using a soft catheter and when fundal contact is avoided** (488). When the embryos are deposited, the entire catheter should be removed immediately as there does not appear to be any benefit in delaying catheter withdrawal (488). After the transfer, the catheter is checked for retained embryos. If present, retained embryos should be immediately retransferred as there is no detriment in pregnancy rates (488). When the embryo transfer is completed, the patient may leave immediately without a period of bed rest (488). Although intrauterine infections decrease pregnancy rates, the efficacy of antibiotic administration at the time of transfer is not supported (488).

Cryopreservation of Embryos

Embryo cryopreservation at the pronuclear, cleavage, and blastocyst stages has permitted multiple transfer cycles from a single oocyte retrieval. Because transfer of cryopreserved embryos is less expensive than a second fresh cycle, overall fertility treatment costs can be optimized. Techniques for embryo cryopreservation include slow freezing and rapid freezing or vitrification. Slow freezing protocols use lower concentrations of cryoprotectants but are more time-consuming when compared to vitrification, which uses high-concentration cryoprotectants for rapid cooling and is less expensive (489). Embryo thawing is accomplished by brief exposure to air and warm water followed by rehydration (490). Although pregnancy rates for frozen embryo transfer (FET) cycles using the two cryopreservation methods are similar, vitrification is associated with higher postthaw embryo survival (93% vs. 76% with slow freezing) (489). **[9] Favorable postthaw embryo survival rates after vitrification has contributed to the increasing success of FET, with live birth rates that are no different than fresh embryo transfer** (491). The success of FET has led to a growing trend toward freezing entire embryo cohorts for transfer at a later date. This strategy has the added advantage of greatly reducing the risk of ovarian hyperstimulation syndrome with reassuring perinatal and obstetric outcomes (492). Although a number of studies report a favorable live birth rate per transfer when using a freeze-all strategy compared with fresh transfer, cumulative birth rates have not been shown to be different (493). Particularly in PCOS patients, a freeze-all strategy with subsequent warmed embryo transfer improved live birth rates compared to fresh transfer, though an increase in preeclampsia and singleton infant birth weight were noted. Well-designed randomized controlled trials are needed before recommending routine use of a freeze-all strategy (493).

Endometrial Preparation for Frozen Embryo Transfer

When FET is combined with a recipient's natural cycle, no exogenous treatment is given and transfer is timed to spontaneous ovulation, performed 7 days following detection of the serum LH surge (333). [9] In medicated FET cycles, E2 supplementation begins in the early follicular phase and is continued for up to 13 to 15 days prior to initiating progesterone (490). Multiple E2 preparations have been described for use in FET cycles, but none have been proven superior (494). Transvaginal US is used to assess endometrial thickness during estrogen therapy and estrogen administration continues until an optimal thickness of ≥6.5 to 8 mm is reached (333,490). Progesterone supplementation begins 48 to 72 hours prior to transfer when cleavage-stage embryos are used and 6 to 7 days prior to transfer when blastocysts will be thawed (490,494) unless different progesterone timing is indicated (333). Several progesterone preparations have been described for use in FET cycles, but none have been proven superior ("Uterine Factor") (494). **Medicated FET cycles offer control and flexibility of transfer timing while maintaining low cancellation rates; however, adequate pituitary suppression may not always be achieved** (495). [9] **A GnRH agonist may be used in conjunction with medicated FET cycles as an added measure to prevent premature LH surges that may adversely affect endometrial maturation** (495). Coordination between the embryo and endometrium is critical to successful implantation (333). For some women, this remains elusive resulting in RIF defined as failure of at least three IVF cycles in which one or two morphologically high-grade embryos are transferred (333). **Prior studies of the transcriptome of the endometrium have shown the ability to accurately catalog the endometrium in all phases of the menstrual cycle and have challenged the assumption that the window in which the endometrium is receptive to embryo implantation is universal in all women** [9] (333). **The Endometrial Receptivity Array (ERA©, Igenomix) has been developed to address the optimal window of implantation in patients with RIF** through the use of a molecular diagnostic tool (333). While the initial reproductive outcomes applying the ERA© in patients with RIF have been promising, more studies incorporating a larger population are needed to validate these results (496).

First Trimester Pregnancy Monitoring

hCG including the a subunit can be detected in spent culture media from the 2PN-stage onward. The production of hCG by the blastocyst can be detected in the serum as early as 7 days posttransfer, and serum quantitative hCG levels may be obtained 11 to 14 days following embryo transfer (490,497). [9] **A serum threshold of 200 mIU/mL of hCG measured 12 days after transfer is 92% and 80% predictive of ongoing pregnancies for day 3 and day 5 embryos respectively, with levels normally rising approximately 40% per day** (497). **If normally rising hCG levels are detected, transvaginal US is planned at 6 to 7 weeks of gestation to determine the**

location of the pregnancy, the number of gestational sacs, and pregnancy viability (497). **[9] In those at high risk for ectopic pregnancy, early diagnosis using serial hCG and US examinations are important to reduce the risk of a ruptured ectopic pregnancy and to improve the success of medical management** (498). **These patients may benefit from transvaginal US at 5.5- to 6-weeks gestation as a gestational sac should become visible in a normal pregnancy during this time** (498). **When concern arises as to pregnancy viability, serial US findings of growth arrest with fetal pole length <20 mm at time of fetal demise correlate with aneuploidy of conceptus.**

[12] TABLE 36-9 Live Birth Rates from IVF Cycles Using Patient's Own Eggs and Uterus

		Age Years					
	All Ages	<35	35–37	38–40	41–42	>42	
Singleton	–	31.9%	24.7%	16.7%	8.7%	2.8%	
Twin		8.8%	6.0%	3.3%	1.2%	0.3%	
Higher-order multiple	–	0.2%	0.1%	0.1%	0.0%	0%	0
All live births	–	40.4–41.4%	30.3–31.5%	19.6–20.6%	9.4–10.4%	2.7–3.4%	n/a

IVF (in-vitro fertilization) 2015 outcomes (139).

ART SUCCESS RATES

IVF can be a highly effective treatment for many patients, but fewer than 200,000 IVF cycles are performed per year. The low IVF utilization rates are thought to be a result of the high cost of IVF and low retention rates among patients after an unsuccessful first IVF cycle. Providers have recommended counseling patients to consider IVF as a course of treatment, if needed, in order to maximize each patient's probability of having a live birth from IVF (499). A patient's decision to pursue medical treatment for infertility is often impacted by personal, financial, and medical factors. The provider's role is to establish the clinical diagnoses, discuss the risks and benefits of various treatment options, and recommend treatment. If the treatment options include COH and IVF (such as in unexplained infertility), providers would typically counsel the patients about the success rates of IUI (with clomid or gonadotropins) and IVF in the context of the patient's clinical data and diagnoses. Patients who are paying out-of-pocket for IVF treatment can benefit from a thorough discussion about the cost of each treatment option in the context of the per-cycle cost and the number of treatments that may be needed for each option. **[1]** Because the latter is directly related to the patient's per-cycle treatment success, understanding the relationship between the personalized IVF success probability and potential cost of IVF can help patients plan and maximize their chances of having a live birth (baby). Public reporting of each IVF center's success rates has been available for more than two decades. There have been significant efforts to

incorporate predictive modeling and technology to provide patient-centric probabilities of IVF success based on each patient's own health data.

National IVF Outcomes Registry

Since 1992, all clinics performing ART in the United States have been required to submit IVF cycle data and outcomes annually to the CDC via the National Assisted Reproductive Technology Surveillance System (NASS) which publishes reports of IVF outcomes analyses (500–504). The Society for Assisted Reproductive Technology (SART) via the Clinic Outcome Reporting System (CORS) publishes a summary of each registered ART clinic's IVF outcomes at https://www.sartcorsonline.com/rptCSR_PublicMultYear.aspx?reportingYear=2015 (139). For most purposes, ART cycles using ICSI and IVF are combined and analyzed as IVF cycles because their success rates are similar. IVF success rates, largely dependent on maternal age, are conventionally summarized from NASS/CDC and SART/CORS in an age-based format as shown in Table 36-9. SART asks that its reports not be used to compare IVF centers, presumably because success rates can be impacted by patient demographics and clinical attributes which vary among IVF centers. SART has been reporting, since 2014, the parameter of cumulative live birth rate, which reflects the chance of achieving a live birth after a fresh or FET within a year of cycle initiated for egg retrieval (139). **[12]** This allows tracking individual outcomes over time, accounting for fresh and frozen transfers stemming from the retrieval (139).

Prediction Models Personalize IVF Success

The ability to provide highly accurate and personalized probabilities of IVF success benefits the individual patient and gives providers insight about prognostic groups and profiles in their patient population. IVF success prediction models are not new, but the use of machine learning to develop and validate prediction models has dramatically improved model performance as defined by prediction accuracy, the ability to rank patients based on the difference in success probabilities using area-under-the-curve (AUC) in a receiver-operating curve analysis, and the percentage of patients who would receive a significantly different probability compared to conventional age-based prognostic classification (505).

Of the clinical data available prior to treatment, the patient's age is a key predictor of COH or IVF success and accounts for over 50% of relative importance of quantifiable predictors of IVF success (150,505,506). However, many other clinical predictors—ovarian reserve, BMI, reproductive history, clinical diagnoses, sperm parameters, total amount of gonadotropins used, oocyte parameters, and embryo scores—impact and predict treatment success. Fertility providers are interested in using data and technology to improve the patient's experience by offering personalized IVF success prognostics.

First, providers should define their goals. The intended goal of the prediction model determines the types of clinical predictors to be used by the model. For example, a prediction model that aims to inform a patient's decision to do her first IVF cycle should not use clinical predictors that can only be known after she starts IVF, such as the amount of gonadotropin used or oocyte and embryo parameters (150,506). A prediction model that aims to inform a patient's decision to do eSET should use clinical predictors —such as the number of blastocysts—that are available up to the day of embryo transfer (507).

When choosing a prediction model, it is important to consider whether the dataset used to develop and test the model reflects the patient population to which the model will be applied. Specifically, several researchers continue to raise the concern that a model developed and tested in one center may not have the same performance or accuracy when applied to another center, or rigorous steps may be required to test and recalibrate the model (508–511). This problem can be partially addressed by using a prediction model developed from data pooled from multiple centers or the national registry, though the applicability of the model to each individual center still needs to be tested (506,512–514). Alternatively, center-specific prediction models can be developed and tested based on each center's own data (150,505,507,515).

Cessation of Therapy

Patients must be accurately informed of estimated success rates and reasonable expectations for all therapeutic interventions (516). Patients with a very poor prognosis have a 2% to 5% chance of achieving a live birth with fertility therapy and those with a futile prognosis have a ≤1% chance (516). Refusing or limiting therapy may be justified if the risk of intervention outweighs the potential benefits (516).

Third Party Reproduction

When gametes and/or the ability to gestate a pregnancy are compromised through circumstances or disease, other reproductive options can be considered. **These include use of donor sperm ("Male Factor"), donor oocytes, donor embryos, a gestational carrier, or a combination of these approaches.** In contrast to donor gametes (sperm or oocytes), the decision to donate embryos is typically made after the embryos have been generated and there is a known surplus. A gestational carrier receives and gestates birth embryos created from the intended mother's oocytes. Patients who choose to utilize a gestational carrier may have irreparable uterine factor infertility or suffer from medical conditions that contraindicate pregnancy. In true surrogacy, the birth mother is also the genetic mother but not the mother who will raise the child. Legal and psychosocial counseling are suggested for all parties embarking on any form of third party reproduction.

Donor Oocyte

[9] Patients with premature ovarian insufficiency, poor oocyte quality, poor ovarian response to stimulation, or failed fertilization or implantation after multiple ART cycles may be candidates to receive donated oocytes. A female same-sex couple may choose to have one partner undergo IVF and place the resulting oocytes fertilized with donor sperm into the other partner (517). With carefully selected donors using nonfrozen oocytes, live birth rates per cycle of donor oocyte IVF are 50% to 60% or higher regardless of the recipient's age (138,139). Recipients must be aware that advanced recipient age is associated with higher risk for preeclampsia, diabetes, and cesarean section (518). Oocyte donors must endure all the interventions and risks of the ART process, except for embryo transfer and luteal support. Because of the intensity of therapy and the potential infectious disease and genetic risks for donor, recipient, and the resulting offspring, oocyte donors must be screened for infectious and heritable disorders similar to those performed for sperm donors ("Male Factor"), and undergo meticulous informed consent and a comprehensive psychosocial evaluation (519). Oocyte donors may be anonymous or known to the recipient (519). Oocyte recipients undergo endometrial preparation as described in the "ART Process" section, which may be synchronized with the donor for a fresh transfer **(Fig. 36-6)** or may be dissociated from the donor retrieval if using cryopreserved oocytes or embryos. Other topics, such as methods for donor recruitment and financial compensation for the donor are challenging issues (520).

Oocyte Cryopreservation

Historically, oocyte donation was restricted to the use of fresh oocytes, requiring coordination between the donor and recipient (519). **[9]** **With the continued evolution of cryopreservation technology, oocyte cryopreservation is a viable alternative and is no longer considered an experimental technique** (519). Oocyte cryopreservation techniques have resulted in excellent oocyte survival after vitrification and warming (519). Subsequent fertilization and pregnancy rates have been similar to patients undergoing IVF/ICSI with fresh oocytes (519), though live birth rates may be somewhat reduced (139). The utilization of cryopreserved oocytes has the potential to offer greater flexibility in pregnancy timing, more choices in the selection of a donor, and reduced cost (519). Multiple applications of this technology have been proposed to include fertility preservation in patients receiving gonadotoxic therapies, patients with genetic conditions, patients who are unable to cryopreserve embryos, and patients who want to electively defer childbearing (519). Oocytes can be cryopreserved when there is insufficient sperm for fertilization at the time of oocyte retrieval (519). Although preliminary data on perinatal outcomes are reassuring, more data are needed before routine oocyte cryopreservation and universal donor oocyte banking can be

recommended (519).

Complications of Assisted Reproductive Technology

Risks of ICSI

Risks of ICSI are detailed in "Male Factor."

Cycle Cancellation

Criteria for cycle cancellation vary; high-performing United States clinics reported a threshold of ≤3 follicles (up to <5 follicles) (428). **[9] Cycle cancellation in normal responders occurred in up to 6% of the cycles as a result of inadequate response and 1.5% of cycles for excessive response** (152), **and risk increases with older age and lower ovarian reserve** (416). In 0.2% to 7% of retrievals, no oocytes will be obtained (461). Two proposed explanations include human error during the administration of hCG and early oocyte atresia despite normal follicular response (461).

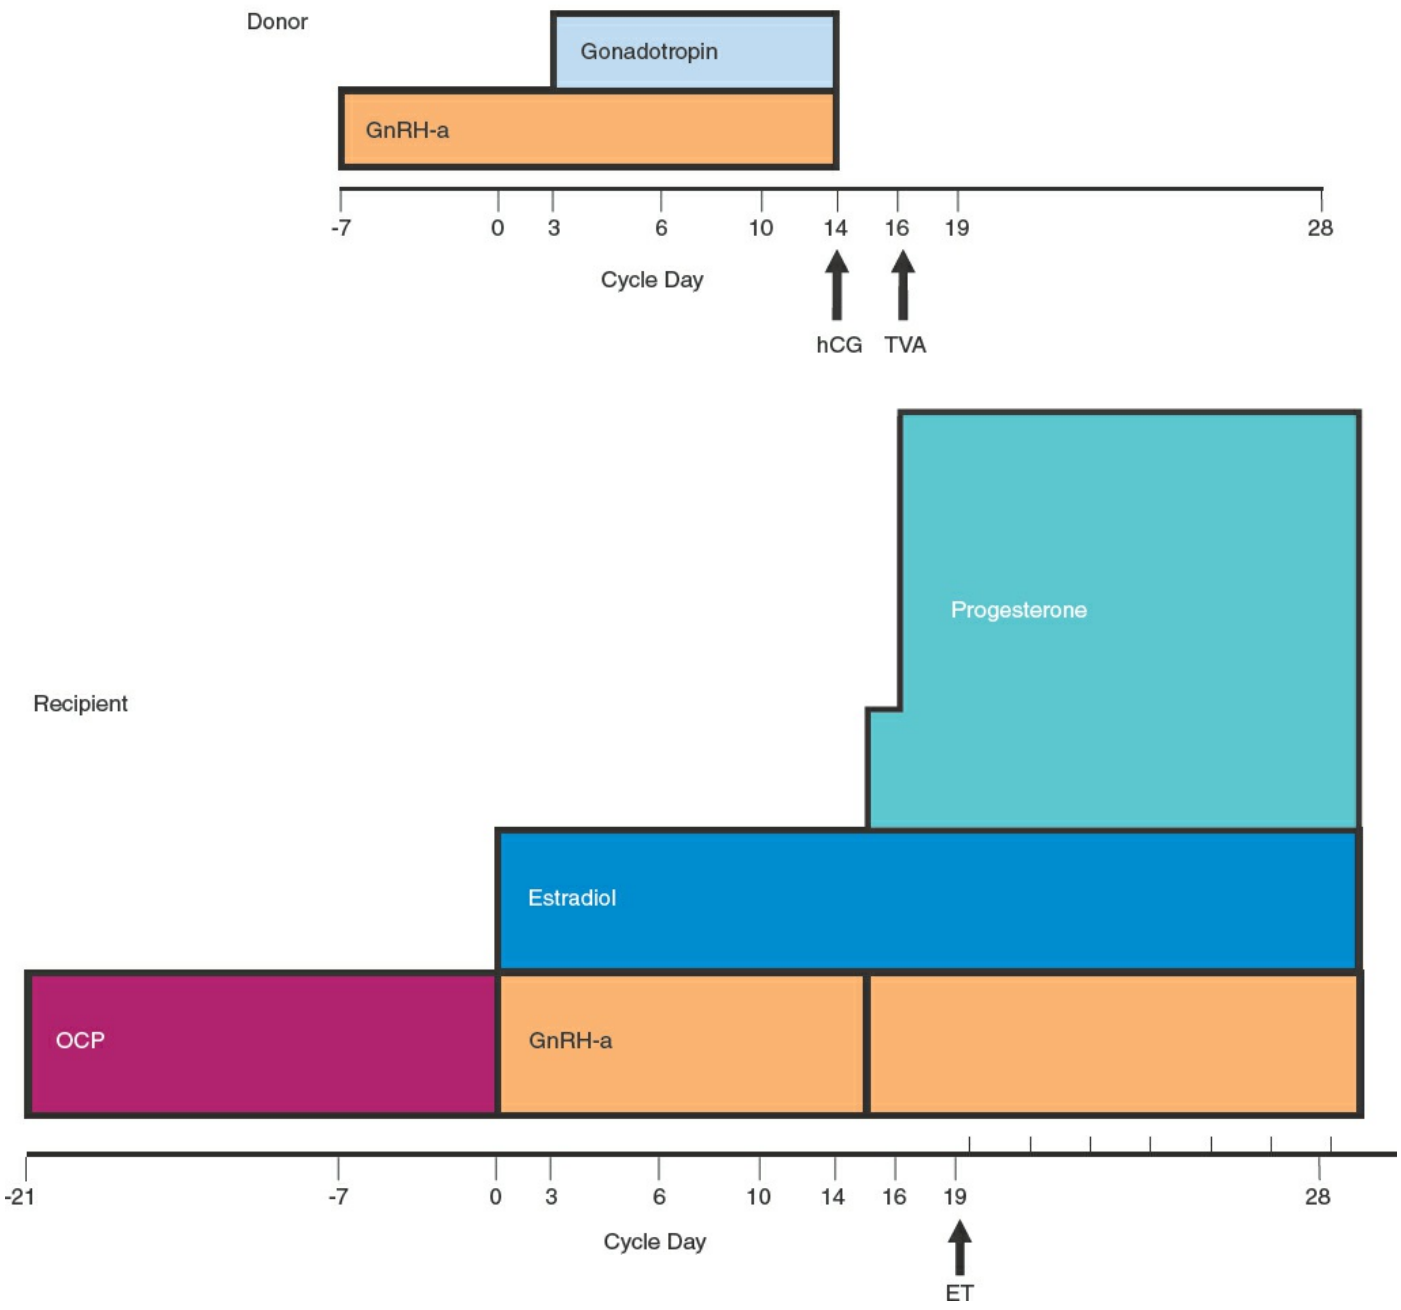

FIGURE 36-6 Regimens of ovarian stimulation and hormone replacement used to synchronize the development of ovarian follicles in the oocyte donor and the endometrial cycle in the recipient. hCG, human chorionic gonadotropin; OCP, oral contraceptive pill; GnRH-a, gonadotropin releasing hormone agonist; TVA, ultrasound-guided transvaginal aspiration of oocytes. (Adapted from **Chang PL, Sauer MY**. Assisted reproductive techniques. Stenchever MA, ed. Atlas of Clinical Gynecology, Mishell DR, ed. Reproductive Endocrinology. Vol. 3. Philadelphia, PA: Current Sciences Group; 1998, with permission.)

Oocyte Retrieval

The risks of oocyte retrieval include bleeding requiring transfusion, injury to adjacent structures requiring laparotomy, formation of a pelvic abscess leading to loss of reproductive function despite prophylaxis, and risks related to anesthesia (521).

Multiple Gestation

As the majority of ART cycles involve the transfer of more than one embryo, multiple gestation occurs at higher rates than for spontaneous conception (3%). This has social, medical, emotional, and financial ramifications (501,522). **[10]** **Although the majority of complications of multiple gestations occur with high-order (ê3) multiples, twins have increased risks for low birth weight, preterm birth, and neurologic deficits when compared to singletons** (522,523). **[10]** Despite this, 20% of infertile patients view multiple pregnancy as a desired outcome (501). Because most patients lack insurance coverage for IVF, patients may push their physicians to take greater risks when deciding on the number of embryos to transfer (501). The multiple pregnancy risk is higher in patients under the age of 35 who are undergoing IVF since their embryos are typically of better quality and implantation rates are higher, but multiple pregnancy can occur at any reproductive age (138,139). With increasing adherence to guidelines suggesting limitations on the number of embryos to transfer in a given ART cycle and improved implantation rates that allow single embryo transfer, the multiple infant live birth rate has decreased in most age groups from 2006 through 2015, occurring in 24% in women aged <35, 23% aged 35 to 37, and 20% age 38 to 40 (138). However, the multiple live birth rate increased in that same time period slightly to 18% aged 41 to 42 and 12% aged >42 (138). **[10]** Most multiple pregnancies arising from ART are dizygotic, but monozygotic twinning occurs in 3.2% of IVF cycles (compared to a background rate of 0.4%) (501). Concerns have been raised that monozygotic twinning might increase after blastocyst culture, but this finding has not been consistent (476,524).

Selective Reduction

Ten percent of multifetal pregnancies spontaneously lose at least one gestational sac during the first trimester. This loss rate increases to 21% in women >35 years of age (525). The spontaneous reduction rate to twins or singletons is much higher for triplets (14%) (526) than for quadruplets (3.5%) **[10]** (525). **Selective pregnancy termination or multifetal reduction may be an option for some patients in whom spontaneous reduction does not occur by 11 to 13 weeks** (527). This involves first karyotyping each fetus through transabdominal chorionic villous sampling to preferentially reduce those that are abnormal, then injecting potassium chloride into the heart of the targeted fetus (527). Although selective reduction carries a 3% to 7% risk of losing the entire pregnancy when performed prior to 19 weeks, this is still lower than the 15% chance of

spontaneously losing an entire triplet pregnancy (523,527). Selective fetal reduction is typically considered for triplet or higher pregnancies, but even reduction from twins to singletons may have benefits (523).

Ectopic and Heterotopic Pregnancy

ART pregnancies effectively bypass the fallopian tubes to achieve pregnancy but ectopic pregnancy (implantation outside the uterus) is still possible. Historically rates of ectopic pregnancy were higher in ART when compared to spontaneous conception, although data have shown **[11]** rates of ectopic pregnancy in ART to be similar to the general population rate of 2% (528). **The absence of an intrauterine pregnancy on transvaginal US evaluation in conjunction with a maternal serum hCG level above a threshold of 1,500 to 2,500 mIU/mL suggests an abnormal gestation** (498). This threshold or discriminatory zone is individualized to each institution depending on the characteristics of the hCG assay used and clinical expertise. A more conservative discriminatory zone decreases the risk of incorrectly diagnosing an ectopic pregnancy and terminating a viable pregnancy (498). **[11]** This is especially important in multiple gestation which will produce higher hCG levels at an earlier stage (498). Heterotopic pregnancy involves concurrent intrauterine and ectopic pregnancy, usually within the tube (529) but ovarian implantations have been reported (530). **[11]** The incidence of heterotopic pregnancy, which is extremely rare in spontaneous conceptions, is notably higher after IVF treatment with an incidence as high as 1% (529). Risk factors for heterotopic pregnancy include multiple gestation, smoking, previous tubal surgery, and prior PID, in addition to ART (529). As with standard ectopic pregnancies, pain and bleeding are the most common presenting findings with heterotopic pregnancies (529). Heterotopic pregnancies are most often diagnosed in the first 5 to 8 weeks of gestation using laparoscopy or laparotomy (529). **Only 26% of heterotopic cases can be diagnosed with transvaginal US, possibly because of difficulties in sonographic interpretation in the presence of concomitant ovarian hyperstimulation** (529). After treatment of a heterotopic gestation with laparoscopy, laparotomy, or US-guided injection of potassium chloride into the extrauterine pregnancy, the overall delivery rate for the intrauterine pregnancy is nearly 70% (529).

Ovarian Hyperstimulation Syndrome

OHSS is a medical complication that is completely iatrogenic and unique to stimulatory infertility treatment (531). **Its symptoms are the result of ovarian enlargement and fragility, extravascular fluid accumulation, and intravascular volume depletion** (532). Proposed mechanisms for the characteristic fluid shifts that accompany OHSS include increased protein-rich fluid secretion from the stimulated ovaries, increased renin and prorenin within follicular fluid, and increased capillary permeability mediated by angiotensin (532). **[11]** **Vascular endothelial growth factor**

(VEGF), whose expression in granulosa cells and serum is augmented by hCG, and a variety of other inflammatory cytokines have been implicated in the pathogenesis of this disease (532). Two distinct patterns of OHSS onset have been described. Early OHSS occurs 3 to 7 days following the hCG trigger and is associated with the administration of exogenous hCG (533). **[11]** Late-onset disease occurs 12 to 17 days after the hCG trigger; it is the result of endogenous hCG secretion from the pregnancy and tends to be more severe with multiple gestation (533). Pregnancy outcomes are inconsistently affected by the presence of OHSS, with higher rates of biochemical losses but similar rates of clinical losses when compared to patients without OHSS (533).

Severity Classification

[11] A RCT (534) described mild, moderate, and severe OHSS classifications considering criteria from Golan (531) and Navot (535) as follows: mild OHSS (grade 1 to 2) is associated with abdominal distention and discomfort with grade 2 including nausea, vomiting or diarrhea accompanied by ovary diameter of at least 5 mm. Moderate or grade 3 includes grade 2 plus sonographic subclinical ascites near the liver or in the pelvis if pocket >9 mm. Severe OHSS (grade 4 to 5) is associated with grade 3 plus clinical ascites, hydrothorax, or dyspnea, with grade 5 including hemoconcentration, renal insufficiency or oliguria, elevated transaminases, venous thromboembolism, or respiratory distress syndrome.

Risk Factors

Mild OHSS occurs commonly in both stimulated non-ART and ART cycles, but severe disease is rare in non-ART cycles (536). Severe disease is more common with ART, occurring in 5% of antagonist and nearly 9% of agonist protocols (534). Polycystic ovary syndrome, polycystic ovarian morphology with attendant elevated anti-mullerian hormone levels (>3.36 ng/mL), and previous episodes of OHSS are major risk factors for the disease (532,534,536,537). E2 concentrations of >3,500 pg/mL and >6,000 pg/mL at the time of hCG trigger were associated with severe OHSS in 1.5% and 38% of patients, respectively (536). More than 20 preovulatory follicles were associated with a 15% incidence of severe OHSS (536). When 20 to 29 oocytes were collected at retrieval, 1.4% of patients developed severe OHSS; this rose to 22.7% with ≥30 oocytes (536).

Management

If outpatient management is appropriate, the patient should be instructed to limit her activity, to weigh herself daily, and to monitor her fluid intake (at least 1 L/day of mostly electrolyte-balanced fluid) and output (532). Daily follow-up by telephone or visit is important and the patient should be reassessed if she notes worsening of the symptoms or if her weight gain increases to more than 2 lb per day (532). **Indications**

for hospitalization include inability to tolerate oral hydration, hemodynamic instability, respiratory compromise, tense ascites, hemoconcentration, leukocytosis, hyponatremia, hyperkalemia, abnormal renal or liver function, and decreased oxygen saturation (532). Fluid intake and urine output need to be carefully measured, and admission to an intensive care setting can be considered if the patient has hyperkalemia, renal failure, respiratory failure, or thromboembolic disease (532). Although IV fluids may worsen ascites, they are essential to correct hypovolemia, hypotension, electrolyte abnormalities and oliguria (532). Albumin 25% can be dosed 50 to 100 mg IV every 4 to 12 hours if further intravascular volume expansion is needed (532). Diuretics can be considered to improve weight gain and oliguria only after hypovolemia has been corrected (532). Thromboembolic prophylaxis should be given (532). Single or repeated transvaginal or transabdominal US–guided paracentesis may relieve pain, hydrothorax, or persistent oliguria (532). **[11]** Rapid large-volume fluid removal can be considered, as compensatory fluid shifts are unlikely to occur in this typically young healthy population, so long as the patient is carefully monitored (532).

OHSS Prevention

No method will prevent OHSS completely, but recognition of high-risk patients is the first step in decreasing that risk (538). PCOS, elevated AMH (>3.4 ng/mL), high peak E2 (>3,500 pg/mL), multifollicular development (≥25 follicles), or a high number of oocytes retrieved (≥24 oocytes) are associated with an elevated risk of OHSS (538).

COH and GnRH Analogs

Careful gonadotropin stimulation for monofollicular development is discussed under "Ovulatory Factor." **For ART, stimulation protocols for high-risk patients include lower initial COH doses of 150 IU to 225 IU and GnRH antagonists for LH surge prevention, which reduce the total dosage and duration of gonadotropin stimulation** (534). **[11]** GnRH antagonists when introduced following oocyte retrieval appear to accelerate regression of severe early OHSS without any adverse effects on pregnancy and live birth rates (539).

Ovulation Triggering

Decreasing the dose of hCG to reduce the incidence of OHSS is controversial (538). **GnRH agonists can be used instead of hCG during antagonist cycles to induce an endogenous LH surge. The very short half-life of endogenous LH may reduce the incidence and/or severity of OHSS** (538). As GnRH agonist triggers are associated with lower pregnancy rates, it may be a preferable option for patients who are not planning a fresh embryo transfer (538). **[11]** For those wanting to continue with a fresh cycle, low-dose hCG coadministered with a GnRH agonist trigger may prevent the lower pregnancy rates observed when a GnRH agonist is used alone (538).

Coasting

Coasting may be considered when E2 levels are >4,500 pg/mL and/or there are 15 to 30 mature follicles present (537). **During coasting, gonadotropin stimulation is withheld and E2 levels are checked daily** (537). An initial rise of E2 is typically observed within the first 48 hours of the coast, but the levels should subsequently plateau or decrease (540). The patient may be triggered when serum E2 levels fall to <3,500 pg/mL (537). **[11]** If GnRH agonists are used for initial LH surge suppression, switching to an antagonist during the coast has been associated with improved outcomes (537).

Cycle Cancellation

[11] Cycle cancellation may be recommended if there are >30 mature follicles, the coast duration is >4 days, or if E2 levels rise to >6,500 pg/mL during coasting (537,540).

Adjunctive Medications

The adjunctive use of metformin is associated with decreased OHSS rates in PCOS patients (541). Aspirin and calcium use appear to decrease the risk of OHSS as separate adjuncts (538). Evidence suggests that the use of letrozole following hCG triggering is effective in preventing moderate to severe early-onset OHSS (542). **Cabergoline, a dopamine agonist that inhibits VEGF production, decreased OHSS rates when given at 0.5 mg daily for 8 days from the day of hCG administration** (538,543). **Long-term use of cabergoline should be avoided as it may be associated with valvular heart disease** (537,540,544). **[11]** The benefit of albumin administration in decreasing rates of OHSS is unclear (538).

Embryo Cryopreservation

[11] Cryopreservation of all embryos without transfer appears to reduce late-onset OHSS although early-onset OHSS may still occur (540). With improved freezing techniques, live birth rates following frozen/thaw transfers are similar to fresh transfer (491). More information on embryo cryopreservation can be found in the "ART Process" section.

In vitro Oocyte Maturation

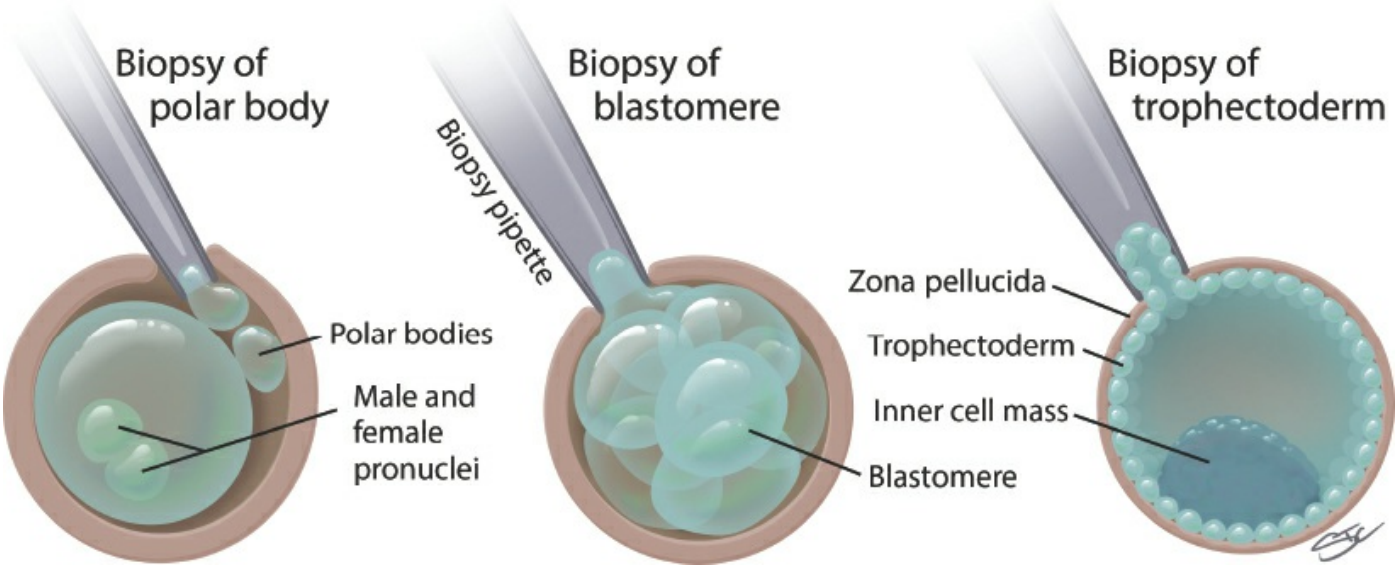
In vitro oocyte maturation (IVM) completely obviates the need to stimulate the ovaries with gonadotropins. During IVM cycles, immature follicles are aspirated following hCG administration, and the retrieved oocytes are grown in vitro until they mature. Mature oocytes are fertilized by insemination or ICSI (545). Randomized trials are still needed to further evaluate this technique (545). IVM is considered an experimental procedure and should only be performed in specialized centers (546). Randomized trials are still needed to further evaluate this technique before it can be recommended as an alternative to conventional ART techniques (547).

Risk of Cancer After Fertility Therapy

Infertility by itself is a predisposing factor for ovarian cancer and breast cancer (548). **Although treatments that promote incessant ovulation and elevated estrogen levels offer biologic plausibility for further increased cancer risk, data regarding the impact of infertility therapy on malignancy are inconsistent and limited by methodologic issues** (548). The practice committee for the American Society of Reproductive Medicine completed an analysis of accumulated data of prior studies addressing the potential risk of cancer with fertility drug use (548). No association between fertility drug use and an increased risk of invasive ovarian cancer, breast cancer, or endometrial cancer could be established when evaluating the available data (548). Although several studies have shown a small absolute risk of borderline ovarian tumors there is a lack of consistent evidence that any particular fertility drug increases the risk of borderline ovarian tumors (548). When considering other cancers, there does not appear to be a risk of invasive thyroid cancer, colon cancer, or cervical cancer (548). **[11]** There is insufficient evidence to determine if there is an increased risk of melanoma or lymphoma (548).

Stress

Stress, as manifested by anxiety or depression, is thought to be increased among women experiencing infertility (549). **Stress is the most common reason for patients, even those with insurance coverage, to terminate fertility treatment** (550). **[11]** Although the preponderance of the evidence suggests that stress does not adversely affect IVF outcome, additional studies are needed before any conclusions can be made (551–553). If psychological disorders are present, treatment should be offered regardless of fertility status.



Neonatal and Child Development

With the ever-growing number of births resulting from ART, it is important to consider potential perinatal risks and long-term childhood outcomes. Multifetal gestation and its subsequent effect on maternal and fetal morbidity and mortality represent the most significant risk of ART (554). Risks of multiple gestation include preterm birth, low birth weight, small for gestational age, congenital anomalies, and perinatal mortality. These risks appear to have an independent association with IVF regardless of fetal number (554). The risk of negative long-term outcomes of children born after IVF are primarily associated with inherent risks of multiple gestation pregnancies. When multiple gestation is excluded the risk is uncertain and underscores the need for further studies (554). **[10]** **The most important step in mitigating neonatal and long-term** pediatric risk associated with IVF is continued emphasis on elective single embryo transfer (487). Patients should have a thorough history and physical performed, addressing any health problems or inherited conditions that could impact future

pregnancy (554).

Preimplantation Genetic Diagnosis and Screening

[9] The primary indication for PGD is to improve the chances of having healthy infants in families at high risk for a specific genetic disease (555). Following embryo biopsy, genetic testing can be performed on a blastomere (cell from day 3 embryo), polar body, or on blastocyst trophectoderm prior to transferring the embryo (556) **(Fig. 36-7)**. Data favor biopsy at the blastocyst stage over the cleavage stage (557). Aneuploidy in embryos most commonly affects chromosomes X, Y, 13, 14, 15, 16, 18, 21, and 22 (556). Fluorescence *in situ* hybridization (FISH) is a technique that assesses aneuploidy, translocation, other structural chromosomal defects, and sex chromosome content (556). FISH is technically limited by the number of distinct chromosomes that can be evaluated, giving the technique an inherently high false negative rate. Newer genetic technologies have been developed that have the ability to assess the entire genome using array comparative genomic hybridization (aCGH), single nucleotide polymorphism (SNP) arrays, and next-generation sequencing (NGS) (558). **[9]** One-quarter of the cases of PGD are performed for single gene disorders, most commonly myotonic dystrophy, Huntington disease, cystic fibrosis, fragile X syndrome, spinal muscular atrophy, tuberous sclerosis, Marfan syndrome, thalassemia and sickle cell anemia (556). Because polymerase chain reaction (PCR) is required for single gene disorder diagnosis, ICSI is performed during ART to avoid contamination from sperm bound to the zona pellucida (556). **[9]** PGD can be used for HLA tissue matching in an effort to produce a child whose cord blood or stem cells could help an existing affected child (556). Disadvantages to PGD include decreased postbiopsy embryo survival, requirements for extended culture with an associated possibility that no embryos will be available for transfer or cryopreservation, false positive and false negative testing results, and controversies regarding disposition of nontransferred embryos (555,556).

[9] FIGURE 36-7 Embryo biopsy procedure. A small opening is made in the zona pellucida and depending on the stage of embryonic development the removal of a polar body (fertilized or unfertilized oocyte), blastomere (cleavage stage 8 cell), or trophectoderm (blastocyst) is performed.

Preimplantation Genetic Screening

PGD is not synonymous with PGS, which is performed in couples without known chromosomal anomaly, mutation, or other genetic abnormalities (555). **[9] PGS focuses on identifying euploid embryos for transfer, with the goal of increasing implantation rates and decreasing miscarriage rates** (558). **[10]** When embryos are known to be euploid, single embryo transfer is universally recommended to decrease the risk of multiple gestation (487). Available genetic testing platforms for PGS are the same as those used in PGD and will equally detect whole chromosome aneuploidy. Newer genetic technologies **(Figs. 36-8** to **36-11)** have added more genetic capabilities to include assessment of segmental aneuploidy, mosaicism, and mitochondrial DNA (mtDNA) copy number (558). Work on mtDNA has suggested that it may have value as a potential biomarker of embryo viability (559). Earlier studies indicated that elevated mtDNA content is associated with implantation failure, although data have not corroborated these findings, suggesting the need for further evaluation of the technology (559–562). Although it seems intuitive that replacing only euploid embryos should improve pregnancy and live birth rates in patients with advanced age, recurrent pregnancy loss, or implantation failure, study outcomes have not been consistent (555,556,563–566). A significant challenge to the application of PGS is chromosomal mosaicism **(Figs. 36-12** and **36-13)**, which arises from mitotic errors during embryo development, and has raised concerns of how well the biopsy sample represents the embryo as a whole, and whether subsequent embryonic self-correction can restore euploidy (567). Mosaic embryos can be considered potentially viable but should be deprioritized for transfer compared to embryos with nonmosaic euploid results as a

result of limited data on neonatal outcomes, diminished implantation, pregnancy, and live birth rates and higher miscarriage risk (568,569). **[9]** Mosaicism involving two or more chromosomes and/or higher amount of aneuploidy (involving more affected cells) could be considered for transfer (568,569) but one study suggests they be further deprioritized compared to embryos with single mosaic chromosome and/or lower degrees of aneuploidy (569). **[11]** Thorough genetic and physician counseling is necessary for the patient to proceed with testing embryos using PGD/PGS and to understand the results if PGS/PGD is performed, in order for an informed decision to be made regarding whether and which embryos to transfer.

polymorphisms (SNP), diploid chromosome 21 is seen on the left, trisomy 21 on the right. (Adapted with permission from **Brezina et al.** [558].)

Preservation of Fertility in Cancer Patients

Improved cancer treatments such as chemotherapy, surgery, and radiotherapy have greatly enhanced survival, such that many cancer survivors contemplate parenthood (570). Unfortunately, those life-saving treatments can diminish fertility potential in men and women (570). Cancer itself does not usually affect oocytes, but certain chemotherapeutic drugs or radiation damage may adversely affect ovarian reserve and uterine function, particularly in older women (570). **[5] If time allows, prior to commencement of cancer treatment, women can undergo an ART cycle with embryo or oocyte cryopreservation, although ovarian tissue preservation and in vitro maturation of oocytes remain experimental** (546). Fertility sparing treatments may be considered in certain situations including radical trachelectomy for cervical cancer, progestin therapy *in lieu* of hysterectomy for uterine cancer, and unilateral oophorectomy for some ovarian tumors (570). Ovarian function may be preserved when ovarian transposition is performed prior to radiation therapy (546). It is unclear whether ovarian suppression with GnRH analogs during chemotherapy or radiation is protective and it is still considered investigational (546). In men, cancer directly affects gametogenesis and cancer treatments cause more fertility damage when given at younger ages (570). **[5] Semen and sperm cryopreservation prior to cancer treatment, when feasible, is the standard fertility preservation method in men** (546).

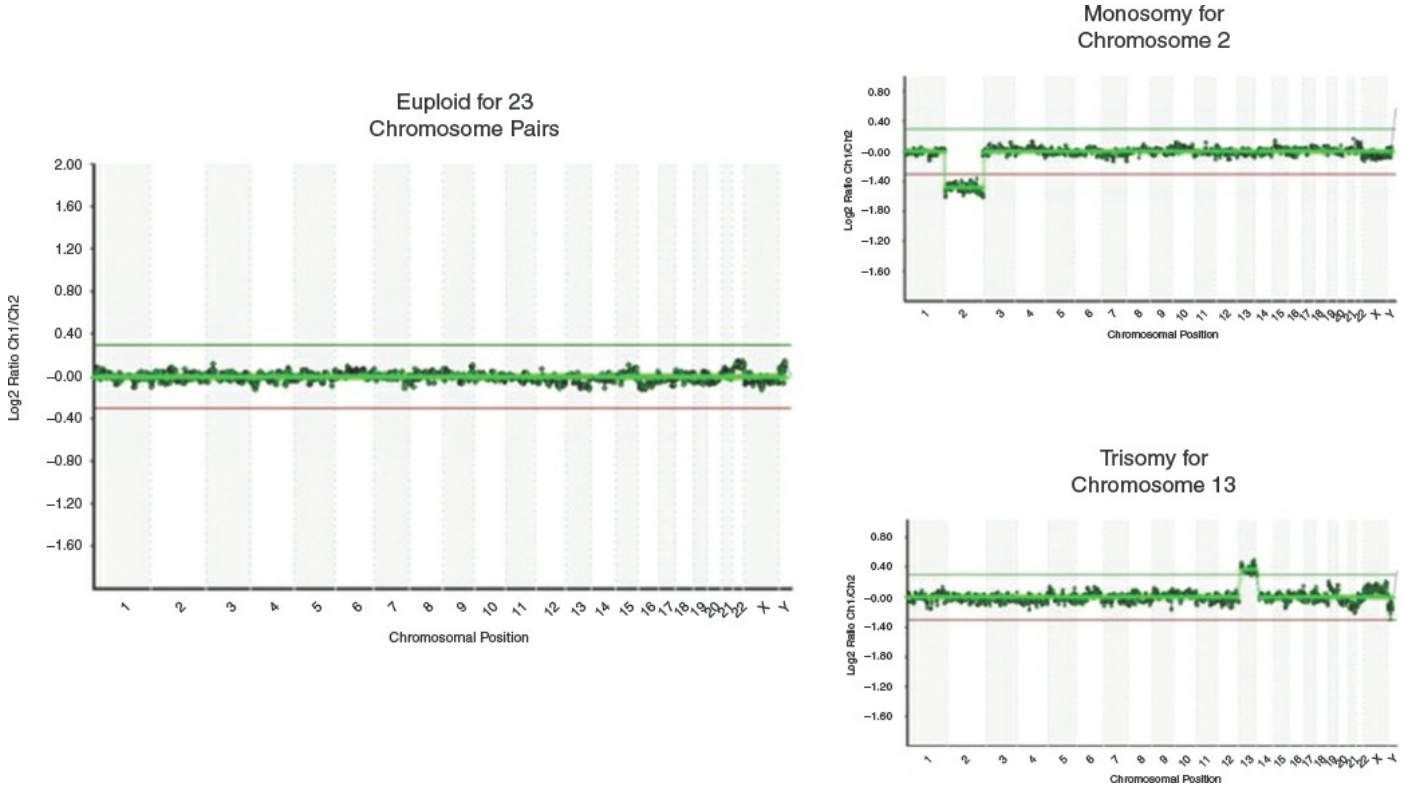

FIGURE 36-9 Detection of abnormalities with different PGS platforms. Using **comparative genomic hybridization (CGH)**, the left panel indicates euploid/diploid results with a relatively equal ratio of green/red fluorescence in all 23 pairs of chromosomes. The top right shows chromosome 2 monosomy with downward deviation indicating a relative lack of green, as compared to red, signal intensity. The bottom right shows chromosome 13 trisomy with upward deviation indicating a relative increase of green, as compared to red, signal intensity. (Adapted with permission from **Brezina et al.** [558].)

KEY POINTS

1 The most common risk factors for the development of endometrial carcinoma are related to prolonged, unopposed estrogen stimulation.

2 Office endometrial aspiration biopsy is the accepted first step in evaluating a woman with abnormal uterine bleeding or suspected endometrial pathology.

3 Serous and clear cell endometrial carcinomas make up less than 10% of endometrial cancers, yet account for more than one-half of all endometrial cancer deaths.

4 Most patients with endometrial cancer should undergo surgical staging, including hysterectomy, bilateral salpingo-oophorectomy, and peritoneal cytology. Lymph node assessment is necessary for most patients, but may be omitted in patients with negligible risk of lymphatic spread.

5 The most important adverse prognostic variables in endometrial cancer are advancing patient age, nonendometrioid or grade 3 histology, deep myometrial invasion, lymph-vascular invasion, large tumor size, cervical extension, lymph node metastasis, and intraperitoneal spread.

6 Postoperative adjuvant radiotherapy and chemotherapy in selected patients with endometrial cancer decreases the risk of local vaginal/pelvic recurrence and improves disease-free survival.

7 Overall 5-year survival rate in endometrial cancer is approximately 75%.

8 Radiotherapy is the best treatment option for patients with isolated local–regional recurrences who have not received prior radiation. Isolated vaginal recurrences may be salvaged in up to 80% of patients.

9 Uterine sarcomas are, in general, the most malignant group of uterine tumors and differ from endometrial cancers with regard to risk factors, diagnosis, clinical behavior, pattern of spread, and management.

Endometrial carcinoma is the most common malignancy of the female genital tract, accounting for almost one-half of all gynecologic cancers in the United States. In 2018, an estimated 63,230 new cases and 11,350 cancer-related deaths are anticipated (1). Endometrial carcinoma is the fourth most common cancer, ranking behind breast, lung, and colorectal cancers, and the sixth leading cause of death from malignancy in women. Overall, about 2.8% of women develop endometrial cancer during their lifetimes. Although endometrial carcinoma usually presents as early-stage disease and often is managed without radical surgery or radiotherapy, deaths from endometrial carcinoma rose by about 2% per year from 2010 to 2014. **Endometrial cancer is a disease that occurs primarily in postmenopausal women and is increasingly virulent with advancing age. The definite role of estrogen in the development of most endometrial cancers is established. Any factor that increases exposure to unopposed estrogen increases the risk for endometrial cancer.**

EPIDEMIOLOGY AND RISK FACTORS

There appear to be two pathogenetic types of endometrial cancer (2). **Type I, accounting for about 75% to 85% of cases, occurs in younger, perimenopausal women with a history of exposure to unopposed estrogen, either endogenous or exogenous.** In these women, tumors begin as hyperplastic endometrium and progress to carcinoma. These "estrogen-dependent" tumors tend to be better differentiated and have a more favorable prognosis than tumors not associated with hyperestrogenism. **Type II endometrial carcinoma occurs in women without estrogenic stimulation of the endometrium.** These spontaneously occurring cancers are not pathologically associated with endometrial hyperplasia, but may arise in a background of atrophic endometrium. They are less differentiated and associated with a poorer prognosis than estrogen-dependent tumors. These "estrogen-independent" tumors tend to occur in older, postmenopausal, thin women and are present disproportionately in African American and Asian women. Over the past decade, molecular genetic studies showed that these two tumor types evolve via distinct pathogenetic pathways (3) (see Types I and II Endometrial Carcinoma: Molecular Aberrations, below).

Several risk factors for the development of endometrial cancer have been identified, **[1] most of which are related to prolonged, unopposed estrogen stimulation of the**

endometrium (Table 37-1) (3–5). Nulliparous women have two to three times the risk of parous women. Infertility and a history of irregular menses as a result of anovulatory cycles (prolonged exposure to estrogen without sufficient progesterone) increase risk. Natural menopause occurring after age 52 years increases the risk for endometrial cancer 2.4-fold compared with women who experienced menopause before 49 years of age, probably as a result of prolonged exposure of the uterus to progesterone-deficient menstrual cycles. **The risk of endometrial cancer is increased 1.5 times for overweight and more than 2.5-fold for obese women** (resulting from excess estrone as a result of conversion of adrenally derived androstenedione by aromatization in peripheral fat) (6). The obesity epidemic in Western countries, together with growing rates of insulin resistance and metabolic syndrome, is expected to increase the incidence of endometrial cancer in coming years.

Table 37-1 Risk Factors for Endometrial Cancer

Characteristic	Relative Risk
Nulliparity	2–3
Late menopause	2.4
Obesity	
21–50 lb overweight	3
>50 lb overweight	10
Diabetes mellitus	2.8
Unopposed *estrogen* therapy	4–8
Tamoxifen therapy	2–3
Atypical endometrial hyperplasia	8–29
Lynch II syndrome	20

Other factors leading to long-term estrogen exposure, such as polycystic ovary syndrome and functioning ovarian tumors, are associated with an increased risk for endometrial cancer. Menopausal *estrogen* therapy without *progestins* increases the risk of endometrial cancer four- to eightfold. This risk increases with higher doses and with more prolonged use and can be reduced to essentially baseline levels by the addition of at least 10 days of *progestin treatment* (7). The use of the antiestrogen *tamoxifen* for treatment of breast cancer is associated with a two- to threefold increased risk for the development of endometrial cancer, although this finding is confounded by the apparent greater risk of endometrial cancer in women who have breast cancer, with or without treatment with *tamoxifen* (5). Analysis of diabetes mellitus is confounded by obesity,

but is thought to be associated with a modest increase in endometrial cancer risk even after adjusting for other factors (8). **Women with Lynch II syndrome (previously referred to as hereditary nonpolyposis colorectal cancer syndrome, or HNPCC), a cancer susceptibility syndrome with germline mutations in mismatch repair genes *MLH1, MSH2,* and *MSH6,* have a 40% to 60% lifetime risk for endometrial and colon cancer** (9). Other medical conditions, such as hypertension and hypothyroidism, are associated with endometrial cancer, but a causal relationship has not been confirmed.

ENDOMETRIAL HYPERPLASIA

Endometrial hyperplasia represents a spectrum of morphologic and biologic alterations of the endometrial glands and stroma, ranging from an exaggerated physiologic state to carcinoma *in situ.* **Clinically significant hyperplasias usually evolve within a background of proliferative endometrium as a result of protracted estrogen stimulation in the absence of progestin influence.** Endometrial hyperplasias are important clinically because they may cause abnormal bleeding, be associated with estrogen-producing ovarian tumors, result from hormonal therapy, and precede or occur simultaneously with endometrial cancer.

The classification scheme endorsed by the International Society of Gynecological Pathologists is based on architectural and cytologic features and long-term studies that reflect the natural history of the lesions (10) **(Table 37-2)**. Architecturally, hyperplasias are either simple or complex, differentiated by complexity and crowding of the glandular elements. **Simple hyperplasia** is characterized by dilated or cystic glands with round to slightly irregular shapes, an increased glandular-to-stromal ratio without glandular crowding, and no cytologic atypia. **Complex hyperplasia** has architecturally complex (budding and infolding) crowded glands, with less intervening stroma without atypia. **Atypical hyperplasia refers to cytologic atypia and can be categorized as simple or complex, depending on the corresponding glandular architecture.** Criteria for cytologic atypia include large nuclei of variable size and shape that have lost polarity, increased nuclear-to-cytoplasmic ratios, prominent nucleoli, and irregularly clumped chromatin with parachromatin clearing **(Fig. 37-1)**.

Table 37-2 Classification of Endometrial Hyperplasias

Type of Hyperplasia	Progression to Cancer (%)
Simple (cystic without atypia)	1
Complex (adenomatous without atypia)	3
Atypical	

Simple (cystic with atypia)	8
Complex (adenomatous with atypia)	29

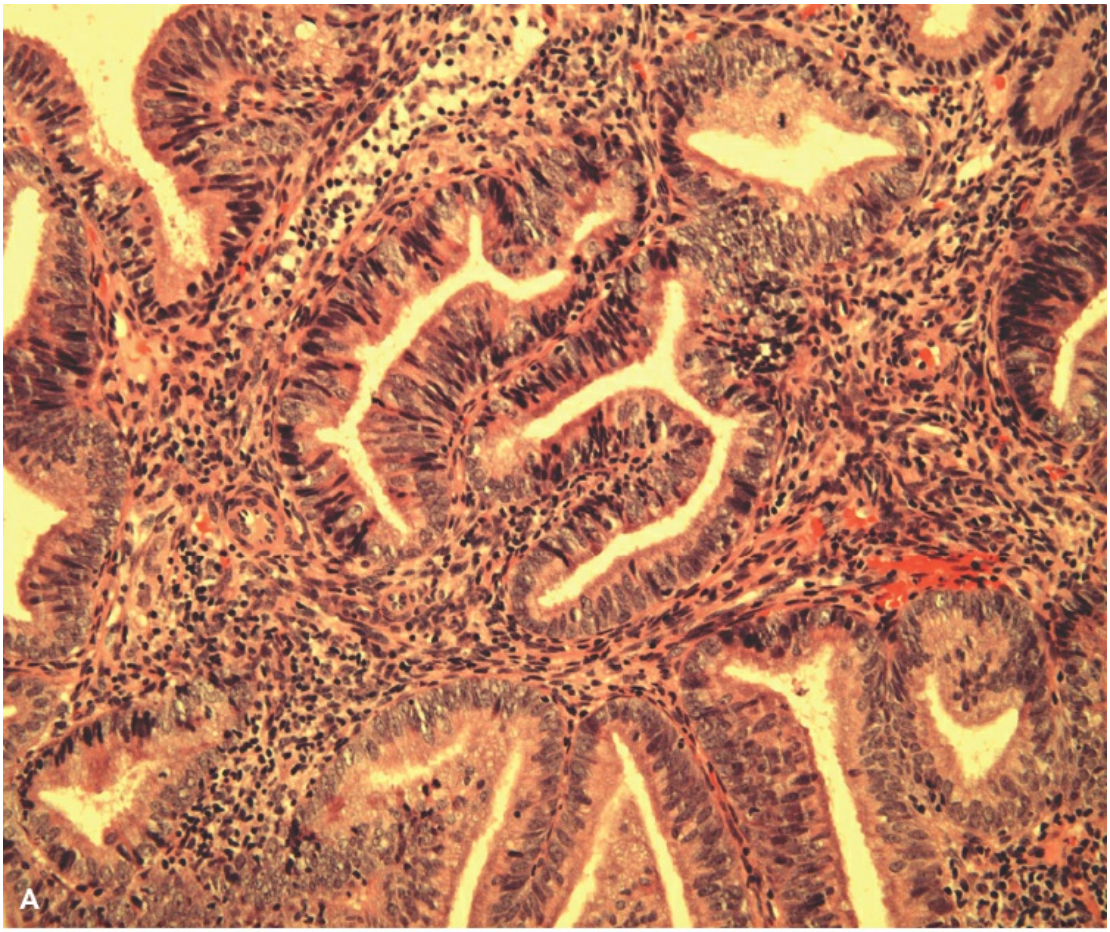
From **Kurman RJ, Kaminski PF, Norris HJ**. The behavior of endometrial hyperplasia: a long term study of "untreated" hyperplasia in 170 patients. *Cancer* 1985;56:403–412, with permission.

The risk of endometrial hyperplasia progressing to carcinoma is related to the presence and severity of cytologic atypia. Kurman et al. retrospectively studied endometrial curettings from 170 patients with untreated endometrial hyperplasia followed for a mean of 13.4 years (11). They found that **progression to carcinoma occurred in 1% of patients with simple hyperplasia, 3% of patients with complex hyperplasia, 8% of patients with atypical simple hyperplasia, and 29% of patients with atypical complex hyperplasia.** Most of the hyperplasias seemed to remain stable (18%) or regress (74%). **As many as 25% to 43% of patients with atypical hyperplasia detected in an endometrial biopsy or curettage specimen will have an associated, usually well-differentiated, endometrial carcinoma detected during hysterectomy (**12). Marked cytologic atypia, a high mitotic rate, and marked cellular stratification are features of atypical endometrial hyperplasia most often associated with the finding of an undiagnosed carcinoma at hysterectomy.

Fertility-Sparing Treatment of Endometrial Hyperplasia and Cancer

Younger patients with endometrial cancer tend to have disorders such as polycystic ovarian syndrome, chronic anovulation, and infertility, indicative of exposure to intrinsic estrogen excess (13). Lesions in this age group are usually well differentiated and of endometrioid subtype with the potential to regress with oral or localized progestational therapy. Although standard treatment for all endometrial cancer is hysterectomy and staging, nonsurgical treatment with hormonal therapy may be an option for appropriately selected women desiring to preserve fertility. Surrogate staging techniques, such as magnetic resonance imaging (MRI), may be employed to evaluate the depth of myometrial invasion or identify extrauterine disease, although low sensitivity has the potential for underdiagnosis (14,15).

High regression rates for endometrial cancer and atypical hyperplasia following treatment with *progestin* therapy are extensively documented (16–20). Relatively small cohorts of patients and reports of hormone failure suggest caution when counseling patients for conservative management (21). A comprehensive review of hormonal treatment of grade 1endometrial cancer, including 27 articles with a combined total of 81 patients, included treatment with a variety of progestational agents. The overall response rate was 76% (62/81) and the median time to regression was 12 weeks (22). The recurrence rate was 24% among responders; nearly all recurrences occurred within 1 year of diagnosis. Only 1 month of progestational treatment was required to achieve a



response in the 76% of patients without recurrence. Twenty patients achieved pregnancy following treatment. It is important to note that 24% (19/81) of the original cohort never responded to treatment, and only 68% had any documented follow-up endometrial sampling. Progestational therapy can successfully treat disease while preserving fertility for patients with atypical hyperplasia and well-differentiated presumed stage I endometrial cancer. Appropriate patient selection and exclusion criteria remain undefined. Patients must be counseled that failure to identify recurrence or extension of disease during progestational treatment may lead to a delay in definitive surgery and ultimately a compromised prognosis (18).

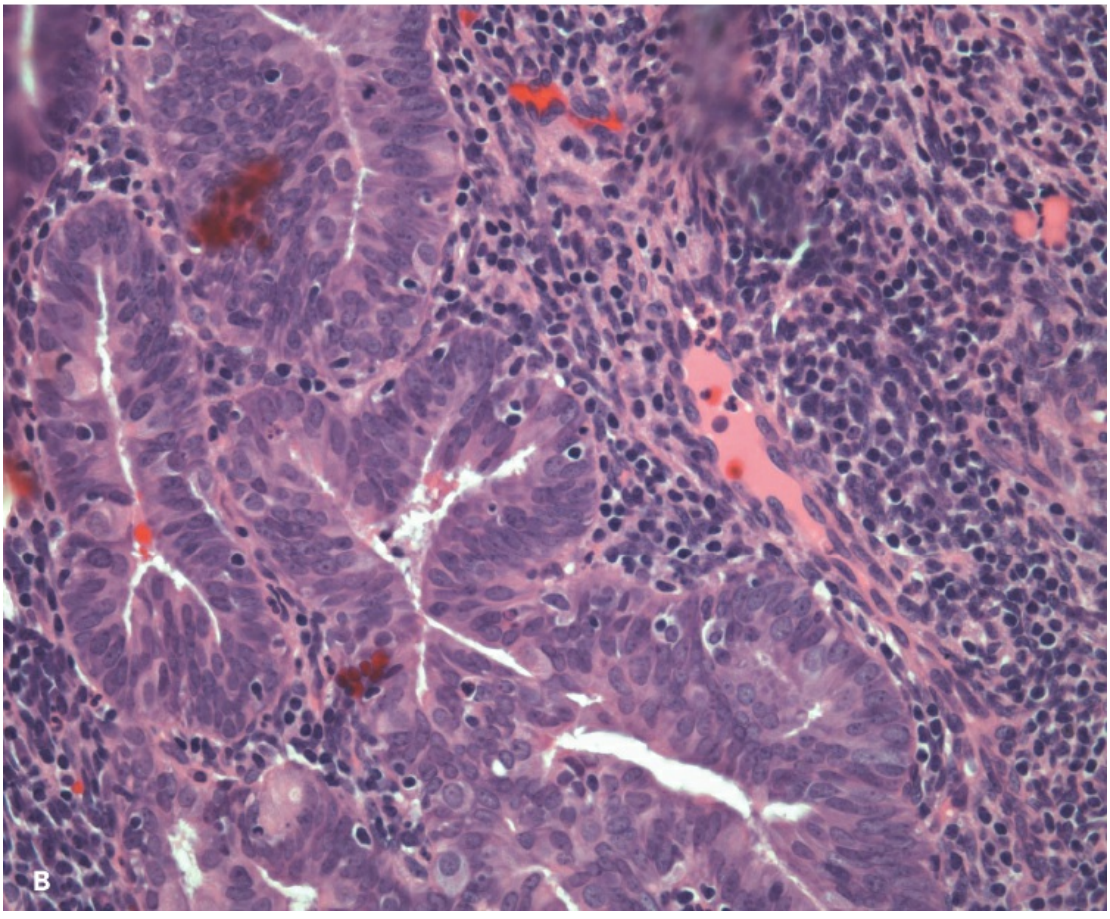
Continuous *progestin* therapy with *megestrol acetate* (40 to 160 mg per day) is probably the most reliable treatment for reversing complex or atypical hyperplasia, recognizing that higher doses may be associated with reduced compliance secondary to side effects. No clear consensus exists for an optimal follow-up interval. Therapy should be continued for at least 3 to 6 months, and endometrial biopsy should be performed to assess response. **Periodic endometrial biopsy or transvaginal ultrasonography is advisable in patients being monitored on progestin therapy for atypical hyperplasia because of the presence of undiagnosed cancer in at least 25% of cases and the high recurrence rate after treatment with progestins.** In this setting the use of progesterone should be considered a temporary, rather than long-term, treatment. **For women with atypical complex hyperplasia who no longer desire fertility, hysterectomy is recommended.**

ENDOMETRIAL CANCER SCREENING IN THE GENERAL POPULATION

Screening for endometrial cancer should not be undertaken because of the lack of an appropriate, cost-effective, and acceptable test that reduces mortality. **Routine Papanicolaou (Pap) testing is inadequate, and endometrial cytologic assessment is too insensitive and nonspecific to be useful in screening for endometrial cancer, even in a high-risk population.** Transvaginal ultrasonographic examination of the uterus and endometrial biopsy are too expensive to be employed as screening tests.

Screening for endometrial cancer or its precursors may be justified for certain high-risk women, such as members of families with hereditary nonpolyposis colorectal cancer (23). Women taking *tamoxifen* receive no benefit from routine screening with transvaginal ultrasonography or endometrial biopsy (24,25). Similarly, there is insufficient evidence to recommend screening for endometrial cancer in women because of a history of unopposed estrogen therapy, late menopause, nulliparity, infertility or failure to ovulate, obesity, diabetes, or hypertension (26).

A



B

FIGURE 37-1 Atypical hyperplasia (complex hyperplasia with severe nuclear atypia) of endometrium. **A:** The proliferative endometrial glands reveal considerable crowding and papillary infoldings. The endometrial stroma, although markedly diminished, can still be recognized between the glands. **B:** Higher magnification demonstrates disorderly nuclear arrangement and nuclear enlargement and irregularity. Some contain small nucleoli. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Most patients with endometrial cancer present with abnormal perimenopausal or postmenopausal uterine bleeding when the tumor is still confined to the uterus. Application of an appropriate and accurate diagnostic test in this situation usually results in early diagnosis and a high cure rate with timely treatment. It is important to recognize that the workup of abnormal uterine bleeding should include endometrial biopsy even in premenopausal patients, as 5% of cases are in women under the age of 40.

Surveillance and Prevention in Patients at High Risk

Most endometrial carcinomas are sporadic, but at least 10% of cases have a hereditary basis (27,28). Two genetic models were described in the development of familial endometrial cancer: Lynch II syndrome and patients with a predisposition for endometrial cancer alone, both of which are inherited in an autosomal dominant fashion (29). The majority of studies focused on the increased incidence of endometrial cancer associated with Lynch II syndrome, a highly penetrant disorder (80% to 85%) (30). Lynch II syndrome is caused by an inherited mutation in one of the following mismatch repair genes: *hMSH2, hMLH1, PMS1, PMS2,* or *hMSH6* (31). The disorder is characterized by early age (average age younger than 45 years) at onset of neoplastic lesions in a variety of tissues, including the colon, uterus, stomach, ureters, ovaries, and skin (30,32). The lifetime risk of endometrial cancer in women with Lynch II syndrome is 32% to 60% and the lifetime risk of ovarian cancer is 10% to 12% (33,34). Colorectal cancer is less prevalent in women with Lynch II syndrome than in men, whose risk approaches 100%. In a study of 1,763 patients from 50 Lynch II syndrome families in the Finnish Cancer Registry, the cumulative incidence of colorectal cancer in women was 54% by age 70, while the cumulative incidence of endometrial cancer was 60%, supporting surveillance (9,33,35). No effective screening method has been identified for patients at increased risk for ovarian cancer.

The Mallorca group, composed of experts in the treatment of hereditary gastrointestinal cancers from nine countries, recommended the following endometrial cancer surveillance strategy for patients with Lynch II syndrome: annual pelvic examination, transvaginal ultrasound, and endometrial biopsy beginning at 35 to 40 years of age (36). These recommendations are by expert opinion only, and it is unknown whether these interventions are cost-effective or will impact mortality from endometrial or ovarian cancer in patients with Lynch II syndrome. An attractive alternative to early

detection is prophylactic surgery after completion of childbearing (37). A multi-institutional, matched case-control study found that prophylactic hysterectomy with bilateral salpingo-oophorectomy is an effective primary prevention strategy in women with Lynch II syndrome. No woman with hysterectomy and bilateral salpingo-oophorectomy developed endometrial, ovarian, or peritoneal carcinoma during the period of follow-up. In contrast, endometrial cancer developed in 33% and ovarian cancer in 5% of women who did not undergo prophylactic surgery (34).

Recognizing that 3% to 5% of endometrial cancers can be attributed to Lynch syndrome, a new diagnosis of endometrial cancer represents an opportunity to identify patients with germline mutations. Clinical screening using protocols such as the Amsterdam or Bethesda criteria has been used in the past, but the use of molecular tumor testing has been shown to improve the rate of Lynch II detection (38). For example, in 2007 the Society of Gynecologic Oncology developed clinical practice guidelines to identify women who may benefit from germline Lynch testing. Bruegl et al. attempted to validate these guidelines in an unselected cohort of patients with endometrial cancer and reported poor sensitivity (32.6%, 95% confidence interval [CI] 19.2%–48.5%), showing that a majority of Lynch II patients were missed using this criteria. They went on to show that universal screening was ultimately more cost effective than the SGO model (39). Another study by Goverde et al. found universal testing in endometrial cancer patients under age 70 was cost-effective (6,668 British pounds/life year gained) as a result of the prevention of colorectal cancer in index patients and their relatives (40). Performing immunohistochemistry for *MLH1*, *MSH2*, *MSH6*, and *PMS2* expression is one cost effective model that is available in most laboratories. Recognizing that loss of *MLH1* is most often caused by hypermethylation, such analyses should be completed to appropriately triage patients to germline testing (41).

There are rare reports of pedigrees in which family members are affected by endometrial cancer alone, and genetic studies have not found a germline mutation associated with site-specific endometrial cancer (29,42,43). A population-based study of endometrial cancer and familial risk in younger women (Cancer and Steroid Hormone, or CASH, Study Group) reported that a history of endometrial cancer in a first-degree relative increased the risk of endometrial cancer by nearly threefold (odds ratio of 2.8; 95% CI, 1.9%–4.2%) (44). A significant association was found with colorectal cancers, with an observed odds ratio of 1.9 (95% CI, 1.1%–3.3%). The presence of Lynch II syndrome families within the cohort may explain the latter association, but a family history of endometrial cancer was an independent risk factor for endometrial cancer, after adjusting for age, obesity, and number of relatives (44).

Endometrial cancer and breast cancer share some of the same reproductive and hormonal risk factors such as nulliparity and exposure to unopposed estrogen (4,45,46). However, a familial association between breast and endometrial cancer is uncertain

(46). Although it has been posited that patients with *BRCA* mutations were at elevated risk for endometrial cancer (in addition to breast and ovarian cancer), this increase in risk may be present only in those patients with a personal history of breast cancer who are taking *tamoxifen* (47).

ENDOMETRIAL CANCER

Clinical Features

Symptoms

Endometrial carcinoma most often occurs in women in the sixth and seventh decades of life, at an average age of 60 years; 75% of cases occur in women older than 50 years of age. **About 90% of women with endometrial carcinoma have vaginal bleeding or discharge as their only presenting symptom.** Most women recognize the significance of postmenopausal bleeding and seek medical consultation within 3 months. Some women experience pelvic pressure or discomfort indicative of uterine enlargement or extrauterine disease spread. Bleeding may not have occurred because of cervical stenosis, especially in older patients, and may be associated with hematometra or pyometra, causing a purulent vaginal discharge. This finding is often associated with a poor prognosis (48). **Less than 5% of women diagnosed with endometrial cancer are asymptomatic.** In the absence of symptoms, endometrial cancer is usually detected following an abnormal Pap test, discovery of cancer in a uterus removed for some other reason, or evaluation of an abnormal finding on a pelvic ultrasonography examination or computed tomography (CT) scan obtained for an unrelated reason. Women who are found to have malignant cells on Pap test are more likely to have other poor prognostic factors (49).

Abnormal perimenopausal and postmenopausal bleeding should always be taken seriously and be properly investigated, no matter how minimal or nonpersistent. Causes may be nongenital, genital extrauterine, or uterine. Nongenital tract sites should be considered based on the history or examination, including testing for blood in the urine and stool. Invasive tumors of the cervix, vagina, and vulva are usually evident on examination, and any abnormalities should be biopsied. Traumatic bleeding from an atrophic vagina may account for up to 15% of all causes of postmenopausal vaginal bleeding. This diagnosis can be considered if inspection reveals a thin, friable vaginal wall, but the possibility of a uterine source of bleeding must first be eliminated.

Possible uterine causes of perimenopausal or postmenopausal bleeding include endometrial atrophy, endometrial polyps, *estrogen* therapy, hyperplasia, and cancer (50,51) (Table 37-3). Uterine leiomyomas should never be accepted as a cause of postmenopausal bleeding. **Endometrial atrophy is the most common endometrial finding in women with postmenopausal bleeding, accounting for 60% to 80% of**

such bleeding. Women with endometrial atrophy usually were menopausal for about 10 years. **Endometrial biopsy often yields insufficient tissue or only blood and mucus, and usually bleeding ceases after biopsy.** Endometrial polyps account for 2% to 12% of postmenopausal bleeding. Polyps are often difficult to identify with office endometrial biopsy or curettage. Hysteroscopy, transvaginal ultrasonography, or both, may be useful adjuncts in identifying endometrial polyps. Unrecognized and untreated polyps may be a source of continued or recurrent bleeding, leading eventually to unnecessary hysterectomy.

Estrogen therapy is an established risk factor for endometrial hyperplasia and cancer. **The risk for endometrial cancer is four to eight times greater in postmenopausal women receiving unopposed *estrogen* therapy, and the risk increases with time and higher *estrogen* doses.** This risk can be decreased by the addition of a *progestin* to the *estrogen,* either cyclically or continuously. Endometrial biopsy should be performed as indicated to assess unscheduled bleeding or annually in women not taking a *progestin.* **Endometrial hyperplasia occurs in 5% to 10% of patients with postmenopausal uterine bleeding.** The sources of excess estrogen should be considered, including obesity, exogenous estrogen, or an estrogen-secreting ovarian tumor. **Less than 10% of patients with postmenopausal bleeding have endometrial cancer.**

Table 37-3 Causes of Postmenopausal Uterine Bleeding

Cause of Bleeding	Percentage
Endometrial atrophy	60–80
Estrogen replacement therapy	15–25
Endometrial polyps	2–12
Endometrial hyperplasia	5–10
Endometrial cancer	10

Premenopausal women with endometrial cancer invariably have abnormal uterine bleeding, which is often characterized as menometrorrhagia or oligomenorrhea, or cyclical bleeding that continues past the usual age of menopause. The diagnosis of endometrial cancer must be considered in premenopausal women if abnormal bleeding is persistent, recurrent or if obesity or chronic anovulation is present.

Signs

Physical examination seldom reveals any evidence of endometrial carcinoma, although **obesity is a commonly associated constitutional factor.** Special attention should be given to the more common sites of metastasis. Peripheral lymph nodes should be

assessed carefully. Abdominal examination is usually unremarkable, except in advanced cases in which ascites or hepatic or omental metastases may be palpable. On gynecologic examination, the vaginal introitus and suburethral area, and the entire vagina and cervix, should be carefully inspected and palpated. Bimanual rectovaginal examination should be performed specifically to evaluate the uterus for size and mobility, the adnexa for masses, the parametria for induration, and the cul-de-sac for nodularity.

Diagnosis

[2] Office endometrial aspiration biopsy is the accepted first step in evaluating a patient with abnormal uterine bleeding or suspected endometrial pathology. The diagnostic accuracy of office-based endometrial biopsy is 90% to 98% when compared with subsequent findings at dilation and curettage (D&C) or hysterectomy (52).

The narrow plastic cannulas are relatively inexpensive, often can be used without a tenaculum, cause less uterine cramping (improving patient acceptance), and are successful in obtaining adequate tissue samples in more than 95% of cases. If cervical stenosis is encountered, a paracervical block can be performed, and the cervix can be dilated. Premedication with an antiprostaglandin agent can reduce uterine cramping. Complications following endometrial biopsy are exceedingly rare; uterine perforation occurs in only 1 to 2 cases per 1,000. Endocervical curettage may be performed at the time of endometrial biopsy if cervical pathology is suspected. **A Pap test is an unreliable diagnostic test because only 30% to 50% of patients with endometrial cancer have abnormal Pap test results (**53).

Hysteroscopy and D&C should be reserved for situations in which cervical stenosis or patient tolerance does not permit adequate evaluation by aspiration biopsy, bleeding recurs after a negative endometrial biopsy, or the specimen obtained is inadequate to explain the abnormal bleeding. Hysteroscopy is more accurate in identifying polyps and submucous myomas than endometrial biopsy or D&C alone (54).

Transvaginal ultrasonography may be a useful adjunct to endometrial biopsy for evaluating abnormal uterine bleeding and selecting patients for additional testing (55). Transvaginal ultrasonography, with or without endometrial fluid instillation (sonohysterography), may be helpful in distinguishing between patients with minimal endometrial tissue whose bleeding is related to perimenopausal anovulation or postmenopausal atrophy and patients with significant amounts of endometrial tissue or polyps who are in need of further evaluation. The finding of an endometrial thickness greater than 4 mm, a polypoid endometrial mass, or a collection of fluid within the uterus requires further evaluation. Although most studies agree that an endometrial thickness of less than 5 mm in a postmenopausal woman is consistent with atrophy, more

data are needed before ultrasonography findings can be considered to eliminate the need for endometrial biopsy in a patient with symptoms (56).

Pathology

The histologic classification of carcinoma arising in the endometrium is shown in Table 37-4 (10,57).

Endometrioid Adenocarcinoma

The endometrioid type of adenocarcinoma accounts for about 80% of endometrial carcinomas. These tumors are composed of glands that resemble normal endometrial glands; they have columnar cells with basally oriented nuclei, little or no intracytoplasmic mucin, and smooth intraluminal surfaces **(Fig. 37-2)**. As tumors become less differentiated, they contain more solid areas, less glandular formation, and more cytologic atypia. The well-differentiated lesions may be difficult to separate from atypical hyperplasia.

Table 37-4 Classification of Endometrial Carcinomas

Endometrioid adenocarcinoma Variants Villoglandular or papillary Secretory With squamous differentiation
Mucinous carcinoma
Papillary serous carcinoma
Clear cell carcinoma
Squamous carcinoma
Undifferentiated carcinoma
Mixed carcinoma

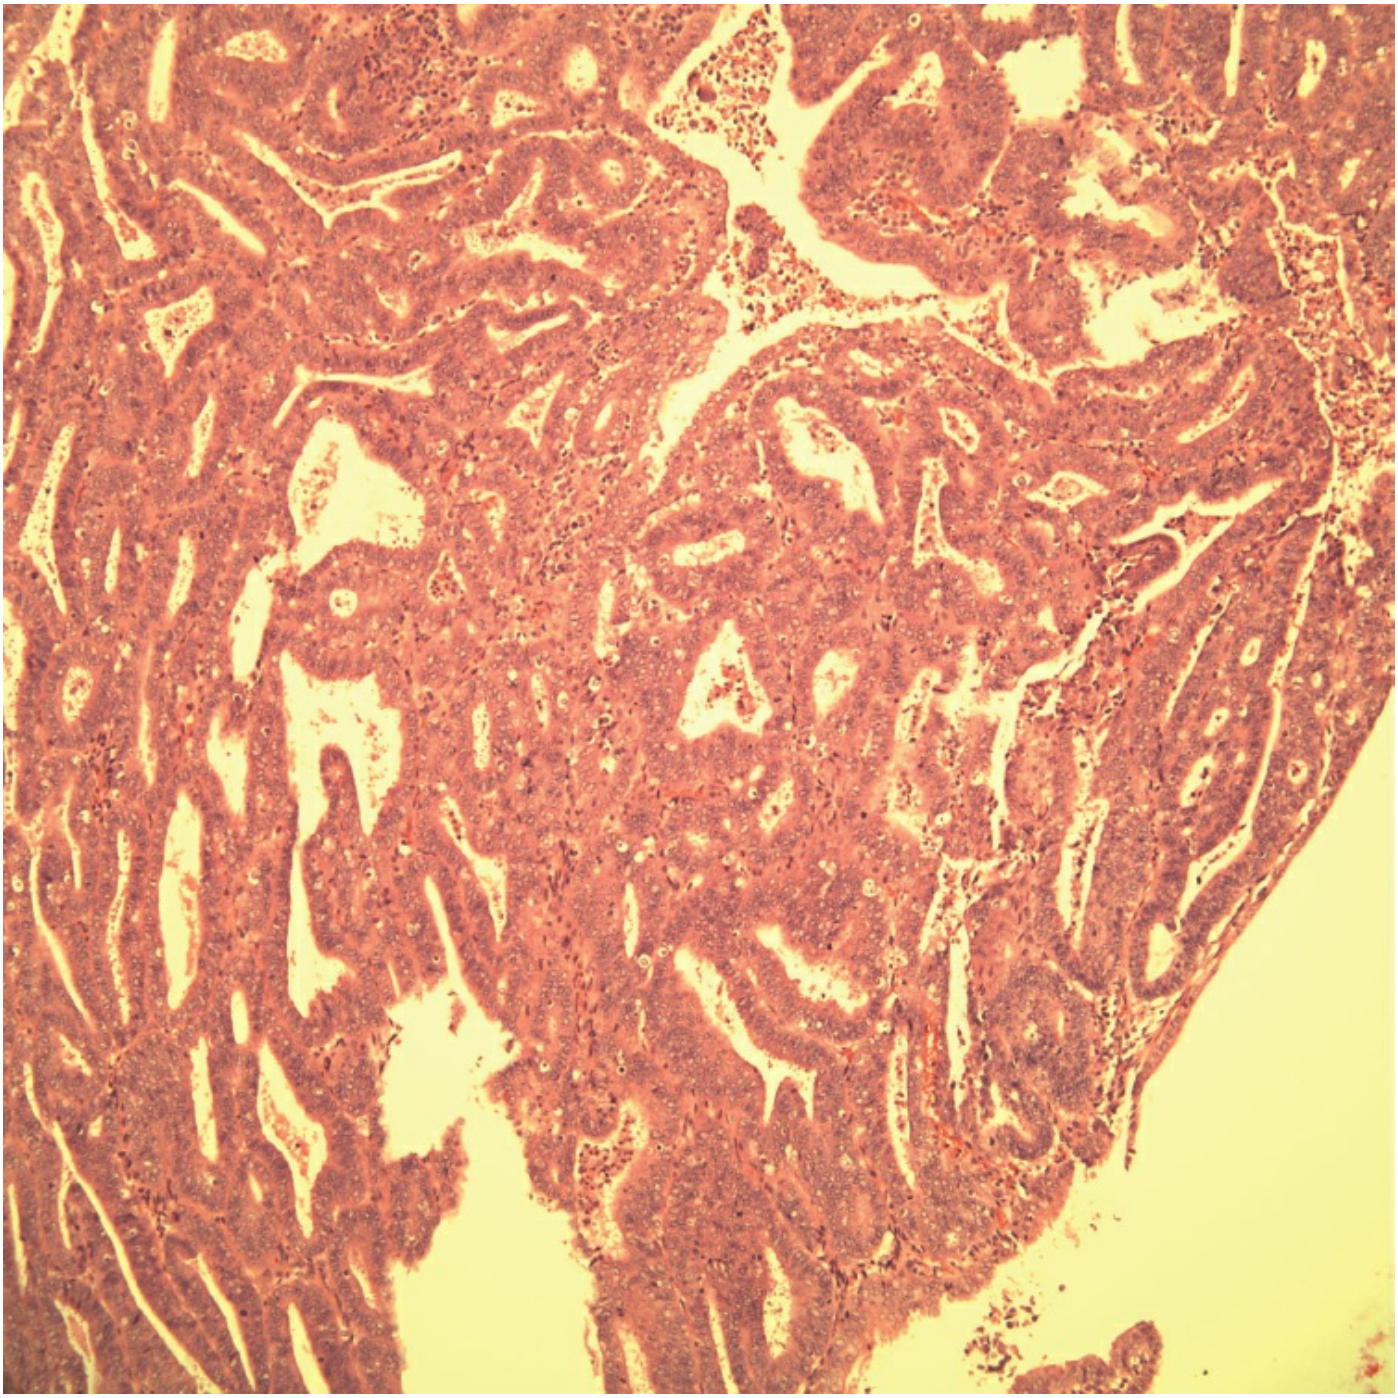


FIGURE 37-2 Well-differentiated adenocarcinoma of endometrium. The glands and complex papillae are in direct contact with no intervening endometrial stroma, the so-called back-to-back pattern. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Criteria that indicate the presence of invasion and are used to diagnose carcinoma are desmoplastic stroma, back-to-back glands without intervening stoma, extensive papillary pattern, and squamous epithelial differentiation. These changes, with the exception of the infiltrating pattern with desmoplastic reaction, require an area of involvement equal to or exceeding one-half of a low-power microscopic field (LPF) (>1 LPF; 4.2 mm in diameter) (58,59).

The differentiation of a carcinoma, expressed as its grade, is determined by architectural growth pattern and nuclear features (Table 37-5). In the International Federation of Gynecology and Obstetrics (FIGO) grading system proposed in 1989, tumors are grouped into three grades: *grade 1,* 5% or less of the tumor shows a solid growth pattern; *grade 2,* 6% to 50% of the tumor shows a solid growth pattern; and *grade 3,* more than 50% of the tumor shows a solid growth pattern. The presence of notable nuclear atypia that is inappropriate for the architectural grade increases the tumor grade by one.

Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component. This FIGO system is applicable to all endometrioid carcinomas, including its variants, and to mucinous carcinomas. In serous and clear cell carcinomas, nuclear grading takes precedence; however, most investigators believe that these two carcinomas should always be considered high-grade lesions, making grading unnecessary.

Table 37-5 FIGO Definition for Grading of Endometrial Carcinoma

Histopathologic Degree of Differentiation:
G1 <5% nonsquamous or nonmorular growth pattern
G2 6–50% nonsquamous or nonmorular growth pattern
G3 >50% nonsquamous or nonmorular growth pattern
Notes on Pathologic Grading:
Notable nuclear atypia, inappropriate for the architectural grade, raises a grade 1 (G1) or grade 2 (G2) tumor by one grade
In serous adenocarcinoma, clear cell adenocarcinoma, and squamous cell carcinoma, nuclear grading takes precedence
Adenocarcinomas with squamous differentiation are graded according to the nuclear grade of the glandular component

FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obst* 2009;105:103–104.

About 15% to 25% of endometrioid carcinomas have areas of squamous differentiation (Fig. 37-3). In the past, tumors with benign-appearing squamous areas were called *adenoacanthomas,* and tumors with malignant-looking squamous elements were called *adenosquamous carcinomas.* It is recommended that the term *endometrial carcinoma with squamous differentiation* be used to replace these two designations because the degree of differentiation of the squamous component parallels that of the glandular component, and the behavior of the tumor is largely dependent on the grade of

the glandular component (60).

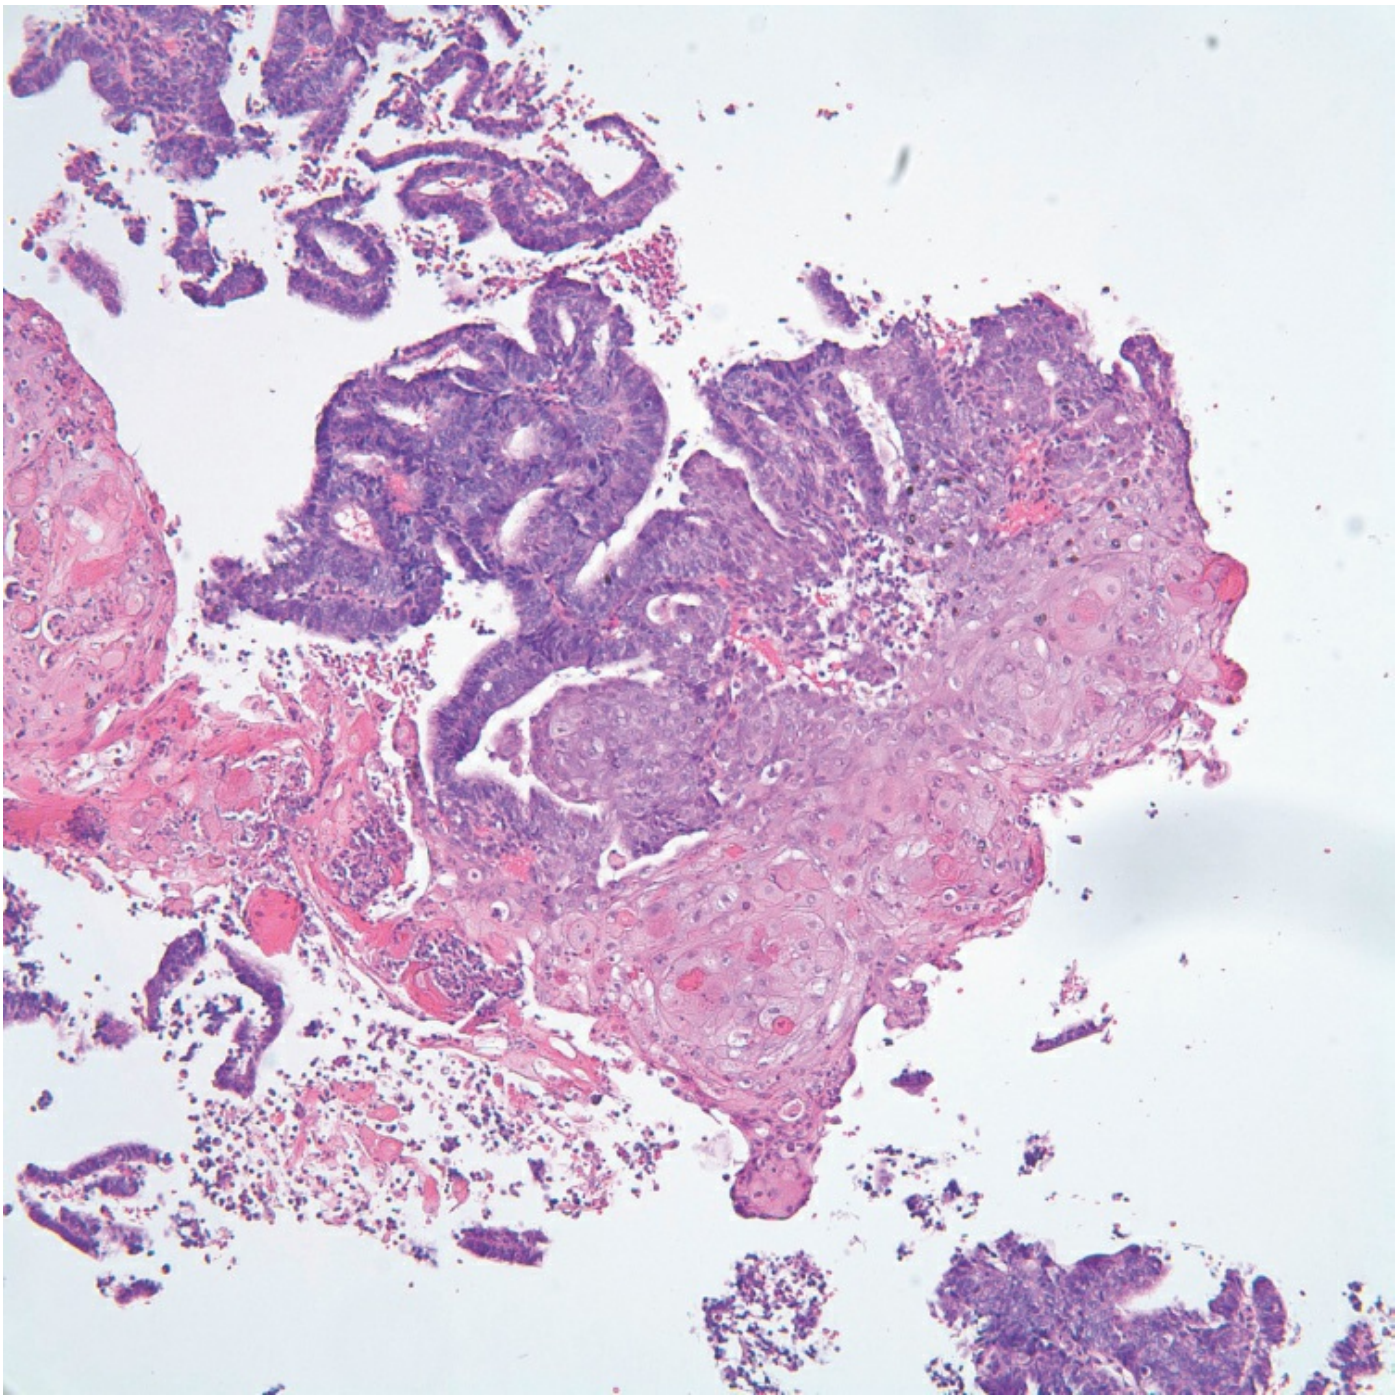

FIGURE 37-3 Adenocarcinoma with squamous differentiation of endometrium. This lesion is also classified as adenoacanthoma. Squamous cells with eosinophilic cytoplasm and distinct cell borders form solid clusters in the lumina of neoplastic glands. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

A *villoglandular* configuration is present in about 2% of endometrioid carcinomas (61). In these tumors, the cells are arranged along fibrovascular stalks, giving a papillary appearance but maintaining the characteristics of endometrioid cells.

The villoglandular variants of endometrioid carcinomas are always well-differentiated lesions that behave like the regular endometrioid carcinomas, and they should be distinguished from serous carcinomas. ***Secretory carcinoma*** **is a rare variant of endometrioid carcinoma that accounts for about 1% of cases (**62). It occurs mostly in women in their early postmenopausal years. The tumors are composed of well-differentiated glands with intracytoplasmic vacuoles similar to early secretory endometrium. These tumors behave as regular well-differentiated endometrioid carcinomas and have an excellent prognosis. Secretory carcinoma may be an endometrioid carcinoma that exhibits progestational changes, but a history of progestational therapy is rarely elicited. Secretory carcinoma must be differentiated from clear cell carcinoma because both tumors have predominately clear cells. These two tumors can be distinguished by their structure: secretory carcinomas have uniform glandular architecture, uniform cytology, and low nuclear grade, whereas clear cell carcinomas have more than one architectural pattern and a high nuclear grade.

Mucinous Carcinoma

About 5% of endometrial carcinomas have a predominant mucinous pattern in which more than one-half of the tumor is composed of cells with intracytoplasmic mucin (63). Most of these tumors have a well-differentiated glandular architecture; their behavior is similar to that of common endometrioid carcinomas, and the prognosis is good. It is important to recognize mucinous carcinoma of the endometrium as an entity and to differentiate it from endocervical adenocarcinoma. Features that favor a primary endometrial carcinoma are the merging of the tumor with areas of normal endometrial tissue, presence of foamy endometrial stromal cells, presence of squamous metaplasia, or presence of areas of typical endometrioid carcinoma.

Serous Carcinoma

About 3% to 4% of endometrial carcinomas resemble serous carcinoma of the ovary and fallopian tube (64). Most often, these tumors are composed of fibrovascular stalks lined by highly atypical cells with tufted stratification **(Fig. 37-4)**. Psammoma bodies are frequently observed.

[3] ***Serous carcinomas,*** **also referred to as** ***uterine papillary serous carcinomas,*** **are considered high-risk lesions.** The first description in 1982 noted that this entity usually occurred in elderly, hypoestrogenic women who presented with advanced-stage disease and accounted for up to one-half of deaths from endometrial carcinoma (64). Since then, several reports documented the aggressive nature and poor prognosis of serous carcinomas.

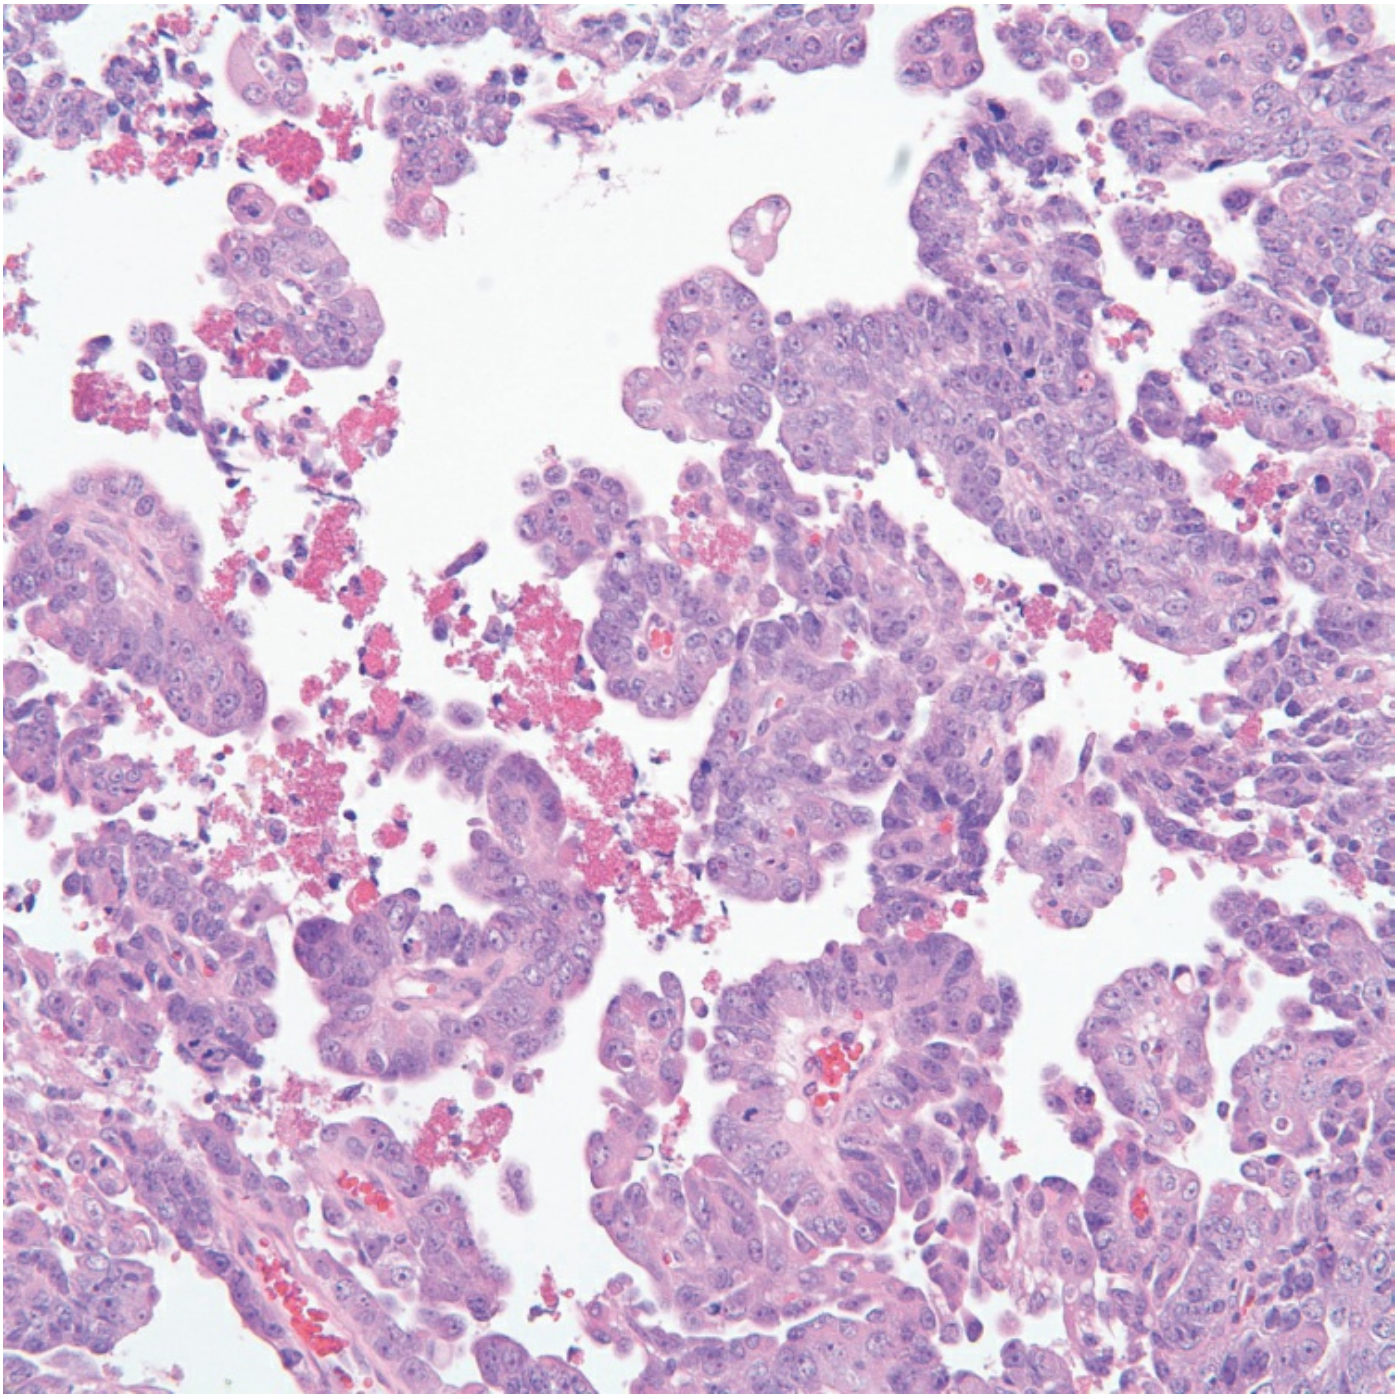

FIGURE 37-4 Serous carcinoma of endometrium. Branching papillae are supported by delicate fibrovascular cores and lined with columnar cells with moderate nuclear atypism, multiple nucleoli, and mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

They are commonly admixed with other histologic patterns, but mixed tumors behave as aggressively as pure serous carcinomas. Even patients with a very small proportion of serous features (5%) remain at high risk of recurrence (65). Serous carcinomas are often associated with lymph–vascular space and deep myometrial invasion. The presence of lymph node metastases, positive peritoneal cytology, and intraperitoneal

tumor does not necessarily correlate with increasing myometrial invasion. **Even when these tumors appear to be confined to the endometrium or endometrial polyps without myometrial or vascular invasion, they behave more aggressively than endometrioid carcinomas and have a propensity to spread intra-abdominally, simulating the behavior of ovarian carcinoma.** In one series, 37% of patients with serous carcinomas of the endometrium confined to a polyp demonstrated extrauterine disease when subjected to exploration and surgical staging (66).

A multi-institutional review of 206 patients with surgical stage I and II serous carcinomas demonstrated recurrence in 21% (65). Substage and treatment with platinum-based chemotherapy were associated with improved overall survival. Survival of surgically staged patients without myometrial invasion or extrauterine disease is between 89% and 100%, suggesting that observation may be appropriate in select patients, particularly in elderly patients with comorbidities (67). However, stage I patients, particularly those with myometrial invasion, remain at high risk of peritoneal and vaginal recurrence. Therefore, platinum-based chemotherapy and vaginal brachytherapy should be considered in these patients (67–69).

Surgical treatment of advanced disease is no different from the endometrioid subtype, consisting of complete extirpation of visible disease (68). In one investigation from the Mayo Clinic, cytoreduction to microscopic residual was associated with a median overall survival of 51 versus 12 months for those patients with any residual (70). Postoperative treatment of advanced disease in the United States consists of chemotherapy and pelvic radiation, with or without para-aortic radiation. The Gynecologic Oncology Group (GOG) study GOG184 included serous carcinomas and randomized patients to *carboplatin* and *paclitaxel* versus *cisplatin, doxorubicin (Adriamycin),* and *paclitaxel* together with tumor volume–directed radiation (71). The former regimen demonstrated similar outcomes with less toxicity. Limited data suggest that delivering radiation "sandwiched" with chemotherapy improves progression-free and overall 3-year survival rates (72). Ongoing studies are evaluating the role of chemotherapy alone for these tumors, especially because of the high rate of peritoneal dissemination and recurrences. It remains unknown whether radiation improves survival when added to chemotherapy.

Clear Cell Carcinoma

Clear cell carcinoma accounts for less than 5% of all endometrial carcinomas (73). Clear cell carcinoma usually has a mixed histologic pattern, including papillary, tubulocystic, glandular, and solid types. The cells have highly atypical nuclei and abundant clear or eosinophilic cytoplasm. Often, the cells have a hobnail configuration arranged in papillae with hyalinized stalks **(Fig. 37-5)**.

Clear cell carcinoma characteristically occurs in older women and like serous carcinoma is considered a poor prognosticator. Traditionally clear cell carcinoma was

associated with very poor outcomes with overall survival rates varying from 33% to 64%. A multi-institutional review of 99 patients with uterine clear cell carcinoma documented only one recurrence (vaginal) in the 22 patients without extrauterine disease subjected to thorough surgical staging (74). Considering all 49 patients with stage I or II disease (regardless of the extent of staging), only one hematologic failure was noted. These data argue against the use of systemic therapy in patients with clear cell carcinoma limited to the pelvis, while the 10% vaginal cuff failure suggests that vaginal brachytherapy alone may be sufficient treatment. In contrast, others argued for systemic treatment of patients with stage I disease (75).

Complete surgical staging is important because 52% of patients with clinical stage I clear cell carcinoma have metastatic disease. Patients who undergo a complete cytoreduction appear to have improved progression-free and overall survivals compared to women left with residual disease following surgery (74). Postoperative therapy for patients with advanced disease is platinum based (75).

Squamous Carcinoma

Squamous carcinoma of the endometrium is rare. Some tumors are pure, but most have a few glands. To establish primary origin within the endometrium, there must be no connection with or spread from cervical squamous epithelium. Squamous carcinoma often is associated with cervical stenosis, chronic inflammation, and pyometra at the time of diagnosis. This tumor has a poor prognosis, with an estimated 36% survival rate in patients with clinical stage I disease (76).

Simultaneous Tumors of the Endometrium and Ovary

Synchronous endometrial and ovarian cancers are the most frequent simultaneously occurring genital malignancies, with a reported incidence of 1.4% to 3.8% (77,78). **Most commonly, the ovarian and endometrial tumor are well-differentiated endometrioid adenocarcinomas of low stage, resulting in an excellent prognosis.** Patients often are premenopausal and present with abnormal uterine bleeding. The ovarian cancer usually is discovered as an incidental finding and is diagnosed at an earlier stage because of the symptomatic endometrial tumor, leading to a more favorable outcome. Up to 29% of patients with endometrioid ovarian adenocarcinomas have associated endometrial cancer. If more poorly differentiated, nonendometrioid histologic subtypes are present, or if the uterine and ovarian tumors are histologically dissimilar, the prognosis is less favorable. Immunohistochemical studies, flow cytometry, and assessment of molecular DNA patterns to detect loss of heterozygosity (LOH) may be helpful in distinguishing between metastatic and independent tumors, but the differential diagnosis can usually be determined by conventional clinical and pathologic criteria.

Pretreatment Evaluation

After establishing the diagnosis of endometrial carcinoma, the next step is to evaluate the patient thoroughly to determine the best and safest approach to management of the disease. A complete history and physical examination are of utmost importance. Patients with endometrial carcinoma are often elderly and obese with a variety of medical problems, such as diabetes mellitus and hypertension, which complicate surgical management. Any abnormal symptoms, such as bladder or intestinal symptoms should be evaluated.

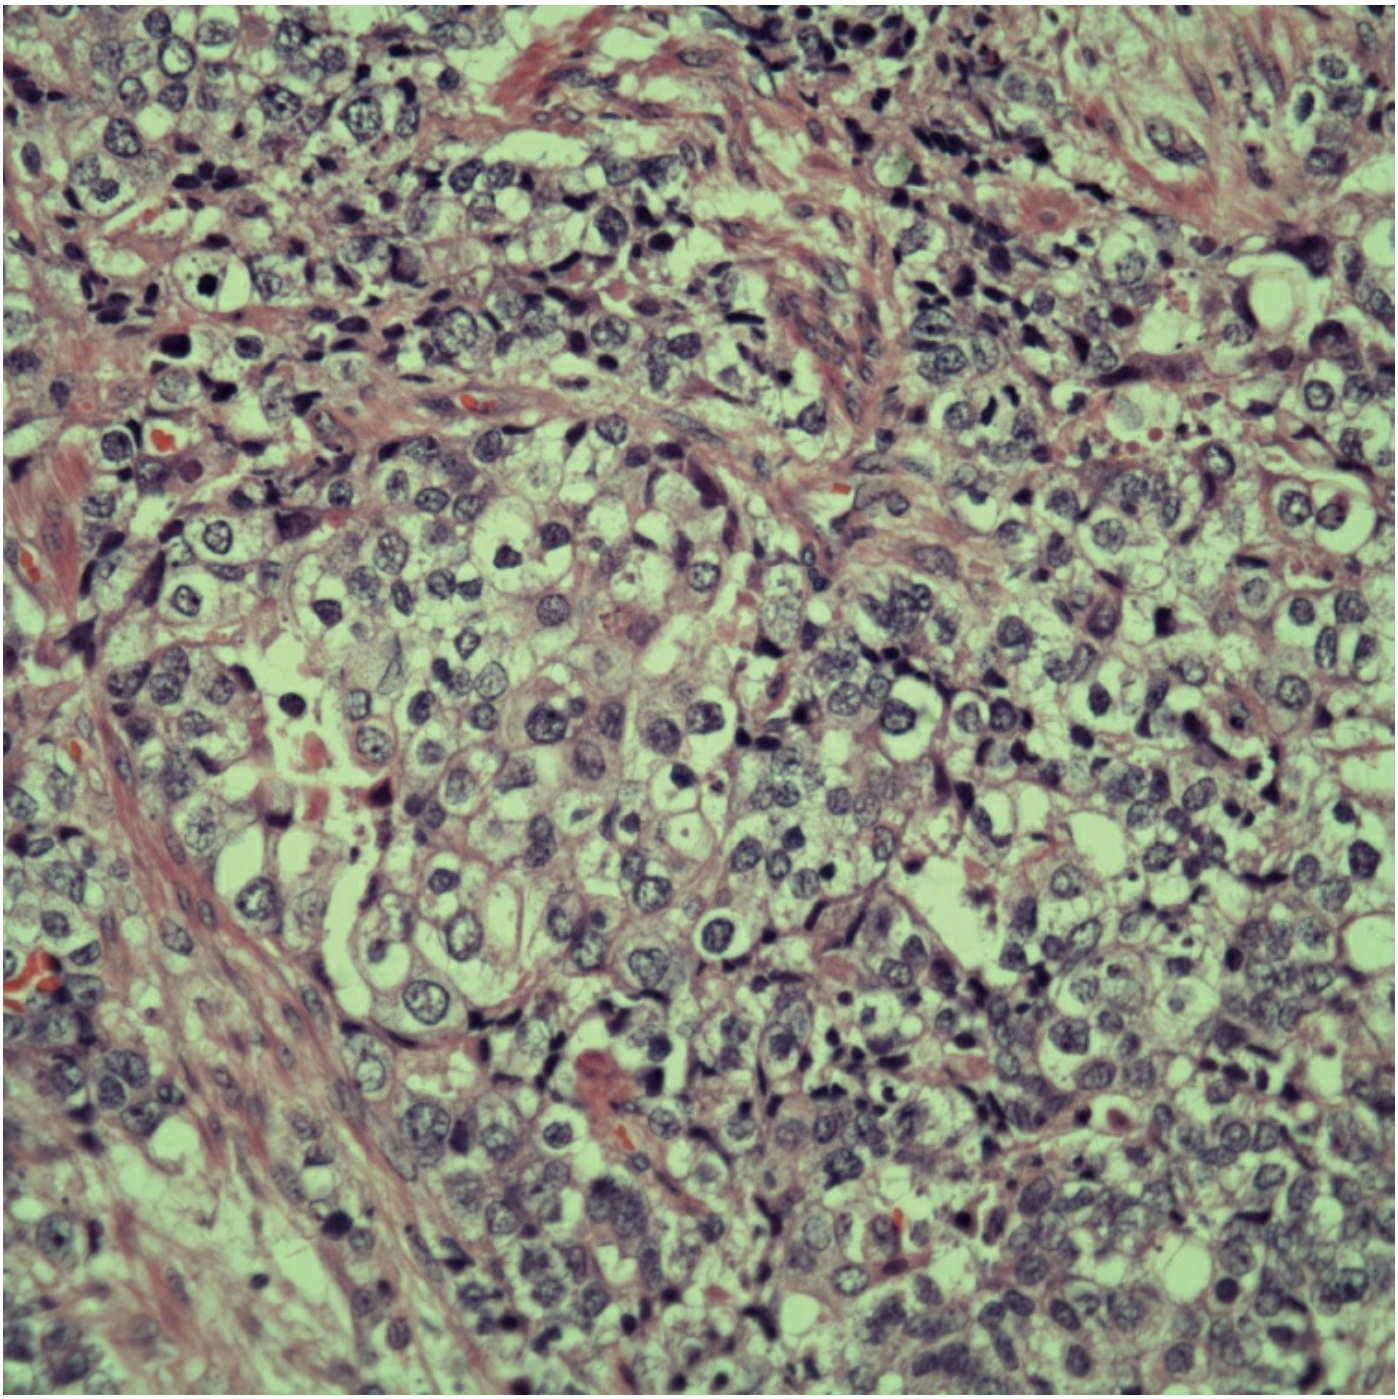

FIGURE 37-5 Clear cell adenocarcinoma of the endometrium. Back-to-back glands lined by polygonal to columnar cells with distinct cell membrane, abundant granular to clear cytoplasm, and variably sized nuclei (including binucleated and multinucleated forms) with prominent nucleoli (magnification ×400). (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

On physical examination, attention should be directed to enlarged or suspicious lymph nodes, including the inguinal area, abdominal masses, and possible areas of cancer spread within the pelvis. Evidence of distant metastasis or locally advanced disease in the pelvis, such as gross cervical involvement or parametrial spread, may alter the treatment approach.

Chest radiography should be performed to exclude pulmonary metastasis and to evaluate the cardiorespiratory status of the patient. Other routine preoperative studies should include electrocardiography, complete blood and platelet counts, and blood type and screen. Other preoperative or staging studies are neither required nor necessary for most patients with endometrial cancer. **Studies such as cystoscopy, colonoscopy, intravenous pyelography, and barium enema are not indicated unless dictated by patient symptoms, physical findings, or other laboratory tests (**79). CT scanning of the abdomen and pelvis may be considered in patients with type II uterine cancer to determine if minimally invasive surgery is appropriate. Stage IV disease is usually clinically evident based on patient symptomatology and clinical examination. Ultrasonography and MRI can be used to assess myometrial invasion preoperatively with a fairly high degree of accuracy (80,81). This information may be of use in planning the surgical procedure with regard to whether lymph node sampling should be undertaken.

Serum CA125, an antigen that is elevated in the blood of 80% of patients with advanced epithelial ovarian cancers, is elevated in most patients with advanced or metastatic endometrial cancer. In one study, 78% of endometrial cancer patients with lymph node metastases had an elevated preoperative CA125 level (82). Preoperative measurement of serum CA125 may help determine the extent of surgical staging and, if elevated, may be useful as a tumor marker in assessing response to subsequent therapy (83,84).

Clinical Staging

Clinical staging, according to the 1971 FIGO system, should be performed only in patients who are deemed not to be surgical candidates because of their poor medical condition or the degree of disease spread (85). The current FIGO staging is surgical, which has supplanted the old clinical system. With improvements in preoperative and postoperative care, anesthesia administration, and surgical techniques, almost all patients are medically suitable for operative therapy. A small percentage of patients will not be candidates for surgical staging because of gross cervical involvement,

parametrial spread, invasion of the bladder or rectum, or distant metastasis.

Surgical Staging

Widely accepted management of endometrial cancer consists of hysterectomy, [4] removal of remaining adnexal structures, and appropriate surgical staging in patients considered at risk for extrauterine disease (86,87). Surgical staging has been recommended for patients with endometrial cancer since 1988 (87). In spite of this general recommendation, the incorporation of a systematic pelvic and para-aortic lymphadenectomy in all patients is not universally accepted (88,89). This recommendation became more controversial after the publication of two large prospective randomized trials that failed to demonstrate improved outcomes for patients who underwent pelvic lymphadenectomy (90,91). These two studies show differences in their design: in the ASTEC trial all women with clinical stage I were included without exclusion criteria, whereas the Italian study excluded women with stage IA and IB grade 1 tumors, and nonendometrioid malignancies. In the Italian study, systematic nodal dissection was performed, as opposed to pelvic node sampling in the ASTEC trial (median number of lymph nodes harvested 30 vs. 12, respectively). The studies share characteristics that could lead to misinterpretation of their results. The percentage of nodal positivity is low in both studies (13% and 9%), suggesting that regardless of differences in exclusion criteria, low-risk cases were included in both studies, thus diluting possible (if any) therapeutic benefit of lymphadenectomy. Neither study used the information derived from lymphadenectomy to target postoperative treatment (i.e., to spare patients with negative nodes from radiotherapy or to target postoperative treatment to the metastatic areas), thus eliminating a potential benefit.

GOG33 demonstrated that patients with absent or superficial myometrial invasion have a low probability of lymphatic metastases (92)**, and this risk approaches zero for patients with endometrioid grade 1 or 2 disease, superficial myometrial invasion, and tumor diameter less than 2 cm** (93). An observational study reported a significant survival benefit of para-aortic lymphadenectomy in patients at intermediate or high risk of recurrence (based on presence of histologic grade 3 or deep myometrial invasion, or lymphovascular invasion, or evidence of spread outside of the uterine corpus), compared to patients who had hysterectomy with pelvic lymphadenectomy but without para-aortic lymphadenectomy. This benefit was not observed in patients with low-risk endometrial cancer (94). The Postoperative Radiation Therapy in Endometrial Carcinoma (PORTEC) study identified patients with stage IC, grade 3 endometrial carcinoma as being at high risk of early distant spread and death when treated with hysterectomy only (no staging), followed by pelvic external beam radiation therapy. These patients had a 31% risk of distant recurrence (89). Patients with the greatest potential to benefit from surgical staging are those with risk

factors such as histologic grade 3, deep myometrial invasion, or lymphovascular invasion (see Surgical Treatment for a discussion of sentinel lymph node biopsy).

In summary, surgical staging should (a) identify patients with disseminated disease who are at high risk of recurrence; (b) target postoperative treatment; (c) reduce the number of patients potentially requiring postoperative treatment when the provided information is used appropriately (avoiding the risk of morbidity without reasonable benefit); and (d) possibly eradicate lymphatic disease. In spite of these potential benefits in high-risk patients, prospective randomized data demonstrating a survival advantage or reduction in overall morbidity resulting from a potential reduction of adjuvant treatment are not available.

Table 37-6 Carcinoma of the Endometrium (2008)

Stage I[a]	Tumor confined to the corpus uteri
IA[a]	No or less than half myometrial invasion
IB[a]	Invasion equal to or more than half of the myometrium
Stage II[a]	Tumor invades cervical stroma, but does not extend beyond the uterus[b]
Stage III[a]	Local and/or regional spread of the tumor
IIIA[a]	Tumor invades the serosa of the corpus uteri and/or adnexae[c]
IIIB[a]	Vaginal and/or parametrial involvement[c]
IIIC[a]	Metastases to pelvic and/or para-aortic lymph nodes[c]
IIIC1[a]	Positive pelvic nodes
IIIC2[a]	Positive para-aortic lymph nodes with or without positive pelvic lymph nodes
Stage IV[a]	Tumor invades bladder and/or bowel mucosa, and/or distant metastases
IVA[a]	Tumor invasion of bladder and/or bowel mucosa
IVB[a]	Distant metastases, including intra-abdominal metastases and/or inguinal lymph nodes

[a]Either G_1, G_2, or G_3.

[b]Endocervical glandular involvement only should be considered as Stage I and no longer as Stage II.

[c]Positive cytology has to be reported separately without changing the stage.

FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Gynecol Obst* 2009;105:103–104.

The FIGO published the updated surgical staging system for endometrial cancer

(Table 37-6) (95). In comparison with recommendations from 1988, the new system introduces the following changes: (a) former stages IA and IB are combined; (b) former stage IIA was eliminated so that only the presence of cervical stroma involvement is considered stage II disease; (c) peritoneal cytologic findings positive for endometrial cancer are no longer a criterion for disease upstaging (although FIGO still recommends the collection of peritoneal washing, recognizing the predictive value of positive cytologic findings when combined with other poor prognosis factors); and (d) stage IIIC was divided into IIIC1 and IIIC2 in accordance with the absence or presence of positive para-aortic nodes. The presence of parametrial disease is now formally recognized as stage IIIB disease.

Prognostic Variables

Although disease stage is the most significant variable affecting survival, [5] a number of other individual prognostic factors for disease recurrence or survival are known, including tumor grade, histopathology, depth of myometrial invasion, patient age, and surgical-pathologic evidence of extrauterine disease spread (**Tables 37-7** and **37-8**). Other factors, such as **tumor size, peritoneal cytology, hormone receptor status, flow cytometric analysis, and oncogene perturbations, are implicated as having prognostic importance.**

Table 37-7 Surgical-Pathologic Findings in Clinical Stage I Endometrial Cancer

Surgical-Pathologic Finding	Percentage of Patients
Histology	
Adenocarcinoma	80
Adenosquamous	16
Other (papillary serous, clear cell)	4
Grade	
1	29
2	46
3	25
Myometrial invasion

Aortic lymph node metastasis	6
Other extrauterine metastasis	6

Modified from **Creasman WT, Morrow CP, Bundy BN, et al.** Surgical pathologic spread patterns of endometrial cancer. *Cancer* 1987;60:2037–2041, with permission.

Age

In general, younger women with endometrial cancer have a better prognosis than older women. Two reports observed no deaths related to disease in patients with endometrial cancer diagnosed before 50 years of age (96,97). Another series demonstrated a 60.9% 5-year survival rate for patients older than 70 years of age, compared with 92.1% survival rate for patients younger than 50 years of age (98). Decreased survival was associated with an increased risk for extrauterine spread (38% vs. 21%) and deep myometrial invasion (57% vs. 24%) for these two groups. **[7]** The GOG reported 5-year survival rates of 96.3% for patients 50 years of age or younger; 87.3% for patients 51 to 60 years; 78% for patients 61 to 70 years; 70.7% for patients 71 to 80 years; and 53.6% for patients older than 80 years (99).

Increased risk for recurrence in older patients was related to a higher incidence of grade 3 tumors or unfavorable histologic subtypes; however, age appears to be an independent prognostic variable. Increasing patient age appears to be independently associated with disease recurrence in endometrial cancer (100,101). In one study, the mean age at diagnosis of patients who had recurrence or died of disease was 68.6 years, compared with 60.3 years for patients without recurrence. For every 1 year increase in age, the estimated rate of recurrence increased 7%. None of the patients younger than 50 years of age developed recurrent cancer, compared with 12% of patients aged 50 to 75 years and 33% of patients older than 75 years (102).

Histologic Type

Nonendometrioid histologic subtypes account for about 10% of endometrial cancers and carry an increased risk for recurrence and distant spread (103–105). In a retrospective review of 388 patients treated at the Mayo Clinic for endometrial cancer, 52 (13%) had an uncommon histologic subtype, including 20 adenosquamous,

14 serous, 11 clear cell, and 7 undifferentiated carcinomas. In contrast to the 92% survival rate among patients with endometrioid tumors, the overall survival for patients with one of these more aggressive subtypes was only 33%. At the time of surgical staging, 62% of the patients with an unfavorable histologic subtype had extrauterine spread of disease (103).

Histologic Grade

Histologic grade of the endometrial tumor is strongly associated with prognosis (86,92,102,106–108). In one study, recurrences developed in 7.7% of grade 1 tumors, 10.5% of grade 2 tumors, and 36.1% of grade 3 tumors. Patients with grade 3 tumors were in excess of five times more likely to have a recurrence than were patients with grades 1 and 2 tumors. The 5-year disease-free survival rates for patients with grades 1 and 2 tumors were 92% and 86%, respectively, compared with 64% for patients with grade 3 tumors (149). Another study reported similar results, noting recurrences in 9% of patients with grades 1 and 2 tumors compared with 39% of patients with grade 3 lesions (107). Increasing tumor anaplasia is associated with deep myometrial invasion, cervical extension, lymph node metastasis, and both local recurrence and distant metastasis.

Table 37-8 Prognostic Variables in Endometrial Carcinoma

Age
Histologic type
Histologic grade

Lymph–vascular space invasion
Isthmus–cervix extension
Adnexal involvement
Lymph node metastasis
Intraperitoneal tumor
Tumor size
Peritoneal cytology
Hormone receptor status
DNA ploidy/proliferative index
Genetic/molecular tumor markers

Tumor Size

Tumor size is a significant prognostic factor for lymph node metastasis and survival in patients with endometrial cancer (93,109,110). One report determined tumor size in 142 patients with clinical stage I endometrial cancer and found lymph node metastasis in 4% of patients with tumors 2 cm or smaller, in 15% of patients with tumors larger than 2 cm, and in 35% of patients with tumors involving the entire uterine cavity (108). Tumor size better defined an intermediate-risk group for lymph nodes metastasis (i.e., patients with grade 2 tumors with less than 50% myometrial invasion). Overall, these patients had a 10% risk for lymph node metastasis, but there was no nodal metastasis associated with tumors 2 cm or smaller, compared with 18% when tumors were larger than 2 cm. Five-year survival rates were 98% for patients with tumors 2 cm or smaller, 84% for patients with tumors larger than 2 cm, and 64% for patients with tumors involving the whole uterine cavity (109).

Hormone Receptor Status

Estrogen receptor and progesterone receptor levels are prognostic indicators for endometrial cancer independent of grade in several studies (111–114). Patients whose tumors are positive for one or both receptors have longer survival times than patients whose carcinomas lack the corresponding receptors. Even patients with metastasis have an improved prognosis with receptor-positive tumors (112). Progesterone receptor levels appear to be stronger predictors of survival than estrogen receptor levels, and the higher the absolute level of the receptors, the better the prognosis.

DNA Ploidy and Proliferative Index

About two-thirds of endometrial adenocarcinomas have a diploid DNA content as determined by flow cytometric analysis (113,115–118). **The proportion of nondiploid tumors increases with stage, lack of tumor differentiation, and depth of myometrial invasion.** In several studies, DNA content was related to clinical course of the disease, with death rates reported to be higher in women whose tumors contained aneuploid populations of cells. The proliferative index is related to prognosis.

Myometrial Invasion

Because access to the lymphatic system increases as cancer invades into the outer one-half of the myometrium, increasing depth of invasion is associated with increasing likelihood of extrauterine spread and recurrence (92,107,119). The association of depth of myometrial invasion with extrauterine disease and lymph node metastases was reported (92). Of patients without demonstrable myometrial invasion, only 1% had pelvic lymph node metastasis, compared with patients with outer one-third myometrial invasion who had 25% pelvic and 17% aortic lymph node metastases. Deep

myometrial invasion (>50% for all stages; ≥66% for stage I) is the strongest predictor of hematogenous recurrence (120). Survival decreases with increasing depth of myometrial invasion. In general, patients with noninvasive or superficially invasive tumors have an 80% to 90% 5-year survival rate, whereas those with deeply invasive tumors have a 60% survival rate. The most sensitive indicator of the effect of myometrial invasion on survival is distance from the tumor–myometrial junction to the uterine serosa. Patients with tumors that are less than 5 mm from the serosal surface are at much higher risk for recurrence and death than those with tumors greater than 5 mm from the serosal surface (121).

Lymph–Vascular Space Invasion

Lymph–vascular space invasion (LVSI) appears to be an independent risk factor for recurrence and death from all types of endometrial cancer (92,122,123). The overall incidence of LVSI in early endometrial cancer is about 15%, although it increases with increasing tumor grade and depth of myometrial invasion. One study reported LVSI in 2% of grade 1 tumors and 5% of superficially invasive tumors, compared with 42% of grade 3 tumors and 70% of deeply invasive tumors (124). LVSI was demonstrated to be a strong predictor of lymphatic dissemination and lymphatic recurrence (125). Another study reported deaths in 26.7% of patients with clinical stage I disease with LVSI, compared with 9.1% of those without LVSI (126). Likewise, an 83% 5-year survival rate was reported for patients without demonstrable LVSI, compared with a 64.5% survival rate for those in whom LVSI was present (181). Using multivariate analysis, LVSI correlated significantly with survival of patients with stage I endometrial adenocarcinomas in another report (123).

Isthmus and Cervix Extension

The location of the tumor within the uterus is important. Involvement of the uterine isthmus, cervix, or both, is associated with an increased risk for extrauterine disease, lymph node metastasis, and recurrence. Cervical stromal invasion was a strong predictor of lymphatic dissemination and lymphatic recurrence, especially for pelvic lymph nodes (125). One study reported that if the fundus of the uterus alone was involved with tumor, there was a 13% recurrence rate, whereas if the lower uterine segment or cervix was involved with occult tumor, there was a 44% recurrence rate (105). A subsequent GOG study found that tumor involvement of the isthmus or cervix without evidence of extrauterine disease was associated with a 16% recurrence rate and a relative risk of 1.6 (86). Patients with cervical involvement tended to have higher-grade, larger, and more deeply invasive tumors, undoubtedly contributing to the increased risk for recurrence.

Peritoneal Cytology

Several historical reports noted increased recurrence rates and decreased survival rates

and, on this basis, recommended treatment for positive cytology (127,128). Most of the studies included patients with other evidence of extrauterine disease spread and were performed without appropriate multivariate analysis and with patients who were incompletely staged. The GOG study critically analyzed 1,180 clinical stages I and II endometrial cancer patients in whom appropriate surgical and pathologic staging was performed (86). Considering only the 697 patients for whom peritoneal cytology status and adequate follow-up were available, 25 (29%) of 86 patients with positive cytology developed recurrence, compared with 64 (10.5%) of 611 patients with negative cytology. They noted that 17 of the 25 recurrences in the positive cytology group were outside the peritoneal cavity.

In contrast to these reports, an equal number of studies found no significant relationship between malignant peritoneal cytology and an increased incidence of disease recurrence in the absence of other risk factors such as extrauterine disease (128–130). Patients with positive peritoneal cytology as the only site of extrauterine disease (i.e., no adnexal or uterine serosal invasion) and without poor prognosticators (i.e., myometrial invasion more than 50%, nonendometrioid histologic subtype, grade 3, lymph-vascular space invasion, cervical invasion) have a very favorable outcome with an absence of extra-abdominal recurrences (131). These patients have an associated 5-year survival of 98% to 100% even when not treated with adjuvant therapy (99,142). Patients with positive cytology in addition to poor prognostic factors demonstrate a high rate (47%) of distant extra-abdominal failure and may potentially benefit from systemic chemotherapy. **Positive peritoneal cytology seems to have an adverse effect on survival only if the endometrial cancer has spread to the adnexa, peritoneum, or lymph nodes, not if the disease is otherwise confined to the uterus (**132). These considerations led to the omission of cytology as a factor impacting stage in the FIGO 2009 staging criteria.

The following conclusions may be reached regarding the prognostic implications of positive peritoneal cytology:

1. **Positive peritoneal cytology is associated with other known poor prognostic factors.**
2. **Positive peritoneal cytology in the absence of other evidence of extrauterine disease or poor prognostic factors has no significant effect on recurrence and survival.**
3. **Positive peritoneal cytology, when associated with other poor prognostic factors or extrauterine disease, increases the likelihood for distant and intra-abdominal disease recurrence and has a significant adverse effect on survival.**
4. **Use of several different therapeutic modalities has not resulted in any proven benefit to patients with endometrial cancer and positive peritoneal cytology.**

Stage IIIA: Adnexal or Uterine Serosal Involvement

Most patients with stage IIIA disease have other poor prognostic factors that place them at high risk for recurrence. One series described treatment of all patients with serosal or adnexal invasion (or both) with whole-abdomen radiotherapy. Failures were observed outside the abdomen in 100% of patients with full-thickness myometrial invasion or uterine serosal invasion, and in 20% to 25% of cases in the presence of isolated adnexal invasion (86,133). These patients may benefit from postoperative systemic chemotherapy.

Lymph Node Metastasis

Lymph node metastasis is the most important prognostic factor in clinical early-stage endometrial cancer. Of patients with clinical stage I disease, about 10% will have pelvic and 6% will have para-aortic lymph node metastases. Patients with lymph node metastases have almost a sixfold higher likelihood of developing recurrent cancer than patients without lymph node metastases. One study reported a recurrence rate of 48% with positive lymph nodes, including 45% with positive pelvic nodes and 64% with positive aortic nodes, compared with 8% with negative nodes. **The 5-year disease-free survival rate for patients with lymph node metastases was 54%, compared with 90% for patients without lymph node metastases (**99). One series examined patients with lymph node metastases in addition to other extrauterine sites of disease (vagina, uterine serosa, positive peritoneal cytology, adnexal invasion). The recurrence rates were 67% (41% extranodal) for those with lymphatic dissemination versus 32% (5% extranodal) for those with other sites of extrauterine disease spread (131).

Intraperitoneal Metastases

Extrauterine metastasis, excluding peritoneal cytology and lymph node metastasis, occurs in about 4% to 6% of patients with clinical stage I endometrial cancer. Gross intraperitoneal spread is highly correlated with lymph node metastases; one study noted that 51% of patients with intraperitoneal tumor had positive lymph nodes, whereas only 7% of patients without gross peritoneal spread had positive nodes (92). Extrauterine spread other than lymph node metastasis is significantly associated with tumor recurrence. Another study found that 50% of patients with extrauterine disease developed recurrence, compared with 11% of patients without extrauterine disease, making recurrence almost five times more likely in patients with extrauterine disease spread. The 5-year disease-free survival rate for patients with nonlymphatic extrauterine disease was 50%, compared with 88% in other patients (99). Predictors of peritoneal relapse include stage IV disease or stage II or III disease with two or more of the following risk factors: cervical invasion, positive peritoneal cytology, positive lymph nodes, and nonendometrioid histology (134).

Types I and II Endometrial Carcinoma: Molecular Aberrations

Based on their etiologic and pathologic features, sporadic endometrial cancer is classified into two subtypes (2,87). Type I (endometrioid histology) represents the majority of lesions (approximately 80%), which are mostly low grade, estrogen receptor positive, associated with hyperestrogenism, and arise from atypical complex hyperplasia (135). Hyperestrogenism may be attributed to obesity with peripheral conversion of androgens to estrogens, anovulation, or exposure to excessive exogenous estrogen (87,136–138). Obesity, polycystic ovarian syndrome, *tamoxifen* use, and unopposed *estrogen* use are all associated with increased risk of endometrial cancer. Other associated findings include late onset of menopause, nulliparity, diabetes mellitus, and hypertension. The molecular basis for the progression from hyperplasia to invasive endometrial carcinoma as a result of hyperestrogenism remains unknown because the involvement of only a minority of factors is reproducible (139). In contrast, type II endometrial cancer (serous, clear cell carcinoma) appears to be unrelated to high estrogen levels and often develops in nonobese women. Type II cancers arise from its precursor, endometrial intraepithelial carcinoma (EIC) adjacent to an atrophic endometrium background in relatively older women (140). Distinct molecular changes are associated with these two subtypes. Common genetic changes in endometrioid endometrial cancer include mutations in *PTEN* (141–144), or β-catenin genes (145). In contrast, type II cancers frequently demonstrate alterations in HER2/*neu,* p53, p16, E-cadherin, and loss of LOH (146). These distinct molecular alterations underscore prognostic differences. Type I endometrial cancer is limited to the uterus in 70% of cases with a 5-year survival greater than 85%. Type II endometrial cancer displays a more aggressive clinical course and a poor prognosis; even in tumors with little or no myometrial invasion, more than one in three patients will have extensive extrauterine spread with complete surgical staging, resulting in an overall survival of 20% (66,70,73,147).

Inactivation of the *PTEN* tumor–suppressor gene is one of the earliest aberrations observed in endometrial cancer precursors and is the most common genetic defect in type I cancers, observed in up to 83% of tumors (141). Tumors with *PTEN* mutations tend to be well differentiated and minimally invasive (148). Approximately 20% of sporadic endometrioid cancers demonstrate a molecular phenotype referred to as microsatellite instability (MSI) (149,150). Microsatellites are short segments of repetitive DNA bases scattered throughout the genome. MSI describes the accumulation of sequence changes in these DNA segments that occur because of the inactivation of intranuclear proteins that comprise the mismatch repair system (151). Inactivation of *MLH1*, a component of the mismatch repair system, is a common event in type I endometrial cancer. This alteration occurs through hypermethylation of CpG islands in the gene promoter, a process known as epigenetic silencing (152,153). This is in contrast to colon cancer, in which MSI and inactivation of the mismatch repair genes

occurs through mutations in mismatch repair genes, including *hMSH2, hMLH1, PMS1, PMS2,* or *hMSH6* (31). MSI and abnormal methylation of *MLH1* are early events in endometrial carcinogenesis and are described in precancerous lesions (154,155). Mutations in codons 12 or 13 of the K-ras oncogene are reported in 10% to 20% of endometrial adenocarcinomas (156). The presence of mutations of K-ras appears to be an independent unfavorable prognostic factor (157,158).

Chromosomal instability with extensive genomic derangements is commonly found in type II endometrial cancers (159). The most frequent genetic alteration is TP53 mutation, present in about 90% of serous carcinomas (160,161). In contrast to endometrioid carcinoma, MSI is rare (<5%), as are K-ras and *PTEN* mutations (144,162). Other genetic alterations that occur more frequently in serous compared to endometrioid carcinomas are inactivation of p16 (45%) and overexpression and gene amplification of HER2/*neu* oncogene (45% and 70%, respectively) (160,163). HER-2/*neu* overexpression is related to diminished, progression-free survival (164,165). E-cadherin, an oncogene responsible for cell-to-cell adhesion that seems to play a critical role in initiation and progression of endometrial neoplasia, is absent or reduced in 62% to 87% of cases. Loss of E-cadherin is often associated with advanced stage and LOH in both serous and clear cell carcinomas (166,167).

Surgical Treatment

The most common current protocol for surgical management of endometrial cancer includes peritoneal cytology, hysterectomy and bilateral salpingo-oophorectomy, and surgical staging. In patients with nonendometrioid cancer, omentectomy along with appendectomy and peritoneal biopsies may be performed. The need to perform lymphadenectomy continues to evolve from complete pelvic and para-aortic lymphadenectomy historically, to lymphadenectomy based on risk factors for dissemination, to the increasingly common use of sentinel lymph node biopsy (168,169). The National Comprehensive Cancer Network (NCCN)® states that lymph node assessment can be performed using either strategy (170).

Selective lymphadenectomy based on a surgical algorithm is determined by histology, tumor grade, tumor size, extent of myometrial invasion, and presence of extra-uterine disease. Lymphadenectomy is omitted altogether for patients without endometrioid tumors measuring less than 2 cm in size and less than 50% myometrial invasion. The decision to administer postoperative radiation, chemotherapy, or both, is predicated on the final results of pathologic examination of the surgical specimen and cytology, according to previously described criteria (168).

Sentinel lymphadenectomy is performed using a standardized cervical injection of indocyanine green and fluorescence imaging in patients with clinical stage I endometrial cancer of all histologies and grades. Identified sentinel lymph nodes are evaluated using

hematoxylin, eosin, and immunohistochemistry staining. A multicenter trial showed a 97.2% sensitivity and negative predictive value of 99.6% for the sentinel lymph node technique (171). Patients with macrometastases in sentinel lymph nodes are treated according to previous algorithms (172). Adjuvant therapy for low-volume sentinel lymph node metastases is still under debate (173).

Vaginal Hysterectomy

Vaginal hysterectomy may be considered for patients with endometrial cancer and multiple morbidities and in some circumstances may be preferable to radiation therapy alone. Vaginal hysterectomy with bilateral salpingo-oophorectomy alone may be acceptable treatment for patients with low-risk tumors (endometrioid, grade 1 or 2, <50% myometrial invasion, and tumor diameter <2 cm). In one report, a 94% survival rate was found in 56 patients with clinical stage I endometrial carcinoma treated by vaginal hysterectomy, with or without postoperative radiotherapy (mostly brachytherapy). Three-fourths of these patients had grade 1 lesions (174). Other groups have reported excellent outcomes for patients treated with vaginal hysterectomy with curative intent (175,176).

Laparoscopic Management

Advances in endoscopic technologies and power sources allowed application of a laparoscopic approach to the management of endometrial cancer. Since 1992, there were multiple reports documenting the feasibility of laparoscopically assisted vaginal hysterectomy with bilateral salpingo-oophorectomy and laparoscopic lymphadenectomy for staging and treatment of patients with endometrial cancer (177–180). These early studies demonstrated no differences in lymph node counts, estimated blood loss, and recurrence or survival rates with laparoscopy versus laparotomy, whereas decreased perioperative morbidity, longer operating times, shorter hospital stays, and earlier return to work were associated with laparoscopy.

Although the literature has isolated case reports of port site metastases, there are few data documenting the incidence. Martinez et al. analyzed 1,216 patients with endometrial and cervical cancer and showed that the port site metastasis rate was less than 0.5%; no port site metastases occurred after excluding patients with peritoneal disease (181).

A large prospective study by GOG randomized patients to laparoscopy versus laparotomy for the primary treatment of patients with endometrial cancer (182). Over 2,500 patients were enrolled, 1,696 to laparoscopy and 920 to laparotomy. Consistent with early reports, patients randomized to laparoscopy had shorter hospital stay (52% more than 2 days vs. 94% in the laparotomy group), less blood loss, and fewer postoperative complications (14% vs. 21%). The rate of intraoperative complications was similar, and the operative time was longer in the laparoscopy cohort. There was no difference in lymph node counts, and stage distribution was identical between groups. A

follow-up quality-of-life investigation of the same cohorts revealed improved Functional Assessment of Cancer Therapy–General (FACT-G) scores, better physical functioning, better body image, less pain and its interference with quality of life, and an earlier resumption of normal activities and return to work over the 6-week recovery period in the laparoscopic group (183). Although the differences were modest and negligible by 6 months, the analysis was performed as per intention to treat. Of concern was the 24% rate of conversions in the laparoscopic cohort; only 4% were converted because of advanced disease. Improvements in laparoscopic equipment and surgical technique have drastically decreased this conversion rate to 2.4% in a subsequent trial (184).

The use of extraperitoneal laparoscopic staging for para-aortic lymphadenectomy was reported in a prospective investigation of 293 patients with endometrial cancer (185). The extraperitoneal approach greatly improved exposure by circumventing handling of the small bowel and was successful in over 90% of unselected patients up to a BMI of 51. There was no difference in lymph node counts, all dissections were performed to the level of the renal veins, and significant improvements in blood loss, postoperative complications, and length of stay were noted compared to the laparotomy group. If full para-aortic lymphadenectomy is necessary in an obese patient, the extraperitoneal approach offers the most reliable method to consistently perform a thorough dissection.

Robotic-assisted surgery gained popularity for endometrial cancer treatment (see Chapter 28). Improved instrumentation and visualization allow minimally invasive surgery to be performed by surgeons with less laparoscopic experience, and in patients, particularly obese patients, who otherwise might not be candidates for minimally invasive surgery. In one report limited to obese patients with endometrial carcinoma, the robotic approach offered reduced operating times, less blood loss, higher lymph node yields, and shorter hospital stays compared to laparoscopy (186).

When not limited to obese patients, robotic-assisted surgery appears to offer the same benefits as laparoscopy in regards to postoperative morbidity and convalescence compared to laparotomy, but with shorter operative times (187). Long-term survival in patients treated with laparoscopy for their endometrial cancer show comparable outcomes, and can be expected to apply to robotic surgery, as it is simply an advanced laparoscopic tool. A GOG trial showed three-year recurrence rates of 11.4% with laparoscopy versus 10.2% with open surgery, and 5-year survival was 90% in both arms (188).

Radical Hysterectomy

Radical hysterectomy, with removal of the parametria and upper vagina, and bilateral pelvic lymphadenectomy, does not improve survival of patients with clinical stage I disease compared with extrafascial hysterectomy and bilateral

salpingo-oophorectomy alone (189–191). Radical hysterectomy increases intraoperative and postoperative morbidity and should not be performed for treatment of apparent early endometrial cancer. In the presence of demonstrable invasion of the cervix, a modified extrafascial hysterectomy may be performed. This may improve outcomes and decrease the risk of local recurrences, especially if postoperative local radiation is not planned in younger patients (192).

Radiation Therapy as Primary Treatment

Primary surgery followed by individualized radiation therapy is the most widely accepted treatment for early-stage endometrial cancers. About 5% to 15% of endometrial cancer patients have severe medical conditions that render them unsuitable for surgery (86). These patients tend to be elderly and obese with multiple chronic or acute medical illnesses, such as hypertension, cardiac disease, diabetes mellitus, and pulmonary, renal, and neurologic diseases.

Several series show that radiotherapy is effective treatment for patients with inoperable endometrial cancer (Table 37-9) (193,194). One reported on the treatment of 120 patients with clinical stage I and 17 patients with clinical stage II endometrial cancer with radiation alone, 85% of whom received only intracavitary radiation. Because of the high incidence of death caused by intercurrent illness in this group of patients, the 5- and 10-year overall survival rates were only 55% and 28%, respectively, compared with disease-specific survival rates of 87% and 85%, respectively. There was no difference in disease-specific survival rates between patients with stage I and II disease. Intrauterine cancer recurred in 14% of patients, and extrauterine pelvic disease recurred in 3%. The authors treated 15 patients with stage III and IV disease, usually with a combination of external-beam and intracavitary radiation therapy, yielding a 5-year disease-specific survival rate of 49%. Five patients (3%) had serious late complications of radiation therapy (194).

Although it is generally agreed that intracavitary radiation is necessary to achieve adequate local control, the indications for external-beam radiation therapy in the primary treatment of endometrial cancer are less well defined. Patients with cervical involvement and known or suspected extrauterine pelvic spread undoubtedly would benefit from external-beam radiation therapy. Theoretically, external-beam radiation could sterilize microscopic nodal disease and possibly increase the radiation dose to deep myometrial or subserosal uterine disease, which may receive an insufficient dose from intracavitary radiation alone. A correlation between tumor grade and recurrence was noted in several reports. One found that the 5-year progression-free survival rate for medically inoperable patients with clinical stage I disease treated with radiotherapy alone was 94% for grade 1, 92% for grade 2, and 78% for grade 3 tumors (193).

The decision to treat a patient who has endometrial cancer with radiation alone must include a careful analysis of the relative risks and benefits of surgery. Although

radiation alone can produce excellent survival and local control, it should be considered for definitive treatment only if the operative mortality rate is estimated to exceed the 10% to 15% risk for uterine recurrence that is expected with radiation treatment alone.

Patterns of Metastatic Dissemination: Implications for Postoperative and Disease-Based Adjuvant Treatment

Endometrial cancer is commonly diagnosed early in its natural history with approximately 80% of patients presenting with stage I disease. Nevertheless, approximately one of every three women who die of endometrial cancer was considered to have early locoregional disease at primary diagnosis. The majority of treatment failures and the accompanying compromised longevity probably result from the failure to recognize sites of occult extrauterine dissemination at primary diagnosis. Traditional postoperative therapy (modality based) for high-risk endometrial cancer is external-beam radiotherapy that is frequently supplemented with vaginal brachytherapy. This approach improves local control but not survival in early-stage disease (88,195).

Understanding the different pathways of metastatic dissemination of endometrial cancer and their predictive factors allows the development of an individualized model for target-based therapeutic approaches to the predicted site(s) of failure. The natural

history of epithelial corpus cancer includes four potential routes of metastasis: (a) contiguous extension (mainly to the vagina); (b) hematogenous dissemination; (c) lymphatic embolization; and (d) exfoliation with intraperitoneal spread. On the basis of regression analysis, independent pathologic risk factors predictive of the four routes of metastatic spread were identified:

1. **Contiguous extension: histologic grade 3 and lymph-vascular space invasion are proven predictors of vaginal relapse in stage I endometrial cancer (**196).
2. **Hematogenous: deep myometrial invasion is the strongest predictor of hematogenous recurrence (>50% for all stages and ê66% for stage I) (**119,120).
3. **Lymphatic: lymphatic failure is more likely to occur when cervical stroma involvement or positive lymph nodes are present (**125).
4. **Peritoneal: predictors of peritoneal relapse are: (a) stage IV disease; or (b) stage II or III disease with two or more of the following risk factors: cervical invasion, peritoneal cytologic results positive for endometrial cancer, positive lymph nodes, and nonendometrioid histologic findings (**134).

Patients with the risk factors summarized in Table 37-10 account for 35% of the overall population with endometrial cancer, but 89% of the observed hematogenous, lymphatic, and peritoneal relapses. Importantly, 46% of the patients considered at risk subsequently experienced a recurrence in one or more of the three sites, compared with only 2% of patients not judged to be at risk based on these criteria (p <0.001). The identification of subgroups of patients at risk for the different patterns of recurrence would allow postoperative treatment targeted to the predicted areas of tumor dissemination. The recurrence sites predicted by risk factors would presuppose different adjuvant treatment strategies. Patients at risk for hematogenous or peritoneal recurrence would potentially benefit from systemic cytotoxic treatment, while patients at risk for lymphatic or vaginal recurrence would potentially benefit from radiation treatment directed at areas at risk.

Table 37-10 Rates of Recurrence at 5 Years According to the Different Risk Categories for 915 Patients

Risk Category	Recurrence at 5 Years (%)
Hematogenous	
All stages	
Myometrial invasion ≤50%	4
Myometrial invasion >50%	28
Stage I (negative lymph nodes)	

Myometrial invasion <66%	2
Myometrial invasion ≥66%	34
Lymphatic	
No risk factors	2
CSI and/or positive lymph nodes	31
Peritoneal	
Stage IV disease	63
Stage II–III disease and ≥2 risk factors[a]	21
Stage I–III disease and ≤1 risk factor[a]	1
Overall[b]	
Not at risk[c]	2
At risk[c]	46

[a]CSI, nonendometrioid histologic subtype, positive lymph nodes, or positive result on peritoneal cytologic evaluation.

[b]Excluding vaginal recurrences.

[c]For at least one of the three categories of recurrence (i.e., hematogenous, lymphatic, or peritoneal).
CSI, cervical stromal invasion.

MODALITIES OF POSTOPERATIVE TREATMENT

Observation

Patients with grades 1 and 2 lesions without myometrial invasion or any of the above risk factors (Table 37-10) have an excellent prognosis and require no postoperative therapy. In a GOG study, there were no recurrences and a 100% disease-free 5-year survival rate in the 91 patients in this category, 72 of whom received no additional treatment after hysterectomy (86). Other investigators reported equally favorable results with only surgical therapy in similar patients (197).

Vaginal Vault Radiation

Vaginal brachytherapy is an attractive alternative to external radiation therapy (ERT). High-dose rate (HDR) brachytherapy is well tolerated with low rates of severe or chronic complications. Vaginal control rates with the more convenient, better-tolerated HDR brachytherapy are comparable to control rates with the lengthier low-dose rate

(LDR) brachytherapy. Pearcey and Petereit established the HDR dosing of 21 Gy to 5-mm depth in three fractions as the standard brachytherapy dose, providing local control rates of 98% to 100% (198). Additional retrospective data demonstrate 96% to 98% vaginal control rates with HDR in high-risk early-stage endometrial cancer (199,200). Retrospective data suggest that the vaginal relapse rate after brachytherapy averages 4% to 5% (Table 37-11) and this is similar to the 5-year vaginal failure rate of 3.5% reported among the highest-risk patients who received ERT in PORTEC-1 (88,199,201,202).

Table 37-11 Recurrence in High-Risk, Comprehensively Staged, Early-Stage Endometrial Cancer after Adjuvant Vaginal Brachytherapy Alone (No Pelvic ERT)

Author (Ref.)	No. of Patients	Lymphadenectomy Performed	Postoperative Vaginal Brachytherapy	No. of Recurrences *N* (%)
Orr et al. (287)	115	+	+	6 (5.2)
Mohan et al. (288)	28	+	+	2 (7)
Chadha et al. (289)	38	+	+	3 (7.9)
Fanning (201)	66	+	+	2 (3)
Horowitz et al. (199)	102	+	+	10 (9.8)
Straughn et al. (290)	56	+	+	0 (0)
Solhjem et al. (202)	100	+	+	0 (0)
Total	505			23 (4.6)[a]

[a]Includes 18 distant (78% of all recurrences), 3 vaginal (13%), 1 isolated pelvic sidewall (4.3%), 1 unknown site (4.3%).

ERT, external radiation therapy.

PORTEC-2 randomized patients with apparent uterine-confined endometrial cancer at high risk for recurrence (>60 years of age with grade 1 or 2, stage IB and grade 3, stage IA; or any age, any grade IIA with <50% myometrial invasion), to pelvic ERT (46 Gy, in 23 fractions) versus vaginal brachytherapy (21 Gy in three HDR fractions or 30 Gy LDR, to a depth of 0.5 cm). At 3 years, there was no difference in vaginal failure rates (0.9% for vaginal brachytherapy, 2% for pelvic ERT; $p = 0.97$). There was a higher rate of nonvaginal pelvic relapse in the brachytherapy group (3.6%) compared to the ERT group (0.7%; $p = 0.03$), however, the absolute difference was small and there was no difference in overall survival (203). The difference between nonvaginal pelvic recurrences may be a reflection of unrecognized lymph node metastases at the time of initial surgery treated with ERT. One concern regarding PORTEC-2 is that there was not a surgery-only control in the study. However, the highest-risk endometrial cancer subgroup in PORTEC-1 (patients >60 years of age with grade 3 or deeply invasive

grade 1 or 2, all stage I) was similar to the cohort included in PORTEC-2 and the locoregional recurrence rate in patients who did not receive adjuvant ERT in PORTEC-1 was 18% (88).

Grade 3 histology and lymph-vascular invasion are proven predictors of vaginal relapse in stage I endometrial cancer. Patients with these risk factors are the most likely group to benefit from vaginal vault brachytherapy (196). Although vaginal recurrences can be successfully treated and controlled in up to 81% of cases, the addition of vaginal brachytherapy to the initial surgical intervention can significantly reduce the risk of such recurrences (204).

External Pelvic Radiation

Radiation therapy traditionally was suggested to patients who were deemed to have intermediate or high risk of recurrence, according to grade and depth of myometrial invasion. Several retrospective studies and large, randomized trials did not show an overall survival benefit for intermediate- and high-risk patients with stage I endometrial cancer (or occult IIA endometrial cancer according to the 1988 FIGO staging) who received adjuvant pelvic radiotherapy.

[6] The PORTEC trial tested the role of postoperative pelvic radiation therapy for presumed stage I endometrial cancer in 714 patients. Eligibility criteria were stage IB, grades 1 to 2, and stage IA, grades 2 to 3; patients with stage IA, grade 3, were only 10% of the study population, and lymph node biopsies and peritoneal cytology were not required. Local–regional recurrences developed in 14% of the surgery group, compared with 4% of the postoperative pelvic radiation group. Overall, the 5-year survival rate was no different between the two groups (85% vs. 81%, respectively) (88). These results were confirmed by GOG99, a prospective, randomized investigation of surgery alone (including lymphadenectomy to the level of the inferior mesentery artery in some patients) versus surgery plus adjuvant pelvic radiation in intermediate-risk endometrial cancer (stages IA to IIB occult). Of 392 patients accrued to the study, more than 80% were actually low-risk patients (90.6% stage I, 81.6% grades 1 to 2, 82% <50% myometrial invasion). Disease recurrence was reduced by 58% ($p = 0.007$) with the use of postoperative pelvic radiation. After 2 years, the cumulative recurrence rate was 12% in the group with no postoperative treatment compared with 3% in the group that received pelvic radiation. The pelvic failure rate was 8.9% in the surgery-alone group compared with 1.6% in the postoperative pelvic radiation group. **Overall survival rates were not significantly improved in patients receiving postoperative pelvic radiation compared with those treated only with surgery (92% vs. 86%, respectively)** (259). **The intergroup ASTEC/EN.5 trial provided further confirmation that external-beam radiation therapy in patients at intermediate to high risk of recurrence has no significant effect on overall survival** (205).

Postoperative whole-pelvis external-beam radiation usually involves the delivery

of 4,500 to 5,040 cGy in 180 cGy daily fractions over 5 to 6 weeks to a field encompassing the upper one-half of the vagina inferiorly, the lower border of the L4 vertebral body superiorly, and 1 cm lateral to the margins of the bony pelvis. The dose of radiation at the surface of the vaginal apex usually is boosted to 6,000 to 7,000 cGy by a variety of techniques. The most frequently reported side effects are gastrointestinal, usually abdominal cramps and diarrhea, although more serious complications such as bleeding, proctitis, bowel obstruction, and fistula can occur and may require surgical correction. The urinary system may be affected in the form of hematuria, cystitis, or fistula. The overall complication rate ranges from 25% to 40%; and the rate of serious complications requiring surgical intervention is about 1.5% to 3%.

External-beam pelvic radiation does not appear to impact survival in patients with high-risk stage I endometrial cancer. Patients with extrauterine pelvic disease, including adnexal spread, parametrial involvement, and pelvic lymph node metastases, in the absence of extrapelvic disease, are likely to benefit from postoperative pelvic radiation.

Extended-Field Radiation

Patients with histologically proven para-aortic node metastases or patients at risk for para-aortic disease, but without surgical evaluation, are candidates for extended-field radiation therapy. The entire pelvis, common iliac lymph nodes, and para-aortic lymph nodes are included within the radiation field. The para-aortic radiation dose is limited to 4,500 to 5,000 cGy. **Extended-field radiotherapy appears to improve survival in patients with endometrial cancer who have positive para-aortic lymph nodes** (86,206).

Five-year survival rates of 47% and 43% were reported for patients with surgically confirmed isolated para-aortic lymph node metastases and for those with para-aortic and pelvic lymph node metastases, respectively, using postoperative extended-field radiation. In one report, only one case of severe enteric morbidity occurred in 48 patients, a complication rate of 2% (207). In a GOG study, 37 of 48 patients with positive para-aortic nodes received postoperative para-aortic radiation, 36% of whom remained tumor free at 5 years (86). A comparison of patients with positive para-aortic nodes treated with *megestrol acetate* alone versus *megestrol acetate* and extended-field radiation showed that the survival rate in the patients receiving extended-field radiation was significantly better: 53% versus 12.5%, respectively (208). In another study of 18 patients with positive para-aortic nodes, 5-year survival rates were 67% for microscopic nodal disease and 17% for gross nodal disease (209).

Whole-Abdomen Radiation

Whole-abdomen radiation therapy (WART) was historically reserved for patients with stages III and IV endometrial cancer. It was also considered for patients with serous or carcinosarcomas, which have a propensity for upper abdominal recurrence (210–213). WART is rarely used since the publication of GOG122, which showed favorable progression free and overall survival in advanced endometrial carcinoma with chemotherapy as opposed to WART (see section on "Chemotherapy") (214). The recommended dose to the whole abdomen is 3,000 cGy in 20 daily fractions of 150 cGy, with kidney shielding at 1,500 to 2,000 cGy, along with an additional 1,500 cGy to the para-aortic lymph nodes and 2,000 cGy to the pelvis. Gastrointestinal side effects, including nausea, vomiting, and diarrhea, sometimes make it necessary to interrupt therapy, but it is rare for patients to discontinue treatment because of these symptoms. Hematologic toxicity can be expected to occur during whole-abdomen radiation, but it is usually mild. The incidence of late complications, mainly chronic diarrhea and small bowel obstruction, is low (5% to 10%).

Progestins

Because most endometrial cancers have estrogen and progesterone receptors, and *progestins* were used successfully to treat metastatic endometrial cancer, postoperative adjuvant *progestin* therapy attempted to reduce the risk of recurrence. This therapy is attractive because it provides systemic treatment and has few side effects. Unfortunately, **several large randomized, placebo-controlled studies failed to identify a benefit for adjuvant *progestin* therapy (**215,216).

Chemotherapy

Adjuvant cytotoxic chemotherapy was studied in a few trials. The GOG treated 181 patients who had poor prognostic factors with postoperative radiation and randomly assigned patients to receive no further therapy or *doxorubicin* chemotherapy. After 5 years of observation, there was no difference in recurrence rates between the two groups (217).

The GOG122 trial compared whole-abdominal radiotherapy versus systemic chemotherapy (eight cycles of *doxorubicin* and *cisplatin*) in 388 patients with stage III or IV disease who underwent maximal surgical resection of disease to less than 2 cm. Its results showed a significant advantage of chemotherapy on 5-year survival (214). Patients who received chemotherapy had a 13% improvement in 2-year progression-free survival (50% vs. 46%) and an 11% improvement in overall 2-year survival (70% vs. 59%) compared with patients treated with whole-abdomen radiation. This study was the first to suggest an improvement in outcome for use of adjuvant chemotherapy compared with radiation, but toxicity was more prevalent with chemotherapy. Patients with gross residual disease were assigned to the radiation arm, almost guaranteeing failure; and overall, 55% of patients experienced a recurrence or progression during the

study period (218). GOG184 randomized 552 patients with advanced disease to six cycles of *cisplatin* and *doxorubicin* with or without *paclitaxel* following surgical debulking and radiotherapy. Side effects were more pronounced with the three-drug regimen, and recurrence-free survival (RFS) at 36 months was no different between arms (62% vs. 64% for the three-drug regimen). The investigation was closed to patients with stage IV disease during the trial, but subgroup analysis suggested a 50% reduction in recurrence or death in the 57 patients with gross residual disease who received *cisplatin, doxorubicin,* and *paclitaxel* (71).

The PORTEC-3 trial and GOG258 investigated the combination of chemotherapy and radiotherapy in advanced or high-risk endometrial cancer. PORTEC-3 is investigated overall survival and failure-free survival of patients with high-risk and advanced stage endometrial carcinoma treated after surgery with chemoradiation followed by chemotherapy versus pelvic radiation alone (219). **The results of the large randomized trial showed that the addition of 4 cycles *carboplatin* and *paclitaxel* chemotherapy to standard external-beam radiotherapy resulted in a statistically significant improvement of progression-free survival (75.5% vs. 68.6%, HR = 0.71) with no significant benefit to overall survival (81.8% vs. 76.7%, HR = 0.76). The investigators recommended that women with high-risk endometrial cancer should be individually counseled about this combined treatment, and that continued follow-up is needed to evaluate long-term survival.**

GOG258 compared chemoradiation followed by chemotherapy versus chemotherapy alone in advanced endometrial cancer (220). The open-label randomized phase III trial compared treatment with *cisplatin* and tumor volume-directed radiation followed by *carboplatin* and *paclitaxel* for four cycles (C-RT) versus *carboplatin* and *paclitaxel* treatment for six cycles (CT). The preliminary analysis showed that combined modality regimen did not increase RFS in patients with optimally debulked stage III/IVA endometrial carcinoma (HR 0.9, 95% CI [0.74,1.1]). C-RT reduced the rate of local recurrence compared to CT. The estimates for 5-year overall survival are 70% for the C-RT arm versus 73% for the CT arm, and long-term survival and quality-of-life data to be reported as the data mature.

Regarding the use of chemotherapy in high-risk populations with early-stage endometrial cancer, the European Organisation for Research and Treatment of Cancer, along with the Nordic Society of Gynecologic Oncology, presented the results of a collaborative trial comparing external radiotherapy versus chemoradiotherapy in patients with stages I or II or IIIC1 (positive pelvic nodes only) and one of the following characteristics: grade 3 or myometrial invasion greater than 50%, DNA aneuploidy, or clear cell or serous histologic type. Performance of a systematic lymphadenectomy was optional. A total of 375 patients were enrolled over a 10-year period and the study was closed early because of slow recruitment. The hazard ratio for progression-free survival was 0.58 (95% CI, 0.34%–0.99%) in favor of

chemoradiation after a median follow-up of 3.5 years (221).

The Japanese GOG randomized patients to pelvic radiotherapy versus platinum-based chemotherapy in patients with stage IB to IIIC endometrial cancer and myometrial invasion greater than 50%. Assessment of para-aortic nodal status was performed in only 29% of cases. The investigators found no differences between the two experimental arms in terms of progression-free survival and overall survival. A subgroup analysis of 120 patients with either (a) stage IB tumor and age greater than 70 years or grade 3 endometrioid adenocarcinoma; or (b) stage II or IIIA tumor (positive cytologic findings) showed that chemotherapy was associated with significantly improved disease-free and overall survival rates (222).

The benefits achieved with combined chemoradiation, identification of the best chemotherapeutic regimen, and the identification of subgroups of patients who may benefit from these treatments deserves further investigation.

Clinical Stage II

Endometrial cancer involving the cervix either contiguously or by lymphatic spread has a poorer prognosis than disease confined to the corpus (192,223–226). Preoperative assessment of cervical involvement is difficult. **Endocervical curettage has relatively high false-positive (50% to 80%) and false-negative rates.** Histologic proof of cancer infiltration of the cervix or presence of obvious tumor on the cervix is the only reliable means of diagnosing cervical involvement, although ultrasonography, hysteroscopy, or MRI may show cervical invasion.

The relatively small number of true stage II cases in reported series and the lack of randomized, prospective studies preclude formulation of a definitive treatment plan. **Three areas must be addressed in any treatment plan:**

1. **For optimal results, the uterus should be removed in all patients.**
2. **Because the incidence of pelvic lymph node metastases is about 36% in stage II endometrial cancer, any treatment protocol should include treatment of these lymph nodes.**
3. **Because the incidence of disease spread outside the pelvis to the para-aortic lymph nodes, adnexal structures, and upper abdomen is higher than in stage I disease, attention should be directed to evaluating and treating extrapelvic disease.**

Two approaches usually were used in the treatment of clinical stage II disease:

1. **Radical hysterectomy, bilateral salpingo-oophorectomy, and pelvic and para-aortic lymphadenectomy**
2. **Combined radiation and surgery (external pelvic radiation and intracavitary**

radium or cesium followed in 6 weeks by total abdominal hysterectomy and bilateral salpingo-oophorectomy)

An initial radical surgical approach to treatment of clinical stage II endometrial cancer has the advantage of collecting accurate surgical-pathologic information. Conversely, many patients with endometrial cancer are elderly and obese and have medical problems that make this approach unsuitable. Reported results are no better than those with combined radiation and less radical surgical therapy (192). The use of radical hysterectomy may be limited to patients with anatomic problems that prevent optimum dosimetry or other conditions that conflict with the use of radiation therapy.

The most common, traditional approach to the management of clinical stage II endometrial cancer is to use external and intracavitary radiation followed by extrafascial hysterectomy. This combined approach resulted in 5-year survival rates of 60% to 80%, with severe gastrointestinal or urologic complications occurring in about 10% of patients (224,227,228). Patients who have medically inoperable disease are usually treated with external-beam radiation and one or two intracavitary insertions. Compared with combined radiation and surgery, the results with radiation alone are diminished, but about 50% of patients are long-term survivors **(Table 37-9)** (195).

Another method of management of clinical stage II endometrial cancer that is gaining favor is an initial surgical approach followed by radiation. This method is based on the difficulty in establishing the preoperative diagnosis of cervical involvement in the absence of a gross cervical tumor, the evidence that radiation is equally effective when given after hysterectomy, and the high incidence of extrapelvic disease when the cervix is involved. An extrafascial hysterectomy, bilateral salpingo-oophorectomy, peritoneal washings for cytology, and resection of grossly enlarged lymph nodes are performed. Modified radical or radical hysterectomy can be considered to obtain free margins. These procedures are followed by appropriate pelvic or extended-field external and intravaginal radiation, depending on the results of surgical staging. Excellent results were reported using this treatment scheme (225,229,230).

Clinical Stages III and IV

Clinical stage III disease accounts for about 7% to 10% of all endometrial carcinomas (231–233). Patients usually have clinical evidence of disease spread to the parametria, pelvic sidewall, or adnexal structures; less frequently, there is spread to the vagina or pelvic peritoneum. **Treatment for stage III endometrial carcinoma must be individualized, but initial operative evaluation and treatment should be considered because of the high risk for occult lymph node metastases and intraperitoneal spread when disease is known to extend outside of the uterus into the pelvis.** In the presence of an adnexal mass, the initial impetus for surgery is to determine the nature of

the mass. Surgery is performed to determine the extent of disease and to remove the bulk of the disease if possible. This procedure should include peritoneal washings for cytologic examination, removal of bulky para-aortic and pelvic lymph nodes, biopsy or excision of any suspicious areas within the peritoneal cavity, and omentectomy and peritoneal biopsies. Except in patients with bulky parametrial disease, total abdominal hysterectomy and bilateral salpingo-oophorectomy should be performed. **The goal of surgery is eradication of all macroscopic disease because this finding is of major prognostic importance in the management of patients with clinical stage III disease.** Postoperative therapy can be tailored to the extent of disease.

Results of therapy depend on the extent and nature of disease. A 5-year survival rate of 54% was reported for all patients with stage III disease; however, the survival was 80% when only adnexal metastases were present, compared with 15% when other extrauterine pelvic structures were involved (231). Patients with surgical-pathologic stage III disease have a much better survival rate (40%) than those with clinical stage III disease (16%) (234). Patients who are treated with combined surgery and radiation fare better than patients who receive radiation therapy alone (233).

Stage IV endometrial adenocarcinoma, in which tumor invades the bladder or rectum or extends outside the pelvis, makes up about 3% of cases (233–236). **Treatment of stage IV disease is patient dependent but usually involves a combination of surgery, radiation therapy, and systemic hormonal therapy or chemotherapy.** One objective of surgery and radiation therapy is to achieve local disease control in the pelvis to provide palliative relief of bleeding, discharge, and complications involving the bladder and rectum. In one report, control of pelvic disease was achieved in 28% of 72 patients with stage IV disease treated with radiation alone or in combination with surgery, *progestins,* or both (235). **Several reports noted a positive impact of cytoreductive surgery on survival, the median survival being about three times greater with optimal cytoreduction (18 to 34 months vs. 8 to 11 months, respectively) (**235,236). Pelvic exenteration may be considered in the very rare patient in whom disease is limited to the bladder, rectum, or both (237,238).

Chemotherapy

In cases of advanced disease, chemotherapy with *carboplatin* and *paclitaxel* is now standard treatment (254–258). GOG209 demonstrated *carboplatin* and *paclitaxel* to be not inferior to the combination of *paclitaxel, doxorubicin,* and *cisplatin*, and the toxicity and tolerability profile favored *carboplatin* and *paclitaxel* (256). In a retrospective study, the overall response rate to combination *carboplatin* and *paclitaxel* in patients with either advanced or recurrent endometrial cancer was 43%, but only 5% achieved a complete response and the median survival was 13.2 months (255).

Single-agent chemotherapy options include *paclitaxel*, albumin-bound *paclitaxel, docetaxel, carboplatin, cisplatin, doxorubicin, liposomal doxorubicin*, and *topotecan*.

When single-agents are used as first-line therapy, response rates range from 21% to 36%.

Recurrent Disease

About 15% of patients treated for early (stage I and II) endometrial cancer develop recurrent disease (239,240). In contrast, recurrent disease is detected in up to 50% of patients with advanced (stage III and IV) endometrial cancer (241). More than 50% of recurrences develop within 2 years and about 75% occur within 3 years of initial treatment. The distribution of recurrences is dependent in large part on the type of primary therapy, that is, surgery alone versus surgery plus local or regional radiotherapy. Vaginal and/or pelvic recurrences comprise over 50% of all recurrences in patients treated with surgery alone. Approximately 70% of recurrences in patients treated with combined surgery and radiotherapy (vaginal or external beam) are extrapelvic, most commonly lung, abdomen, lymph nodes (aortic, supraclavicular, inguinal), liver, brain, and bone (242,243).

At the time of diagnosis of recurrent endometrial cancer, approximately one-third of patients are asymptomatic and are only discovered to have recurrent cancer on routine surveillance examinations or radiologic studies. Almost one-half of patients found to have lung metastases on follow-up chest imaging are asymptomatic. Approximately 90% of patients with metastases at other sites have symptoms related to the site of recurrence (244).

Patients with isolated vaginal recurrences fare better (70% 3-year survival) than those with pelvic recurrences (8% 3-year survival), or distant metastases (14% 3-year survival) (240). Patients who initially have well-differentiated tumors or who develop recurrent cancer more than 3 years after the primary therapy tend to have an improved prognosis (245,246).

Surgery

A small subset of patients with isolated recurrent endometrial cancer may benefit from surgical intervention (247). A search for distant recurrences is obligatory, as such patients with metastatic disease are best treated with chemotherapy, unless there is an isolated pulmonary metastasis which may be amenable to excision. Recurrent disease isolated to the central pelvis following radiation is rarely seen. Selected patients with such a recurrence may be candidates for pelvic exenteration (248,249) although morbidity is high and survival rates are low. There is some evidence that radical pelvic resection in conjunction with intraoperative radiation may cure some patients, albeit with a high complication rate (250). Cytoreductive surgery for abdominal pelvic recurrences may be a treatment option for patients where complete gross surgical resection seems possible (251) **(Fig. 37-6)**.

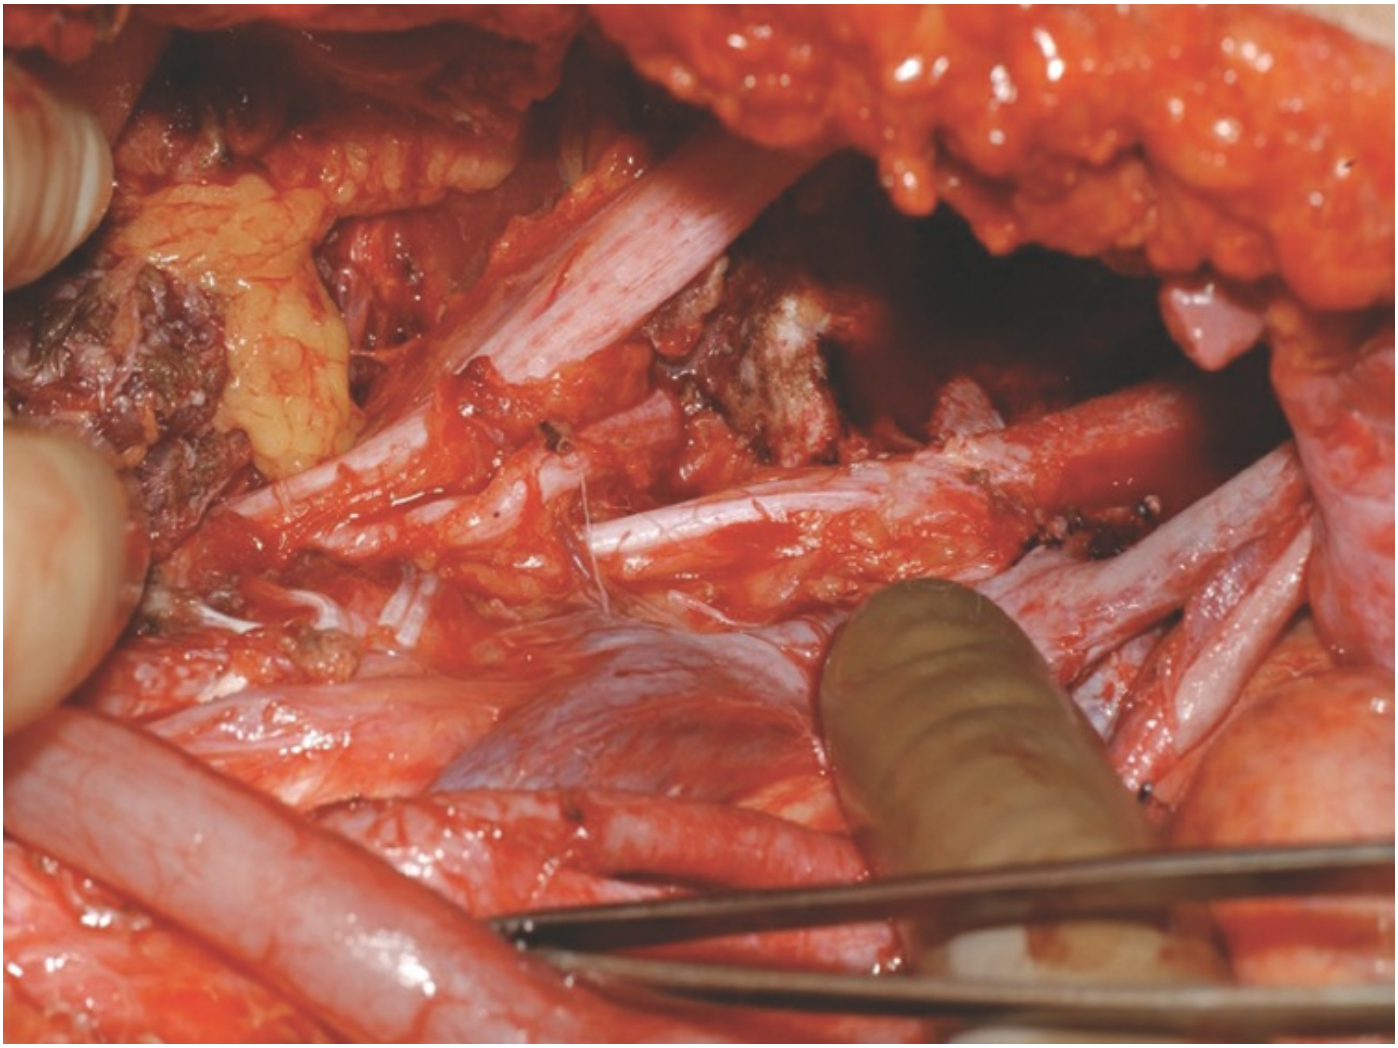

FIGURE 37-6 Radical pelvic sidewall resection. Photo taken of a patient with a left pelvic sidewall recurrence following resection of psoas muscle and bony ilium. Structures from lower to upper aspect of the photo (medial to lateral) include ureter, internal and external iliac artery, common iliac vein, lumbosacral trunk, obturator nerve (sacrificed), and femoral nerve. The cut edge of the psoas muscle is seen at left. (Provided by Sean C. Dowdy, MD, Mayo Clinic.)

Patients with recurrent endometrial cancer are frequently elderly, overweight, and have numerous comorbidities thereby increasing operative and postoperative morbidity and mortality. Patients who are most often helped by surgical approaches to recurrent disease are younger, have well-differentiated endometrial tumors, have a longer time from original treatment to recurrence, and have negative margins or no gross residual disease after surgery (246,247).

Radiation Therapy

[8] Radiotherapy is the best treatment option for patients with isolated local–regional recurrences who have not received prior radiation (239,252,253). The best local control and subsequent cure are achieved by a combination of external pelvic radiation therapy followed by vaginal brachytherapy to deliver a total tumor dose of at least 6,000 cGy. Patients with low-volume disease limited to the pelvis (most of which is contained in the vagina) have the best outcomes. Retrospective studies have shown complete remission rates after salvage radiotherapy for isolated vaginal relapse to be 40% to 80% in previously nonirradiated patients compared to 10% to 25% in patients who have received prior irradiation. Patients who undergo radiation for pelvic extension of disease have much lower reported survival rates of 0% to 26%. Factors associated with improved survival and control of pelvic disease in patients with locally recurrent endometrial cancer who receive radiotherapy include initial low-grade endometrioid histology, younger age at recurrence, recurrent tumor size 2 cm or less, time from initial treatment to recurrence of more than 1 year, vaginal versus pelvic

disease, and use of vaginal brachytherapy.

Chemotherapy

The standard chemotherapy for recurrent metastatic endometrial cancer is the same as that for advanced stage disease, that is, combination chemotherapy with *carboplatin* and *paclitaxel* (257,258). However, there are no randomized controlled trials comparing *carboplatin* and *paclitaxel* in the recurrent setting.

When single agents are used as second-line treatment, response rates range from 4% to 27%; *paclitaxel* being the most active in this setting. *Temsirolimus* and *bevacizumab* may be appropriate single-agent biologic therapy for patients who have progressed on previous cytotoxic therapy, although response rates are low at 4% and 13.5%, respectively (259). Studies have indicated that patients with programmed death ligand 1 (PD-L1) positive tumors and those with MMR-deficient (dMMR) or microsatellite instability high (MSI-H) endometrial cancer may respond to programmed death receptor-1 (PD-1) blockade with *pembrolizumab* (260,261). (See **Tables 37-12** and **37-13**.)

HPC, hydroxyprogesterone caproate (Delalutin); MPA, medroxyprogesterone acetate (Provera, Depo-Provera); MA, megestrol acetate (Megace); IM, intramuscular; PO, oral.

Hormonal Therapy

Hormonal therapy is an excellent management option for patients with asymptomatic recurrent endometrial cancer, especially for those who have low-grade, hormone receptor positive tumors (244,246). Progestin therapy, either megestrol acetate 80 mg twice daily or medroxyprogesterone acetate 50 to 100 mg three times daily, is recommended when radiation therapy, surgery, or both, are not feasible for treatment of localized recurrent cancer or in nonlocalized disease. Progestins have reported response rates ranging from 15% to 25%. Higher response rates are observed with well-differentiated tumors, expression of ER/PR receptors, longer disease-free interval, and location and extent of extrapelvic, especially pulmonary, metastatic disease. Progestin therapy should be given for at least 2 to 3 months before assessing response, and continued for as long as disease is static or in remission. In the presence of a relative contraindication to high-dose progestin therapy (e.g., prior or current thromboembolic disease, severe heart disease, or inability to tolerate progestin therapy), tamoxifen 20 mg twice daily is recommended, yielding response rates of about 10% to 20%. An alternating regimen of progestin and tamoxifen or an aromatase inhibitor may be substituted for a progestational agent, but response rates may be lower and toxicity higher. Failure to respond to hormonal therapy is an indication for initiation of chemotherapy. (See Table 37-14.)

UTERINE SARCOMA

Uterine sarcomas are relatively rare tumors arising from mesenchymal tissues of the uterus, including the uterine muscle and endometrial stroma. They account for approximately 3% of all uterine malignancies (262). In general, [9] uterine sarcomas are some of the most malignant uterine tumors and differ from endometrial carcinomas with regard to diagnosis, clinical behavior, pattern of spread, and management (265).

Classification and Staging

The two most common histologic types of uterine sarcoma are leiomyosarcoma (LMS) and endometrial stromal sarcoma (ESS), which make up approximately 60% and 20% of uterine sarcomas, respectively (Table 37-15). Rarer subtypes of malignant mesenchymal tumors that occur in the uterus are undifferentiated uterine sarcoma (UUS), adenosarcoma, and perivascular epithelioid cell neoplasm (PEComa) (264–266). Carcinosarcomas, also known as malignant mixed müllerian tumors (MMMT), were previously categorized and included in uterine sarcoma treatment algorithms, but are thought to represent high-grade carcinomas with mesenchymal metaplasia (267).

Staging of uterine sarcomas had previously been based on the FIGO staging system for endometrial adenocarcinomas. Recognition of the unique spread pattern and clinical behavior of uterine sarcomas required an independent staging system for each histologic type that was developed for LMS and ESS in 2009 (**Tables 37-16** and **37-17**) (268).

Endometrial Stromal Sarcoma

ESSs occur primarily in perimenopausal women between ages 45 and 50 years, with approximately one-third occurring in postmenopausal women. There is no apparent relationship to parity or associated diseases, and these tumors are rare in African American women. The most frequent symptom is abnormal uterine bleeding; abdominal pain, and pressure caused by an enlarging uterus occur less often, and some patients do not have any symptoms. Pelvic examination usually reveals regular or irregular uterine enlargement, sometimes associated with rubbery parametrial induration. The diagnosis may be determined by endometrial biopsy, but the usual preoperative diagnosis is uterine leiomyoma (267).

ESSs are composed of cells resembling normal endometrial stroma in the proliferative phase. They are divided into two types based on histologic criteria, such as cellular atypia, mitotic activity, and vascular invasion: low-grade ESS and high-grade ESS including undifferentiated sarcoma. Molecular profiling supports dividing these endometrial sarcomas into low- and high-grade entities based on histopathology and clinical behavior and outcomes (266).

Low-grade ESS is distinguished microscopically by mitotic rates of less than 10 MF/10 HPF, slight nuclear atypia, minimal necrosis, and presence of estrogen and progesterone receptors; myometrial and lymph–vascular invasion are common. Up to one-half of these tumors harbor a *JAZF1–SUZ12* gene fusion, which correlates with lower-grade, earlier-stage tumors and may be helpful in diagnosing these tumors and differentiating them from higher-grade endometrial stroma sarcomas (266,269).

Table 37-15 Classifications of Uterine Sarcomas

I. Pure nonepithelial tumors

A. Homologous
1. Endometrial stromal tumors
a. Low-grade stromal sarcoma
b. High-grade or undifferentiated stromal sarcoma
2. Smooth muscle tumors
a. Leiomyosarcoma
b. Leiomyoma variants
1. Cellular leiomyoma
2. Leiomyoblastoma (epithelioid leiomyoma)
c. Benign metastasizing tumors
1. Intravenous leiomyomatosis
2. Benign metastasizing leiomyoma
3. Disseminated peritoneal leiomyomatosis
B. Heterologous
1. Rhabdomyosarcoma
2. Chondrosarcoma
3. Osteosarcoma
4. Liposarcoma
II. Mixed epithelial–nonepithelial tumors
A. Malignant mixed müllerian tumor
1. Homologous (carcinosarcoma)
2. Heterologous
B. Adenosarcoma

Modified from **Clement P, Scully RE**. Pathology of uterine sarcomas. In: Coppleson M, ed. *Gynecologic oncology: Principles and Practice*. New York: Churchill-Livingston, 1981, with permission.

Low-grade ESSs are found to extend beyond the uterus in 40% of cases at the time of diagnosis, but the extrauterine spread is confined to the pelvis in two-thirds of these cases. Upper abdominal, pulmonary, and lymph node metastases are less common. Recurrences occur in almost one-half of cases at an average interval of 5 years after initial therapy and local recurrence is more common than distant metastasis. These tumors tend to have protracted clinical courses (263–267,269,270).

Optimal initial therapy for patients with low-grade ESS consists of surgical excision of all grossly detectable tumors. Total hysterectomy should be performed. The fallopian tubes and ovaries should be removed because of the propensity for tumor extension into the parametria, broad ligaments, adnexal structures, and the possible stimulating effect of estrogen on tumor cells if the ovaries are retained. The relatively low rate of lymph node metastasis in the absence of gross lymph node involvement or extrauterine disease suggests that lymph node dissection is not necessary. Pelvic irradiation is recommended for inadequately excised or locally recurrent pelvic disease. Owing to the indolent nature of the disease, cytotoxic chemotherapy is unlikely to be beneficial. Hormonal therapy with an aromatase inhibitor or progestin yields response rates close to 50% in patients with recurrent or metastatic disease. Recurrent or metastatic lesions may be amenable to surgical excision. Prolonged survival and cure are common even after the development of recurrent or metastatic disease with the overall 5-year survival exceeding 90% (263–267,270).

High-grade ESS and UUS are highly malignant neoplasms, although the prognosis is poorer for the latter. Histologically, both exhibit greater than 10 MF/10 HPF, necrosis, significant cytologic pleomorphim, and prominent myometrial and lymph–vascular invasion. UUS, by definition, lacks recognizable morphologic or immunohistochemical evidence of smooth muscle or endometrial stromal differentiation. Higher-grade ESSs have been found to have a unique genetic rearrangement *YWHAE–FAM22A/B* which correlates with a more aggressive clinical behavior (266,269).

Table 37-16 FIGO Staging for Uterine Endometrial Stromal Sarcoma and Adenosarcoma

Stage	Definition	
I	Tumor limited to uterus	IA: tumor limited to endometrium/endocervix with no myometrial invasion IB: ≤½ myometrial invasion IC: >½ myometrial invasion
II	Tumor extends beyond the uterus, within the pelvis	IIA: adnexal involvement IIB: involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)	IIIA: one site IIIB: more than one site IIIC: metastasis to pelvic and/or para-aortic lymph nodes
IV		IVA: tumor invades bladder and/or rectum IVB: distant metastasis

Prat J. FIGO staging for uterine sarcomas. *Int J Gynecol Obstet* 2009;104:177–178.

Table 37-17 FIGO Staging for Uterine Leiomyosarcoma

Stage	Definition	
I	Tumor limited to uterus	IA: <5 cm IB: >5 cm
II	Tumor extends beyond the uterus, within the pelvis	IIA: adnexal involvement IIB: involvement of other pelvic tissues
III	Tumor invades abdominal tissues (not just protruding into the abdomen)	IIIA: one site IIIB: more than one site IIIC: metastasis to pelvic and/or para-aortic lymph nodes
IV		IVA: tumor invades bladder and/or rectum IVB: distant metastasis

Prat J. FIGO staging for uterine sarcomas. *Int J Gynecol Obstet* 2009;104:177–178.

Treatment of high-grade ESS and UUS should consist of total hysterectomy and bilateral salpingo-oophorectomy. The poor therapeutic results with surgery alone, suggest that adjuvant radiation therapy, chemotherapy, or both, should be used in combination with surgery, however, there is no data to support this. These tumors are not responsive to hormonal therapy. The 5-year disease-free survival rate for these tumors is 25% (263–267,270).

Uterine tumor resembling ovarian sex-cord tumor (UTROSCT) is a rare variant of ESS, which contains elements resembling ovarian sex-cord tumors. Immunohistochemically, these tumors express calretinin, inhibin, CAM5.2, and progesterone receptor; positive staining for calretinin and at least one of the other markers confirms the diagnosis of UTROSCT. The mean age of diagnosis is 52. The most common presenting symptom is abnormal uterine bleeding. Although some of these tumors are large and have infiltrative margins, almost all behave benignly. Endometrial stromal tumors with sex-cord–like elements (ESTSCLE) tend to behave more aggressively with larger tumors, more extrauterine metastases, and a higher rate of recurrence (271).

Leiomyosarcoma

The median age for women with LMS is 54 (range 43 to 63) years, and premenopausal women have a better survival. This malignancy has no relationship with parity, and the incidence of associated diseases is not as high as in endometrial carcinomas. African Americans have a higher incidence and a poorer prognosis than women of other races. A history of prior pelvic radiation can be elicited in about 4% of women with uterine LMS. The incidence of sarcomatous change in benign uterine leiomyomas is reported to be between 0.13% and 0.81%, and most uterine LMSs are unassociated with pre-existing leiomyomas (272–276).

Presenting symptoms, which are usually of short duration (mean = 6 months) and not

specific to the disease, include vaginal bleeding, pelvic pain or pressure, and awareness of an abdominal mass. The principal physical finding is the presence of a pelvic mass. The diagnosis should be suspected if pelvic pain accompanies an enlarging uterus, especially in a postmenopausal woman. Endometrial biopsy, although not as useful as in ESSs or carcinomas, may establish the diagnosis in as many as one-third of cases if the lesion is submucosal. MRI, especially contrast-enhanced MRI, may be more diagnostic than ultrasound or CT in differentiating LMSs and smooth muscle tumors of uncertain malignant potential (STUMP) from leiomyomas (275).

Pathologically, the number of mitoses in uterine smooth muscle tumors has traditionally been considered the most reliable indicator of malignant behavior. Tumors with less than 5 MF/10 HPF behave in a benign fashion and tumors with more than 10 MF/10 HPF are frankly malignant, while tumors with 5 to 10 MF/10 HPF-termed STUMP have a less predictable behavior. In addition to mitotic index greater than 10, other histologic indicators used to classify uterine smooth muscle tumors as malignant are severe cytologic atypia, infiltrating borders, coagulative tumor cell necrosis, and presence of vascular invasion (266,277) **(Fig. 37-7)**. Gross presentation of the tumor at the time of surgery is an important prognostic indicator. Tumors greater than 5 cm, with infiltrating rather than pushing borders, and extension beyond the uterus have a poorer prognosis. The pattern of tumor spread is usually through the myometrium, into pelvic blood vessels and lymphatics, contiguously to pelvic structures and intra-abdominally, and distantly (most often the lungs). Reported survival rates for women with uterine LMS range from 20% to 63% (mean 47%). Younger women with stage I disease do best, while older women and those with advanced disease do least well (272–276).

Surgery is the mainstay of treatment for uterine LMS. For women with uterine-confined disease, total hysterectomy is recommended, optimally avoiding intra-operative morcellation which may increase recurrence and death in women with previously undiagnosed uterine LMS (275,278). Bilateral salpingo-oophorectomy should be done in postmenopausal women and in women with gross extrauterine disease. Preservation of the ovaries in premenopausal women does not increase the risk of recurrence. Retroperitoneal lymphatic spread is rare in women with early-stage disease and lymphadenectomy is not associated with a survival advantage. In women with disease spread outside the uterus, complete cytoreductive surgery or metastasectomy (especially in the lungs) may improve survival (272–276).

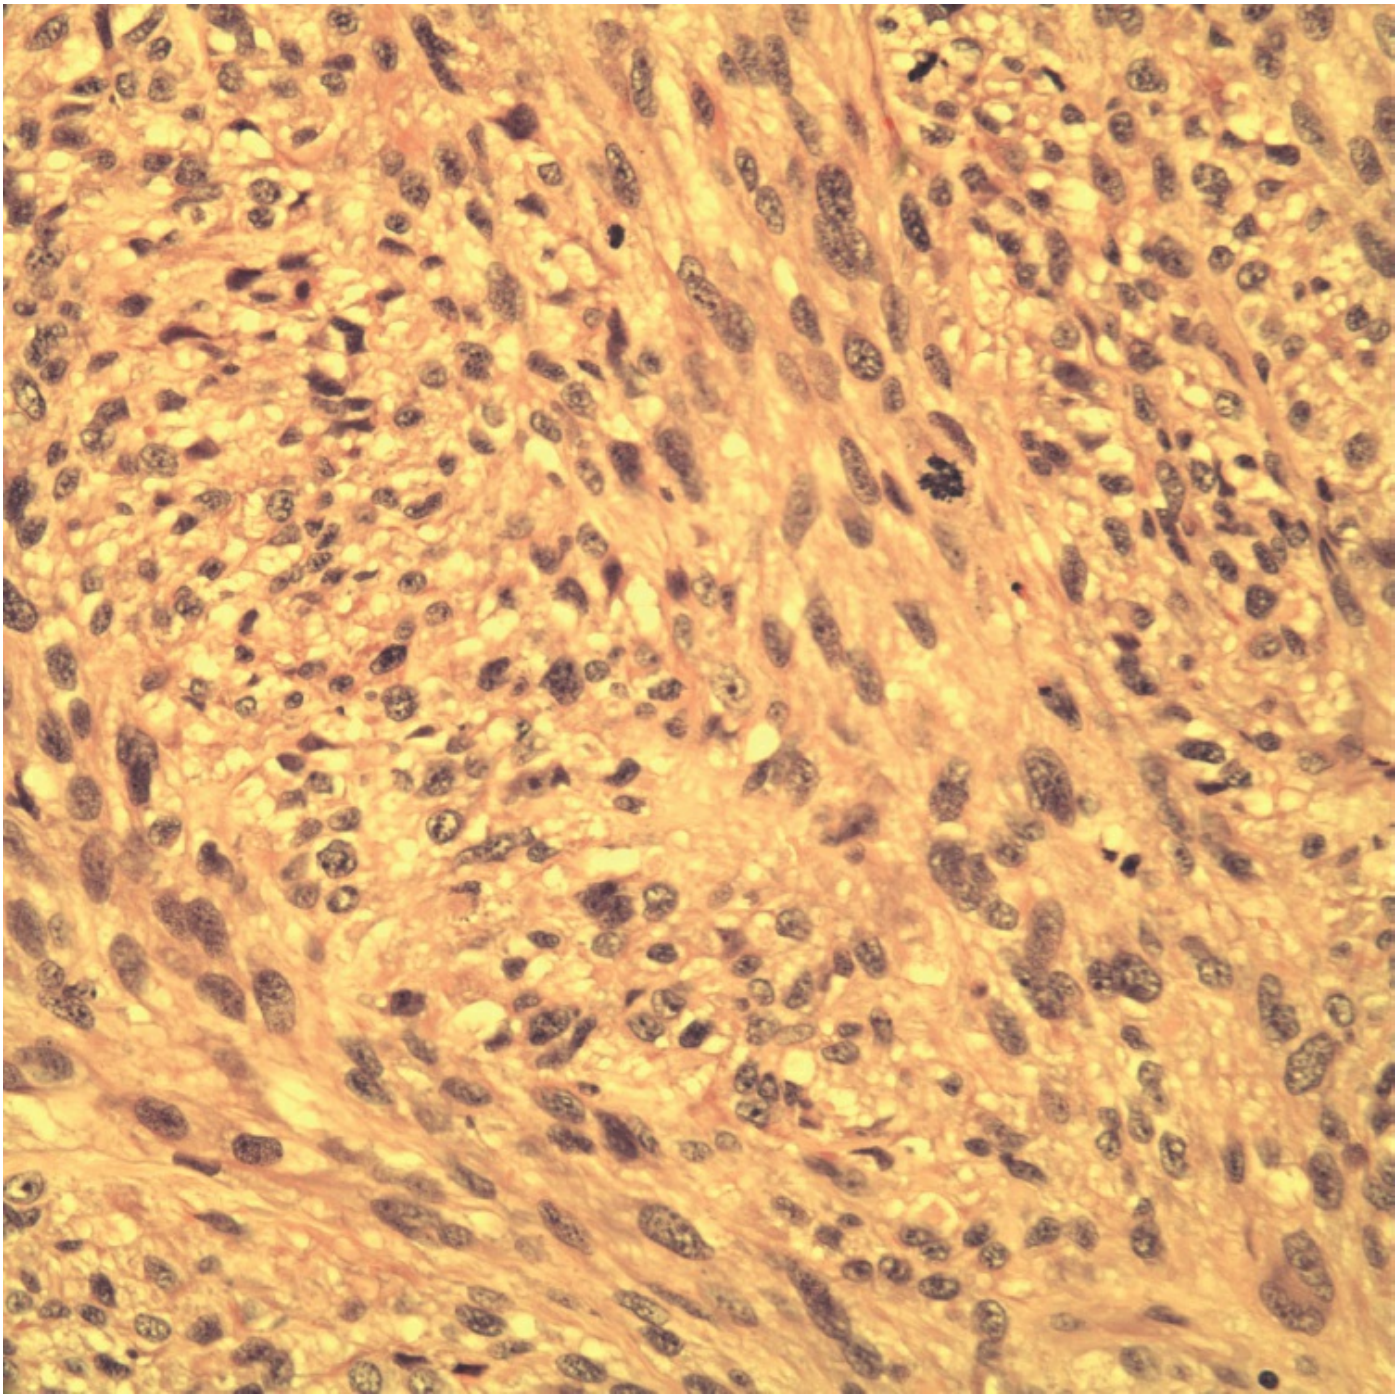

FIGURE 37-7 Leiomyosarcoma of the uterus. Interlacing bundles of spindle cells have fibrillar cytoplasm, irregular and hyperchromatic nuclei, and multiple mitotic figures. (Provided by Gordana Stevanovic, MD, and Jianyu Rao, MD, Department of Pathology, UCLA.)

Radiation therapy does not improve outcomes for women with uterine LMS. Data from a phase III trial conducted by the European Organization for Research and Treatment of Cancer (EORTC) comparing adjuvant postoperative pelvic radiation therapy to observation only for women with early-stage uterine LMS found no differences in overall survival or recurrence rates (279). This lack of benefit of adjuvant postoperative radiotherapy was supported by results from a Surveillance,

Epidemiology, and End Results (SEER) database (280). Therefore, postoperative adjuvant radiation therapy is not recommended for completely-resected, early-stage disease.

Chemotherapy is indicated and increases survival in patients with advanced LMS. Several single agents, such as *dacarbazine, doxorubicin, epirubicin, eribulin, gemcitabine, ifosfamide, liposomal doxorubicin, pazopanib, temozolomide*, and *trabectedin* have been shown to have some activity in treating advanced or metastatic LMSs yielding response rates of 15% to 25%, and *doxorubicin* is the most active. Combination chemotherapy with *gemcitabine/docetaxel* or *doxorubicin/ ifosfamide +/– dacarbazine* has yielded response rates of 53% and 30%, respectively, in advanced uterine LMS, however, median time to progression is usually less than 6 months and survival less than 2 years (259). A phase II trial of the combination of *doxorubicin/olaratumab* versus single-agent *doxorubicin* for the treatment of soft tissue sarcomas including LMSs found the combination to be superior with a median progression-free survival of 6.6 versus 4.1 months and a median overall survival of 26.5 versus 14.7 months, respectively (281). Adjuvant postoperative chemotherapy for early-stage uterine LMS has failed to improve survival or lower the 40% to 70% risk of recurrence, despite its increasing use (282).

Five other clinical pathologic variants of uterine smooth muscle tumors deserve special comment: myxoid LMS, epithelioid LMS, intravenous leiomyomatosis, benign metastasizing uterine leiomyoma, and disseminated peritoneal leiomyomatosis (266,277).

Myxoid LMS is characterized grossly by a gelatinous appearance and apparent circumscribed border. Microscopically, the tumors have a myxomatons stroma and extensively invade adjacent tissue and blood vessels. The mitotic rate may be low (0 to 2 MF/10 HPF), which belies their aggressive behavior and poor prognosis (283). Surgical excision by hysterectomy is the mainstay of treatment. The low mitotic rate and abundance of intracellular myxomatous tissue suggest that these tumors would not be responsive to radiation therapy or chemotherapy.

Epithelioid LMS often forms large fleshy intrauterine masses, commonly associated with hemorrhage. They exhibit a microscopic pattern of epithelioid differentiation consisting of round cells with eosinophilic and granular or clear cytoplasm growing in sheets, nests, or cords in addition to cytologic atypia, increased mitotic activity (>5MF/10 HPF), and tumor cell necrosis. These tumors must be distinguished from placental site trophoblastic tumors and epithelioid trophoblastic tumors. Epithelioid LMSs are aggressive tumors with a prognosis similar to myxoid LMSs, with a propensity for late recurrences. Hysterectomy is the only treatment proven to be of any benefit (277).

Intravenous leiomyomatosis is characterized by the growth of histologically benign smooth muscle into venous channels within the broad ligament and then into uterine and

iliac veins. The intravascular growth takes the form of visible, worm-like projections that extend from a myomatous uterus into the parametria toward the pelvic sidewalls. It may be confused with low-grade stromal sarcoma. Symptoms are related to the associated uterine myomas. Most women are in the late fifth and early sixth decades of life. The prognosis is excellent, even when tumor is left in pelvic vessels. Late local recurrences can occur, and deaths from extension into the inferior vena cava or metastases to the heart have been reported. Estrogen may stimulate the proliferation of these intravascular tumors. Treatment should be total hysterectomy with bilateral salpingo-oophorectomy and excision of any extrauterine tumor when technically feasible. Antiestrogen therapy is appropriate if residual tumor remains after surgery (277).

Benign metastasizing uterine leiomyoma is a rare condition in which a histologically benign uterine smooth muscle tumor acts in a somewhat malignant fashion and produces benign metastasis, usually to the lungs or lymph nodes. In most instances, intravenous leiomyomatosis is not apparent. The metastasizing myomas are capable of growth at distant sites, whereas the intravenous tumors spread only by direct extension within blood vessels. Experimental and clinical evidence suggests that these tumors are stimulated by estrogen. Removing the source of estrogen, by oophorectomy or withdrawal of exogenous estrogen, or by treatment with an antiestrogen or a gonadotropin agonist has an ameliorating effect. Surgical treatment should consist of total hysterectomy, bilateral salpingo-oophorectomy, and resection of pulmonary metastases, if possible (284).

Disseminated peritoneal leiomyomatosis is a rare clinical entity characterized by benign smooth muscle nodules scattered throughout the peritoneal cavity. This condition probably arises as a result of metaplasia of subperitoneal mesenchymal stem cells to smooth muscle, fibroblasts, myofibroblasts, and decidual cells under the influence of estrogen and progesterone. Most reported cases occurred in 30- to 40-year-old women who are or were recently pregnant or who have a long history of oral contraceptive use. Intriguing features of this disease are its grossly malignant appearance, benign histology, and favorable clinical outcome. Intraoperative diagnosis requires frozen-section examination. Extirpative surgery, including hysterectomy, bilateral salpingo-oophorectomy, omentectomy, and excision of as much gross-tumor as possible, may be indicated in menopausal women. Removal of the source of excess estrogen and treatment with progestins or antiestrogens has resulted in regression of unresected tumor masses. Almost all women have a good prognosis (285).

Adenosarcoma

Adenosarcoma consists of an admixture of benign-appearing neoplastic glands and a sarcomatous stroma. It accounts for only about 5% of all uterine sarcomas. Most patients present with postmenopausal uterine bleeding, and the disease is diagnosed or

suspected on endometrial sampling. Most adenosarcomas are well circumscribed and are limited to the endometrium or superficial myometrium. Standard treatment is total hysterectomy and bilateral salpingo-oophorectomy; routine lymph node dissection is not indicated. Because recurrences, mostly in the form of local pelvic or vaginal disease, are reported to occur in up to 40% to 50% of cases, adjuvant postoperative vaginal brachytherapy or pelvic radiation has been recommended. There is little evidence for the use of adjuvant chemotherapy or hormonal therapy. Survival is mainly impacted by the presence or absence of sarcomatous overgrowth, which is found in about 30% of cases. Overall 5-year survival is reported to be 70% to 80% without sarcomatous overgrowth versus 50% to 60% with sarcomatous overgrowth (286).

KEY POINTS

1 Human papillomavirus (HPV) infection is the causal agent of cervical cancer.

2 Screening programs are effective at decreasing the incidence of cervical cancer. Vaccines help decrease the incidence of cervical cancer.

3 The most common histologic type of cervical cancer is squamous, and the relative and absolute incidence of adenocarcinoma is increasing. Both histologies are caused by HPV infection.

4 Cervical cancer is clinically staged, although modern radiographic modalities such as computed tomography, magnetic resonance imaging, ultrasound, or positron emission tomography, if available, may be beneficial for individual treatment planning. The staging system has been updated in 2018.

5 Treatment of cervical cancer is based on stage of disease. Early-stage disease (stages I to IIA) can be treated with either radical surgery or radiation therapy. Advanced stage disease (stages IIB to IV) is best treated with chemoradiation, including brachytherapy.

6 Vaginal cancer is a rare disease with many similarities to cervical cancer. Radiation therapy is the mainstay of treatment for most patients; however, select patients may be treated with radical surgery.

7 Minimally invasive radical hysterectomy. Laparoscopic and robotic radical hysterectomies were being performed with larger degree of frequency in highly selected patients world wide.

Cervical cancer ranks as the third most common gynecologic neoplasm in the United States, behind cancer of the uterine corpus and ovary, mainly as a result of the effectiveness of screening programs. **Worldwide, cervical carcinoma continues to be a significant health care problem. In developing countries, where health care resources are limited, cervical carcinoma is the second most frequent cause of cancer death in women.** Because cervical cancer is preventable, it is imperative that gynecologists and other primary health care providers for women be familiar with vaccination programs, screening techniques, diagnostic procedures, and risk factors for cervical cancer and management of preinvasive disease. Vaginal cancer is a rare tumor that shares an epidemiology and risk factor profile that is similar to cervical cancer.

CERVICAL CANCER

Epidemiology and Risk Factors

Invasive cancer of the cervix is considered a preventable disease because it has a long preinvasive state, cervical cytology screening programs are available, and the treatment of preinvasive lesions is effective. In spite of the preventable nature of this disease, the CDC reported 12,578 new cases of invasive cervical cancer resulting in 4,115 deaths in the United States in 2014 (1). This data are similar to the 2011 statistics, with only a slight decrease (1,2). Nationally, the lifetime probability of developing cervical cancer is 1:128. Although screening programs in the United States are well established, it is estimated that 30% of cervical cancer cases will occur in women who have never had a Papanicolaou (Pap) test. In developing countries, this percentage approaches 60% (3). Nevertheless, the worldwide incidence of invasive disease is decreasing, and cervical cancer is being diagnosed earlier, leading to better survival rates (2,4). The mean age for cervical cancer in the United States is 47 years, and the distribution of cases is bimodal, with peaks at 35 to 39 years and 60 to 64 years of age (2).

There are numerous risk factors for cervical cancer: young age at first intercourse (younger than 16 years), multiple sexual partners, cigarette smoking, race, high parity, low socioeconomic status, and chronic immune suppression. The relationship to oral contraceptive use was debated. Some investigators proposed that use of oral contraceptives might increase the incidence of cervical glandular abnormalities; however, this hypothesis was not consistently supported (5,6). **[1]** Many of these risk factors are linked to sexual activity and exposure to sexually transmitted diseases. Infection with the herpes virus was thought to be the initiating event in cervical cancer; however, infection with human papillomavirus (HPV) was determined

to be the causal agent in the development of cervical cancer, with herpes virus and *Chlamydia trachomatis* likely acting as cofactors. The role of human immunodeficiency virus (HIV) in cervical cancer is mediated through immune suppression (5). The Centers for Disease Control and Prevention described cervical cancer as an acquired immune deficiency syndrome (AIDS)–defining illness in patients infected with HIV (7).

[1] The initiating event in cervical dysplasia and carcinogenesis is infection with HPV. HPV infection was detected in up to 99% of women with squamous cervical carcinoma. HPV is the causative agent in both squamous and adenocarcinoma of the cervix, but the respective tumors may have different carcinogenic pathways (8). There are more than 100 different types of HPV, more than 30 of which can affect the lower genital tract. There are 15 high-risk HPV subtypes; two of the high-risk subtypes, 16 and 18, are found in up to 70% of cervical carcinomas. The mechanism by which HPV affects cellular growth and differentiation is through the interaction of viral E6 and E7 proteins with tumor suppressor genes p53 and Rb, respectively. Inhibition of p53 prevents cell cycle arrest and cellular apoptosis, which normally occurs when damaged DNA is present, whereas inhibition of Rb disrupts transcription factor E2F, resulting in unregulated cellular proliferation (9). Both steps are essential for the malignant transformation of cervical epithelial cells. Initially, there were two HPV vaccines, the quadrivalent *Gardasil* and the bivalent *Cervarix*, approved by the U.S. Food and Drug Administration (FDA). Both protect against HPV subtypes 16 and 18. **[2]** The efficacy of *Gardasil* was 97% to 100% for preventing cervical intraepithelial neoplasia (CIN) grades 2 and 3 caused by HPV 16 or 18 in females who were not previously infected with either HPV 16 or 18 before vaccination; however, efficacy was only 44% in those who were infected prior to vaccination (10). Recently, the FDA has approved a third HPV vaccine, Gardasil-9, which protects against the four subtypes of the quadrivalent vaccine plus an additional five high-risk subtypes (HPV 31/33/45/52/58). In a head-to-head, immunoresponse trial, the 9-valent HPV vaccine showed non-inferior anti-HPV 6/11/16/18 antibody response (11). The efficacy of the 9-valent vaccine in preventing CIN 2,3, VIN 2 or 3, and VAIN 2 or 3 was 97% in the HPV-naïve patient population (12). Long-term data for superior efficacy in HPV 31/33/45/52/58-related clinical outcomes is still pending. The FDA also extended the recommended age indication for Gardisil-9 to include men and women ages 9 to 45. Because these vaccines do not protect against all HPV subtypes, vaccinated women need to continue to receive cervical cancer screening according to published guidelines.

Evaluation

Vaginal bleeding is the most common symptom occurring in patients with cancer of the cervix. Most often, this is postcoital bleeding, but it may occur as irregular or postmenopausal bleeding. Patients with advanced disease may present with a

malodorous vaginal discharge, weight loss, or obstructive uropathy. In asymptomatic women, cervical cancer is most commonly identified through evaluation of abnormal cytologic screening tests. The false-negative rate for Pap tests in the presence of invasive cancer is up to 50%, so a negative Pap test should never be relied on in a symptomatic patient (13).

Initially, all women suspected of having cervical cancer should have a general physical examination performed to include evaluation of the supraclavicular, axillary, and inguinofemoral lymph nodes to exclude the presence of metastatic disease. On pelvic examination, a speculum is inserted into the vagina, and the cervix is inspected for suspicious areas **(Fig. 38-1)**. The vaginal fornices should be closely inspected. With invasive cancer, the cervix is usually firm and expanded, and these features should be confirmed by digital examination. Rectal examination is important to help establish cervical consistency and size, particularly in patients with endocervical carcinomas. Rectal examination is the only way to determine cervical size if the vaginal fornices have been obliterated by menopausal changes or by the extension of disease. Parametrial extension of disease is best determined by the finding of nodularity beyond the cervix on rectal examination.

When obvious tumor growth is present, a cervical biopsy is usually sufficient for diagnosis. If gross disease is not present, a colposcopic examination with cervical biopsies and endocervical curettage is warranted. If the diagnosis cannot be established conclusively with colposcopy and directed biopsies, which may be the case with adenocarcinoma, cervical conization may be necessary.

Colposcopic Findings of Invasion

Colposcopic examination is mandatory for patients with suspected early invasive cancer based on cervical cytology and a grossly normal-appearing cervix. Colposcopic findings that suggest invasion are (i) abnormal blood vessels, (ii) irregular surface contour with loss of surface epithelium, and (iii) color tone change. Colposcopically directed biopsies may permit the diagnosis of frank invasion and thus avoid the need for diagnostic cone biopsy, allowing treatment to be administered without delay. If there is debate about the depth of invasion based on the cervical biopsies, and if the clinical stage may be upstaged to stage IA2 or IB1, the patient should undergo a conization. In the presence of a large cervical biopsy specimen showing invasion greater than 3 mm, or two biopsy specimens separated by 7 mm showing invasive cervical carcinoma, therapy should proceed without delay, and the patient could undergo radical surgery or radiation therapy.

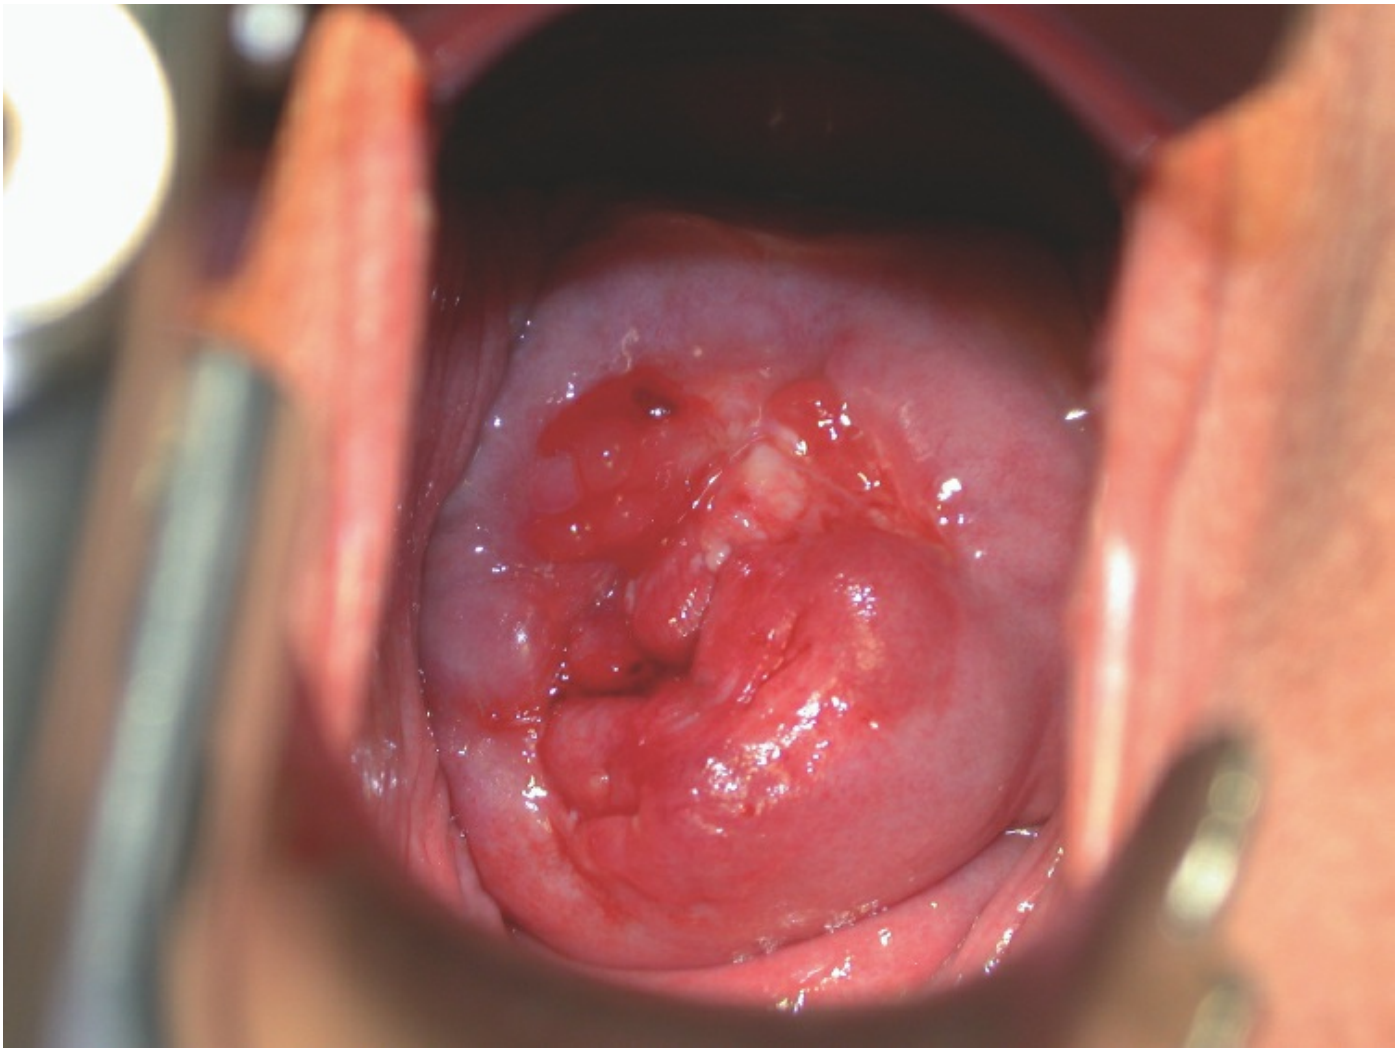

FIGURE 38-1 Gross appearance of cervical cancer on examination.

Abnormal Blood Vessels

Abnormal vessels may be looped, branched, or reticular. **Abnormal looped vessels are the most common colposcopic finding and arise from the punctated and mosaic vessels present in CIN.** As the neoplastic growth process proceeds and the need for oxygen and nutrition increases, angiogenesis occurs as a result of tumor and local tissue production of vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), epidermal growth factor (EGF), and other cytokines, resulting in the proliferation of blood vessels and neovascularization. Punctate vessels push out over the surface of the epithelium in an erratic fashion, producing the looped, corkscrew, or J-shaped pattern of abnormal vessels characteristic of invasive disease. Abnormal blood vessels arise from the cervical stroma and are pushed to the surface as the underlying cancer invades. The normally branching cervical stromal vessels are best observed over nabothian cysts. In this area, the branches are generally at acute angles, with the caliber of vessels becoming smaller after branching, much like the arborization of a tree. The abnormal branching blood vessels seen with cancer tend to form obtuse or

right angles, with the caliber sometimes enlarging after branching. Sharp turns, dilations, and luminal narrowing characterize these vessels. The surface epithelium may be lost in these areas, leading to irregular surface contour and friability.

Abnormal reticular vessels represent the terminal capillaries of the cervical epithelium. Normal capillaries are best seen in postmenopausal women with atrophic epithelium. When cancer involves this epithelium, the surface is eroded, and the capillary network is exposed. These vessels are very fine and short and appear as small comma-shaped vessels without an organized pattern. They are not specific to invasive cancer; atrophic cervicitis may also have this appearance.

Irregular Surface Contour

Abnormal surface patterns are observed as tumor growth proceeds. The surface epithelium ulcerates as the cells lose intercellular cohesiveness secondary to loss of desmosomes. Irregular contour may occur as a result of papillary characteristics of the lesion. **This finding can be confused with a benign HPV papillary growth on the cervix. For that reason, biopsies should be performed on all papillary cervical growths to avoid missing invasive disease.**

Color Tone

Color tone may change as a result of increasing vascularity, surface epithelial necrosis, and in some cases, production of keratin. The color tone is yellow-orange rather than the expected pink of intact squamous epithelium or the red of the endocervical epithelium.

Adenocarcinoma

Adenocarcinoma of the cervix does not have a specific colposcopic appearance. All of the aforementioned blood vessels may be seen in these lesions. Because adenocarcinomas tend to develop within the endocervix, endocervical curettage is required as part of the colposcopic examination, and traditional screening methods are less reliable (13).

Histologic Appearance of Invasion

Cervical conization is required to assess correctly the depth and the linear extent of involvement when microinvasion is suspected. Early invasion is characterized by a protrusion of malignant cells from the stromal–epithelial junction. This focus consists of cells that appear better differentiated than the adjacent noninvasive cells and have abundant pink-staining cytoplasm, hyperchromatic nuclei, and small-to-medium–sized nucleoli (14). **These early invasive lesions form tonguelike processes without measurable volume and are classified as International Federation of Gynecology and Obstetrics (FIGO) stage IA1.** With further progression, more tonguelike processes and isolated malignant cells appear in the stroma, followed by a proliferation

of fibroblasts (desmoplasia) and a bandlike infiltration of chronic inflammatory cells **(Fig. 38-2)**. **With increasing depth of invasion, lesions occur at multiple sites, and the growth becomes measurable by depth and linear extent. Lesions that are less than 3 mm in depth are classified as FIGO stage IA1. Lesions that are 3 to 5 mm or more in depth and up to 7 mm in linear extent are classified as FIGO stage IA2** (15). As the depth of stromal invasion increases, so does the risk of capillary lymphatic space involvement. Dilated capillaries, lymphatic spaces, and foreign-body multinucleated giant cells containing keratin debris are often seen in the stroma.

The depth of invasion should be measured with a micrometer from the base of the epithelium to the deepest point of invasion. **Depth of invasion is a significant predictor for the development of pelvic lymph node metastasis and tumor recurrence. Although lesions that have invaded 3 mm or less rarely metastasize, patients in whom lesions invade between 3 and 5 mm have positive pelvic lymph nodes in 3% to 8% of cases** (16). The significance of the cutoff at 3 mm is not identified completely; it was postulated that small capillary–lymphatic spaces at this level are incapable of facilitating the transport of malignant cells. Uneven shrinkage of tissue by fixative often creates space between the tumor nests and the surrounding fibrous stroma, simulating vascular lymphatic invasion **(Fig. 38-2)**. Therefore, suspected vascular–lymphatic involvement with invasion of less than 3 mm should be interpreted with care. A lack of endothelial lining indicates that the space is a fixation artifact rather than true vascular invasion.

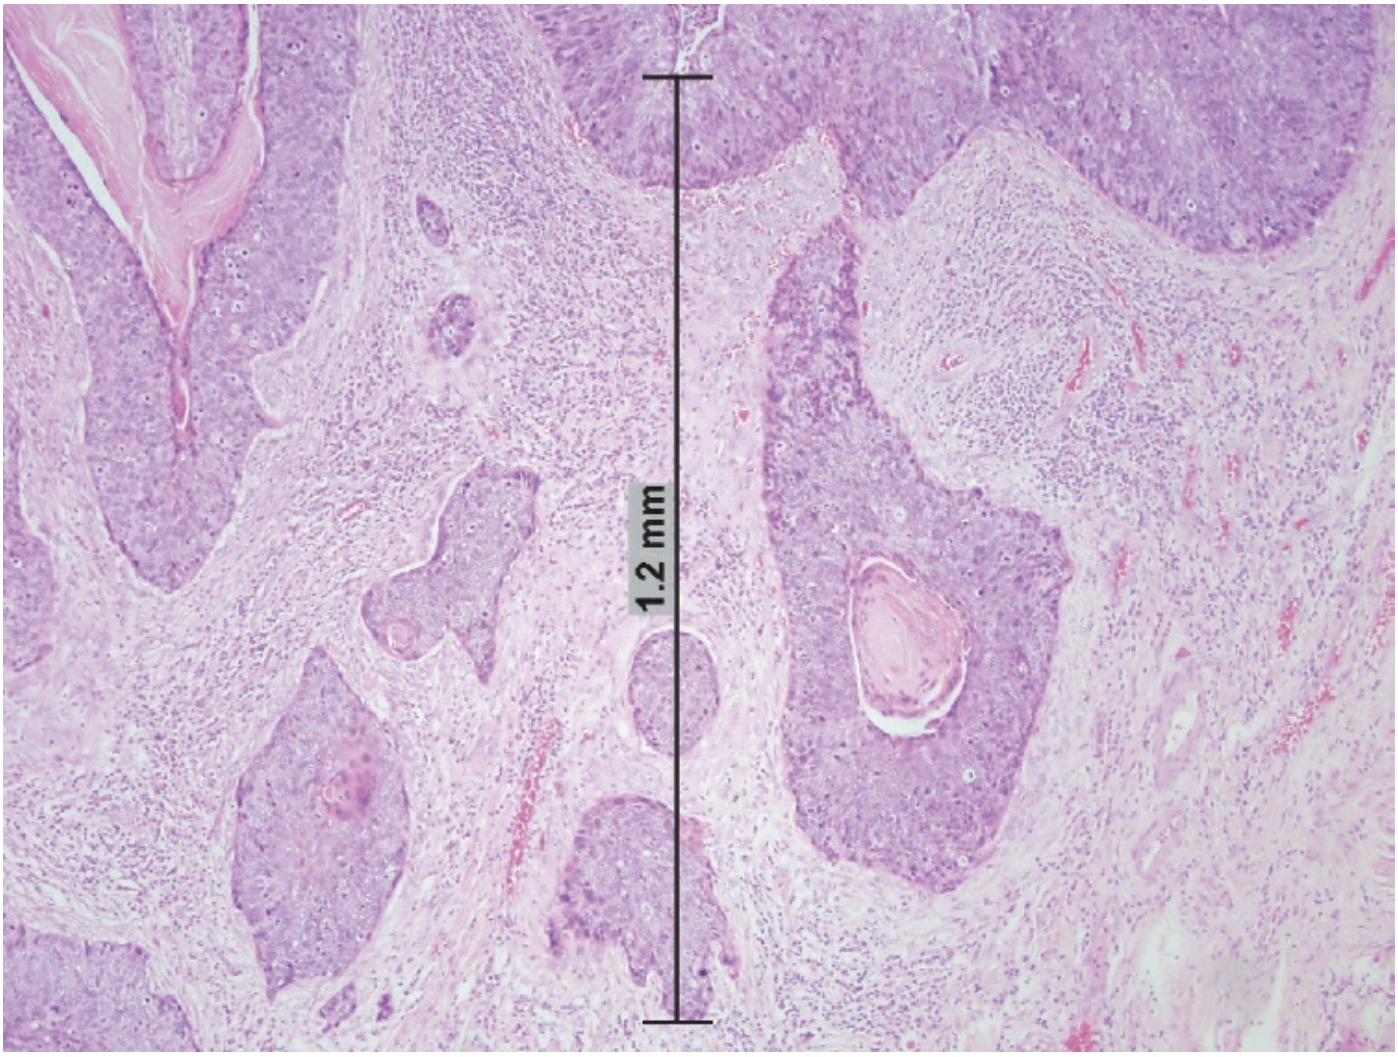

FIGURE 38-2 Microinvasive squamous carcinoma. Multiple irregular tonguelike processes and isolated nests of malignant cells are seen, some surrounded by clear spaces, simulating capillary lymphatic invasion. This is an artifact caused by tissue shrinkage. The depth of stromal invasion is measured from the basement membrane of the overlying cervical intraepithelial neoplasia (CIN). In this case, it is 1.2 mm.

Staging

The FIGO staging system was updated in 2018 to include imaging and pathologic findings and is presnted in Table 38-1 and **Figure 38-3**. The old 2008 FIGO clinical staging system is shown in Table 38-2. The FIGO staging system is applicable to all histologic types of cervical cancer. The reported data presented in this chapter are based on the 2008 staging system.

When there is doubt concerning the stage to which a cancer should be allocated, the earlier stage should be selected. After a stage is assigned and treatment is initiated, the stage must not be changed because of subsequent findings. The upstaging of patients during treatment will produce an erroneous perception of improvement in the results of treatment of low-stage disease. Following is a breakdown of the incidence of cervical cancer by the clinical staging system at diagnosis: 38%,

stage I; 32%, stage II; 26%, stage III; and 4%, stage IV (4,16,17).

In the 2018 staging system, horizontal spread is no longer considered in stage IA, only the depth of invasion is used. Stage IB is now divided into 3 stages, Stages IB1, IB2, and IB3. Stage IB1 denotes lesions that are <2 cm in greatest dimension, reflecting advances fertility-sparing procedures that are now recommended for selected patients with these smaller tumors. Last, Stage III has added a stage with substages to reflect pelvic and paraaortic lymph node metastasis; this is due to the worsening of outcomes when lymph node metastasis is present. See Table 38-1 for the revised 2018 FIGO staging system.

Table 38-1 FIGO Staging of Carcinoma of the Cervix Uteri (2018)

Stage	Description
I	The carcinoma is strictly confined to the cervix (extension to the uterine corpus should be disregarded)
IA	Invasive carcinoma that can be diagnosed only by microscopy, with maximum depth of invasion <5 mm[a]
IA1	Measured stromal invasion <3 mm in depth
IA2	Measured stromal invasion ≥3 mm and <5 mm in depth
IB	Invasive carcinoma with measured deepest invasion ≥5 mm (greater than Stage IA), lesion limited to the cervix uteri[b]
IB1	Invasive carcinoma ≥5 mm depth of stromal invasion, and <2 cm in greatest dimension
IB2	Invasive carcinoma ≥2 cm and <4 cm in greatest dimension
IB3	Invasive carcinoma ≥4 cm in greatest dimension
II	The carcinoma invades beyond the uterus, but has not extended onto the lower third of the vagina or to the pelvic wall
IIA	Involvement limited to the upper two-thirds of the vagina without parametrial involvement
IIA1	Invasive carcinoma <4 cm in greatest dimension
IIA2	Invasive carcinoma ≥4 cm in greatest dimension
IIB	With parametrial involvement but not up to the pelvic wall
III	The carcinoma involves the lower third of the vagina and/or extends to the pelvic wall and/or causes hydronephrosis or nonfunctioning kidney and/or involves pelvic and/or para-aortic lymph nodes[c]
IIIA	The carcinoma involves the lower third of the vagina, with no extension to the pelvic wall

IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney (unless known to be due to another cause)
IIIC	Involvement of pelvic and/or para-aortic lymph nodes, irrespective of tumor size and extent (with r and p notations)[c]
IIIC1	Pelvic lymph node metastasis only
IIIC2	Para-aortic lymph node metastasis
IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. (A bullous edema, as such, does not permit a case to be allotted to Stage IV)
IVA	Spread to adjacent pelvic organs
IVB	Spread to distant organs

When in doubt, the lower staging should be assigned.

[a]Imaging and pathology can be used, where available, to supplement clinical findings with respect to tumor size and extent, in all stages.

[b]The involvement of vascular/lymphatic spaces does not change the staging. The lateral extent of the lesion is no longer considered.

[c]Adding notation of r (imaging) and p (pathology) to indicate the findings that are used to allocate the case to Stage IIIC. Example: If imaging indicates pelvic lymph node metastasis, the stage allocation would be Stage IIIC1r, and if confirmed by pathologic findings, it would be Stage IIIC1p. The type of imaging modality or pathology technique used should always be documented.

From **Bhatla N, Berek JS, Cuello Frede M, et al.** FIGO Committee Report. Revised FIGO staging for carcinoma of the cervix uteri. *Int J Gynecol Obstet* 2019:1–7.

Additional Staging Modalities

Various investigators used lymphangiography, computed tomography (CT), ultrasonography, magnetic resonance imaging (MRI), and positron emission tomography (PET) in an attempt to improve the accuracy of clinical staging (18–28). **These modalities suffer from poor sensitivity and high false-negative rates.** Evaluation of the para-aortic lymph nodes with lymphangiography is associated with a false-positive rate of 20% to 40% and a false-negative rate of 10% to 20% (18–20). Overall, lymphangiography has a sensitivity of 79% and specificity of 73% (23). CT has poor sensitivity (34%) but excellent specificity (97%) (24). The accuracy of CT scanning is 80% to 85%; the false-negative rate is 10% to 15%, and the false-positive rate is 20% to 25% (19–21). Ultrasound has a high false-negative rate (30%), low sensitivity (19%), but high specificity (99%) (22). Early data showed that MRI results were comparable to those of CT scanning, a finding confirmed on meta-analysis (24,25). **A systematic review comparing CT scan with MRI showed that MRI is significantly more sensitive with equivalent specificity.** MRI has excellent sensitivity

on T2-weighted images for the detection of parametrial disease (26).

PET scans are increasingly being utilized alone or in conjunction with CT or MRI to detect metastatic disease. Studies suggest that PET may be more useful than other imaging techniques for the detection of extrapelvic disease, with comparable or better sensitivity and specificity (27). A meta-analysis of 72 studies found PET (75%, 98%) to have superior sensitivity and specificity compared with CT (58%, 92%) and MRI (56%, 93%) for the detection of lymph node metastases (28). PET scans may be better predictors of eventual treatment outcome. Although these studies show promise for the use of PET scans in detecting metastases, its sensitivity in detecting pelvic nodal disease may be limited (29). Integrated PET/CT imaging may prove more sensitive than PET alone, especially for the detection of pelvic adenopathy.

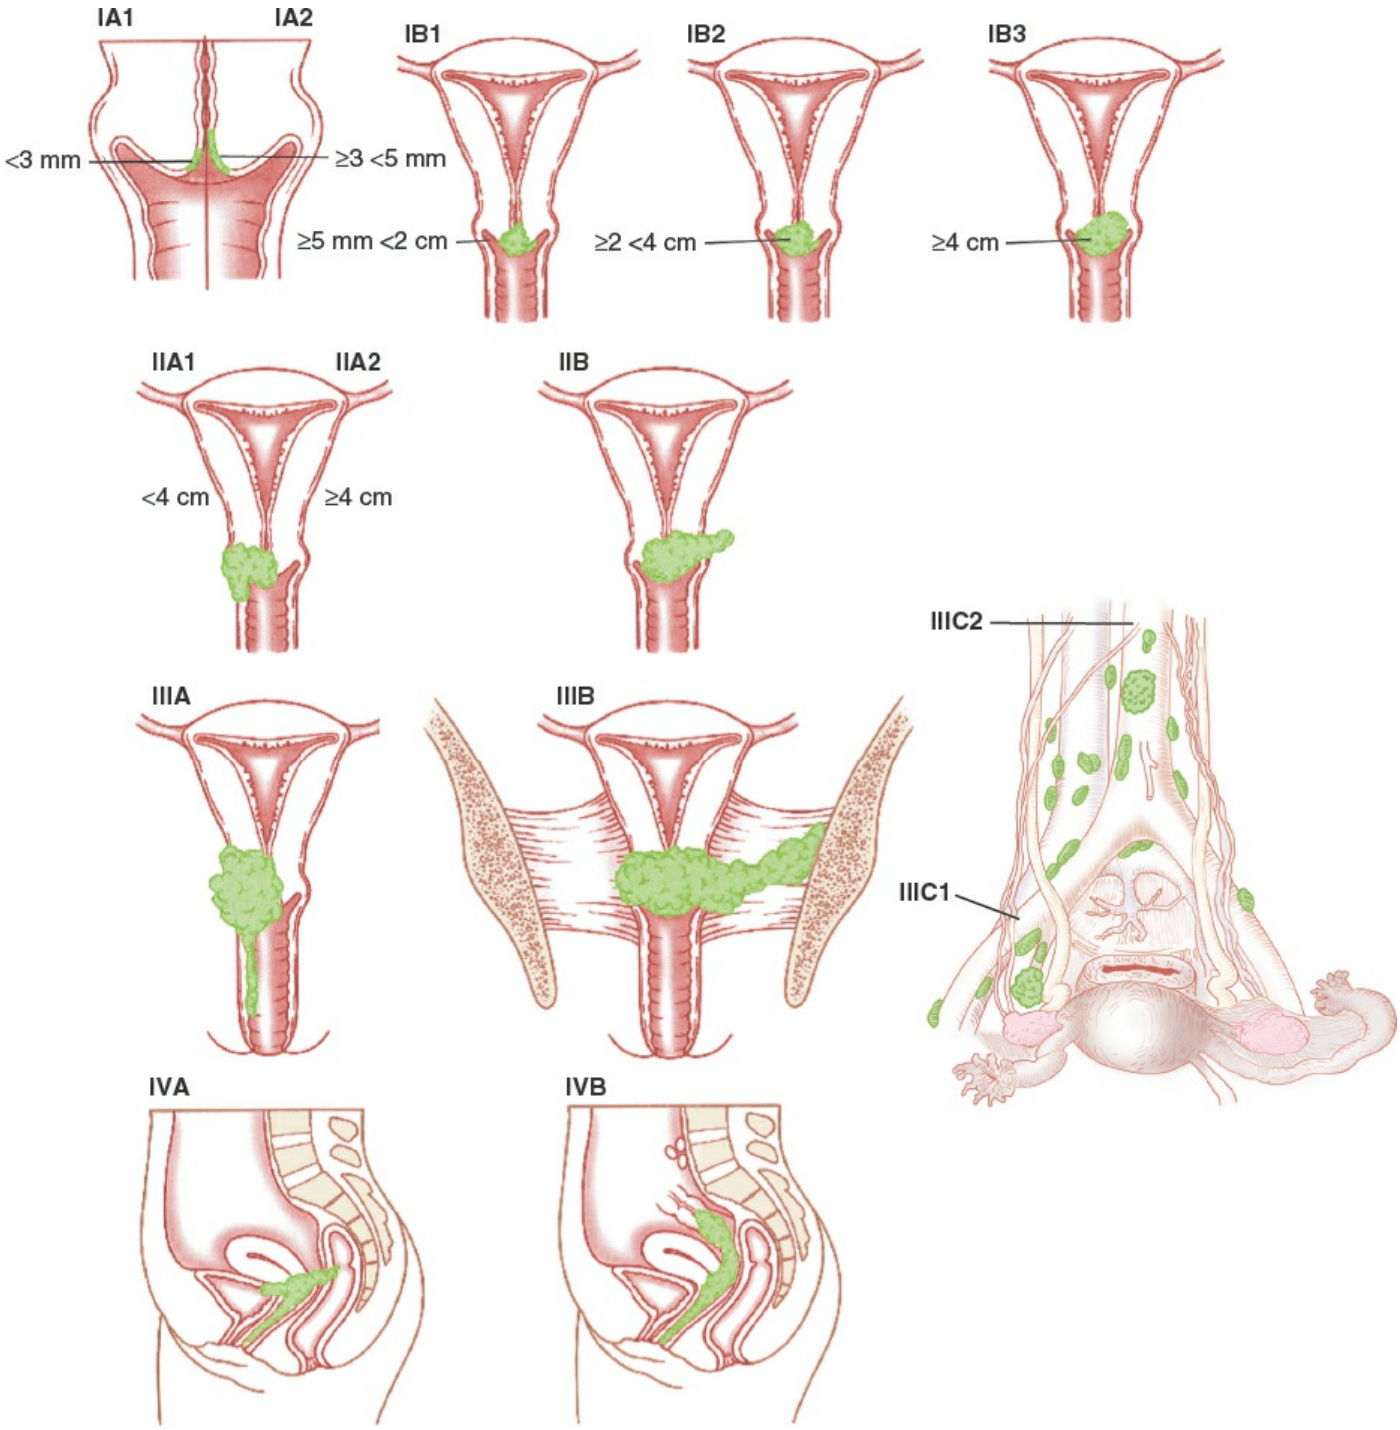

FIGURE 38-3 FIGO Cervical Cancer Staging (2018). (Adapted from **Benedet J, Odicino F, Maisonneuve P, Beller U, Creasman W, Heintz A, Ngan H, and Pecorelli S.** Carcinoma of the cervix uteri. *International Journal of Gynecology & Obstetrics*. 2003;83:41–78.)

When abnormalities are noted on CT, MRI, or PET, radiographic-guided fine-needle aspirations (FNA) can be performed to confirm metastatic disease and individualize treatment planning. [4] The FIGO 2018 staging system incorporates imaging and pathologic measurements in determining the size and extent of the primary tumor and the presence of pelvic and para-aortic metastasis.

The accuracy of clinical staging is limited, and surgical evaluation, although not practical or feasible in all patients, can more accurately identify metastatic disease (30).

Pathology

Squamous Cell Carcinoma

Invasive squamous cell carcinoma is the most common variety of invasive cancer in the cervix. [3] Histologically, variants of squamous cell carcinoma include **large cell keratinizing, large cell nonkeratinizing, and small cell types** (31). Large cell keratinizing tumors consist of tumor cells forming irregular infiltrative nests with laminated keratin pearls in the center. Large cell nonkeratinizing carcinomas reveal individual cell keratinization but do not form keratin pearls **(Fig. 38-4)**. The category of small-cell carcinoma includes poorly differentiated squamous cell carcinoma and small-cell anaplastic carcinoma. If possible, these two tumors should be differentiated. The former contains cells that have small-to-medium-sized nuclei and more abundant cytoplasm than those of the latter. The designation of small-cell anaplastic carcinoma should be reserved for lesions resembling oat cell carcinoma of the lung. Small-cell anaplastic carcinoma infiltrates diffusely and consists of tumor cells that have scanty cytoplasm, round to oval small nuclei, coarsely granular chromatin, and high mitotic activity. The nucleoli are absent or small. **Immunohistochemistry or electron microscopy can differentiate the small-cell neuroendocrine tumors.** Patients with the large cell type of carcinoma, with or without keratinization, have a better prognosis than those with the small-cell variant. Small-cell anaplastic carcinomas behave more aggressively than poorly differentiated squamous carcinomas that contain small cells. Infiltration of parametrial tissue and pelvic lymph node metastasis affect the prognosis.

Table 38-2 FIGO Clinical Staging of Carcinoma of the Cervix Uteri (2008)

Stage I	The carcinoma is strictly confined to the cervix (extension to the corpus would be disregarded)
IA	Invasive carcinoma which can be diagnosed only by microscopy, with deepest invasion ≤5 mm and largest extension ≤7 mm
IA1	Measured stromal invasion of ≤3.0 mm in depth and extension of ≤7.0 mm
IA2	Measured stromal invasion of >3.0 mm and not >5.0 mm with an extension of not >7.0 mm
IB	Clinically visible lesions limited to the cervix uteri or preclinical cancers greater than stage IA[a]
IB1	Clinically visible lesion ≤4.0 cm in greatest dimension
IB2	Clinically visible lesion >4.0 cm in greatest dimension

Stage II	Cervical carcinoma invades beyond the uterus, but not to the pelvic wall or to the lower third of the vagina
IIA	Without parametrial invasion
IIA1	Clinically visible lesion ≤4.0 cm in greatest dimension
IIA2	Clinically visible lesion >4 cm in greatest dimension
IIB	With obvious parametrial invasion
Stage III	The tumor extends to the pelvic wall and/or involves lower third of the vagina and/or causes hydronephrosis or nonfunctioning kidney[b]
IIIA	Tumor involves lower third of the vagina, with no extension to the pelvic wall
IIIB	Extension to the pelvic wall and/or hydronephrosis or nonfunctioning kidney
Stage IV	The carcinoma has extended beyond the true pelvis or has involved (biopsy proven) the mucosa of the bladder or rectum. A bullous edema, as such, does not permit a case to be allotted to stage IV
IVA	Spread of the growth to adjacent organs
IVB	Spread to distant organs

[a]All macroscopically visible lesions, even those with superficial invasion, are allotted to stage IB carcinomas. Invasion is limited to a measured stroma invasion with a maximal depth of 5.0 mm and a horizontal extension greater than 7.0 mm. Depth of invasion should not be greater than 5 mm taken from the base of the epithelium of the original tissue squamous or glandular. The depth of invasion should always be reported in millimeters, even those cases with “early minimal stromal invasion” (~1 mm). The involvement of vascular/lymphatic spaces should not change stage allotment.

[b]On rectal examination, there is no cancer-free space between the tumor and the pelvic wall. All cases with hydronephrosis or nonfunctioning kidney are included, unless they are known to be due to another cause.

FIGO Committee on Gynecologic Oncology. Revised FIGO staging for carcinoma of the vulva, cervix, and endometrium. *Int J Obstet Gynecol* 2009;105:103–104.

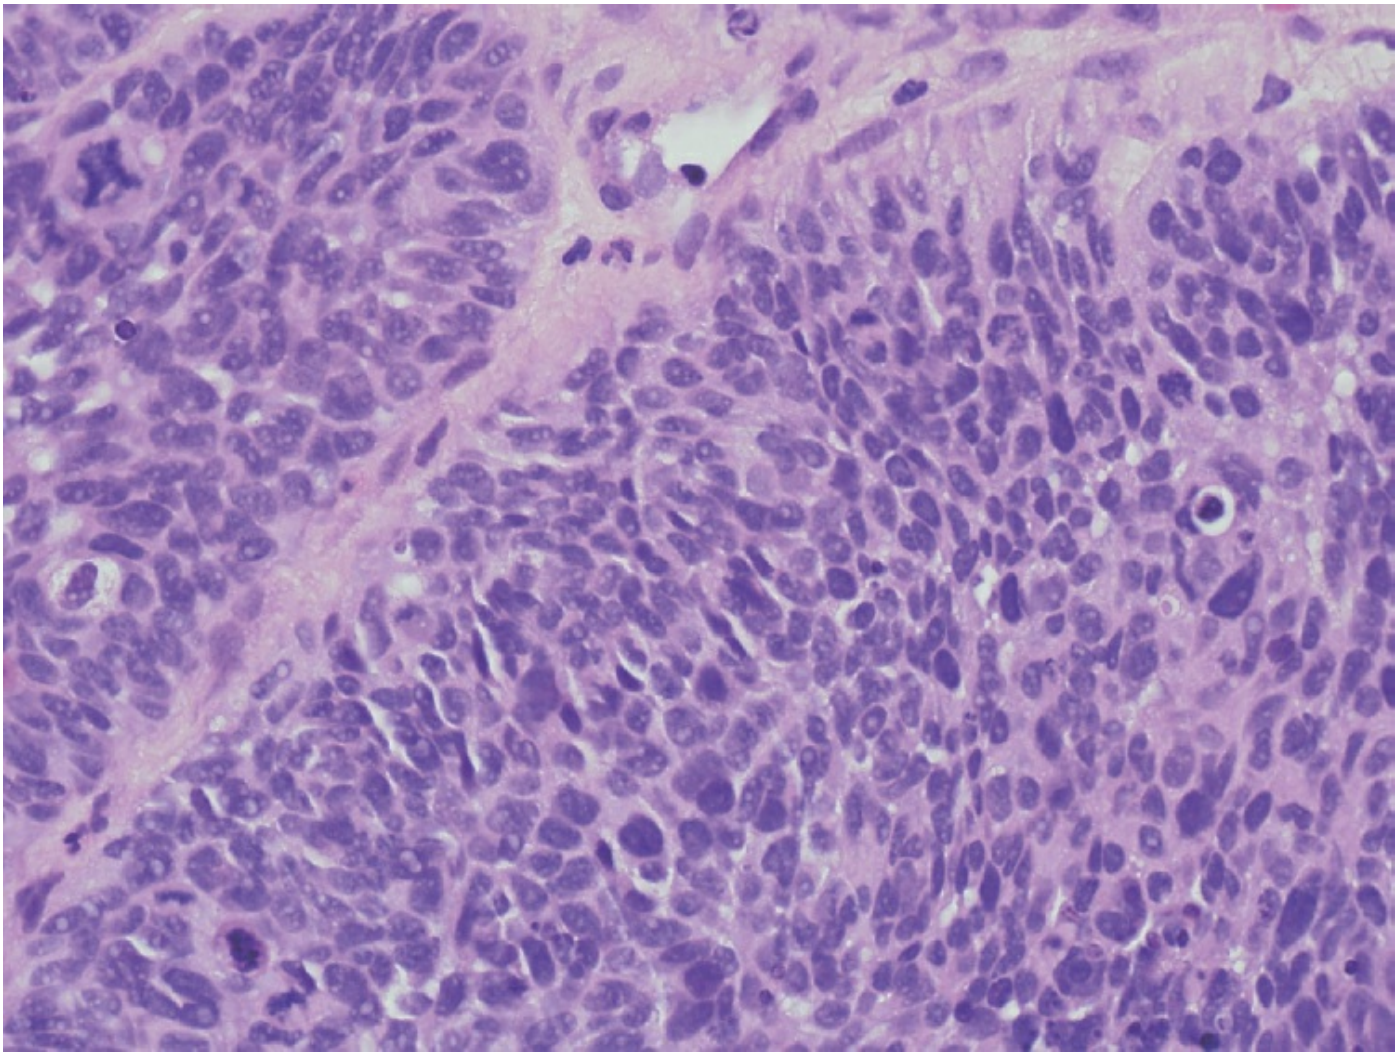

FIGURE 38-4 Invasive squamous cell carcinoma, large cell nonkeratinizing type. Tumor cells form irregular nests and have abundant eosinophilic cytoplasm and distinct cell borders indicative of squamous differentiation.

Other less common variants of squamous carcinoma include **verrucous carcinoma** and **papillary (transitional) carcinoma.** Verrucous carcinomas may resemble giant condyloma acuminatum, are locally invasive, and rarely metastasize. Papillary carcinomas histologically resemble transitional cells of the bladder and may have more typical squamous cell invasion at the base of the lesion. Papillary carcinomas behave and are treated in a manner similar to traditional squamous cell cancers, except that late recurrences were noted.

Adenocarcinoma

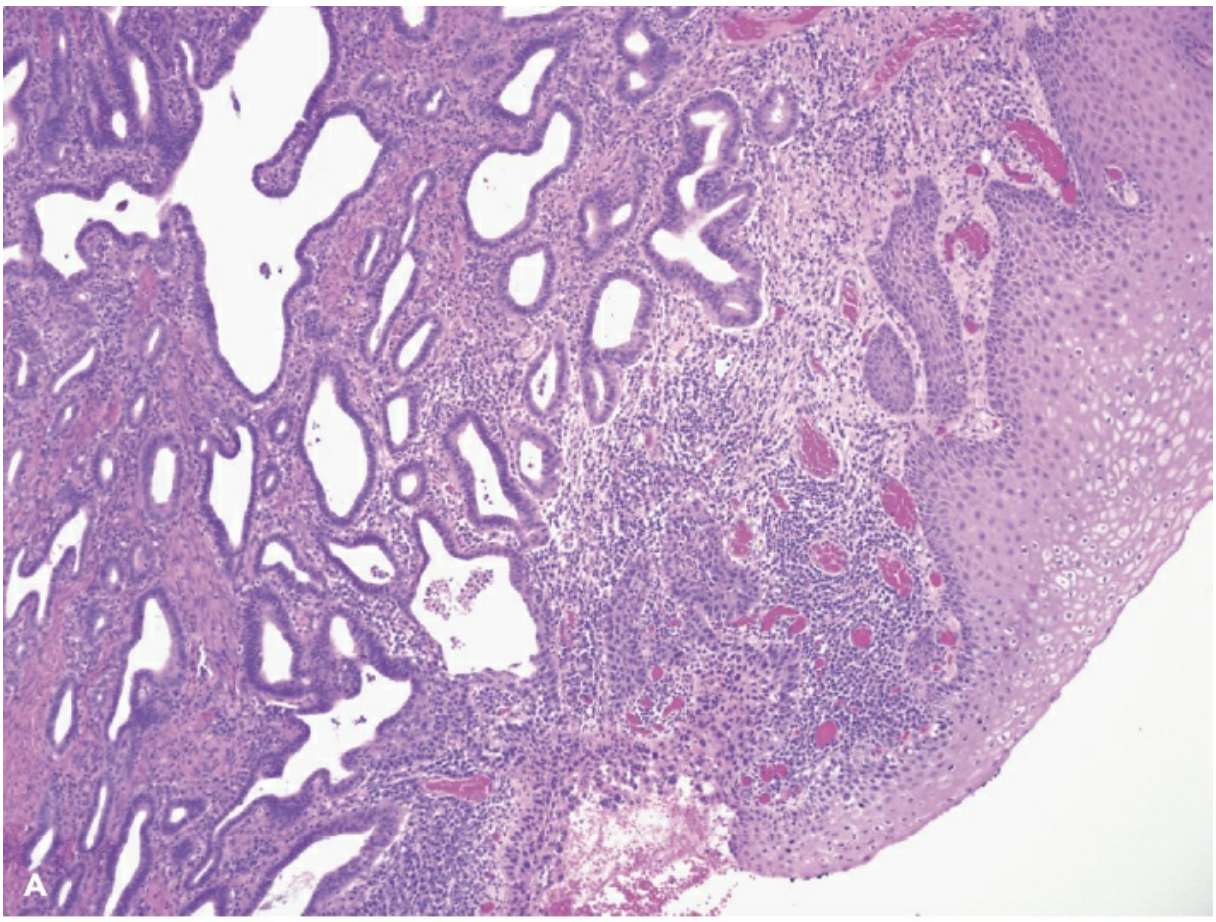
There are an increasing number of cervical adenocarcinomas reported in women in their 20s and 30s. [3] Although the total number of cases of adenocarcinoma is relatively stable, this disease is appearing more frequently in young women, especially as the number of cases of invasive squamous cell carcinoma decreases.

Older reports indicated that 5% of all cervical cancers were adenocarcinomas, whereas newer reports show a proportion as high as 18.5% to 27% (32–34). Much of this proportional increase is related to a decreasing incidence of squamous carcinoma secondary to screening programs (which are less accurate at identifying preinvasion adenocarcinoma), greater exposure to oral contraceptives, and a greater exposure to HPV (5,6).

Adenocarcinoma in situ (AIS) is believed to be the precursor of invasive adenocarcinoma, and it is not surprising that the two often coexist (35). In addition to AIS, intraepithelial or invasive squamous neoplasia occurs in 30% to 50% of cervical adenocarcinomas (36). A squamous intraepithelial lesion may be observed colposcopically on the ectocervix, and the coexistent adenocarcinoma often is higher in the cervical canal.

Patients with AIS who are treated with conization should undergo close clinical follow-up. Endocervical curettage, often used in surveillance, may miss residual or invasive disease, and false-negative rates as high as 50% were reported (37). In addition, skip lesions not resected at the time of conization may be present. For these reasons, hysterectomy should be considered the standard therapy for patients who have completed their childbearing. In two reports, patients with negative cone biopsy margins were followed conservatively, with few requiring repeat surgical procedures (38,39). Because cervical AIS tends to affect women during their reproductive years, a thorough discussion of risks and benefits should take place, and treatment should be individualized.

Adenocarcinoma of the cervix is managed in the same manner used for squamous cell carcinoma. Adenocarcinoma was believed to be associated with a worse prognosis and outcome when compared with squamous cell carcinoma. A study of 203 women with adenocarcinoma and 756 women with squamous carcinoma supported this assertion (33). This study showed 5-year survival rates of 90% versus 60%, 62% versus 47%, and 36% versus 8% for stages I, II, and III, respectively. Although some attributed these rates to a relative resistance to radiation, they are more likely a reflection of the tendency of adenocarcinomas to grow endophytically and to be undetected until a large volume of tumor is present. Adenocarcinomas may be detected by cervical sampling, but less reliably so than squamous carcinomas. A definitive diagnosis often requires cervical conization. When adjusted for tumor size, it appears that there is no difference in prognosis between the two histologic subtypes. In a Gynecologic Oncology Group (GOG) review of patients treated with concurrent *cisplatin* chemotherapy with radiotherapy, survival was equivalent among squamous, adenocarcinoma, and adenosquamous carcinoma subgroups (40).



The clinical features of stage I adenocarcinomas are well studied (33,41,42). These studies identified size of tumor, depth of invasion, grade of tumor, and age of the patient as significant correlates of lymph node metastasis and survival. When matched with

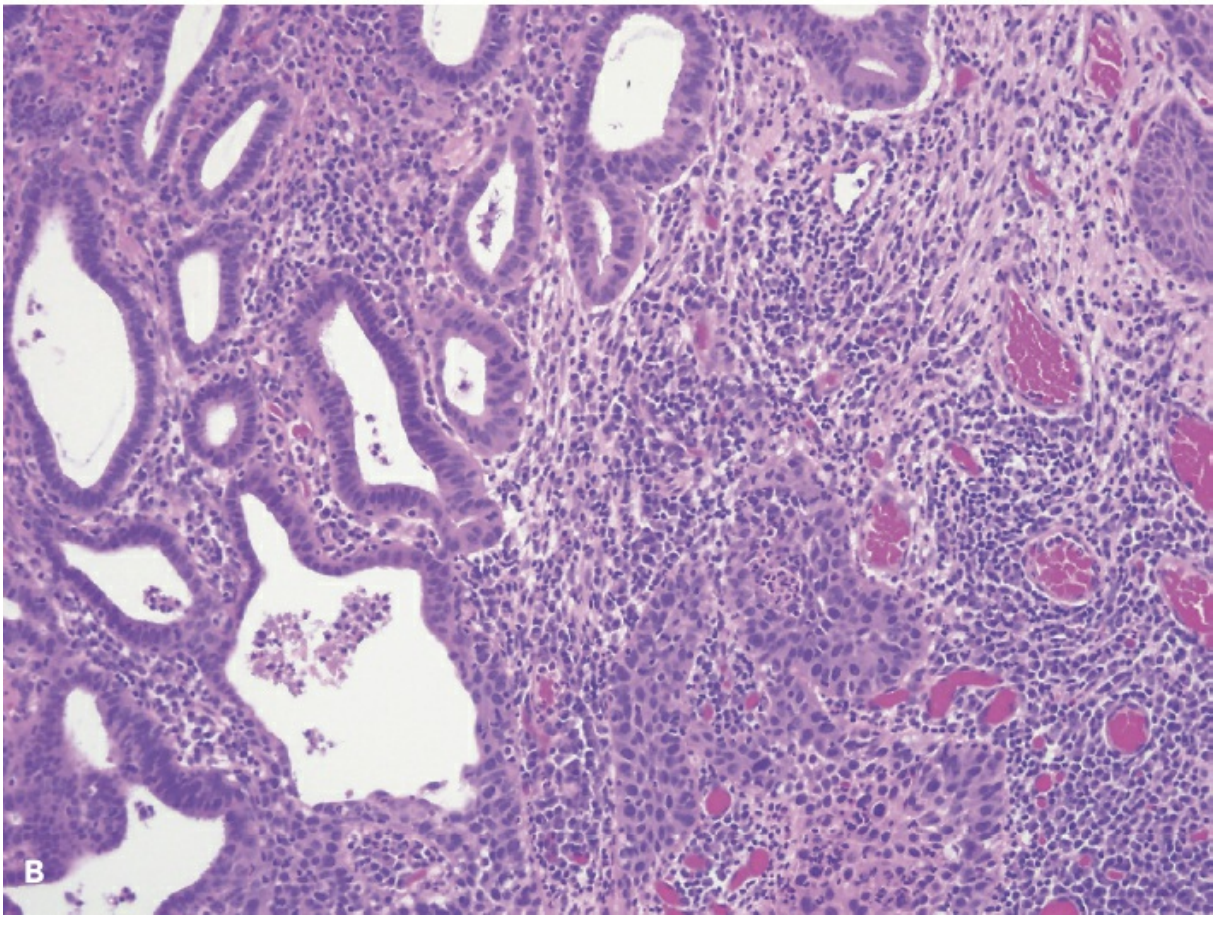
squamous carcinomas for lesion size, age, and depth of invasion, the incidence of lymph node metastases and the survival rate appear to be the same (41,42). **Patients with stage I adenocarcinomas can be selected for treatment according to the same criteria as for those with squamous cancers** (42).

The choice of treatment for bulky stages I and II tumors is controversial. Some advocated treatment with radiation alone, whereas others support radiation plus extrafascial hysterectomy (43–45). In 1975, Rutledge et al. reported an 85.2% 5-year survival rate for all patients with stage I disease treated with radiation alone and an 83.8% survival rate for those who had radiation plus surgery (44). The central persistent disease rate was 8.3%, compared with 4% for those who had radiation plus surgery. In stage II disease, the 5-year survival rate was 41.9% for radiation alone and 53.7% for radiation plus surgery. **A subsequent report revealed no significant difference in survival among patients treated with radiation alone or radiation plus extrafascial hysterectomy** (46).

Invasive adenocarcinoma may be pure **(Fig. 38-5A,B)** or mixed with squamous cell carcinoma. Within the category of pure adenocarcinoma, the tumors are quite heterogeneous, with a wide range of cell types, growth patterns, and differentiation (33). **About 80% of cervical adenocarcinomas consist predominantly of the endocervical type cells with mucin production. The remaining tumors are populated by endometrioid cells, clear cells, intestinal cells, or a mixture of more than one cell type. By histologic examination alone, some of these tumors are indistinguishable from those arising elsewhere in the endom etrium or ovary.** Within each cell type, the growth patterns and nuclear abnormalities vary according to the degree of differentiation. In well-differentiated tumors, tall columnar cells line the well-formed branching glands and papillary structures, whereas pleomorphic cells tend to form irregular nests and solid sheets in poorly differentiated neoplasms. The latter may require mucicarmine and periodic acid–Schiff (PAS) staining to confirm their glandular differentiation.

In a retrospective review of GOG trials of chemoradiation for cervix carcinoma, treatment with radiation alone was associated with worse overall survival (OS) in adenocarcinoma and adenosquamous carcinoma when compared with squamous carcinoma. In contrast, treatment with *cisplatin*-based chemoradiation was associated with similar progression-free and OS between the adenocarcinoma and squamous groups (40).

A



B

FIGURE 38-5 Invasive adenocarcinoma of the cervix, well differentiated. **A:** Irregular glands are lined with tall columnar cells with vacuolated mucinous cytoplasm resembling endocervical cells. **B:** Nuclear stratification, mild nuclear atypism, and mitotic figures are evident in higher power.

There are several special variants of adenocarcinoma. **Minimal deviation adenocarcinoma (adenoma malignum)** is an extremely well-differentiated form of adenocarcinoma in which the branching glandular pattern strongly simulates that of the normal endocervical glands. The lining cells have abundant mucinous cytoplasm and uniform nuclei (47,48). Because of this, the tumor may not be recognized as malignant in small biopsy specimens, thereby causing considerable delay in diagnosis. Special immunohistochemical staining may be required to establish the diagnosis. Earlier studies reported a dismal outcome for women with this tumor, but other studies found a favorable prognosis if the disease is detected early (49). Although rare, similar tumors were reported in association with endometrioid, clear, and mesonephric cell types (50).

An entity described as **villoglandular papillary adenocarcinoma** deserves special attention (51). It primarily affects young women, some of whom are pregnant or users of oral contraceptives. Histologically, the tumors have smooth, well-defined borders, are well differentiated, and are either in situ or superficially invasive. Follow-up information is encouraging. None of these tumors recurred after cervical conization or hysterectomy, and no metastasis was detected among women undergoing pelvic lymphadenectomy. This tumor appears to have limited risk for spread beyond the uterus.

Adenosquamous Carcinoma

Carcinomas with a mixture of malignant glandular and squamous components are known as **adenosquamous carcinomas.** Patients with adenosquamous carcinoma of the cervix were reported to have a poorer prognosis than those with pure adenocarcinoma or squamous carcinoma but a review of patients treated with *cisplatin*-based chemoradiation has shown no difference in survival among the three groups (52).

In mature adenosquamous carcinomas, the glandular and squamous carcinomas are readily identified on routine histologic evaluation and do not cause diagnostic problems. **In poorly differentiated or immature adenosquamous carcinomas, glandular differentiation can be appreciated only with special stains, such as mucicarmine and PAS.** In one study, 30% of squamous cell carcinomas demonstrated mucin secretion when stained with mucicarmine (50). These squamous cell carcinomas with mucin secretion have a higher incidence of pelvic lymph node metastases than do squamous cell carcinomas without mucin secretion, and they are similar to the signet-ring variant of adenosquamous carcinoma (50,53).

Glassy cell carcinoma is recognized as a poorly differentiated form of adenosquamous carcinoma (53). Individual cells have abundant eosinophilic, granular, ground-glass cytoplasm, large round to oval nuclei, and prominent nucleoli. The stroma

is infiltrated by numerous lymphocytes, plasma cells, and eosinophils. Approximately half of these tumors contain glandular structures or stain positive for mucin. The poor diagnosis of this tumor is linked to understaging and resistance to radiotherapy.

Other variants of adenosquamous carcinoma include **adenoid basal carcinoma** and **adenoid cystic carcinoma.** Adenoid basal carcinoma simulates the basal cell carcinoma of the skin (54). Nests of basaloid cells extend from the surface epithelium deep into the underlying tissue. Cells at the periphery of tumor nests form a distinct parallel nuclear arrangement, so-called peripheral palisading. An "adenoid" pattern occasionally develops, with "hollowed-out" nests of cells. Mitoses are rare, and the tumor often extends deep into the cervical stroma.

Adenoid cystic carcinoma of the cervix behaves much like such lesions elsewhere in the body. The tumors tend to invade into the adjacent tissues and metastasize late, often 8 to 10 years after the primary tumor was removed. Like other adenoid cystic tumors, they may metastasize directly to the lung. The pattern simulates that of the adenoid basal tumor, but there is a cystic component, and the glands of the cervix are involved (54). Mitoses may be seen but are not numerous.

Sarcoma

The most important sarcoma of the cervix is **embryonal rhabdomyosarcoma,** which occurs in children and young adults. The tumor has grapelike polypoid nodules, known as botryoid sarcoma, and the diagnosis depends on the recognition of rhabdomyoblasts. **Leiomyosarcomas** and **mixed mesodermal tumors** involving the cervix may be primary but are more likely to be secondary to uterine tumors. **Cervical adenosarcoma** is described as a low-grade tumor with a good prognosis (55).

Malignant Melanoma

On rare occasions, melanosis is seen in the cervix. **Malignant melanoma** may arise de novo in this area. Histopathologically, it simulates melanoma elsewhere, and the prognosis depends on the depth of invasion into the cervical stroma.

Neuroendocrine Carcinoma

The classification of neuroendocrine cervical carcinoma includes four histologic subtypes: **(i) small cell, (ii) large cell, (iii) classical carcinoid,** and **(iv) atypical carcinoid** (56). Neuroendocrine tumors of the cervix are rare, and treatment regimens are based on small case series of patients.

Small-cell (neuroendocrine type) carcinoma of the cervix is aggressive in nature and is similar to cancer arising from the bronchus (57). The hallmark of neuroendocrine tumors is their aggressive malignant behavior with the propensity to metastasize. At the time of diagnosis, it is usually disseminated, with bone, brain, liver, and bone marrow being the most common sites of metastases. In one study of 11 patients

with disease apparently confined to the cervix, a high rate of lymph node metastasis was noted (58). Pathologically, the diagnosis is aided by the finding of neuroendocrine granules on electron microscopy and by immunoperoxidase studies that are positive for a variety of neuroendocrine proteins such as calcitonin, insulin, glucagon, somatostatin, gastrin, and adrenocorticotropic hormone (ACTH). In addition to the traditional staging for cancer of the cervix, these patients should undergo bone, liver, and brain scanning, bone marrow aspiration, and biopsy to evaluate the possibility of metastatic disease. Therapy consists of surgery, chemotherapy, and radiation. Because patients with early-stage disease have distant metastases, multimodal therapy is recommended. The main active chemotherapeutic agent is *etoposide*.

Local therapy alone gives almost no chance of cure of small-cell carcinoma. Regimens of combination chemotherapy improved the median survival rates in small-cell bronchogenic carcinoma, and these regimens are used for treatment of small-cell carcinoma of the cervix. Combination chemotherapy may consist of *vincristine*, *doxorubicin*, and *cyclophosphamide* (*VAC*) or *VP-16* (*etoposide*) and *cisplatin* (*EP*) (59). Patients must be monitored carefully because they are at high risk for developing recurrent metastatic disease (60).

Patterns of Spread

Cancer of the cervix spreads by (i) direct invasion into the cervical stroma, corpus, vagina, and parametrium; (ii) lymphatic metastasis; (iii) blood-borne metastasis; and (iv) intraperitoneal implantation. The incidence of pelvic and para-aortic nodal metastasis is shown in Table 38-3.

The cervix is commonly involved in cancer of the endometrium and vagina. The latter is rare, and most lesions that involve the cervix and vagina are designated cervical primaries. Consequently, the clinical classification is that of cervical neoplasia extending to the vagina, rather than vice versa. Endometrial cancer may extend into the cervix by three modes: direct extension from the endometrium, submucosal involvement by lymph vascular extension, and multifocal disease. The latter is most unusual, but occasionally a focus of adenocarcinoma may be seen in the cervix, separate from the endometrium. This lesion should not be diagnosed as metastasis but rather as multifocal disease. Malignancies involving the peritoneal cavity (e.g., ovarian cancer) may be found in the cul-de-sac and extend directly into the vagina and cervix. Carcinomas of the urinary bladder and colon occasionally extend into the cervix. Cervical involvement by lymphoma, leukemia, and carcinoma of the breast, stomach, and kidney is usually part of the systemic pattern of spread for these malignancies. Isolated metastasis to the cervix in such cases may be the first sign of a primary tumor elsewhere in the body.

Table 38-3 Incidence of Pelvic and Para-Aortic Lymph Node Metastasis by Stage Based on FIGO Clinical Staging (2008)

Stage	No. of Patients	Positive Pelvic Nodes (%)	Positive Para-Aortic Nodes (%)
IA1 (≤3 mm)	179[a]	0.5	0
IA2 (>3–5 mm)	84[a]	4.8	<1
IB	1,926[b]	15.9	2.2
IIA	110[c]	24.5	11
IIB	324[c]	31.4	19
III	125[c]	44.8	30
IVA	23[c]	55	40

Treatment Options

The treatment of cervical cancer is similar to the treatment of any other type of malignancy in that both the primary lesion and potential sites of spread should be evaluated and treated. The therapeutic modalities for achieving this goal include primary treatment with surgery, radiotherapy, chemotherapy, or **[5]** chemoradiation. **While radiation therapy can be used in all stages of disease, surgery is limited to patients with stages I to IIA disease. The 5-year survival rate for stage I cancer of the cervix is approximately 85% with either radiation therapy or radical hysterectomy.** A study using the National Cancer Institute's Surveillance Epidemiology and End Results data by an intent-to-treat analysis showed that patients in the surgery arm had an improved survival when compared with patients in the radiation arm (61). Optimal therapy consists of radiation, or surgery alone, to limit the increased morbidity that occurs when the two treatment modalities are combined. Recent improvements in the treatment of cervical carcinoma include adjuvant chemoradiation in patients discovered to have high-risk cervical carcinoma after radical hysterectomy and in patients with locally advanced cervical carcinoma.

Surgery

There are advantages to the use of surgery instead of radiotherapy, particularly in younger women for whom conservation of the ovaries is important. Chronic bladder and bowel problems that require medical or surgical intervention occur in up to 8% of

patients undergoing radiation therapy (62). Such problems are difficult to treat because they result from fibrosis and decreased vascularity. This is in contrast to surgical injuries, which usually can be repaired without long-term complications. Sexual dysfunction is less likely to occur after surgical therapy than radiation, because of vaginal shortening, fibrosis, and atrophy of the epithelium associated with radiation. Surgical therapy shortens the vagina, but gradual lengthening can be brought about by sexual activity. The epithelium does not become atrophic because it responds either to endogenous estrogen or to exogenous estrogens if the patient is postmenopausal.

Radical hysterectomy is reserved for women who are in good physical condition. Advanced chronologic age should not be a deterrent. With improvements in anesthesia, elderly patients withstand radical surgery almost as well as their younger counterparts (63). **It is prudent not to operate on lesions that are larger than 4 cm in diameter because these patients will require postoperative radiation therapy.** When selected in this manner, the urinary fistula rate is less than 2%, and the operative mortality rate is less than 1% (64,65). A summary of the management of cervical cancer is presented in Table 38-4.

If radiation therapy is needed, transposing the ovaries out of the planned radiation field may preserve ovarian function. Although transposition provides some protection, studies suggest that normal ovarian function is preserved in fewer than 50% of patients (66,67). Metastasis to the ovaries occurs in 0.9% of cases of early-stage cervical cancer, so preservation of the ovaries, particularly with adenocarcinoma, may confer a small recurrence risk (68).

Cone Biopsy of the Cervix

Cone biopsy of the cervix serves a diagnostic and therapeutic role in cervical cancer. The procedure is indicated to confirm the diagnosis of cancer, and to definitively treat stage IA1 disease when preservation of fertility is desired. For effective treatment, there must be no evidence of lymph–vascular space invasion, and both endocervical margins and curettage findings must be negative for cancer or dysplasia. Because stage IA1 cancers have less than a 1% risk of lymph node metastasis, lymphadenectomy is not necessary. If the endocervical margin or curettage is positive for dysplasia or malignancy, further treatment is necessary because these findings are strong predictors of residual disease. For squamous cell carcinoma, the risk of residual disease is 4% if both the endocervical margin and curettage are negative for dysplasia or malignancy, 22% if the endocervical margin alone is positive, and 33% if both are positive (69). In cases of AIS, the status of the cone margins is particularly important, with residual preinvasive and invasive disease noted in up to 25% and 3%, respectively, of cases with negative margins, and up to 80% and 7%, respectively, in cases with positive margins (70,71).

Table 38-4 Management of Invasive Cancer of the Cervix by Stage

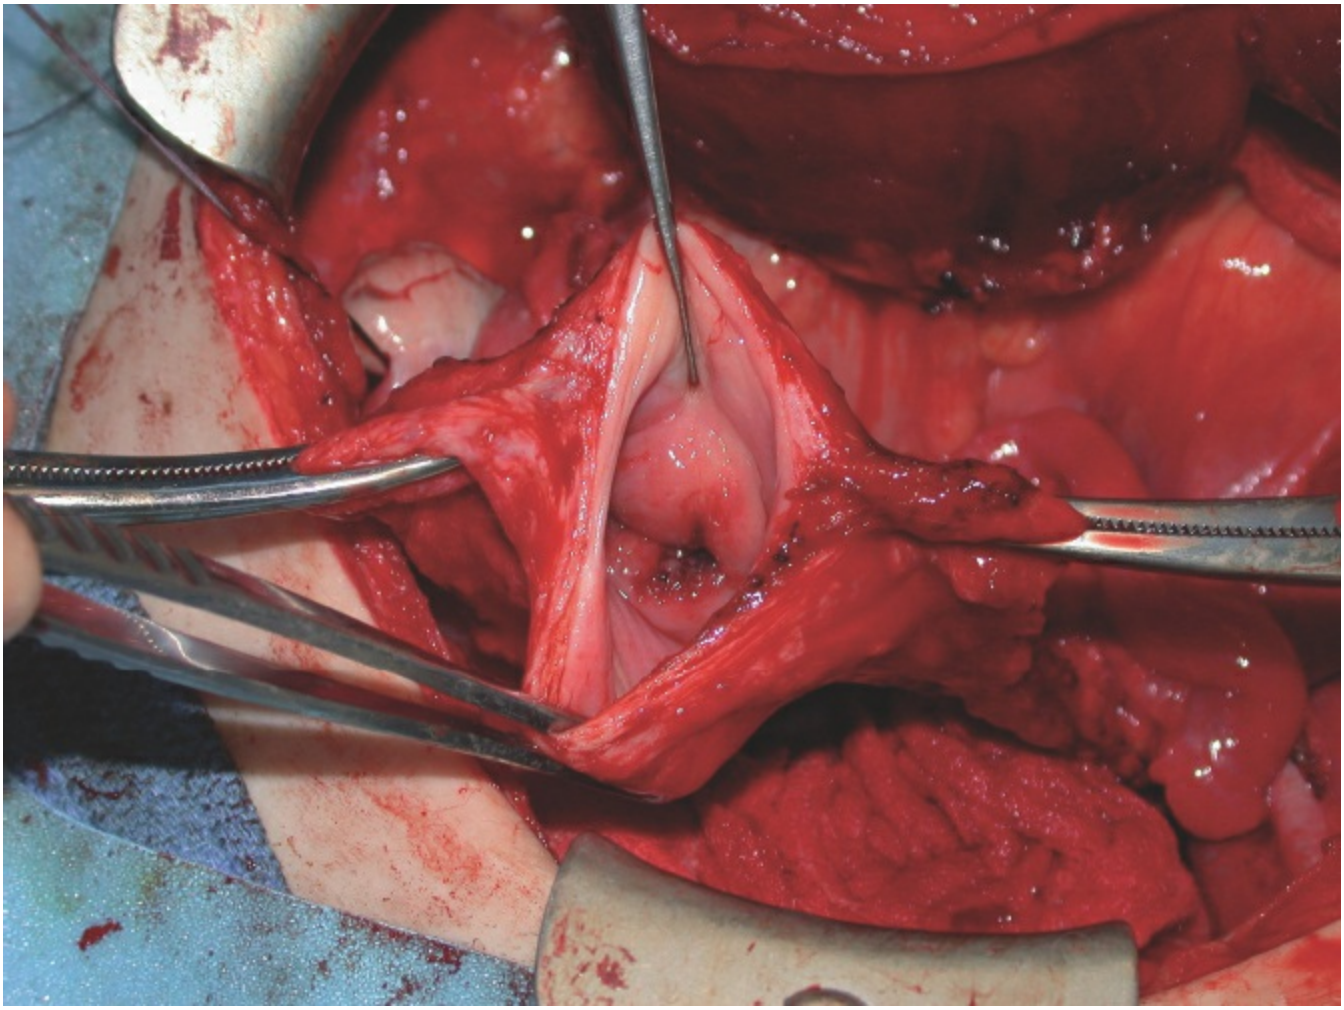
Stage	Disease	Treatment[a]
IA1	<3 mm - LVSI	Conization or Extrafascial Hyst
	<3 mm + LVSI	Modified Rad Trachel **or** Modified Rad Hyst + pelvic lymph **or** SLN
IA2	≥3 mm <5 mm	Modified Rad Trachel **or** Modified Rad Hyst + pelvic lymph **or** SLN
IB1	≥5 mm <2 cm	Mod Rad/Rad Trachel **or** Mod Rad/Rad Hyst + pelvic lymph **or** SLN
IB2	≥2 cm <4 cm	Rad Hyst + pelvic lymph
IB3	≥4 cm	Chemoradiation, pelvic field
IIA1	<4 cm + upper vagina	Rad Hyst + pelvic lymph **or** chemoradiation
IIA2	≥4 cm + upper vagina	Chemoradiation, pelvic field
IIB	+ Parametria not to pelvic wall	Chemoradiation, pelvic field
IIIA	+ Lower vagina	Chemoradiation, pelvic field
IIIB	+ Pelvic wall or hydronephrosis	Chemoradiation, pelvic ± extended field
IIIC1	+ Pelvic lymph nodes	Chemoradiation, pelvic ± extended field
IIIC2	+ Para-aortic lymph nodes	Chemoradiation, pelvic + extended field + systemic chemotherapy
IVA	+ Adjacent pelvic organs	Chemoradiation, pelvic + extended field **or** pelvic exenteration
IVB	+ Distant organs	Systemic chemotherapy ± radiation, pelvic or modified field

LVSI, lymphvascular space invasion; Mod, modified; Rad, radical; Trachel, trachelectomy; Hyst, hysterectomy; lymph, lymphadenectomy; SLN, sentinel lymph node biopsy in selected cases.

[a]Treatment recommendations must be individualized based on the patient's status and specific disease variables.

Simple (Extrafascial) Hysterectomy

Type I hysterectomy is an appropriate therapy for patients with stage IA1 tumors without lymph–vascular space invasion who are not desirous of future fertility. In such cases, lymphadenectomy is not recommended. If lymph-vascular space invasion is found, a type II modified radical hystectormy with pelvic sentinel lymph node biospy or lymphandectomy is appropriate.



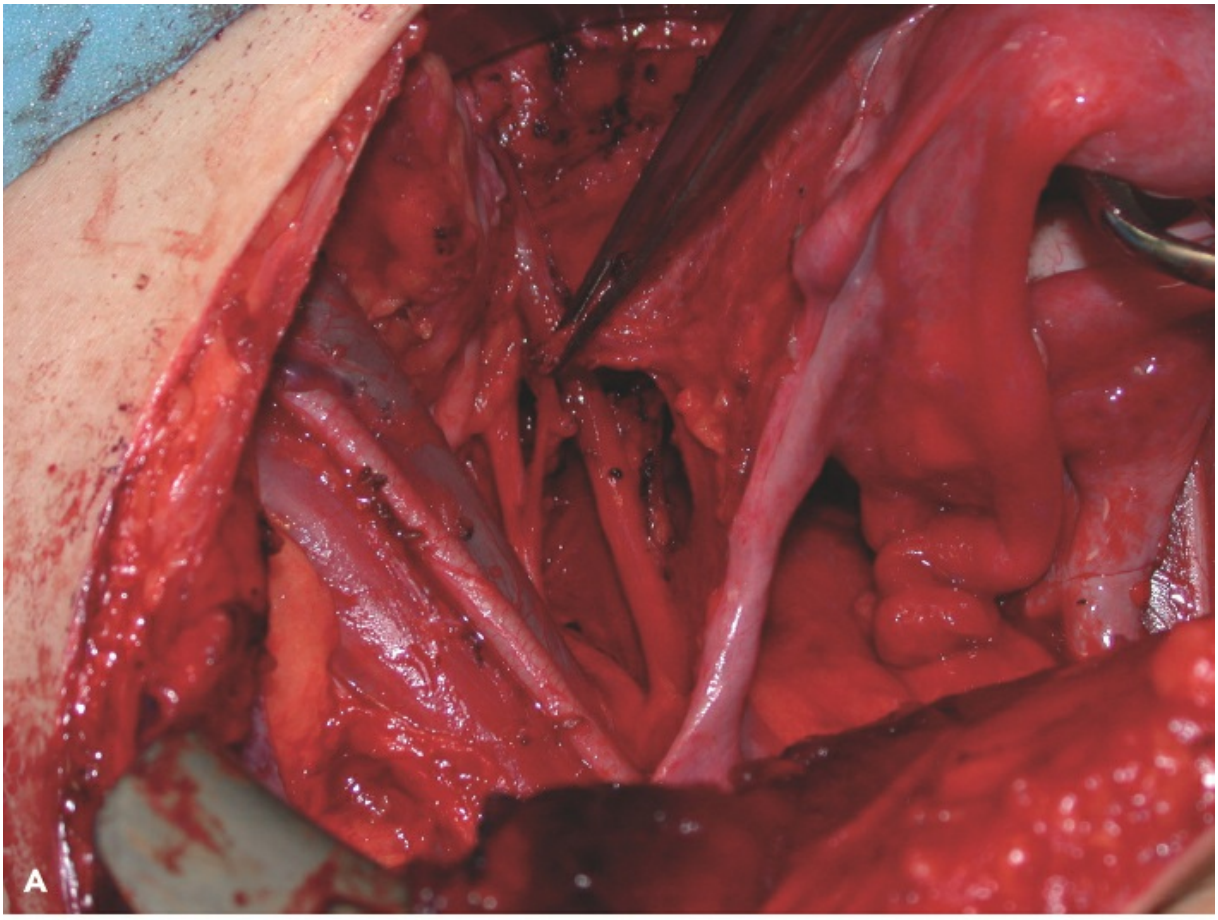


FIGURE 38-6 Abdominal radical trachelectomy.

Radical Trachelectomy

Radical trachelectomy is a procedure that is gaining popularity as a surgical management option for women with stage 1A2 and IB1 disease who desire uterine preservation and fertility. This procedure may be performed vaginally, abdominally, laparoscopically, or robotically (Fig. 38-6), and it usually is accompanied by pelvic lymphadenectomy and cervical cerclage placement. The risk of positive pelvic lymph nodes with stage IA2 cancer may be as high as 8%, indicating the need for lymphadenectomy. Lymphadenectomy may be performed laparoscopically, robotically, or by the open laparotomy technique. Experience with this therapeutic modality is limited, although early results are promising, and it is uncertain whether the long-term outcome is similar to that of traditional therapy. **Patients who are ideal candidates for this procedure have tumors less than 2 cm in diameter and have negative lymph nodes (2018 FIGO Stage IB1).** Lymphadenectomy can be performed at the beginning of the procedure, and depending on those results, the procedure can be continued or abandoned. A retrospective trial comparing patients who had tumors with these

attributes and were treated with either laparoscopic radical hysterectomy or laparoscopic radical trachelectomy showed similar outcomes and recurrence (72). There are limited data on subsequent pregnancy outcomes after radical trachelectomy; however, successful outcomes were reported. A study found that for women attempting to conceive after radical trachelectomy, the 5-year cumulative pregnancy rate was 52.8%, with an increased risk of miscarriage (73). Although radical trachelectomy and lymphadenectomy are performed with curative intent, it should be remembered that if a recurrence develops, definitive therapy with surgery or radiation is necessary.

FIGURE 38-7 A: Radical hysterectomy. An intraoperative photograph showing the lateral dissection during a radical hysterectomy. Note the ureter running beneath the uterine artery (tissue in the clamp). **B:** Radical hysterectomy specimen.

Radical Hysterectomy

The **radical hysterectomy (Fig. 38-7A,B)** performed most often in the United States is that described by Meigs in 1944 (74). **The operation includes pelvic lymphadenectomy along with removal of most of the uterosacral and cardinal ligaments and the upper one-third of the vagina. This operation is referred to as type III radical hysterectomy** (75).

The hysterectomy described by Wertheim is less extensive than a radical hysterectomy and removes the medial half of the cardinal and uterosacral ligaments (65). **This procedure is often referred to as modified radical or type II hysterectomy.** Wertheim's original operation did not include pelvic lymphadenectomy but instead included selective removal of enlarged lymph nodes. **The modified radical hysterectomy (type II) differs from the radical hysterectomy (type III) in the following ways:**

1. **The uterine artery is transected at the level of the ureter, thus preserving the ureteral branch to the ureter.**
2. **The cardinal ligament is not divided near the sidewall but instead is divided close to its midportion near the ureteral dissection.**
3. **The anterior vesicouterine ligament is divided, but the posterior vesicouterine ligament is conserved.**
4. **A smaller margin of vagina is removed.**

Radical hysterectomies can be further classified as extended radical hysterectomy (type IV and type V). In the type IV operation, the periureteral tissue, superior vesicle artery, and as much as three-fourths of the vagina are removed. In the type V operation, portions of the distal ureter and bladder are resected. This procedure is rarely performed because radiotherapy should be used when such extensive disease is encountered (75).

The abdomen is opened through a midline incision or a low transverse incision after the methods of Maylard or Cherney. The low transverse incision requires division of the rectus muscles and provides excellent exposure of the lateral pelvis. It allows adequate pelvic lymphadenectomy and wide resection of the primary tumor. After the abdomen is entered, the peritoneal cavity is explored to exclude metastatic disease. The stomach is palpated to ensure that it has been decompressed to facilitate packing of the intestines. The liver is palpated, and the omentum is inspected for

metastases. Both kidneys are palpated to ensure their proper placement and lack of congenital and other abnormalities. The para-aortic nodes are palpated transperitoneally.

During exploration of the pelvis, the fallopian tubes and ovaries are inspected for any abnormalities. **In premenopausal patients, the ovaries can be conserved.** The peritoneum of the vesicouterine fold and the rectouterine pouch should be inspected for signs of tumor extension or implantation. The cervix is palpated between the thumb anteriorly and the fingers posteriorly to determine its extent, and the cardinal ligaments are palpated for evidence of lateral tumor extension or nodularity.

Lymphadenectomy

After inspection of the abdomen and pelvis, the pelvic and para-aortic lymph nodes should be inspected and palpated. Lymph nodes suspicious for gross disease should be excised and evaluated by frozen section. If metastatic disease is identified, consideration should be given to abandoning radical surgery in favor of primary chemoradiation therapy. If the patient has no gross evidence of metastatic disease, the pelvic lymphadenectomy is begun.

Pelvic Lymphadenectomy

The pelvic lymphadenectomy is begun by opening the round ligaments at the pelvic sidewall and developing the paravesical and pararectal spaces. The ureter is elevated on the medial flap by a Deaver retractor to expose the common iliac artery. The common iliac and external iliac nodes are dissected, with care taken to avoid injuring the genitofemoral nerve, which lies laterally on the psoas muscle. At the bifurcation of the common iliac artery, the external iliac node chain is divided into lateral and medial portions.

The lateral chain is stripped free from the artery to the circumflex iliac vein distally. A hemoclip is placed across the distal portion of the lymph node chain to reduce the incidence of lymphocyst formation. The medial chain is dissected. The obturator lymph nodes are dissected; for this procedure, the lymph nodes are grasped just under the external iliac vein, and traction is applied medially. In most patients, the obturator artery and vein are dorsal to the obturator nerve; however, 10% have an aberrant vein arising from the external iliac vein. The node chain is separated from the nerve and vessels and clipped caudally. Dissection continues cephalad to the hypogastric artery. The cephalad portion of the obturator space should be entered lateral to the external iliac artery and medial to the psoas muscle, where the remainder of the obturator node tissue can be dissected as far cephalad as the common iliac artery. Drainage of the pelvic and para-aortic lymph node beds is not performed because of the increase in complications in patients in whom drains were used (76).

Patients who have bulky cervical tumors or grossly positive pelvic nodes, or for whom frozen section evaluation will be performed, should undergo para-aortic

lymph node evaluation to determine the full extent of disease and to guide adjuvant therapy.

Para-Aortic Lymph Node Evaluation

The bowel is packed to expose the peritoneum overlying the bifurcation of the aorta. The peritoneum is incised medial to the ureter and over the right common iliac artery. A retractor is placed retroperitoneally to expose the aorta and the vena cava. Any enlarged para-aortic lymph nodes are removed, hemoclips are applied for hemostasis, and specimens are sent for analysis by frozen section. If the lymph nodes are positive for metastatic cancer, an option is to discontinue the operation and treat the patient with radiation therapy (74). If the lymph nodes are negative for disease, the left side of the aorta is palpated through the peritoneal incision with a finger passed under the inferior mesenteric artery. The lymph nodes on this side of the aorta are more lateral and nearly behind the aorta and the common iliac artery. If the left para-aortic lymph nodes appear healthy and the cervical tumor is small with no suspicious pelvic lymph nodes, these additional lymph nodes are not submitted for frozen-section analysis. If they are removed, they may be dissected through the incision made for the right para-aortic nodes, or they may be dissected after reflection of the sigmoid colon medially.

Development of Pelvic Spaces

The pelvic spaces are developed by sharp and blunt dissection **(Fig. 38-8)**.

The paravesical space is bordered by the following structures:

1. The obliterated umbilical artery running along the bladder medially
2. The obturator internus muscle along the pelvic sidewall laterally
3. The cardinal ligament posteriorly
4. The pubic symphysis anteriorly

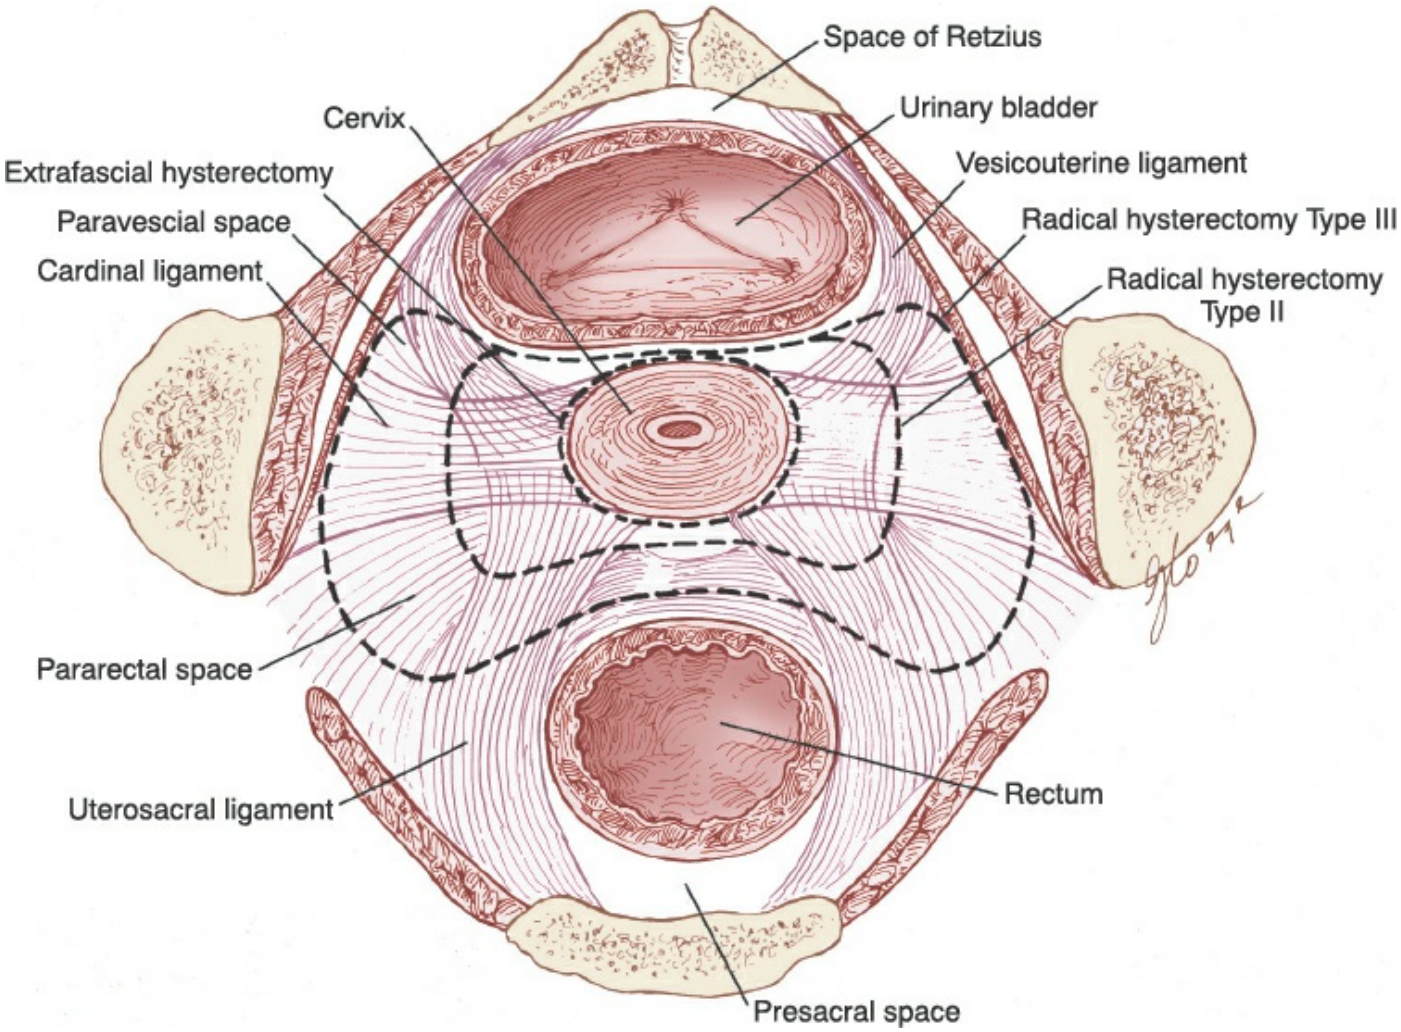

FIGURE 38-8 The pelvic ligaments and spaces. (From **Hacker NF, Vermorken JB.** Cervical cancer. In: Berek JS, Hacker NF. *Berek & Hacker's Gynecologic Oncology*. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:345.)

The attachments of the vagina to the tendinous arch form the floor of the paravesical space.

The pararectal space is bordered by the following structures:

1. Rectum medially
2. Cardinal ligament anteriorly
3. Hypogastric artery laterally
4. Sacrum posteriorly

The coccygeus (levator ani) muscle forms the floor of the pararectal space.

The development of these spaces before pelvic lymphadenectomy will aid in identification and dissection of the pelvic lymph nodes and dissection of the ureter as it passes into the vesicouterine ligament tunnel.

Dissection of the Bladder

The dissection of the bladder from the anterior part of the cervix and vagina is a critical step. Occasionally, tumor extension into the base of the bladder (which cannot be detected with cystoscopy) precludes adequate mobilization of the bladder flap, leading to the abandonment of the operation. Therefore, this portion of the operation should be undertaken early in the procedure. The bladder should be mobilized off of the upper third of the vagina to remove the tumor safely and with adequate margins.

Dissection of the Uterine Artery

The superior vesicle artery is dissected away from the cardinal ligament at a point near the uterine artery. **The uterine artery, which usually arises from the superior vesicle artery, is thus isolated and divided, preserving the superior vesicle arteries.** The uterine vessels are brought over the ureter by application of gentle traction. Occasionally, the uterine vein passes under the ureter.

Dissection of the Ureter

The ureter is dissected free from the medial peritoneal flap at the level of the uterosacral ligament. As the ureter passes near the uterine artery, there is a consistent arterial branch from the uterine artery to the ureter. This branch is sacrificed in the standard radical (type III) hysterectomy but preserved in the modified radical (type II) hysterectomy. Dissection of the ureter from the vesicouterine ligament (ureteral tunnel) may now be accomplished. If the patient has a deep pelvis, ligation of the uterosacral and cardinal ligaments may be undertaken first to bring the ureteral tunnel dissection closer to the operator. The roof of the ureteral tunnel is the anterior vesicouterine ligament. It should be ligated and divided to expose the posterior ligament. **The posterior ligament is divided in the radical (type III) hysterectomy but conserved in the modified radical (type II) hysterectomy.**

Posterior Dissection

The peritoneum across the cul-de-sac is incised, exposing the uterosacral ligaments. **The rectum is rolled free from the uterosacral ligaments, which are divided midway to the sacrum in a radical (type III) hysterectomy and near the rectum in the modified radical (type II) operation. This allows the operator to isolate and separate the cardinal ligament from the rectum.** A surgical clamp is placed on the cardinal ligament at the lateral pelvic sidewall in a radical hysterectomy and at the level of the ureteral bed in the modified radical procedure. A clamp is placed on the specimen side to maintain traction and to ensure that the full cardinal ligament is excised with the specimen. A right-angled clamp is placed caudad to this clamp across the paravaginal tissues. A second paravaginal clamp is usually needed to reach the vagina.

The vagina is entered anteriorly, and a suitable margin of proximal vagina is

removed with the specimen. More vaginal epithelium can be excised if necessary, depending on the previous colposcopic findings. The vaginal edge may be sutured in a hemostatic fashion and left open with a drain from the pelvic space or closed with a suction drain placed percutaneously. The ureteral fistula and pelvic lymphocyst rates from these two techniques are similar.

Complications of Radical Hysterectomy

Acute Complications

The acute complications of radical hysterectomy include (77):

- Blood loss (average, 0.8 L)
- Ureterovaginal fistula (1% to 2%)
- Vesicovaginal fistula (1%)
- Pulmonary embolus (1% to 2%)
- Small bowel obstruction (1%)
- Febrile morbidity (25% to 50%)

Febrile morbidity is most often caused by pulmonary infection (10%) and is seen frequently with pelvic cellulitis (7%) and urinary tract infection (6%). Wound infection, pelvic abscess, and phlebitis all occur in fewer than 5% of patients (78).

Subacute Complications

The subacute effects of radical hysterectomy are postoperative bladder dysfunction and lymphocyst formation. For the first few days after radical hysterectomy, bladder volume is decreased, and filling pressure is increased. The sensitivity to filling is diminished, and the patient is unable to initiate voiding. The cause of this dysfunction is unclear. It is important to maintain adequate bladder drainage during this time to prevent overdistention. Bladder drainage is usually accomplished with a suprapubic catheter. It is more comfortable for the patient and allows the physician to perform cystometrography and determine residual urine volume without the need for frequent catheterization. In addition, the patient is able to accomplish voiding trials at home by clamping the catheter, voiding, and releasing to check the residual urine level. Cystometrography may be performed 3 to 4 weeks after surgery. For the catheter to be discontinued, the patient must be able to sense the fullness of the bladder, initiate voiding, and void with a residual urine level of less than 75 to 100 mL. Otherwise, voiding trials should continue at home until these criteria can be fulfilled.

Lymphocyst formation occurs in fewer than 5% of patients, and the cause is uncertain (78). Adequate drainage of the pelvis after radical hysterectomy may be an important step in prevention. However, routine placement of retroperitoneal drains did not reduce this morbidity (75). Ureteral obstruction, partial venous obstruction, and

thrombosis may occur from lymphocyst formation. Simple aspiration of the lymphocyst is generally not curative, but percutaneous catheters with chronic drainage may allow healing. If this treatment is unsuccessful, operative intervention with excision of a portion of the lymphocyst wall and placement of either large bowel or omentum into the lymphocyst should be performed.

Chronic Complications

The most common chronic effect of radical hysterectomy is bladder hypotonia or, in extreme instances, atony. This condition occurs in about 3% of patients, regardless of the method of bladder drainage used (79,80). It may be a result of bladder denervation and not simply a problem associated with bladder overdistention (81). Voiding every 4 to 6 hours, increasing intra-abdominal pressure with Credé's maneuver, and intermittent self-catheterization may be used to manage bladder hypotonia.

Ureteral strictures are uncommon in the absence of postoperative radiation therapy, recurrent cancer, or lymphocyst formation (81). If the stricture is associated with lymphocyst formation, treatment of the lymphocyst usually alleviates the problem. Strictures that occur after radiation therapy should be managed with ureteral stenting. If a ureteral stricture is noted in the absence of radiotherapy or lymphocyst formation, recurrent carcinoma is the most common cause. A CT scan of the area of obstruction should be obtained and cytologic assessment by FNA should be performed if there is a target lesion to exclude carcinoma. If the results of these tests are negative, a ureteral stent may be placed to relieve the stricture. Close observation for recurrent carcinoma is necessary, and the diagnosis of recurrence may ultimately require laparotomy.

Nerve-Sparing Radical Hysterectomy

Nerve-sparing radical hysterectomies were described in an attempt to diminish the bladder dysfunction, sexual dysfunction, and colorectal motility disorders commonly encountered after traditional radical hysterectomy. Multiple techniques were described involving the identification of the pelvic autonomic nerves at the sacral promontory followed by various surgical methods of nerve preservation as the nerves transit the cardinal ligaments. These techniques are promising and in small series did reduce postoperative bladder dysfunction (82,83).

Minimally Invasive Radical Hysterectomy

[7] **Laparoscopic and Robotic Radical Hysterectomies were being performed with large degree of frequency in highly selected patients world wide.** The use of laparoscopy in cervical cancer patients is appealing because it may lead to less blood loss, improved cosmetic results, shorter duration of hospitalization, and faster recovery. In one large series of 200 women with stages IA1 to IIB cervical cancer treated with laparoscopic lymphadenectomy followed by radical vaginal hysterectomy, the authors found a 5-year survival rate comparable to patients treated with a similar abdominal

approach and a comparable rate of intraoperative complications (84).

One study reports comparable body mass index, operative times, parametrial margin, and number of lymph nodes collected when compared with open cases. Robotic cases had significantly shorter hospital stays and blood loss, while having significantly larger incidence of postoperative bladder dysfunction (85–88).

Minimally Invasive Versus Open Radical Hysterectomy

Although there are benefits to minimally invasive procedures, a non-inferiority randomized control trial showed that minimally invasive radical hysterectomies were associated with a lower rate disease-free survival at 86.0% compared to open radical hysterectomy at 96.5% at 4.5 years (89). This study also showed worse overall survival at the 3-year rate of 91.2% versus 97.1% in the minimally invasive versus open radical hysterectomy respectively. This study reported that minimally invasive radical hysterectomy is inferior to open radical hysterectomy in respect to disease-free survival and overall survival (90). While the explanation for this finding is unclear, it was suggested that spread of malignant cells by the uterine manipulator or CO_2 gas insufflation are potential causes.

Another study utilizing the National Cancer data base also showed that patient with IA2 and IB1 undergoing a minimally invasive radical hysterectomy had a higher 4 year mortality rate compared to those who underwent and open radical hysterectomy (91).

Sentinel Lymph Node Evaluation

Sentinel lymph node detection has become an integral part of the management strategy for breast cancer and melanoma and is being investigated as a diagnostic tool in multiple human malignancies, including carcinoma of the cervix. The sentinel node is a specific lymph node (or nodes) that is the first to receive drainage from a malignancy and is a primary site of nodal metastasis. In theory, the presence or absence of metastatic disease in the sentinel node should reflect the status of the nodal basin as a whole. Thus, a negative sentinel lymph node would allow omission of lymphadenectomy of the involved nodal basin. Sentinel lymph nodes are detected through perilesional injection of radiolabeled technetium-99 or blue dye followed by intraoperative identification of the sentinel lymph nodes utilizing handheld gamma probes or visual identification of blue-stained nodes. These techniques are primarily applicable in patients with early-stage disease and clinically negative lymph nodes, in whom lymph node status may influence the extent of the procedure or the use of adjuvant treatment.

National Comprehensive Cancer Network guidelines on the use of sentinel lymph node mapping in cervical cancer recommend the technique be considered in tumors less than 2 cm (90). The procedure is performed by **direct cervical injection with dye or radiocolloid technetium-99 into the cervix, usually at the 3 and 9 o'clock positions**

of the cervix. The sentinel lymph nodes are identified at by direct visualization at time of laparotomy or laparoscopy of colored dye, a fluorescent camera if indocyanine green (ICG) was used, or a gamma probe if ^{99}Tc was used. The nodes are commonly located medial to the external iliac, ventral to the hypogastric, or in the superior aspect of the obturator space (90).

Sentinel nodes can be detected in 80% to 100% of cervical cancer patients, and these rates were confirmed by both laparotomy and laparoscopy. A combination of dye and radiolabeled techniques appears to be superior for the detection of sentinel lymph nodes over either technique used alone. Test sensitivity of 65% to 87% can be expected with a 90% to 97% negative predictive value. The likelihood of detecting sentinel nodes may depend on the tumor volume, the time from injection to retrieval of the sentinel nodes, and the volume of dye or radiolabeled tracer injected. Sentinel node detection rates do not appear to be influenced by prior cold knife cone biopsy. Although increasingly used, **the role of sentinel node detection in early-stage cervix cancer continues to be defined** (92).

Postoperative Management

Prognostic Variables for Early-Stage Cervical Cancer (IA2–IIA)

The survival of patients with early-stage cervical cancer after radical hysterectomy and pelvic lymphadenectomy depends on the presence or absence of several intermediate and high-risk pathologic factors (79,93–107).

Intermediate risk factors for recurrent disease are:

1. Large tumor size
2. Cervical stromal invasion to the middle or deep one-third
3. Lymph–vascular space invasion

High risk factors for recurrent disease are:

1. Positive or close margins
2. Positive lymph nodes
3. Microscopic parametrial involvement

Patients treated with radical hysterectomy who have intermediate or high risk factors have a 30% and 40% risk, respectively, of recurrence within 3 years (108–110).

Lesion Size

Lesion size is an independent predictor of survival. Patients with lesions smaller

than 2 cm have a survival rate of approximately 90%, and patients with lesions larger than 2 cm have a 60% survival rate (97). **When the primary tumor is larger than 4 cm, the survival rate drops to 40%** (95,105). An analysis of a GOG prospective study of 645 patients showed a 94.6% 3-year disease-free survival rate for patients with occult lesions, 85.5% for those with tumors smaller than 3 cm, and 68.4% for patients with tumors larger than 3 cm (106).

Depth of Invasion

Patients in whom depth of invasion is less than 1 cm have a 5-year survival rate of approximately 90%, but the survival rate falls to 63% to 78% if the depth of invasion is more than 1 cm (79,106,110–113).

Parametrial Spread

Patients with spread to the parametrium have a 5-year survival rate of 69%, compared with 95% when the parametrium is negative. When the parametrium is involved and pelvic lymph nodes are positive, the 5-year survival rate falls to 39% to 42% (98,114).

Lymph–Vascular Space Involvement

The significance of finding lymph–vascular space involvement is somewhat controversial. Several reports show a 50% to 70% 5-year survival rate when lymph–vascular space invasion is present and a 90% 5-year survival rate when invasion is absent (79,97,101,115,116). Others found no significant difference in survival if the study is controlled for other risk factors (106,107,117–120). Lymph–vascular space involvement may be a predictor of lymph node metastasis and not an independent predictor of survival.

Lymph Nodes

The variable that is most independently predictive of survival is the status of the lymph nodes. Patients with negative nodes have an 85% to 90% 5-year survival rate, whereas the survival rate for those with positive nodes ranges from 20% to 74%, depending on the number of nodes involved and the location and size of the metastases (102–104,107,110,113,119–121).

Data on lymph node status is summarized as follows:

1. When the common iliac lymph nodes are positive, the 5-year survival rate is about 25%, compared with about 65% when only the pelvic lymph nodes are involved (114,122,123).
2. Bilateral positive pelvic lymph nodes portend a less favorable prognosis (22% to 40% survival rate) than unilateral positive pelvic nodes (59% to 70%) (122,123).
3. The presence of more than three positive pelvic lymph nodes is accompanied by a

68% recurrence rate, compared with 30% to 50% when three or fewer lymph nodes are positive (102,120).

4. Patients in whom tumor emboli are the only findings in the pelvic lymph node have an 82.5% 5-year survival rate, whereas the survival rate is 62.1% and 54% with microscopic invasion and macroscopic disease, respectively (90).

Given the high risk of recurrent disease in surgically treated patients with early-stage cervical cancer who exhibit intermediate- or high-risk pathologic factors, adjuvant radiation or chemoradiation therapy should be considered.

Primary Radiation Therapy

[5] Radiotherapy can be used to treat all stages of cervical cancer, with cure rates of about 70% for stage I, 60% for stage II, 45% for stage III, and 18% for stage IV (4). A comparison of surgery and radiation for treatment of low-stage disease is shown in Table 38-5. Primary radiation treatment plans consist of a combination of external beam radiation therapy to treat the regional lymph nodes and to decrease the tumor volume, and brachytherapy delivered by intracavitary applicators and/or interstitial implants to provide a treatment boost to the central tumor. Intracavitary therapy alone may be used in patients with early disease when the incidence of lymph node metastasis is negligible.

The treatment sequence can depend on tumor volume. Patients commonly receive 5 weeks of pelvic external beam radiation upfront, with brachytherapy introduced at week 4. In some cases, stage IB lesions smaller than 2 cm may be treated first with an intracavitary source to treat the primary lesion, followed by external therapy to treat the pelvic lymph nodes. Larger lesions require external radiotherapy first to shrink the tumor and to reduce the anatomic distortion caused by the cancer. Tumor shrinkage averaging >1 cm per week can be achieved with adequate external beam radiation prior to starting brachytherapy (124,125). Such a treatment strategy enables the radiation oncologist to physically implant brachytherapy applicators and achieve dosimetric radiation coverage of the tumor target volume.

Table 38-5 Comparison of Surgery Versus Radiation for Stage IB/IIA Cancer of the Cervix

	Surgery	Radiation
Survival	85%	85%
Serious complications	Urologic fistulas 1–2%	Intestinal and urinary strictures and fistulas 1.4–5.3%
Vagina	Initially shortened, but may lengthen with regular intercourse	Fibrosis and possible stenosis, particularly in postmenopausal patients

Ovaries	Can be conserved	Destroyed
Chronic effects	Bladder atony in 3%	Radiation fibrosis of bowel and bladder in 6–8%
Applicability	Best candidates are younger than 65 years of age, <200 lb, and in good health	All patients are potential candidates
Surgical mortality	1%	1% (from pulmonary embolism during intracavitary therapy)

Cervix cancer brachytherapy has classically been delivered with low dose rate (LDR) technique involving inpatient admission and x-ray film–based radiation dose prescription to "point A." Over decades, multiple advances in radiation oncology have resulted in improved brachytherapy techniques (e.g., image-guided adaptive brachytherapy [IGABT]) that have translated to superior survival, better tumor control, less side effects, and improved safety. The RetroEMBRACE study included 731 locally advanced cervix cancer patients from 12 centers who received external beam radiation ± chemotherapy plus 3D IGABT from 1998 to 2008. Patients achieved excellent local control (91%), pelvic control (87%), OS (74%), and cancer-specific survival (79%) with limited severe morbidity (126).

One chief modern innovation in cervix cancer brachytherapy is the shift from classically prescribing dose to a generic "point A" localized via 2D x-ray films, to volumetrically prescribing dose shaped to the patient's individual tumor geometry as defined on 3D MRI or CT imaging. The 2D approach delivers similar brachytherapy treatments to all patients regardless of tumor geometry or patient anatomy, which can result in underdosing of larger tumors or overdosing of smaller tumors plus over-irradiation of the adjacent bladder, rectum, and sigmoid. In contrast, the modern 3D approach permits individualization and shaping of the radiation prescription dose to fit patient's tumor and normal organ anatomy. The French multicenter STIC trial compared classical 2D versus modern 3D approaches in 705 cervix cancer patients, prospectively demonstrating that 3D brachytherapy resulted in improved local control and half the toxicity seen with 2D brachytherapy (127).

In classical 2D cervix brachytherapy, usual doses delivered are 7,000 to 8,000 cGy to point A (defined as 2 cm superior to the external cervical os and 2 cm lateral to the internal uterine canal) and 6,000 cGy to point B (defined as 3 cm lateral to point A), limiting the bladder and rectal dosage to less than 6,000 cGy. To achieve this level, it is necessary to adequately pack the bladder and bowel away from the intracavitary source. Localization films and careful calculation of dosimetry are mandatory to optimize the dose of radiation and to reduce the incidence of bowel and bladder complications. Local control depends on delivering an adequate dose to the tumor from the intracavitary source.

In modern 3D IGABT, usual cumulative radiation doses delivered are 8,500 to 9,500

cGy to the high-risk CTV D90 per GEC-ESTRO recommendations and 8,000 to 9,000 cGy per American Brachytherapy Society recommendations (128). This is often achieved with a radiation treatment course of 25 to 28 days once daily external beam fractions, plus 4 to 5 brachytherapy fractions. The cumulative dose to control a cervix tumor is related to the tumor's volume, with higher doses required to control larger tumors (129). Image-guided computerized planning is performed on CT or MRI images acquired of the patient's pelvis with brachytherapy applicators in place. An updated CT or MRI scan is performed with each brachytherapy applicator insertion, so that the radiation plan can be adapted to match shrinking geometry of the tumor and sculpted away from the daily position of the bladder, rectum, and sigmoid. Cumulative dose refers to the combined dose from external beam radiation plus all brachytherapy fractions, converted to a 2 Gy per fraction equivalent. The high-risk CTV (clinical target volume) consists of the entire cervix plus any clinically/radiographically identifiable tumor at time of brachytherapy (130). "D90" refers to 90% of the HR-CTV receiving the highest radiation doses. Typically, dose constraints to organs at risk are specified to the D2cc, or the 2 cc of the organ receiving the highest radiation dose. GEC-ESTRO recommendations include keeping the cumulative D2cc dose to bladder <90 Gy EQD2, rectum <75 Gy EQD2, sigmoid <75 Gy EQD2 (131). The current EMBRACE II protocol (www.embracestudy.dk) for cervix cancer suggests more stringent D2cc constraints with the goal of further reducing toxicity.

Another chief innovation in modern cervix brachytherapy has been the use of newer radiation isotopes and loading techniques. Classic 2D brachytherapy is often performed with LDR isotopes such as cesium-137. LDR isotopes like Cs-137 are placed manually by hand, require inpatient admissions for extended overnight irradiation over 1 to 3 days with prolonged patient immobilization, DVT prophylaxis, and the need for careful radiation shielding/precautions taken by potentially exposed medical personnel. LDR isotopes are only capable of emitting therapeutic radiation at a rate of less than 0.4 Gy per hour, whereas high-dose rate (HDR) isotopes can treat at a speed of greater than 12 Gy per hour. Modern 3D brachytherapy is most often performed with the HDR isotope iridium-192 (Ir-192). Ir-192 is capable of delivering the prescribed brachytherapy radiation dose in just a few minutes, typically delivered in the ambulatory/outpatient setting with a robotic remote afterloader system that minimizes radiation exposure to medical personnel.

Pulsed-dose rate (PDR) brachytherapy is a relatively uncommon technique mostly seen at specialized academic centers. PDR uses an Ir-192 HDR source with a pulsed treatment regimen designed to mimic the radiobiologic effects of LDR treatment. Like LDR, PDR brachytherapy requires patient immobilization and admission (132).

Although brachytherapy was traditionally prescribed using a low-dose rate technique, high-dose rate techniques are becoming more popular. Proponents of high-dose rate techniques argue that the exposure of radiation to medical personnel is

less, ambulatory therapy is possible, and total treatment time is less. Advocates of low-dose rate techniques cite literature suggesting that complication rates are higher with high-dose rate therapy. Several published trials show that there may be slight stage-related differences in survival between patients treated with low- and high-dose rate regimens, but the techniques have comparable survival and complication rates (133–135). A Cochrane review of published studies comparing LDR versus HDR brachytherapy for locally advanced cervix cancer showed no significant differences in OS, disease-specific survival, recurrence-free survival, local control, recurrence, metastases, or treatment-related complications. However, these conclusions were based on a small (4) number of trials that met inclusion criteria (136).

Newer combined intracavitary/interstitial brachytherapy applicators permit successful treatment of bulky and/or irregularly shaped tumor targets, and can often obviate the need to treat with the more morbid techniques of Syed and MUPIT template needle implants. An important innovation in the treatment of cervix cancer is the development of newer brachytherapy applicators that allow interstitial needles to be incorporated into the standard geometry of classical intracavitary tandem and ovoids, or tandem and ring, applicators (137). The incorporation of interstitial needles permits more effective dosing of tumor targets beyond the normal reach of standard intracavitary brachytherapy applicators while keeping adjacent organs at risk within safe radiation limits (138). Patients on the retroEMBRACE study with locally advanced cervix cancer receiving combined intracavitary and interstitial brachytherapy treatment (versus intracavitary only) had an improved therapeutic ratio, with a 10% increase in local control seen in those with larger tumors (cervix + tumor volume > 30 cm^3) (139).

Clinical staging is imprecise and fails to accurately predict disease extension to the para-aortic nodes in 7% of patients with stage IB, 18% with stage IIB, and 28% with stage III disease (140). Such patients will have “geographic” treatment failures if standard pelvic radiotherapy ports are used. As a result, treatment plans for these patients are individualized based on CT scans, PET scans, and biopsies of the para-aortic lymph nodes for consideration of extended-field radiotherapy. The routine use of extended-field radiation for prophylactic para-aortic radiation without documentation of distant metastasis to the para-aortic nodes was evaluated and is not practiced because of the increased enteric morbidity associated with this treatment modality. If available, PET/CT scans are encouraged as they can detect potential pelvic, para-aortic, or supraclavicular nodal involvement, which in turn relates to clinical stage, potential recurrence, and survival outcomes (141).

Intensity-Modulated Radiation Therapy

Intensity-modulated radiation therapy (IMRT) continues to be a significant therapeutic development. IMRT is an external beam radiation technique that improves

upon older 3D conformal radiation therapy (3D-CRT) external beam techniques. While 3D-CRT is capable of projecting block or polygonal-shaped radiation into target tumors, IMRT is capable of projecting curved, even concave, conformal radiation that is more precisely shaped to the target tumor space. IMRT permits more accurate irradiation of tumor targets and significantly enhances sparing of nearby normal organs. In the treatment of cervix cancer, use of IMRT could reduce radiation dose to multiple organs at risk including bone marrow, rectum, bladder, small bowel, and femurs. Technically, IMRT is achieved with volumetric image-based (CT or MRI) radiation treatment planning in which the radiation oncologist manually draws the tumor/target volume(s) on a computerized dosimetry system, followed by a computer algorithm that generates a set of treatment external beam angles and patterns that conform to the physician-delineated target(s) while meeting prescription goals and normal organ radiation constraints. IMRT has been used in postoperative and intact cervix cancer patients, and is an advanced technique under active investigation within radiation oncology.

Prior to the advent of IMRT, women receiving pelvic radiation typically received 3D-CRT "four field box" plans that delivered full external beam prescription dose (45 to 50 Gy) to their rectum, bladder, femurs, small bowel, and bone marrow. IMRT allows the radiation oncologist to essentially sculpt dose away from these organs at risk to reduce radiation side effects. For postoperative cervix (and endometrial) cancer patients, the NRG-RTOG 1203 TIME-C trial demonstrated that 278 women randomized between IMRT and 3D-CRT had, with IMRT, better patient-reported bowel and bladder function (EPIC, FACT-Cx, PRO-CTCAE) and less use of antidiarrheal medications. Longer follow-up is needed to evaluate long-term toxicity (142).

A consensus guideline for IMRT use in intact cervix cancer was published in 2011, with IMRT targeting the gross tumor, entire cervix, uterus, parametria, ovaries, and vaginal tissues (143). The amount of vaginal length covered can vary from half to full depending on the extent of vaginal disease. For involvement of uterosacral ligaments, IMRT coverage of the mesorectum is advised. The INTERTECC-2 study was an international multicenter phase II clinical trial of 83 stages IB to IVA intact cervix cancer patients who received weekly *cisplatin* concurrent with daily IMRT treatments followed by intracavitary brachytherapy. Patients who received IMRT had reduced acute hematologic and GI toxicity compared with 3D-CRT treatment (144). However, the cervix and uterus are known to be quite mobile, capable of up to 3.5 cm shifts (even retroversion/anteversion) between daily radiation fractions as evidenced by daily cone beam CT scans acquired on the treating linear accelerator (145). IMRT plans for intact cervix cancer need to be carefully designed to account for the possibility of significant interfraction cervix movement caused by cervix/uterus mobility and variations in daily bladder and rectal filling. In the case of node-positive cervix cancer patients, IMRT with simultaneous integrated boost (SIB or "dose painting") allows simultaneous

delivery of higher external beam radiation dose (e.g., 55 Gy in 2.2 Gy per fraction) to FDG+ nodes beyond the reach of brachytherapy, while maintaining standard fraction dosing (45 Gy in 1.8 Gy per fraction) to central disease that will receive the remainder of curative radiation via brachytherapy boosts (146,147). Cervix cancer patients requiring irradiation of para-aortic nodes can potentially benefit from IMRT, which is associated with low rates of GI toxicities (6.5% acute and late) and no duodenal-specific toxicities even in the setting of concurrent radiosensitizing chemotherapy (148).

Despite the technical sophistication of IMRT, in the field of radiation oncology, IMRT is considered complementary to brachytherapy and not a replacement for brachytherapy. A SEER propensity score matching analysis of 7,359 patients with stages IB2 to IVA cervix cancer indicated that inclusion of brachytherapy as part of definitive treatment was independently associated with significantly higher cause-specific survival (CSS; 64.3% vs. 51.5%, P <0.001) and OS (58.2% vs. 46.2%, P <0.001) (149). The study identified a significant decrease in American brachytherapy utilization from 83% in 1988 to a nadir of 43% in 2003 (and some recovery to 58% in 2009) quite possibly driven in the early 2000s by attempted substitution of brachytherapy by IMRT. This suggests a strong need to improve modern brachytherapy training in the field of radiation oncology and promote awareness of brachytherapy's importance to collaborating gynecologic oncologists.

Adjuvant Radiation

In an effort to improve survival rates, postoperative radiotherapy was recommended for patients with high and intermediate risk factors such as metastasis to pelvic lymph nodes, invasion of paracervical tissue, deep cervical invasion, or positive surgical margins (79,94,97,98,114,119,120,150). Although most authors agree that postoperative radiotherapy is necessary in the presence of positive surgical margins, the use of radiation in patients with other high-risk factors is controversial. Increasing evidence supports the use of adjuvant radiation. Particularly controversial, and best studied, is the use of radiation in the presence of positive pelvic lymph nodes. The rationale for treatment is the knowledge that pelvic lymphadenectomy does not remove all of the nodal and lymphatic tissue and subsequent radiotherapy can eradicate microscopic disease. The hesitancy to recommend postoperative radiotherapy derives from the significant rate of postradiation bowel and urinary tract complications (151). Most of the available data are retrospective. However, a randomized study by the GOG comparing radiation with no further treatment for patients at high risk for recurrence with negative pelvic nodes revealed a 30% serious complication rate, 16% reoperation rate, and a 2% mortality rate as a result of treatment-related complications (152).

Based on retrospective studies, it appears that postoperative radiation therapy for positive pelvic nodes can decrease pelvic recurrence but does not improve 5-

year actuarial survival rates. One multi-institutional study showed no difference in survival in patients with three or fewer positive pelvic nodes (59% vs. 60%) (120). However, there seemed to be a benefit when radiotherapy was given to those with more than three positive nodes.

In a study of 60 pairs of irradiated and nonirradiated women matched for age, lesion size, number, and location of positive nodes after radical hysterectomy, no significant difference was found in projected 5-year survival rates (72% for surgery alone, 64% for surgery plus radiation) (153). The proportion of recurrences confined to the pelvis was 67% in patients treated with surgery only and 27% in patients treated with postoperative radiation ($P = 0.03$). In a Cox regression analysis of 320 women who underwent radical hysterectomy, for the 72 who received postoperative radiation, there was a significant decrease in pelvic recurrence but no survival benefit (103). A multi-institutional retrospective study was performed on 185 women with positive pelvic nodes after radical hysterectomy, including 103 who received postoperative radiotherapy (105). Multivariate analysis disclosed that radiotherapy was not an independent predictor of survival, whereas age, lesion diameter, and number of positive nodes did influence survival. These authors concluded that additional treatment is needed to improve survival rates. Because survival is limited by distant recurrence, the addition of chemotherapy to postoperative radiotherapy was proposed. A 75% disease-free survival rate was reported at 3 years in 40 high-risk patients given *cisplatin*, *vinblastine*, and *bleomycin* after radical hysterectomy, and a 46% disease-free survival rate was found in 79 comparable patients who refused treatment (154). Only 4 (11.8%) of 34 patients with positive pelvic nodes had recurrences, whereas disease recurred in 8 (33%) of 24 untreated patients with positive nodes. An 82% rate of disease-free survival was reported at 2 years among 32 patients who were treated postoperatively with radiation therapy plus *cisplatin* and *bleomycin* (155).

The location of lymph node metastases apparently is relevant to postirradiation recurrence rates. When common iliac lymph nodes are involved, the survival rate drops to 20%. As the number of positive pelvic nodes increases, the percentage of positive common iliac and low para-aortic nodes increases (i.e., 0.6% when pelvic lymph nodes are negative, 6.3% with one positive pelvic node, 21.4% with two or three positive nodes, and 73.3% with four or more positive nodes). This information was used to recommend extended-field radiotherapy to patients with positive pelvic lymph nodes in an attempt to treat undetected extrapelvic nodal disease (115). A 3-year disease-free survival rate of 85% occurred in patients with positive pelvic nodes, and a survival rate of 51% occurred in patients with positive common iliac nodes; these rates are better than the survival rates of 50% and 23%, respectively, for historical control groups receiving radiotherapy to the pelvis alone.

The GOG reported the results of a randomized controlled trial on patients with cervical cancer treated by radical hysterectomy and found to have at least two of

the following risk factors: capillary lymphatic space invasion, more than one-third stromal invasion, and large tumor burden (109). A total of 277 patients were entered into the study, with 140 patients randomized to no further therapy and 137 patients randomized to adjuvant pelvic radiotherapy. **Patients with these risk factors who were treated postoperatively with radiation therapy had a statistically significant (47%) decrease in recurrent disease.** After extensive follow-up, there is no statistically significant difference in mortality rates (156). The morbidity with combination therapy was acceptable, with a low rate of enteric and urinary complications. A second GOG study of patients with high-risk cervical cancer randomized patients to concurrent chemoradiation therapy or radiation therapy alone (108).

Concurrent Chemoradiation

Radiation therapy fails to achieve tumor control in 20% to 65% of patients with advanced cervical cancer. Chemotherapy, despite its relative lack of success in treating patients with cervical cancer, was evaluated as neoadjuvant treatment in combination with surgery. **Concomitant use of chemotherapy and radiation was studied extensively by the GOG and results of five randomized studies were reported.** The concept of chemoradiation encompasses the benefits of systemic chemotherapy with the benefits of regional radiation therapy. **The use of chemotherapy to sensitize cells to radiation therapy improved local–regional control.** These results changed the way cervical cancer is treated in many medical centers.

An intergroup trial involving the GOG, the Southwestern Oncology Group, and the Radiation Therapy Oncology Group evaluated postoperative chemoradiation therapy in patients with stage IA2, IB, or IIA cervical cancer who had positive pelvic lymph nodes, positive parametrial extension, or positive vaginal margins at the completion of radical hysterectomy (155). A total of 243 patients were assessed in this trial, with 127 receiving chemoradiation (*cisplatin*, *5-fluorouracil* [*5-FU*], radiation therapy) and 116 receiving radiation. **The results of this trial showed a statistically significant improvement in progression-free survival (PFS) and overall survical (OS) at 43 months for the patients receiving concurrent chemoradiation.** The 4-year survival rates for the patients receiving chemoradiation versus radiation alone were 81% and 71%, respectively. The toxicity levels in the two groups were acceptable, with a higher rate of hematologic toxicity in the concurrent chemoradiation arm. **This study showed that in patients with these high-risk factors after radical hysterectomy for stages IA2, IB, and IIA disease, chemoradiation is the postoperative treatment of choice.**

Concurrent chemoradiation was evaluated in patients with advanced cervical carcinoma. GOG protocol 85 was a prospective study that enrolled patients with stages

IIb to IVA cervical cancer and compared concurrent chemoradiation (157). There were 177 patients treated with *cisplatin*, *5-FU*, and radiation. These patients were compared with 191 patients treated with *hydroxyurea* and radiation. The median follow-up of patients who were alive at the time of the analysis was 8.7 years. Patients who received concurrent chemoradiation and were treated with *cisplatin* and *5-FU* had a statistically significant improvement in progression-free interval and OS (157). Hematologic toxicity levels in the two groups were similar. **This study showed that *cisplatin*-based concurrent chemoradiation was a superior treatment when compared with *hydroxyurea* and concurrent radiation.**

GOG Protocol 120 was initiated to evaluate patients with negative para-aortic nodes and cervical carcinoma stages IIB to IVA treated with concurrent chemoradiation. The treatment arms in this study consisted of radiation plus weekly *cisplatin*; or *cisplatin*, *5-FU*, and *hydroxyurea*; or *hydroxyurea*. There were 176 patients in the weekly *cisplatin* arm; 173 patients in the *cisplatin*, *5-FU*, and *hydroxyurea* arm; and 177 patients in the *hydroxyurea* arm (158). The two treatment arms with *cisplatin*-based chemotherapy and radiation showed an improvement in progression-free interval and OS at a median follow-up of 35 months. The relative risks for progression of disease or death were 0.55 and 0.57, respectively, for patients treated with *cisplatin*-based chemotherapy and radiation, compared with the patients treated with *hydroxyurea* and radiation (158). **This study confirmed the findings of GOG Protocol 85 and reaffirmed the finding that *cisplatin*-based concurrent chemoradiation is the treatment of choice for patients with advanced-stage cervical cancer.**

A third GOG trial evaluated patients with stages IB to IVA cervical cancer. Of the patients enrolled in this study, 70% had stage IB or IIA disease (159). A total of 403 patients were enrolled and evaluated. The 5-year survival rates were 73% in patients treated with chemoradiation and 58% in patients treated with radiation therapy alone. The cumulative rates of disease-free survival at 5 years were 67% in patients treated with concurrent chemoradiation and 40% in patients treated with radiation therapy alone. Survival and progression-free intervals for patients receiving concurrent chemoradiation were significantly improved (159). **The results of this study suggested that chemoradiation is the treatment of choice for stages IIB to IVA disease and that those patients with stages IB2 and IIA disease may benefit from chemoradiation.**

A GOG study of chemoradiation comparing concurrent *cisplatin* and radiation with radiation alone in patients with bulky IB cervical cancer included adjuvant hysterectomy after completion of the radiation (160). There were 183 patients assigned to the concurrent chemotherapy and radiation arm and 186 patients treated with radiation alone. The median duration of follow-up was 36 months, with disease recurrence detected in 37% of the patients treated with radiation alone, compared with

21% who were treated with concurrent chemoradiation (160). The 3-year survival rates were 83% in the group who received concurrent chemoradiation and 74% in the group who received radiation alone (160). The study included adjuvant hysterectomy after completion of radiation treatment. Because the results did not show an improvement in survival by using adjuvant hysterectomy, the authors concluded that adjuvant hysterectomy would not be part of their recommendations. **This study supports the results of previous studies and shows that patients with bulky stages IB and IIA cervical cancer treated with concurrent chemoradiation have survival rates superior to those treated with radiation alone. These two studies indicate that patients with bulky stages IB and IIA disease should have primary treatment consisting of chemoradiation, with the chemotherapy agent being weekly *cisplatin*.**

Based on 2,042 patients enrolled on prior GOG trials, modern nomograms have been developed to predict 2-year PFS, 5-year OS, and pelvic recurrence risk for women with locally advanced cervix cancer treated with definitive chemoradiation. Prognostic factors include histology, race/ethnicity, performance status, tumor size, FIGO stage, grade, presence of pelvic and para-aortic nodes, and use of *cisplatin*-based chemotherapy (161).

Surgical Staging Before Radiation

Surgical staging procedures designed to discover positive lymph nodes may be forgone with use of PET/CT imaging studies. The use of transperitoneal exploration was associated with a 16% to 33% mortality rate from radiotherapy-induced bowel complications and a 5-year survival rate of only 9% to 12% (162,163). **To avoid these complications, extraperitoneal dissection of the para-aortic nodes is recommended, and the radiation dose should be reduced to 5,000 cGy or less** (164,165). **When this approach is used, postradiotherapy bowel complications occur in fewer than 5% of patients, and the 5-year survival rate is 15% to 26% in patients with positive para-aortic nodes** (22,166,167). Survival appears to be related to the amount of disease in the para-aortic nodes and to the size of the primary tumor. In patients whose metastases to the para-aortic lymph nodes are microscopic and whose central tumor has not extended to the pelvic sidewall, the 5-year survival rate improves to 20% to 50% (168,169). Surgical staging techniques have improved to include laparoscopic assessment of the para-aortic and pelvic lymph nodes. Studies demonstrated benefit from surgical staging with improved survival and changes in treatment plans in 40% of patients (165,166). When PET/CT is compared with surgicopathologic staging of para-aortic lymph nodes, some patients with histologically positive para-aortic lymph nodes are missed with surgicopathologic staging (170).

Management of Grossly Positive Para-Aortic Lymph Nodes

The management of patients with macroscopic or grossly positive para-aortic

lymph nodes discovered at the time of surgery or by imaging studies is controversial. It is likely that grossly positive nodes may be beyond the ability of radiation therapy alone to sterilize. Therefore, to improve survival, additional therapy is required. In a representative study of the multiple reports in the literature, lymph node metastases were noted in 133 of 266 patients. Pelvic and para-aortic nodes were positive in 44 patients and positive para-aortic nodes were noted in only 2 patients. Five- and 10-year survival rates were similar for patients with macroscopically positive resectable nodes and microscopically positive nodes. Patients with unresectable nodal disease had a worse survival rate than those with resectable disease. All patients underwent extraperitoneal lymph node resections and subsequent radiotherapy. There was a 10% incidence of severe morbidity related to radiation use. Consistent with other reports in the literature, this study showed that **extraperitoneal debulking lymphadenectomy confers a survival advantage similar to that enjoyed by patients with micrometastatic disease without additional morbidity** (30). The topic nevertheless remains in debate because chemoradiation may permit the treatment of larger volume disease without the need for surgical debulking.

Prophylactic Para-Aortic Radiation Therapy

Prophylactic extended-field radiation therapy is an alternative to surgical staging of the para-aortic lymph node chain in women with advanced cervical cancer judged to be at high risk but without radiologic or clinical evidence of para-aortic lymph node involvement. This treatment strategy was evaluated in 441 patients with stages I to III disease (171). High rates of gastrointestinal toxicity were noted in the treatment group. There was no difference in disease-free survival or OS between the control and treated groups, although treated patients had fewer para-aortic failures. A lack of difference in survival rates in this study may be related to high local and regional failure rates, suggesting that ideal patients for prophylactic radiotherapy would be those in whom there is a high likelihood of achieving pelvic control. A survival benefit was noted in a study by the Radiation Therapy Oncology Group, in which 367 patients with stages IB to IIB disease were randomized to pelvic radiotherapy versus pelvic and extended field radiotherapy (172). The extended field treatment arm suffered more grade 4 and 5 toxicity, confirming previous studies. Complicating the issue is another study from the Radiation Therapy Oncology Group revealing that in locally advanced cervical cancer, pelvic radiation therapy with concurrent *cisplatin* chemotherapy was superior to extended-field radiation therapy (159). There are no large prospective trials that compare pelvic chemoradiation with extended-field chemoradiation. Given the potential toxicity, it seems prudent to administer extended-field radiation only to patients with suspected para-aortic node involvement.

Supraclavicular Lymph Node Biopsy

Although not standard practice, the performance of a supraclavicular lymph node biopsy was advocated in patients with positive para-aortic lymph nodes before the initiation of extended-field irradiation and in patients with a central recurrence before exploration for possible exenteration. The incidence of metastatic disease in the supraclavicular lymph nodes in patients with positive para-aortic lymph nodes is 5% to 30% (173). Node enlargement and increased metabolic activity can be assessed with chest PET/CT scanning. Cytologic assessment by FNA can obviate the need for an excisional biopsy and should be performed if any enlarged nodes are present. If the scalene lymph nodes are positive, palliative chemotherapy should be considered.

Complications of Radiation Therapy

Perforation of the uterus may occur (~9%) with the insertion of the uterine tandem. This is particularly a problem for elderly patients and those who had a previous diagnostic conization procedure. When perforation is recognized, an LDR tandem should be removed, and the patient should be observed for bleeding or signs of peritonitis. Survival may be decreased in patients who have uterine perforation, possibly because these patients have more extensive uterine disease (174). Fever may occur after insertion of the uterine tandem and ovoids. Fever most often results from infection of the necrotic tumor and occurs 2 to 6 hours after insertion of the intracavitary system. If uterine perforation was excluded by ultrasonography, intravenous broad-spectrum antibiotic coverage, usually with a *cephalosporin*, should be administered. If the fever does not decrease promptly or if the temperature is higher than 38.5°C, an aminoglycoside and a *bacteroides* species–specific antibiotic should be administered. If fever persists or if the patient shows signs of septic shock or peritonitis, any LDR intracavitary system must be removed. Antibiotics are continued until the patient recovers, and any LDR intracavitary application is delayed for 1 to 2 weeks. In case of HDR brachytherapy, antibiotics can be given and the tandem should be repositioned into proper place so that the HDR radiation treatment (typically only several minutes duration) can be delivered without delay followed by removal of the applicators (175). The use of intraoperative real-time transabdominal ultrasound guidance during placement of the brachytherapy tandem can significantly reduce the chance of perforation and help ensure an accurate brachytherapy implant.

Acute Morbidity

The acute effects of radiotherapy are caused by ionizing radiation on the epithelium of the intestine and bladder and occur after administration of 2,000 to 3,000 cGy. Symptoms include diarrhea, abdominal cramps, nausea, frequent urination, and occasional bleeding from the bladder or bowel mucosa. Bowel symptoms can be treated with a low-gluten, low-lactose, and low-protein diet. Antidiarrheal and antispasmodic agents may help. Bladder symptoms may be treated with antispasmodic

medication. Severe symptoms may require a week of rest from radiotherapy.

Chronic Morbidity

The chronic effects of radiotherapy result from radiation-induced vasculitis and fibrosis and are more serious than the acute effects. These complications occur several months to years after radiotherapy is completed. The bowel and bladder fistula rate after pelvic radiation therapy for cervical cancer is 1.4% to 5.3%, respectively (62,64). Other serious toxicity (e.g., bowel bleeding, stricture, stenosis, or obstruction) occurs in 6.4% to 8.1% of patients (62,64).

Radiation Proctopathy

Rectal bleeding after pelvic radiotherapy (radiation proctopathy) commonly self-resolves over time. Patients with continued bleeding can be offered at least flexible sigmoidoscopy to rule out causes unrelated to radiation therapy. For radiation-induced bleeding, first-line sucralfate enemas can be used. For refractory bleeding, interventions such as argon plasma coagulation, laser therapy and formalin can be considered (176).

Rectovaginal Fistula

Rectovaginal fistulas or rectal strictures occur in fewer than 2% of patients. The successful closure of fistulas with bulbocavernosus flaps or sigmoid colon transposition was reported (177,178). Occasionally, resection with anastomosis is feasible. Diversion resulting in colostomy may be the optimal therapy in patients who have poor vascular supply to the pelvis and a history of an anastomotic leak or breakdown from prior repairs.

Small Bowel Complications

Patients with previous abdominal surgery are more likely to have pelvic adhesions and thus sustain more radiotherapy complications in the small bowel. The terminal ileum may be particularly susceptible to chronic damage because of its relatively fixed position at the cecum. Patients with small bowel complications have a long history of crampy abdominal pain, intestinal rushes, and distention characteristic of partial small bowel obstruction. Often, low-grade fever and anemia accompany the symptoms. **Patients who have no evidence of disease should be treated aggressively with total parenteral nutrition, nasogastric suction, and early surgical intervention after the anemia resolves and good nutritional status is attained.** The type of procedure performed depends on individual circumstances (179). Small bowel fistulas that occur after radiotherapy rarely close spontaneously while total parenteral nutrition is maintained. Recurrent cancer should be excluded; aggressive fluid replacement, nasogastric suction, and wound care should be instituted. Fistulography and a barium enema should be performed to exclude a combined large and small bowel fistula. The fistula-containing loop of bowel may be either resected or isolated and left in situ. In the

latter case, the fistula will act as its own mucous fistula.

Urinary Tract

Chronic urinary tract complications occur in 1% to 5% of patients and depend on the dose of radiation to the base of the bladder. Vesicovaginal fistulas are the most common complication and usually require supravesicular urinary diversion. Occasionally, a small fistula can be repaired with either a bulbocavernosus flap or an omental pedicle. Ureteral strictures are usually a sign of recurrent cancer, and a cytologic sample should be obtained at the site of the obstruction using FNA guided by a CT scan. If the findings are negative, the patient should undergo exploratory surgery to evaluate the presence of recurrent disease. If radiation fibrosis is the cause, ureterolysis may be possible or indwelling ureteral stents may be passed through the open urinary bladder to relieve obstruction.

Chemotherapy

Neoadjuvant Chemotherapy

Randomized trials were initiated by the GOG and other large centers to determine the efficacy of neoadjuvant chemotherapy. **In the era of effective chemoradiation therapy, there is no evidence that neoadjuvant chemotherapy offers superior results or a survival advantage over standard therapy.**

Chemotherapy for Advanced Disease

Chemotherapy was studied in advanced cervical cancer with mixed results (180–183). Doublet therapy compared four *cisplatin*-containing doublets (*gemcitabine*, *paclitaxel*, *topotecan*, *vinorelbine*), and there were no major differences in OS, although the *cisplatin* and *paclitaxel* doublet trended toward the best results (GOG 204) (184). **Studies showed comparable survival and lower toxicity with *carboplatin* and *paclitaxel* compared with *cisplatin* and *paclitaxel* (185). A survival benefit was demonstrated when *bevacizumab*, an anti-VEGF-A monoclonal antibody, was added to the combination of platinum-based chemotherapy in patients with metastatic, persistent, or recurrent cervical carcinoma (GOG 240). However, the addition of bevacizumab to the combination increased the risk of fistula formation** (186).

While multiagent regimens offer an improved response rate and several months longer OS, they are more toxic than single-agent regimens. **For women who cannot tolerate combination chemotherapy, single-agent chemotherapy with *carboplatin* is an appropriate treatment.**

Treatment of Cervical Cancer by Stage

[5] *Stage IA*

Until 1985, no FIGO recommendation existed concerning the size of lesion or the depth

of invasion that should be considered microinvasive (stage IA). This led to considerable confusion and controversy in the literature. Over the years, as many as 18 different definitions were used to describe microinvasion. In 1974, the Society of Gynecologic Oncologists recommended a definition that is accepted by FIGO: **A microinvasive lesion is one in which neoplastic epithelium invades the stroma to a depth of less than 3 mm beneath the basement membrane and in which lymphatic or blood vascular involvement is not demonstrated.** The purpose of defining microinvasion is to identify a group of patients who are not at risk for lymph node metastases or recurrence and who therefore may be treated with less than radical therapy.

Diagnosis must be determined on the basis of a cone biopsy of the cervix. The treatment decision rests with the gynecologist and should be based on a review of the conization specimen with the pathologist. It is important that the pathologic condition be described in terms of (i) depth of invasion, (ii) presence or absence of lymph–vascular space invasion, and (iii) margin status. These variables are used to determine the degree of radicality of the operation and whether the regional nodes should be treated (171).

Stage IA1 <3 mm Invasion

Lesions with invasion less than 3 mm have less than 1% incidence of pelvic node metastases. Within this group, it appears that the patients most at risk for nodal metastases or central pelvic recurrence are those with definitive evidence of tumor emboli in lymph vascular spaces (77,187). Therefore, patients with less than 3 mm invasion and no lymph–vascular space invasion may be treated with extrafascial hysterectomy without lymphadenectomy. Therapeutic conization appears to be adequate therapy for these patients if preservation of childbearing capability is desired. Surgical margins and postconization endocervical curettage must be free of disease. If there is lymph–vascular space invasion, a type I (extrafascial) or II (modified radical) hysterectomy with pelvic lymphadenectomy should be considered.

Treatment of microinvasive cervical adenocarcinoma is complicated by a lack of agreement on approaches. Reports show that patients with stage IA1 cervical adenocarcinoma may be treated in a fashion similar to patients with this stage and a squamous lesion (111–113). Some experts disagree with this interpretation because of the difficulty in establishing a pathologic diagnosis of microinvasion from a frankly invasive adenocarcinoma. **Patients diagnosed with microinvasive cervical adenocarcinoma should have expert pathologic assessment before considering treatment with extrafascial hysterectomy or conization alone.**

Stage IA2 ≥3 mm to <5 mm Invasion

Lesions with invasion of greater than or equal to 3 to 5 mm have a 3% to 8%

incidence of pelvic node metastases; thus, pelvic lymphadenectomy or sentinel lymph node mapping is necessary for these lesions (187,188). The primary tumor may be treated with a modified radical hysterectomy (type II) or a radical trachelectomy if preservation of fertility is desired. If intermediate- or high-risk pathologic factors are identified in the surgical specimen, adjuvant radiation or chemoradiation therapy is recommended.

[5] ***Stages IB1, IB2, and IIA1 Invasive Cancer***

Stage IB lesions are subdivided into stage IB1, which denotes lesions that have 5 mm or more stromal invasion and are smaller than 2 cm in maximum diameter, and stage IB2, for lesions that are 2 cm or larger and less than 4 cm, and IB3, which denotes lesions that are 4 cm or larger. Patient's with lesions 2 cm or less may be managed with either a radical trachelectomy or type III radical hysterectomy with pelvic lymphadenectomy. Radical trachelectomy should be restricted to candidates who desire future fertility with low-risk disease and a tumor size less than 2 cm. The para-aortic lymph node chain should be evaluated if pelvic nodal disease is encountered. Adjuvant radiation therapy is recommended if intermediate risk factors are identified postoperatively. Adjuvant chemoradiation is indicated if high-risk features are found.

Alternatively, primary chemoradiation therapy with curative intent is appropriate. A comparison of radical hysterectomy with radiation resulted in similar survival rates for the two treatment modalities. Several studies comparing patients treated by either radical hysterectomy or radiation therapy showed similar survival rates and outcomes for both groups (93,189). However, patients treated with type III radical hysterectomy who subsequently received postoperative radiation had a higher rate of intestinal and urinary morbidity compared with patients treated with either modality alone. Therefore, some clinicians advocate using radiation and avoiding surgery in these patients because many will require adjuvant postoperative radiation.

[5] ***Bulky Stages IB3 and IIA2 Invasive Cancer***

Patients with bulky IB3 and IIA2 disease may be treated with either primary chemoradiation or radical surgery. Because many of these patients will have intermediate- or high-risk factors postoperatively, strong consideration should be given to primary chemoradiation. If surgical therapy is desired, a type III radical hysterectomy with pelvic and para-aortic lymphadenectomy, followed by adjuvant chemoradiation if intermediate- or high-risk factors are present, is appropriate therapy. This option has the benefits of complete surgical staging and ovarian preservation, if desired. Disadvantages of primary surgery include increased morbidity if multimodality therapy is utilized (189).

Stages IIB to IIIB Invasive Cancer

Therapy for patients with stage IIB or greater cervical cancer traditionally was radiation therapy. Primary pelvic radiotherapy fails to control disease progression in 30% to 82% of patients with advanced cervical carcinoma (4). Two-thirds of these failures occur in the pelvis (190). A variety of agents were used in an attempt to increase the effectiveness of radiation therapy in patients with large primary tumors. **Because chemoradiation was superior to radiation therapy alone, chemoradiation is the preferred treatment strategy for these patients, with *cisplatin* the chemotherapy agent of choice.** Nodal involvement, particularly the para-aortic lymph nodes, is the most important factor related to survival.

Stage IIIC1 and IIIC2

The updated staging system adds this new category to reflect metastatic disease to the pelvic lymph nodes (Stage IIIC1) and/or the para-aortic lymph nodes (Stage IIIC2). If the pelvic lymph nodes only are involved, chemoradiation to the pelvis is the recommended treatment, while if the para-aortic lymph nodes are involved, extended-field radiation with chemosensitization can be used and this can be followed by systemic chemotherapy (191–195).

[5] *Stages IVA and IVB Cancer*

Primary exenteration may be considered for patients with direct extension to the rectum or bladder, but it is rarely performed. For patients with extension to the bladder, the survival rate with radiation therapy is as high as 30%, with a urinary fistula rate of only 3.8% (196). The presence of tumor in the bladder may prohibit cure with radiation therapy alone; thus, consideration must be given to removal of the bladder on completion of external beam radiation treatment. This is particularly true if the disease persists at that time and the geometry is not conducive to brachytherapy. Rectal extension is less commonly observed but may require diversion of the fecal stream before chemoradiation to avoid septic episodes from fecal contamination. In certain clinical situations, such as with patients who have stage IVA disease and present with vesicovaginal or rectovaginal fistula, urinary or rectal diversion may be performed, followed by chemoradiation.

Patients with stage IVB cervical carcinoma are candidates for chemotherapy and palliative pelvic radiation therapy. Control of symptoms with the least morbidity is of primary concern in this patient population.

Patient Evaluation and Follow-Up After Therapy

Patients who receive radiotherapy should be monitored closely to assess treatment response. Tumors may be expected to regress for up to 3 months after radiotherapy. During the pelvic examination, progressive shrinkage of the cervix and possible stenosis of the cervical os and surrounding upper vagina are expected and should be noted. During rectovaginal examination, careful palpation of the uterosacral

and cardinal ligaments for nodularity is important. Cytologic assessment by FNA of suspicious areas should be performed to allow early diagnosis of persistent disease. In addition to the pelvic examination, the supraclavicular and inguinal lymph nodes should be carefully examined, and cervical or vaginal assessment should be performed every 3 to 6 months for 2 years and then every 6 to 12 months for the next 3 to 5 years. Endocervical curettage may be performed in patients with large central tumors (90).

Patients with isolated recurrences may benefit from surgical resection. Metastasis to the lung is reported in 1.5% of cases of patients with advanced disease. Solitary nodules are present in 25% of cases with metastasis. Resection of a solitary nodule in the absence of other persistent disease may yield some long-term survivors (197). After radical hysterectomy, about 80% of recurrences are detected within 2 years (198). The larger the primary lesion, the shorter the median time is to recurrence (199). Although CT, PET, or IVP is not a part of routine postradiotherapy surveillance, it should be performed if a pelvic mass is detected or if other symptoms warrant evaluation. The finding of ureteral obstruction after radiotherapy in the absence of a palpable mass may indicate unresectable pelvic sidewall disease, but this finding should be confirmed, usually by FNA cytologic assessment (200).

Special Considerations

Cervical Cancer During Pregnancy

The incidence of invasive cervical cancer associated with pregnancy is 1.2 in 10,000 (201). A Pap test should be performed on all pregnant patients at the initial prenatal visit, and any grossly suspicious lesions should be biopsied. Diagnosis is often delayed during pregnancy because bleeding is attributed to pregnancy-related complications. **If the result of the Pap test is positive for malignant cells, and invasive cancer cannot be diagnosed using colposcopy and biopsy, a diagnostic conization procedure may be necessary. Conization in the first trimester of pregnancy is associated with hemorrhagic and infectious complications, and an abortion rate as high as 33%** (202,203). **Because conization subjects the mother and fetus to complications, it should not be performed before the second trimester and only in patients with colposcopy findings consistent with cancer, biopsy-proven microinvasive cervical cancer, or strong cytologic evidence of invasive cancer.** Inadequate colposcopic examination may be encountered during pregnancy in patients who had prior ablative therapy. Close follow-up throughout pregnancy may allow the cervix to evert and develop an ectropion, allowing satisfactory colposcopy in the second or third trimester. Patients with obvious cervical carcinoma may undergo cervical biopsy and clinical staging similar to that of nonpregnant patients.

After conization, there appears to be no harm in delaying definitive treatment

until fetal maturity is achieved in patients with stage IA cervical cancer (202,204,205). Patients with less than 3 mm of invasion and no lymphatic or vascular space involvement may be followed to term. Historically, these patients were allowed to deliver vaginally, and a hysterectomy was performed 6 weeks postpartum if further childbearing was not desired. However, in a multivariate analysis of 56 women with cervical cancer diagnosed during pregnancy and 27 women with cervical cancer diagnosed within 6 months of delivery, vaginal delivery was the most significant predictor of recurrence. In addition, most recurrences after vaginal delivery involved distant sites. The ideal delivery method for these patients is not known definitively; however, strong consideration should be given to performing a cesarean birth in women with cervical cancer of any stage (206). If vaginal delivery is chosen, close inspection of the episiotomy site is required during follow-up because of rare reports of metastatic cervical cancer at these locations (207).

Patients with 3 to 5 mm of invasion and those with lymph–vascular space invasion may be followed to term or delivered early after establishment of fetal pulmonary maturity (202,205). They may have cesarean delivery, immediately followed by modified radical hysterectomy and pelvic lymphadenectomy. **Patients with more than 5 mm invasion should be treated as having frankly invasive carcinoma of the cervix.** Treatment depends on the gestational age of the pregnancy and the wishes of the patient. Modern neonatal care affords a 75% survival rate for infants delivered at 28 weeks of gestation and 90% for those delivered at 32 weeks of gestation. Fetal pulmonary maturity can be determined by amniocentesis, and prompt treatment can be instituted when pulmonary maturity is documented. Although timing is controversial, it is probably unwise to delay therapy for longer than 4 weeks (204,205). The recommended treatment is classic cesarean delivery followed by radical hysterectomy with pelvic lymphadenectomy. There should be a thorough discussion of the risks and options with both parents before any treatment is undertaken.

Patients with stages II to IV cervical cancer should be treated with radiotherapy. If the fetus is viable, it is delivered by classic cesarean birth, and therapy is begun postoperatively. If the pregnancy is in the first trimester, external radiation therapy can be started with the expectation that spontaneous abortion will occur before the delivery of 4,000 cGy. In the second trimester, a delay of therapy may be entertained to improve the chances of fetal survival. If the patient wishes to delay therapy, it is important to ensure fetal pulmonary maturity before delivery is undertaken. Neoadjuvant chemotherapy has been administered to women during pregnancy with cervical cancer after 13 weeks gestation, without clear short-term harm to the fetus, although longer clinical follow-up is necessary (208).

The clinical stage is the most important prognostic factor for cervical cancer during pregnancy. OS for these patients is slightly better because an increased

proportion of these patients have stage I disease. For patients with advanced disease, there is evidence that pregnancy impairs the prognosis (202,205). The diagnosis of cancer in the postpartum period is associated with a more advanced clinical stage and a corresponding decrease in survival (206).

Cancer of the Cervical Stump

Cancer of the cervical stump was more common many decades ago when supracervical hysterectomy was popular; because this operation is being performed more frequently, this situation may become increasingly familiar. Early-stage disease is treated surgically, with very little change in technique from that used when the uterus is intact (209). **Radical parametrectomy with upper vaginectomy and pelvic lymphadenectomy is the standard procedure.** Advanced-stage disease may present a therapeutic problem for the radiation oncologist if the length of the cervical canal is less than 2 cm. This length is necessary to allow satisfactory placement of the uterine tandem. If the uterine tandem cannot be placed, radiation therapy can be completed with vaginal ovoids or external beam techniques such as IMRT. Radiation oncology departments skilled in combined interstitial/intracavitary brachytherapy offer the ability to achieve curative brachytherapy coverage of cervical stump carcinomas. Intravaginal ovoids abutting the stump can be loaded with interstitial needles arrayed through the entire diameter and thickness of the stump to achieve comprehensive tumor coverage.

Pelvic Mass

The origin of a pelvic mass must be clarified before treatment is initiated. A CT urogram can exclude a pelvic kidney, and a barium enema helps to identify diverticular disease or carcinoma of the colon. An abdominal x-ray film may show calcifications typically associated with benign ovarian teratomas or uterine leiomyomas. Pelvic ultrasonography differentiates between solid and cystic masses and indicates uterine or adnexal origin. Solid masses of uterine origin are most often leiomyomas and do not need further investigation.

Pyometra and Hematometra

An enlarged fluid-filled uterine cavity may be a pyometra or a hematometra. The hematometra can be drained by dilation of the cervical canal and will not interfere with treatment. The pyometra should be drained, and the patient should be given antibiotics to cover *Bacteroides* species, anaerobic *Staphylococcus* and *Streptococcus* species, and aerobic coliform bacterial infection. Placement of a large mushroom catheter through the cervix was advocated, but the catheter may become obstructed, leading to further occlusion of the drainage. Repeated dilation of the cervix with aspiration of pus every 2 to 3 days is more effective.

If the disease is stage I, a radical hysterectomy and pelvic lymphadenectomy

may be performed. However, a pyometra is usually found in patients with advanced disease, and thus radiotherapy is required. External-beam therapy can begin after the pyometra is healed. Patients often have a significant amount of pus in the uterus or a tubo-ovarian abscess without signs of infection; therefore, a normal temperature and a normal white blood cell count do not necessarily exclude infection. Repeat physical examination or pelvic ultrasonography is necessary to ensure adequate drainage.

Cervical Carcinoma After Extrafascial Hysterectomy

When invasive cervical cancer is found after simple hysterectomy, further treatment is predicated on the extent of disease. Microinvasive disease in patients at low risk for lymph node metastasis does not require further treatment. Invasive disease may be treated with radiotherapy or reoperation involving a pelvic lymphadenectomy and radical excision of parametrial tissue, cardinal ligaments, and the vaginal stump (210).

Reoperation

Reoperation is indicated for a young patient who has a small lesion and in whom preservation of ovarian function is desirable. It is not indicated for patients who have positive margins or obvious residual disease (210). Survival rates after radical reoperation are similar to those after radical hysterectomy for stage I disease.

Concurrent *cisplatin*-based chemoradiation is recommended for gross residual disease, positive imaging, disease in the lymph nodes or parametrium, or a positive surgical margin; individualized brachytherapy is clearly indicated for a positive vaginal margin (211).

Radiation Therapy

Survival after radiotherapy depends on the volume of disease, the status of the surgical margins, and the length of delay from surgery to radiotherapy. Patients with microscopic disease have a 95% to 100% 5-year survival rate; the 5-year survival rate is 82% to 84% in those with macroscopic disease and free margins, 38% to 87% in those with microscopically positive margins, and 20% to 47% in those with obvious residual cancer (212–214). A delay in treatment of more than 6 months is associated with a 20% survival rate (214).

Acute Hemorrhage

Occasionally, a large lesion can produce life-threatening hemorrhage. A biopsy of the lesion should be performed to verify neoplasia, and a vaginal pack soaked in Monsel's solution (*ferric subsulfate*) should be packed tightly against the cervix. After proper evaluation, **external radiation therapy can be started with the expectation that control of bleeding may require 8 to 10 daily treatments at 180 to 200 cGy per day.** Broad-spectrum antibiotics should be used to reduce the incidence of infection. If the

patient becomes febrile, the pack should be removed. Rapid replacement of the pack may be necessary, and a fresh pack should be immediately available. This approach to management of hemorrhage in patients previously untreated is preferable to exploration and vascular ligation. **Vascular embolization under fluoroscopic control may be required in severe cases, and this procedure may obviate a laparotomy.** However, vascular occlusion ultimately may lead to decreased blood flow and oxygenation of the tumor, compromising the effectiveness of subsequent radiotherapy.

Ureteral Obstruction

Treatment of bilateral ureteral obstruction and uremia in previously untreated patients should be determined on an individual basis. Transvesical or percutaneous ureteral catheters should be placed in patients with no evidence of distant disease, and radiotherapy with curative intent should be instituted. Patients with metastatic disease beyond curative treatment fields should be presented with the options of ureteral stenting, palliative radiotherapy, and chemotherapy. With aggressive management, a median survival rate of 17 months may be achieved for these patients (215).

Barrel-Shaped Cervix

The expansion of the upper endocervix and lower uterine segment by tumor is referred to as a **barrel-shaped cervix. Patients with tumors larger than 6 cm in diameter have a 17.5% central failure rate when treated with radiotherapy alone because the tumor at the periphery of the lower uterine segment is too far from the standard intracavitary source to receive an adequate tumoricidal dose** (216). Attempts were made to overcome this problem radiotherapeutically by means of interstitial implants into the tumor with a perineal template, but high central failure rates were reported with this technique (217).

One approach is to use a combination of radiotherapy and surgery for treatment of patients with a barrel-shaped cervix. An extrafascial hysterectomy is performed 2 to 3 months after the completion of radiation therapy in an effort to resect a small, centrally persistent tumor. The dose of external radiotherapy is reduced to 4,000 cGy, and a single intracavitary treatment is given, which is followed by an extrafascial hysterectomy (218,219). This method appears to result in a lower rate of central failure (2%), although it is not clear that the OS rate is improved. **There is disagreement concerning the need for extrafascial hysterectomy**, and the GOG is undertaking a randomized study to compare adjuvant hysterectomy with radiotherapy alone in patients who have no evidence of occult metastases in the para-aortic nodes (see stages IB and IIA discussion).

The narrow upper vagina of older patients may preclude the use of an intracavitary source of radiation. Because of the significant OS advantage experienced by patients who successfully receive brachytherapy boosts, placement of brachytherapy applicators

with smaller geometry (mini-ovoids, or tandem and cylinder, or tandem alone) should be strongly considered prior to switching to an external beam-only regimen. Patients receiving their entire course of therapy from external beam radiation have a higher central failure rate and more significant bowel and bladder morbidity. If stage I disease is present in such a patient, a radical hysterectomy with pelvic lymphadenectomy is preferable, if the patient's medical condition allows this approach. There may be a role for IMRT and/or stereotactic radiation boosts in the management of such tumors.

Recurrent Cervical Cancer

Treatment of recurrent cervical cancer depends on the mode of primary therapy and the site of recurrence. Patients who were treated initially with surgery should be considered for radiation therapy, and those who had radiation therapy should be considered for surgical treatment. Chemotherapy is palliative only and is reserved for patients who are not considered curable by either surgery or radiation therapy.

Radiotherapy for recurrence after surgery consists primarily of external treatment. Vaginal ovoids may be placed in patients with isolated vaginal cuff recurrences. Patients with a regional recurrence may require interstitial implantation with a Syed type of template in addition to external therapy. A 25% survival rate can be expected in patients treated with radiation for a postsurgical recurrence (198).

Radiation Retreatment

Retreatment of recurrent pelvic disease by means of radiotherapy with curative intent is confined to patients who had suboptimal or incomplete primary therapy. This may allow the radiation oncologist to deliver curative doses of radiation to the tumor. The proximity of the bladder and rectum to the cancer and the relative sensitivity of these organs to radiation injury are the major deterrents to retreatment with radiation. The insertion of multiple interstitial radiation sources into locally recurrent cancer through a perineal template or next-generation combined intracavitary/interstitial applicator may help overcome these dosimetric considerations (210,220). The fistula rates can be high, and those consequences must be considered before interstitial therapy is initiated. For patients considered curable with interstitial implant therapy, pelvic exenteration is a better treatment choice. Palliative radiotherapy can be given to patients with localized metastatic lesions that are deemed incurable. Painful bony metastases, central nervous system lesions, and severe urologic or vena caval obstructions are specific indications.

Surgical Therapy

Surgical therapy for postirradiation recurrence is limited to patients with central pelvic disease. A few carefully selected patients with small-volume disease limited to the cervix may be treated with an extrafascial or radical hysterectomy. However, the

difficulty of assessing tumor volume and the 30% to 50% rate of serious urinary complications in these previously irradiated patients have led most gynecologic oncologists to recommend pelvic exenteration as a last chance for cure (221,222).

Exenteration

There are three types of exenterative procedures: (i) an anterior exenteration (removal of the bladder, vagina, cervix, and uterus), (ii) a posterior exenteration (removal of the rectum, vagina, cervix, and uterus), and (iii) a total exenteration (removal of bladder and rectum with the vagina, cervix, and uterus) (Fig. 38-9). A total exenteration that includes a large perineal phase removes the entire rectum and leaves the patient with a permanent colostomy and a urinary conduit (infralevator). In selected patients, a total exenteration may take place above the levator muscle (supralevator), leaving a rectal stump that may be anastomosed to the sigmoid, thus avoiding a permanent colostomy.

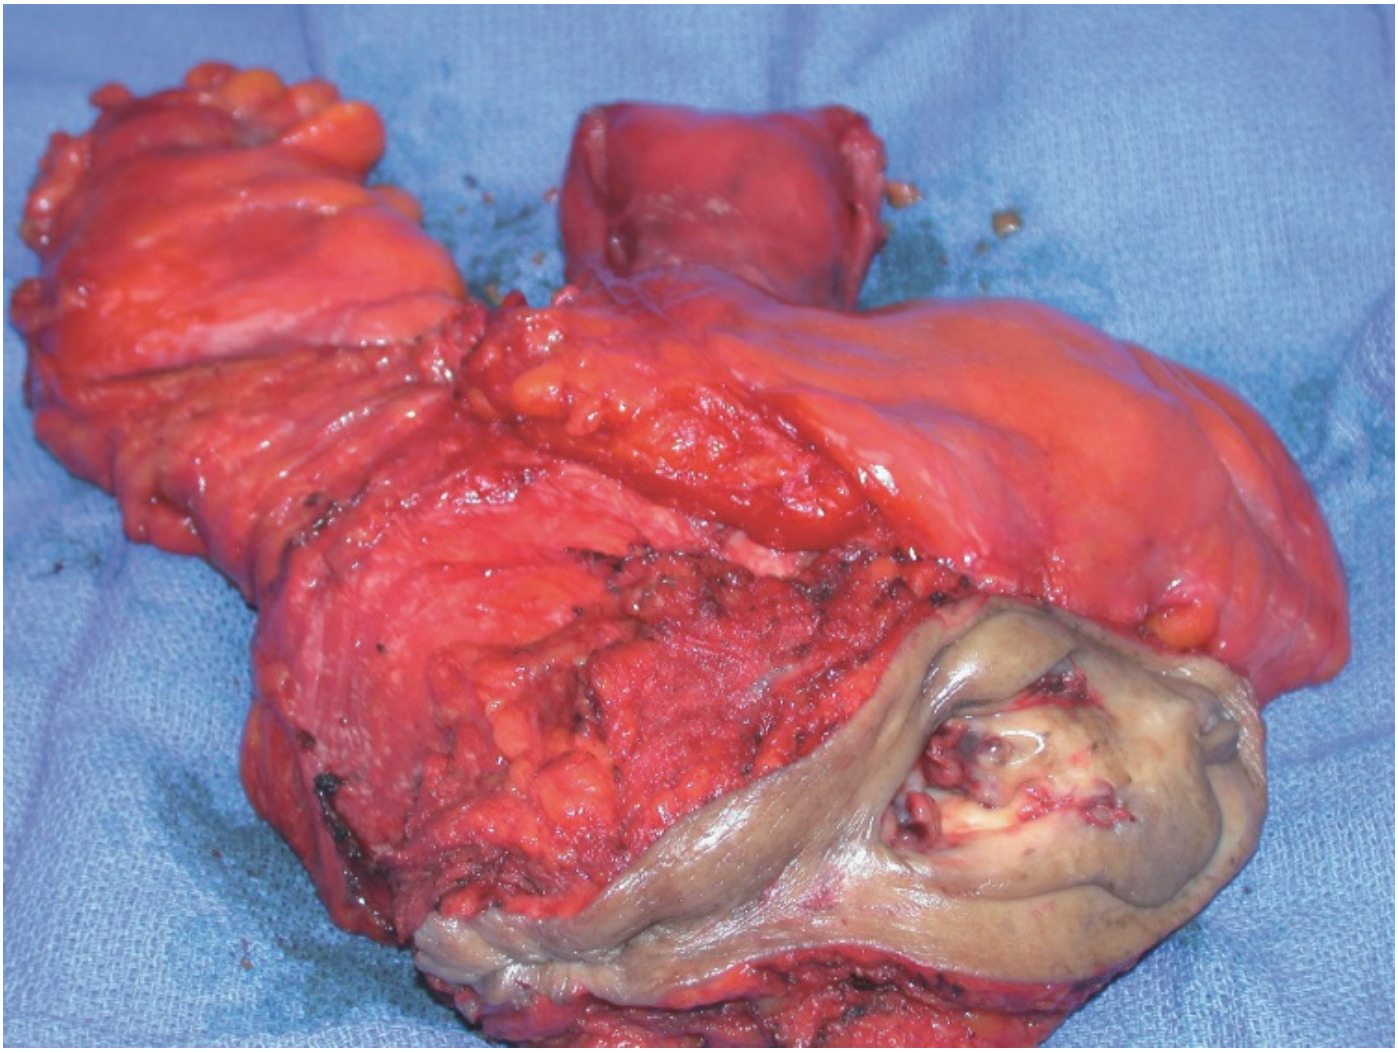

FIGURE 38-9 Pelvic exenteration specimen.

Preoperative Evaluation and Patient Selection

It is imperative to search for metastatic disease before the patient undergoes an exenteration. The presence of metastatic disease in this setting is considered a contraindication to exenterative procedures. Physical examination includes careful palpation of the peripheral lymph nodes with FNA cytologic sampling of any nodes that appear suspicious. A random biopsy of nonsuspicious supraclavicular lymph nodes is advocated by some clinicians but is not routinely practiced (174,223). A PET/CT scan of the chest and abdomen and pelvis CT help in the detection of liver metastases and enlarged nodes. Cytologic study of any abnormality should be undertaken with CT-guided FNA. If a positive cytologic diagnosis is obtained, it will obviate the need for exploratory laparotomy.

Extension of the tumor to the pelvic sidewall is a contraindication to exenteration; however, this may be difficult for even the most experienced examiner to determine because of radiation fibrosis. If any question of resectability arises, exploratory laparotomy and parametrial biopsies should be offered (224–227). **The clinical triad of unilateral leg edema, sciatic pain, and ureteral obstruction is nearly always pathognomonic of unresectable disease on the pelvic sidewall.** Preoperatively, the patient should be prepared for a major operation. Total parenteral nutrition may be necessary to place the patient in an anabolic state for optimal healing. A bowel preparation, preoperative antibiotic administration, and prophylaxis for deep venous thrombosis with low-dose *heparin* or pneumatic calf compression should be undertaken (228). Surgical mortality increases with age, and the operation should rarely be considered in a patient who is older than 70 years. Other medical illnesses should be taken into account. When life expectancy is limited, exenterative surgery is unwise.

Anterior Exenteration

Candidates for anterior exenteration are those in whom the disease is limited to the cervix and anterior portion of the upper vagina. Proctoscopic examination should be performed because a positive finding would mandate a total exenteration. However, a negative proctoscopic examination finding does not exclude disease in the rectal muscularis, and findings at laparotomy still must be considered. The presence of disease in the posterior vaginal mucosa directly over the rectum mandates removal of the underlying rectum.

Posterior Exenteration

A posterior exenteration is rarely performed for recurrent cervical cancer. It is indicated, however, for the patient with an isolated posterior vaginal recurrence in which dissection of the ureters through the cardinal ligaments will not be necessary.

Total Exenteration

Total exenteration with a large perineal phase is indicated when the disease

extends to the lower part of the vagina (Fig. 38-9). Because distal vaginal lymphatics may empty into the nodal basins of the inguinal region, these nodes should be carefully evaluated preoperatively. A supralevator total exenteration with low rectal anastomosis is indicated in the patient whose disease is confined to the upper vagina and cervix (229,230). Samples from margins of the rectal edge should be obtained for frozen-section evaluation because occult metastases to the muscularis may occur.

The development of techniques to establish continent urinary diversion helps improve a woman's physical appearance after exenteration (231–233). When both a rectal anastomosis and a continent diversion are performed, the patient will not have a permanent external appliance. Associated psychological trauma in such cases may be avoided. **Every effort should be made to create a neovagina simultaneously with the exenteration** (234). This procedure helps in the reconstruction of the pelvic floor after extirpation of the pelvic viscera. Regardless of whether a neovagina is constructed, it is desirable to mobilize the omentum on the left gastroepiploic artery to create a new pelvic floor.

Surgical mortality from exenterative procedures has steadily decreased to less than 10%. Common causes of postoperative death are sepsis, pulmonary thromboembolism, and hemorrhage. Fistulas of the gastrointestinal and genitourinary tract are serious surgical complications, with a 30% to 40% mortality rate despite attempts at surgical repair. The risk for fistula formation is decreased if nonirradiated segments of bowel are used for formation of the urinary conduit (228). **The 5-year survival rate is 33% to 60% for patients undergoing anterior exenteration and 20% to 46% for those undergoing total exenteration** (224–234). Survival rates are worse for patients with recurrent disease (larger than 3 cm), invasion into the bladder, positive pelvic lymph nodes, and recurrence diagnosed within 1 year after radiotherapy (227). The 5-year survival rate of patients with positive pelvic lymph nodes is less than 5%; thus, the performance of an extensive lymphadenectomy in the irradiated field is not warranted. Discontinuation of the procedure is advisable if any nodes are positive for metastatic cancer. Patients who have any disease in the peritoneal cavity have no chance of survival.

Laterally Extended Endopelvic Resection

Locally recurrent cervical cancer in a previously irradiated field is associated with a dismal prognosis. Exenterative therapy traditionally was reserved for the highly select patient with centrally recurrent disease, a selection criteria that excludes most patients with recurrence. A technique called the **laterally extended endopelvic resection (LEER)** procedure was described, which offers a surgical treatment option for patients with recurrent disease involving the pelvic sidewall. The LEER procedure involves extending the lateral resection plane of the traditional pelvic exenteration to include resection of the internal iliac vessels; the endopelvic portion of the obturator internus

muscle; and the coccygeus, iliococcygeus, and pubococcygeus muscles. Extension of the surgical plane allows for resection of lateral tumors with a negative margin. Experience with it is limited to one center, which reports as high as a 62% recurrence-free survival, but as high as 70% moderate-to-severe morbidity (235).

Chemotherapy for Recurrent Cervical Cancer

Recurrent cervical cancer is not considered curable with chemotherapy (236–238). Several clinical trials with various drugs (e.g., *carboplatin*, *cisplatin*, and *paclitaxel*) showed response rates of up to 45%. Most responses are partial; complete responses are unusual and limited to patients with chest metastases in whom the dose of drug delivered to the disease is better than that delivered to the fibrotic postirradiated pelvis (237,238). The uptake of chemotherapy to recurrent tumor in a previously irradiated field may be compromised because of altered blood supply caused by that radiation.

***Carboplatin* and *paclitaxel* combination chemotherapy is as effective and less toxic than the *cisplatin* and *paclitaxel* combination** (185). **Combination chemotherapy with *carboplatin– paclitaxel–bevacizumab* may produce better survival, but it is more toxic than doublet chemotherapy** (186). **Single-agent *carboplatin* is an acceptable alternative in these patients whose disease cannot be cured.**

Palliative Therapy

Palliative therapy for patients with incurable disease consists of radiation or chemotherapy or both. **Palliative radiation therapy is intended to relieve symptoms of pain or bleeding associated with advanced disease and may be administered as either external beam therapy (teletherapy) or brachytherapy.** Special care should be given to previously irradiated sites because additional radiation therapy may be associated with unacceptable morbidity. Single or multiagent palliative chemotherapy may be used with variable response rates. Symptomatic recurrent disease within previously irradiated fields may not respond well to palliative chemotherapy.

VAGINAL CARCINOMA

[6] Primary vaginal cancer is a relatively uncommon tumor, representing only 2% to 3% of malignant neoplasms of the female genital tract. In the United States, it is estimated that there were 1,312 new cases in 2014, and 430 deaths from the disease (1). Squamous histology accounts for 80% (239). **Primary vaginal cancer should be differentiated from cancers metastatic to the vagina, which constitute the majority of cancers found in the vagina (84%)** (240).

Table 38-6 FIGO Staging of Vaginal Cancer

Stage I	The carcinoma is limited to the vaginal wall
Stage II	The carcinoma has involved the subvaginal tissue but has not extended to the pelvic wall
Stage III	The carcinoma has extended to the pelvic wall
Stage IV	The carcinoma has extended beyond the true pelvis or has involved the mucosa of the bladder or rectum; bullous edema as such does not permit a case to be allotted to stage IV
IVA	Tumor invades bladder and/or rectal mucosa and/or direct extension beyond the true pelvis
IVB	Spread to distant organs

FIGO, International Federation of Gynecology and Obstetrics.

From **Beller U, Benedet JL, Creasman WT, et al.** Carcinoma of the vagina. FIGO 26th Annual Report on the Results of Treatment in Gynecological Cancer. *Int J Gynecol Obstet* 2006;95:S29–S42 and FIGO Committee on Gynecologic Oncology. Current FIGO staging for cancer of the vagina, fallopian tube, ovary, and gestational trophoblastic neoplasia. *Int J Gynecol Obstet* 2009;105:3–4.

Staging

The FIGO staging of vaginal cancer dictates that a tumor extending to the vagina from the cervix be regarded as a cancer of the cervix, whereas a tumor involving both the vulva and the vagina should be classified as a cancer of the vulva.

The FIGO staging for vaginal carcinoma is shown in Table 38-6. **Staging is performed by clinical examination** and, if indicated, cystoscopy, proctoscopy, and chest and skeletal radiography. Information derived from lymphangiography, CT, MRI, or PET cannot be used to change the FIGO stage; however, it can be used for planning treatment. Less than 30% of vaginal cancers present at stage I (241–243).

Surgical staging and resection of enlarged lymph nodes may be indicated in selected patients. FIGO staging does not include a category for microinvasive disease. Because vaginal cancer is rare and treatment is by radiotherapy, there is very little information concerning the spread of disease in relation to depth of invasion, lymph–vascular space invasion, and size of the lesion.

Etiology

The association of cervical cancer with HPV suggests that vaginal cancer has a similar association (244). A study of 341 cases revealed that in younger patients, the disease seemed to be related to HPV infection, while in older patients, there was no association (243). **As many as 30% of women with vaginal cancer have a history of cervical cancer treated within the previous 5 years** (186,235–247). As with cervical cancer, there appears to be a premalignant phase called **vaginal intraepithelial neoplasia**

(VAIN) (see Chapter 16). **The exact incidence of progression to invasive vaginal cancer from VAIN is not known;** however, there are documented cases of invasive disease occurring despite adequate treatment of VAIN (248,249).

By convention, any new vaginal carcinoma developing at least 5 years after cervical cancer is considered a new primary lesion. There are three possible mechanisms for the occurrence of vaginal cancer after cervical neoplasia:

1. Residual disease in the vaginal epithelium after treatment of the cervical neoplasia
2. New primary disease arising in a patient with increased susceptibility to lower genital tract carcinogenesis (the role of HPV in this setting is suspected)
3. Increased susceptibility to carcinogenesis caused by radiation therapy

Screening

Routine screening of all patients for vaginal cancer is inappropriate. For women who had a cervical or vulvar neoplasm, the Pap test is an important part of routine follow-up with each physician visit, because these patients are at an increased lifetime risk for developing vaginal cancer. It is recommended that Pap test surveillance for vaginal cancer be performed yearly after the patient has completed surveillance for cancer of the cervix or vulva. **For women who had a hysterectomy for benign disease and have no antecedent history of CIN 2–3, performance of Pap testing is unnecessary. If the patient has a history of cervical dysplasia or cervical cancer, yearly screening is recommended.** When adjusted for age and prior cervical disease, the incidence of vaginal cancer is not increased in women who had hysterectomy for benign disease (250). Because primary vaginal tumors tend to be multicentric, the entire vaginal mucosa should be considered at-risk. Therefore, in addition to screening cytology, careful bimanual examination of the entire vagina and vulva is recommended for women at high risk.

Symptoms

Painless vaginal bleeding and discharge are the most common symptoms of vaginal cancer. With more advanced tumors, urinary retention, bladder spasm, hematuria, and frequency of urination may occur. In a large series, 14% were asymptomatic and diagnosis was made by routine examination or abnormal cytology (243). Tumors developing on the posterior vaginal wall may produce rectal symptoms, such as tenesmus, constipation, or blood in the stool.

Diagnosis

The diagnostic workup includes a complete history and physical examination, careful

speculum examination and palpation of the vagina, and bimanual pelvic and rectal examinations. **It is important to rotate the speculum to obtain a careful view of the entire vagina because posterior wall lesions frequently occur and may be overlooked.**

In early squamous cell lesions, the diagnosis is often suggested by an abnormal HPV or Pap test result; however, this is not true for clear-cell adenocarcinomas, which are characterized by submucosal growth. In these cases, the diagnosis is suggested by cytologic findings in only 33% of cases. Visually suspicious areas in the vagina should be evaluated with a targeted biopsy using the same instruments as those used for cervical biopsies. Careful palpation of the vagina may be helpful in detecting submucosal irregularities. **The most common site of vaginal cancer is in the upper one-third of the vagina on the posterior wall.** The developing tumor may be missed during initial inspection because of obscured visualization caused by the blades of the speculum (251). Colposcopy is valuable in evaluating patients with abnormal HPV or Pap test results, unexplained vaginal bleeding, or ulcerated erythematous patches in the upper vagina. A colposcopically targeted biopsy may not allow a definitive diagnosis, and a partial vaginectomy may be necessary to determine invasion. Occult invasive carcinoma may be detected by such an excision, particularly in patients who have a history of prior hysterectomy in whom the vaginal vault closure may bury some of the vaginal epithelium at risk for cancer (252).

Pathology

Cancer of the vagina spreads most often by direct extension into the pelvic soft tissues and adjacent organs. Metastases to the pelvic and para-aortic lymph nodes may occur in advanced disease. Lesions in the lower one-third of the vagina may spread directly to the inguinal femoral lymph nodes and the pelvic nodes (253). Hematogenous dissemination to the lungs, liver, or bone may occur as a late phenomenon.

Squamous cell carcinomas are the most common form of vaginal cancer, occurring in 80% to 90% of cases. These tumors most commonly occur in the upper one-third, posterior wall of the vagina. The mean age of patients with squamous cell cancer is 60 years (254,255).

Malignant melanoma is the second most common cancer of the vagina, accounting for 2.8% to 5% of all vaginal neoplasms (256–258). Other histologic subtypes include adenocarcinoma and sarcoma.

Primary adenocarcinoma of the vagina is rare, constituting 9% of primary tumors of the vagina. The most common adenocarcinoma of the vagina is metastatic, originating from the colon, endometrium, ovary, or, rarely, pancreas and stomach. In general, adenocarcinomas affect a younger population of women, regardless of whether they were exposed to *diethylstilbestrol* (*DES*) *in utero* (259).

Adenocarcinomas may arise in wolffian rest elements, periurethral glands, and foci of endometriosis (260). In women exposed to *DES in utero*, adenocarcinoma may develop in vaginal adenosis.

DES was used in the United States from 1940 until 1971 to maintain high-risk pregnancies in women with a history of spontaneous abortions. In 1970, seven young women were reported with clear-cell adenocarcinoma of the vagina **(Fig. 38-10)**; later, an association between this cancer and maternal ingestion of *DES* during pregnancy was identified (261). Subsequently, more than 500 cases of clear-cell cancer of the vagina and cervix were reported to the Registry for Research on Hormonal Transplacental Carcinogenesis.

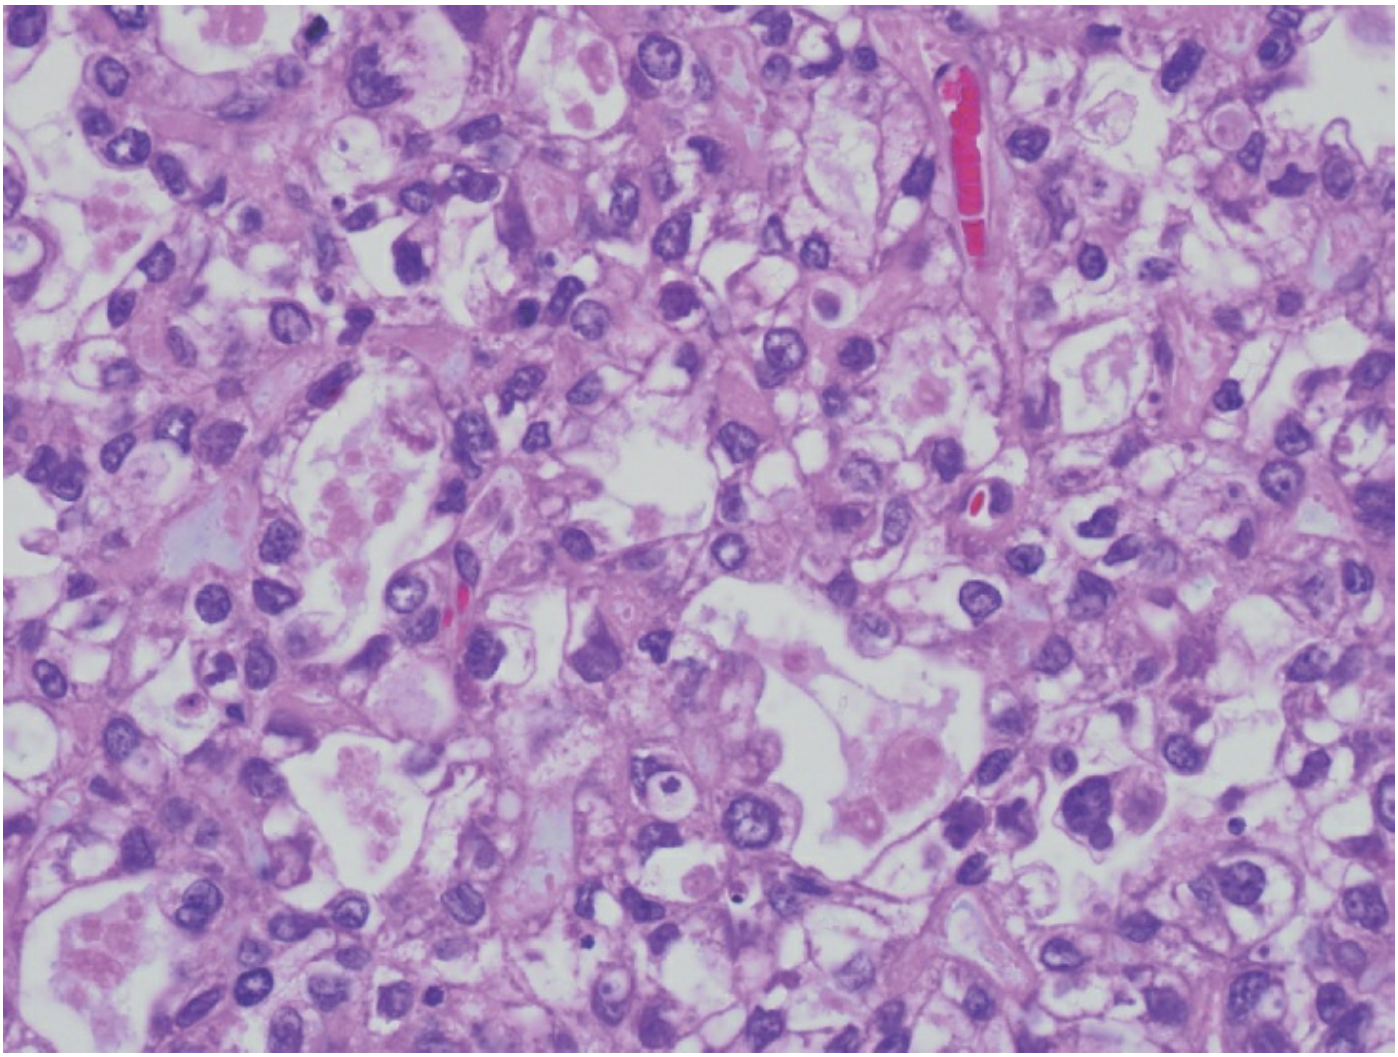

FIGURE 38-10 Vaginal clear-cell carcinoma. Note the formation of tubules with hobnail cells lining the lumen. These cells are characterized by nuclear protrusion into the apical cytoplasm.

The estimated risk for developing clear-cell adenocarcinoma for an exposed offspring is 1 in 1,000 or less. The mean age of diagnosis is 19 years (262). Because the use of *DES* in pregnant women was discontinued in 1971, most of these tumors

probably have been discovered. Clear-cell adenocarcinoma in women with a history of in utero exposure to *DES* typically presented in the exocervix or anterior, upper one-third of the vagina. These tumors varied greatly in size and were most frequently exophytic and superficially invasive. Stage is the most important prognostic factor. Other statistically significant factors included a tubulocystic growth pattern, size less than 3 cm^2, and less than 3 mm of stromal invasion. It is uncertain, however, what will happen to this cohort of women as they move into their fifth, sixth, and seventh decades of life. Continued surveillance of these women is indicated.

Ninety-seven percent of cases of vaginal clear-cell adenocarcinoma are associated with adenosis. Adenosis is characterized by the presence of persistent müllerian-type glandular epithelium. Although adenosis is the most common histologic abnormality in women exposed to *DES in utero*, adenosis can be found in women without a history of exposure. Adenosis typically appears as red, grapelike clusters in the vagina.

Malignant melanoma of the vagina is rare and lethal, occurring most often in white women. The average age of these patients is 58 years (263). Most lesions are deeply invasive, corresponding to a Clark level IV when compared with the staging for vulvar melanomas. The most common location of these tumors is in the lower one-third of the vagina (264). Melanomas have a wide variety of size, color, and growth patterns (262,265). Radical excision (vaginectomy, hysterectomy, and pelvic lymphadenectomy) is the mainstay of treatment. The goal of treatment is to avoid local (vaginal) recurrence, which is the most common site of recurrence (263,264). The need to dissect regional lymph nodes is uncertain. Because the disease is deeply invasive, hematogenous spread is the most common lethal recurrence. There is no difference in OS of patients with local as opposed to radical excision (263). The survival rate is approximately 10% at 5 years.

The most common benign and malignant mesenchymal tumors of the vagina in adult women are smooth muscle tumors (266). Vaginal sarcomas are usually fibrosarcomas or leiomyosarcomas and are extremely rare. Radical local excision, followed by adjuvant chemotherapy or radiation therapy, is the indicated treatment.

The most common malignant mesenchymal tumor of the vagina in children and infants is botryoid rhabdomyosarcoma (Fig. 38-11). Botryoid sarcoma is usually found in the vagina during infancy and early childhood, in the cervix during the reproductive years, and in the corpus uteri during postmenopausal years. Preoperative chemotherapy with *vincristine*, *actinomycin D*, and *cyclophosphamide*, followed by conservative surgery or radiation, has improved survival.

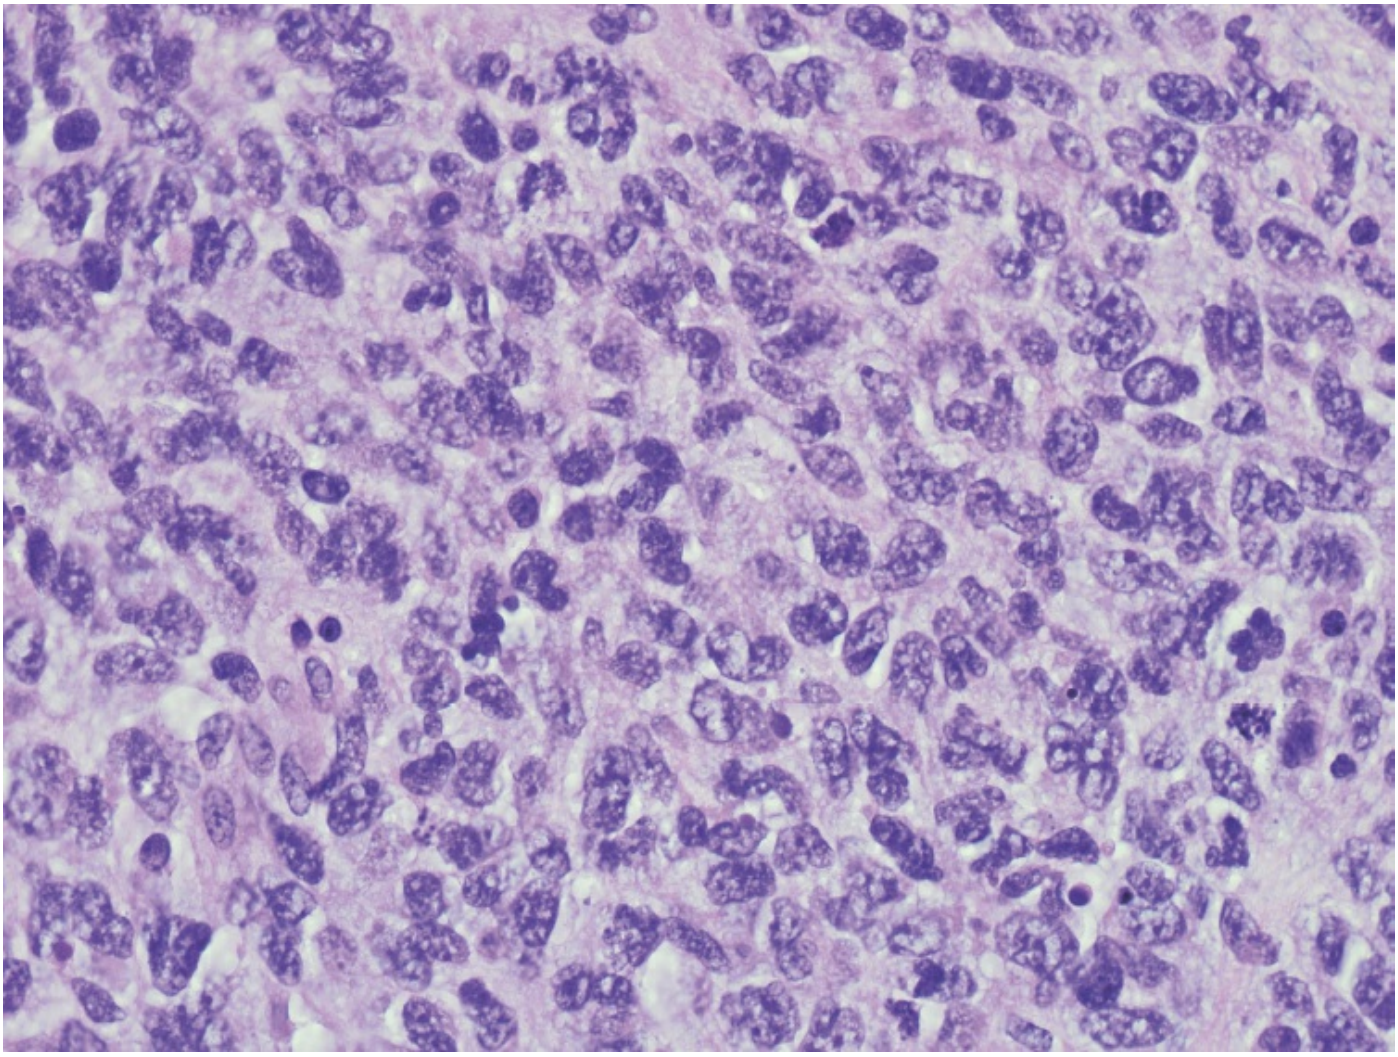

FIGURE 38-11 Embryonal rhabdomyosarcoma of the vagina (botryoid sarcoma). This lesion consists of primitive mesenchymal cells and rhabdomyoblasts, which have abundant eosinophilic cytoplasm. With further differentiation, cross-striations may become evident.

[6] Treatment

Treatment selection is based on the clinical examination, CT scan results, chest radiography results, age, and condition of the patient. PET scans may give more accurate information about disease spread than MRI or CT scan alone (267). Most tumors are treated by radiation therapy. Surgery is limited to selected cases. These are as follows:

1. **Women with stage I disease involving the upper posterior vagina may be treated by radical vaginectomy and pelvic lymphadenectomy.** If the uterus is in situ, it is removed as a radical hysterectomy specimen. When margins are clear and lymph nodes are negative, no additional therapy is necessary.
2. **Patients with stage IV disease with either rectovaginal or vesicovaginal fistula** may be candidates for primary pelvic exenteration with pelvic and para-aortic

lymphadenectomy (262). Low rectal anastomosis, continent urinary diversion, and vaginal reconstruction are indicated and are more successful in these nonirradiated patients than in patients who received prior radiation therapy.

3. **Women with central pelvic recurrence after radiation therapy are candidates for pelvic exenteration similar to that used for cervical cancer.**
4. **Surgical staging with resection of enlarged lymph nodes followed by radiation therapy may improve the control of pelvic disease.**

Radiation therapy is the treatment of choice for all patients except those described previously. Small superficial lesions may be treated with intracavitary radiation alone (262). **Larger, thicker lesions should be treated first with external teletherapy to decrease tumor volume and to treat the regional pelvic nodes, followed by intracavitary and interstitial therapy to deliver a high dose to the primary tumor** (255,263). If the uterus is intact and the lesion involves the upper vagina, an intrauterine tandem and ovoids can be used. If the uterus was previously removed, a vaginal cylinder may be used for superficial irradiation. When brachytherapy is used, high- and low-dose rate techniques were described. If the lesion is more than 0.5-cm thick, interstitial radiation techniques can improve the dose distribution to the primary tumor. Surgical exploration or laparoscopy at the time of insertion of Syed interstitial implants defines more precisely the placement of the needles and ensures that needles do not pass into adherent loops of bowel. Extended-field radiation may be used for vaginal cancer in a manner similar to its use for cervical carcinoma, although there is no experience reported with the use of this technique in the treatment of vaginal cancer. Likewise, there is little reported experience with combination chemoradiation treatment (268). Although there will never be enough patients for a proper randomized control trial, concurrent use of *5-FU* and *cisplatin* was highly successful in anal and cervical cancer and thus should be considered for treatment of vaginal cancer.

Sequelae

The proximity of the rectum, bladder, and urethra leads to a major complication rate of 10% to 15% for surgery and radiation treatment. For large tumors, the risk of bladder or bowel fistula is significant. Radiation cystitis and proctitis are common, as are rectal strictures or ulcerations. Radiation necrosis of the vagina occasionally occurs, requiring debridement, and often leads to fistula formation. Vaginal fibrosis, stenosis, and stricture are common after radiation therapy. **Use of vaginal dilators and resumption of regular sexual relations should be encouraged, along with the use of topical *estrogen* to maintain adequate vaginal function.**

Survival

The overall 5-year survival rate for patients with vaginal cancer is 52% (Table 38-7). This reflects the difficulties of treatment and the fact the disease presents at late stage. **For patients with stage I disease, the 5-year survival rate is 74%.** Most recurrences are in the pelvis, either from enlarged regional nodes or from large central tumors. Radiation techniques, including interstitial implants with Syed template and combination chemoradiation, are the mainstay of therapy. Careful evaluation of patients who receive radiation therapy to detect central recurrence may allow some patients to be saved by pelvic exenteration. Because of the rarity of vaginal cancer, these patients should be treated in a center that is familiar with the complexity of treatment and modalities of therapy.

Table 38-7 Primary Vaginal Carcinoma: 5-Year Survival

Stage	No. of Patients	No. Surviving 5 Years	Percentage
I	509	378	74.3
II	622	333	53.5
III	377	128	34.0
IV	163	24	15.3
Total	**1,671**	**864**	**51.7**

Melanoma
Carcinoid Tumors
Lymphoma and Leukemia

KEY POINTS

1 The peak age incidence of invasive epithelial ovarian cancer is approximately 60 years. About 30% of ovarian neoplasms in postmenopausal women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are malignant. The average age at diagnosis of patients with borderline tumors is approximately 46 years.

2 Ovarian cancer is associated with low parity and infertility. Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective, with a risk reduction of 0.3 to 0.4.

3 Oral contraceptive use reduces the risk of epithelial ovarian cancer—women who use oral contraceptives for 5 or more years reduce their relative risk by 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).

4 Given the false-positive results for CA-125 and transvaginal ultrasonography, particularly in premenopausal women and the absence of evidence from randomized trials that screening with CA-125 and TVUS reduces the mortality of ovarian cancer, these tests should not be used routinely to screen women for ovarian cancer.

5 Most epithelial ovarian cancers are sporadic, but up to one-quarter of cases may be associated with germline mutations in predisposing genes and may be hereditary. Hereditary ovarian cancers, particularly those caused by *BRCA1* mutations, occur at a younger age, typically about 10 years earlier than sporadic ovarian cancers.

6 Most hereditary ovarian cancers result from germline mutations in the *BRCA1* and *BRCA2* genes. The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., maternal and paternal sides of the family history for breast and ovarian cancer) must be carefully evaluated in all patients with epithelial ovarian cancer, fallopian tube cancer, and peritoneal cancer. It is important to note that almost 40% of women with BRCA-associated ovarian cancer do not have a family history and hence genetic testing should be offered to all women with ovarian cancer.

7 In unaffected women with a known *BRCA1* mutation, the value of prophylactic salpingo-oophorectomy is well established and is the most effective way to reduce the risk of these cancers and reduce mortality.

8 The importance of thorough surgical staging cannot be overemphasized, because subsequent treatment and prognosis will be determined by the stage of the disease. All patients with suspected ovarian cancer should be evaluated by a gynecologic oncologist. Patients with advanced-stage ovarian cancer (stage IIIC or IV) should have clinical evaluation including chest, abdomen and pelvis imaging. Patients determined to have a poor performance status, a high perioperative risk, or a low probability of attaining optimal cytoreduction to no visible, or palpable, residual disease, or at least cytoreduction to less than 1 cm of residual disease, should be considered for neoadjuvant chemotherapy prior to attempt at interval cytoreductive surgery after two to three cycles of chemotherapy. Patients with advanced ovarian cancer who are medically fit for major surgery and who potentially have resectable disease should be offered primary cytoreductive surgery followed by adjuvant chemotherapy. In the United States, primary cytoreductive surgery is preferred, if there is a high likelihood of achieving optimal cytoreduction with acceptable morbidity from surgery. Prior to initiating neoadjuvant chemotherapy, the pathologic diagnosis of ovarian, fallopian tube, or peritoneal cancer must be made on biopsy.

9 Combination chemotherapy with *carboplatin* and *paclitaxel* (CP) is recommended for patients with high-risk, low-stage disease. For advanced-stage epithelial ovarian cancer, the choice of intravenous (IV) versus intraperitoneal (IP) *platinum* and *taxane* chemotherapy with the addition of bevacizumab should be individualized.

10 The ICON8 trial did not confirm the JGOG study that showed that a dose-dense regimen of weekly paclitaxel and 3-weekly carboplatin was significantly superior to the standard every 3-week chemotherapy regimen of both drugs. Therefore 3-weekly regimens remain the standard of care in non-Japanese women.

11 BRCA-associated ovarian cancers have increased sensitivity to platinum chemotherapy and to poly (ADP-ribose) polymerase (PARP) inhibitors. PARP inhibitors are approved to treat selected patients with recurrent ovarian cancer and for maintenance therapy following response to platinum-based chemotherapy in the recurrent setting. There is good evidence from a number of randomized trials that maintenance therapy with PARP inhibitors results in a significant increase in the progression-free survival (PFS), particularly in BRCA mutation carriers (including tumors with somatic BRCA mutations). PARP inhibitors *niraparib* and *olaparib* are U.S. Food and Drug Administration (FDA) approved for maintenance therapy in patients with platinum-sensitive disease with a partial or complete response to platinum-based chemotherapy. PFS is improved with these agents regardless of BRCA status, although the PFS is significantly longer in patients with BRCA mutations. Maintenance therapy with *rucaparib* was reported to be associated with significant improvement in PFS in patients with platinum-sensitive recurrent ovarian cancer after response to chemotherapy, with the benefits being greater in women with somatic or germline BRCA (gBRCA) mutations.

12 In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant. In contrast to the relatively slow-growing epithelial ovarian tumors, germ cell malignancies grow rapidly.

13 The most common types of malignant germ cell tumors are dysgerminomas, immature teratomas, and endodermal sinus tumors (EST). Preservation of fertility should be standard in most patients. The most effective chemotherapy is *bleomycin*, *etoposide*, and *cisplatin* (BEP).

14 Stromal tumors include adult granulosa cell tumors, which are low-grade malignancies. They account for 70% of ovarian sex cord–stromal tumors. Granulosa cell tumors are the most common type of malignant ovarian sex cord–stromal tumors. In premenopausal women, they can be treated conservatively. Adjuvant chemotherapy is of unproven value.

15 Metastatic tumors to the ovaries are most frequently from the breast and gastrointestinal tract.

16 Epithelial serous fallopian tube carcinomas and peritoneal cancers are the same as ovarian cancer and are treated in the same way, with staging and cytoreductive surgery followed by *platinum* and *taxane* chemotherapy. The distinction between high-grade serous ovarian, fallopian tube, and peritoneum cancers is an anachronism because as most high-grade serous cancers arise from the fimbriae of the fallopian tube.

Ovarian cancer is the second most common gynecologic cancer in the United States but it accounts for the majority of deaths from these cancers. Epithelial cancers are the most common ovarian/fallopian malignancy, and at initial diagnosis, over two-thirds of patients have advanced disease. Ovarian cancer represents a major surgical challenge as the aim is to resect all visible disease. Optimal therapy includes maximal attempt at surgical cytoreduction to no gross disease, or at least optimal debulking (to <1 cm of residual disease), followed by *platinum*-based combination chemotherapy. It has the highest fatality-to-case ratio of all the gynecologic malignancies. There are nearly 22,280 new cases annually in the United States, and 14,240 women can be expected to succumb to their illness (1). Ovarian cancer is the seventh most common cancer in women in the United States, accounting for 3% of all malignancies, 6% of deaths from cancer in women, and almost one-third of invasive malignancies of the female genital organs. Ovarian cancer is the fifth most common cause of death from malignancy in women. **The lifetime risk of being diagnosed with ovarian cancer is 1% to 1.5% and of dying from ovarian cancer is almost 0.5%** (2).

EPITHELIAL OVARIAN CANCER

Developments, based in part on meticulous pathologic assessment of risk-reducing salpingo-oophorectomy specimens from BRCA patients, have completely changed our perception and understanding of "ovarian" cancer. While previously thought to be derived from the coelomic epithelium on the surface of the ovary or from ovarian inclusion cysts, it is now apparent that most serous carcinomas originate from the fallopian tube (3)**, while other subtypes (clear cell, endometrioid) are derived from endometriosis.** A detailed classification of the histologic types of epithelial tumors of the ovary is presented in Table 39-1. Neoplastic transformation can

occur when the cells are genetically predisposed to oncogenesis, exposed to an oncogenic agent, or both (4).

Table 39-1 Epithelial Ovarian Tumors

Histologic Type	Cellular Type
I. Serous	Endosalpingeal
A. Benign	
B. Borderline	
C. Malignant	
II. Mucinous	Intestinal, endocervical
A. Benign	
B. Borderline	
C. Malignant	
III. Endometrioid	Endometrial
A. Benign	
B. Borderline	
C. Malignant	
IV. Clear-cell	Müllerian
A. Benign	
B. Borderline	
C. Malignant	
V. Brenner	Transitional
A. Benign	
B. Borderline (proliferating)

Pathology

Invasive Cancer

Seventy-five percent to 80% of epithelial cancers are of the serous histologic type. Less common types are endometrioid (10%), clear cell (5%), mucinous (5%), transitional, and undifferentiated carcinomas, with the last two types representing less than 1% of epithelial lesions (2). Each of the major tumor types is named on the basis of a histologic pattern that resembles the epithelium in the lower genital tract (4). For example, serous tumors have an appearance similar to that of the glandular epithelial lining of the fallopian tube, endometrioid tumors resemble proliferative endometrium, and clear cell tumors resemble secretory or gestational endometrium. Mucinous tumors may contain cells that resemble endocervical glands, but more commonly these cells resemble the gastrointestinal epithelium. Transitional tumors are so named because of a resemblance to the epithelium in Walthard rests and bladder urothelium.

There is growing evidence that many, if not most, high-grade serous carcinomas of the ovary arise from the fimbrial end of the fallopian tube rather than from the ovary (5,6). **Serous epithelial ovarian cancers can be separated into two distinct groups—type I and type II serous tumors—as they differ considerably in the cell of origin, molecular pathogenesis, and their biologic behavior** (7). **Type I tumors include serous borderline tumors and low-grade serous carcinoma; they are genetically stable, do not have p53 mutations, and may have mutations in *KRAS* or *BRAF*. In contrast, type II serous tumors are rapidly growing, highly aggressive neoplasms that may have precursor lesions in the fimbriae of the fallopian tube; most are advanced stage at diagnosis** (8). **The type II tumors are genetically unstable and almost universally have p53 mutations.**

Borderline Tumors

An important group of tumors to distinguish are *tumors of low malignant potential*, also called the *borderline tumors*. Borderline tumors tend to remain confined to the ovary for long periods, they occur predominantly in premenopausal women, and are associated with a very good prognosis (2,4,8–13). They are diagnosed most frequently in women between the ages of 30 and 50 years, whereas invasive carcinomas occur more often in women between the ages of 50 and 70 years (2).

Although uncommon, extraovarian implants may occur with serous borderline tumors. These implants are characterized as either *noninvasive* or *invasive (analogous to low-grade serous carcinoma)*. The latter has a higher likelihood of progression, in the peritoneal cavity, which can ultimately lead to intestinal obstruction caused by associated fibrosis and death (2,7).

Classification of Epithelial Ovarian Tumors

Serous Tumors

Serous tumors are so classified because they resemble tubal secretory cells. *Psammoma bodies* are frequently found in these neoplasms, and they are made up of concentric rings of calcification. Several hypotheses pertaining to the origin and development of psammoma bodies are proposed, including apoptosis of tumor cells and osteoinductive cytokines produced by macrophages, which result in calcification that can be extensive (7). In the wall of the mesothelial invaginations, papillary ingrowths are common, representing the early stages of development of a papillary serous cystadenoma. There are many variations in the proliferation of these mesothelial inclusions. Several foci may be lined with flattened inactive epithelium; in adjacent cavities, papillary excrescences are present, often resulting from local irritants (2).

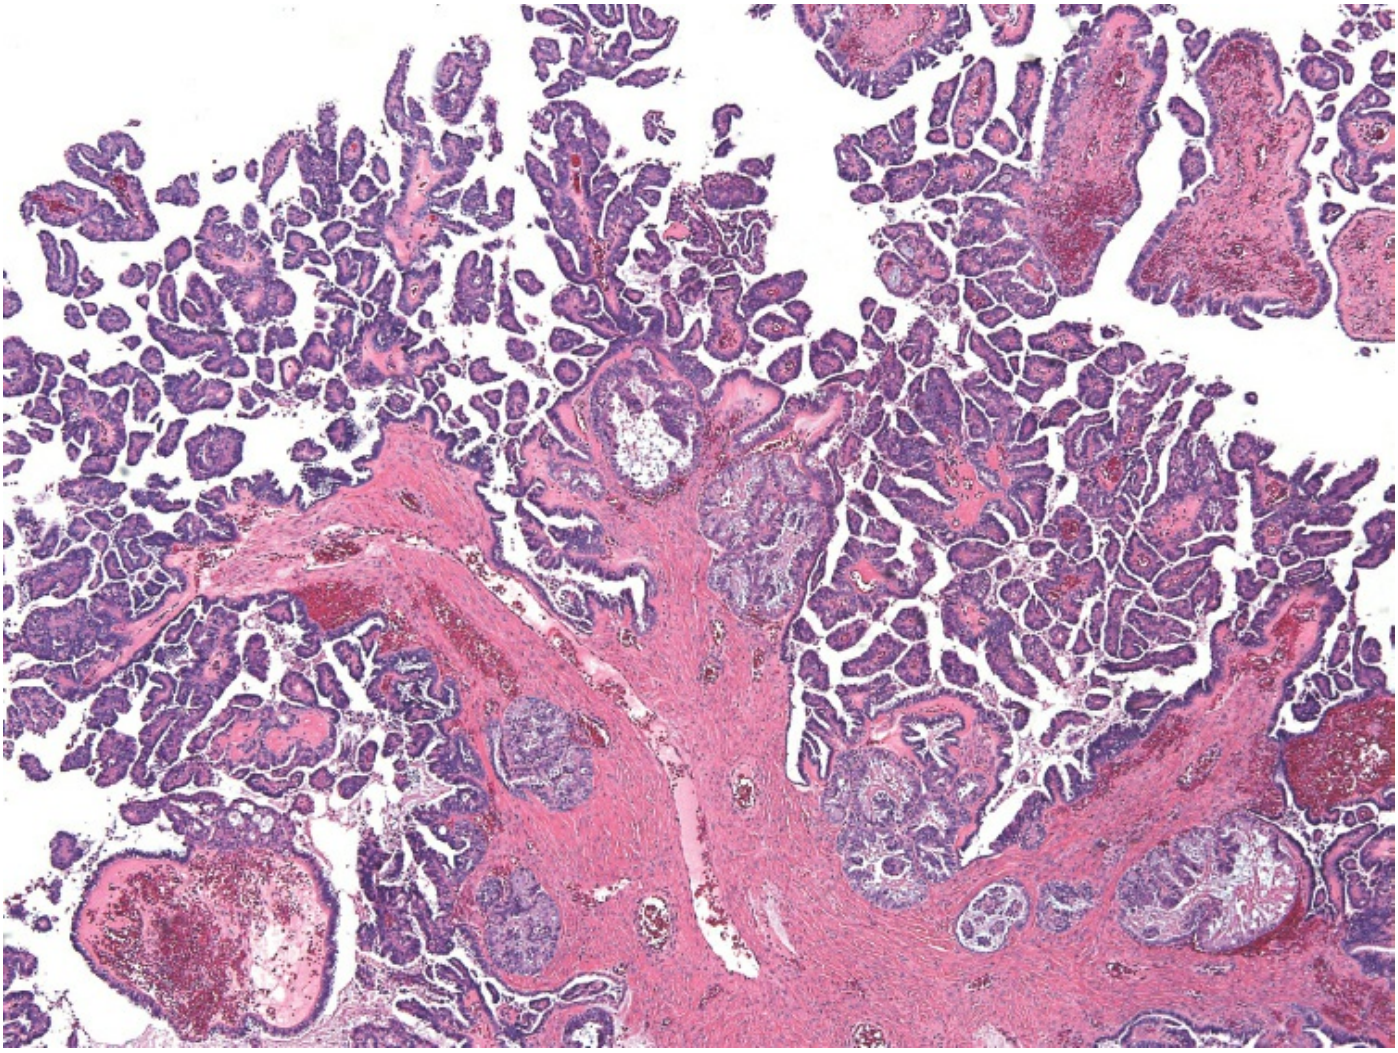

FIGURE 39-1 Serous borderline tumor of the ovary. Complex papillary fronds with hierarchical branching are lined with pseudostratified columnar cells. The epithelium and the stroma are clearly separated by a basement membrane, indicating no stromal invasion.

Borderline Serous Tumors

Approximately 10% of all ovarian serous tumors fall into the category of a tumor of low malignant potential or borderline tumor (Fig. 39-1), and 50% occur before the age of 40 years. The criteria for the diagnosis of serous borderline tumors are as follows (12):

1. Epithelial hyperplasia in the form of pseudostratification, tufting, cribriform, and micropapillary architecture
2. Mild nuclear atypia and mild increased mitotic activity
3. Detached cell clusters
4. Absence of destructive stromal invasion (i.e., without tissue destruction)

Serous borderline tumors that are composed of an exuberant micropapillary architecture are designated as serous borderline tumors with micropapillary features

(Fig. 39-2); these tumors are more frequently bilateral, exophytic, and high stage than the usual serous borderline tumor.

It should be emphasized that up to 40% of serous borderline tumors are associated with spread beyond the ovary, but high-stage disease does not necessarily warrant a diagnosis of an invasive carcinoma. The diagnosis of a serous borderline tumor versus serous carcinoma is based on the histologic features of the primary tumor (12). Up to 10% of women with ovarian serous borderline tumors and extraovarian implants may have invasive implants (i.e., low-grade serous carcinoma), and these can behave more aggressively (14). The 5-year overall survival for women with invasive implants (low-grade serous carcinoma) is about 50% if stringent criteria are applied (11,14–16). Most implants are noninvasive (11,17). In the noninvasive implants, papillary proliferations of atypical cells involve the peritoneal surface and form smooth invaginations (11). In contrast, the invasive implants resemble well-differentiated serous carcinoma and are characterized by atypical cells forming irregular glands with sharp borders. Implants are usually confined to the abdominal cavity and may be seen in the pelvis, omentum, and adjacent tissues, including lymph nodes, but spread outside the abdominal cavity is rare. Death can occur as the result of intestinal obstruction (17–20).

Borderline serous tumors may harbor foci of stromal microinvasion (19). Most patients are young and their tumors are International Federation of Obstetrics and Gynecology (FIGO) stage I. Stromal microinvasion is increased about ninefold in pregnant women with serous borderline tumors.

The presence of stromal microinvasion is associated with lymphovascular space invasion in the primary ovarian tumor (and likely represents a form of true stromal invasion), but it is not associated with an aggressive clinical course, and patients with this finding should be managed in the same way as patients without stromal microinvasion.

Serous Carcinomas

In malignant serous tumors, stromal invasion is present (2). The grade of tumor is important and needs to be documented. In low-grade serous adenocarcinomas, papillary and glandular structures predominate **(Fig. 39-3)**; high-grade neoplasms are characterized by solid sheets of cells, nuclear pleomorphism, and high mitotic activity **(Fig. 39-4)**. Laminated, calcified psammoma bodies are found in 80% of serous carcinomas. ***Serous psammocarcinoma*** **is a rare variant of serous carcinoma characterized by massive psammoma body formation and low-grade cytologic features.** At least 75% of the epithelial nests are associated with psammoma body formation. Patients with serous psammocarcinoma have a protracted clinical course and a relatively favorable prognosis; their clinical course more closely resembles that of high-stage, progressive serous borderline tumor than serous carcinoma.

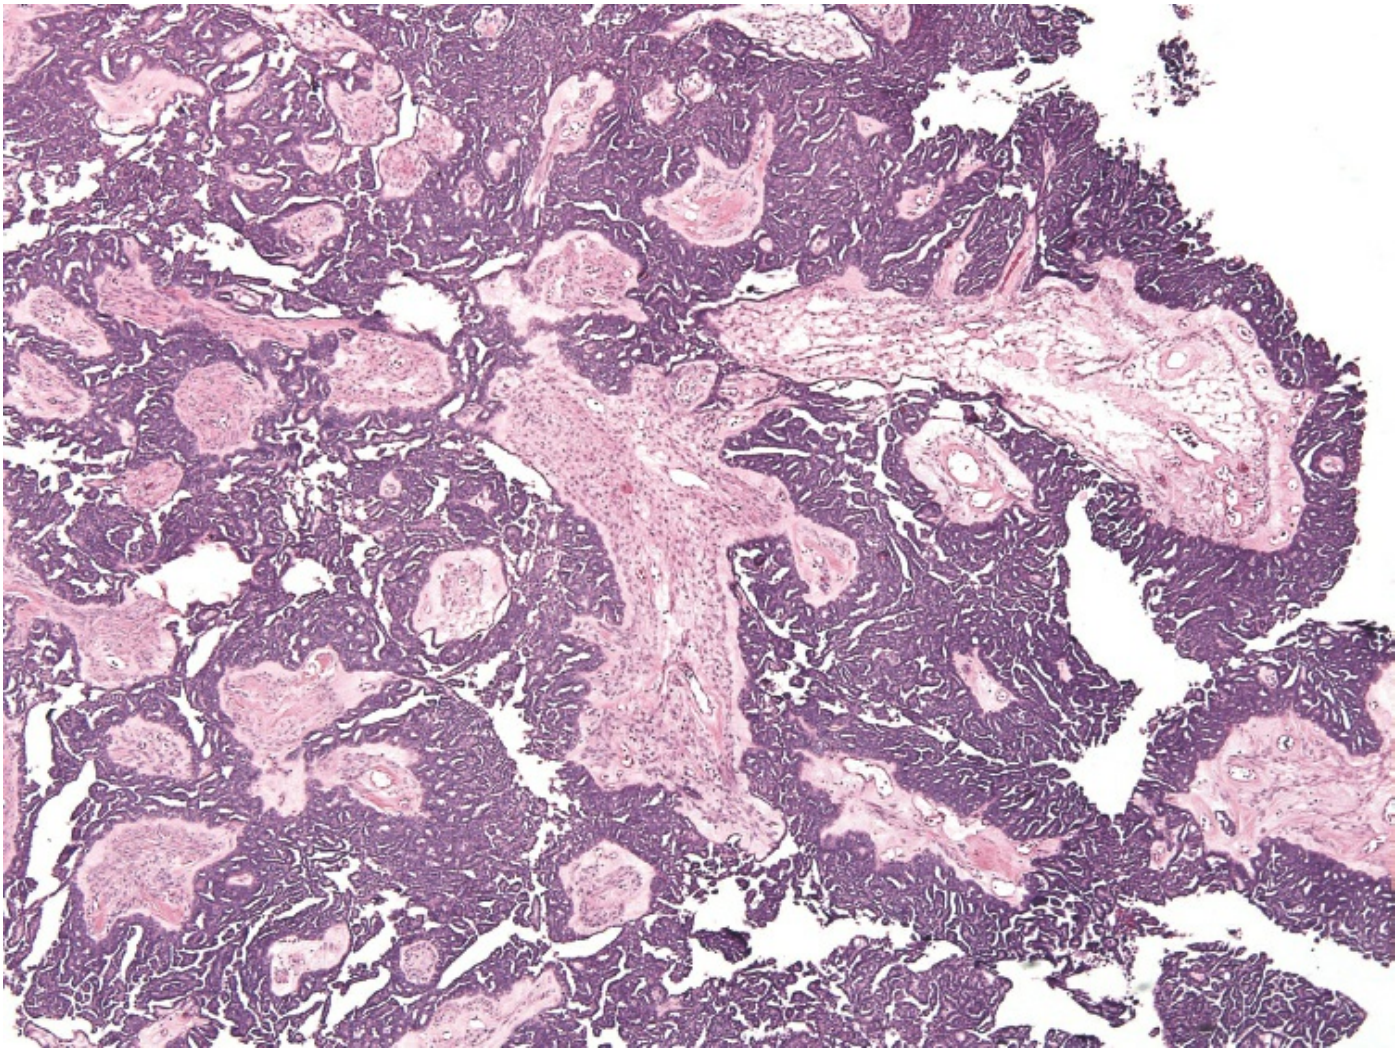

FIGURE 39-2 Serous borderline tumor with micropapillary features. The papillae have a nonhierarchical branching pattern and are lined by a monomorphous population of cells.

Mucinous Tumors

These cystic ovarian tumors have loculi lined with mucin-secreting epithelium. The lining epithelial cells contain intracytoplasmic mucin and resemble those of endocervix, gastric pylorus, or intestine. **They represent about 8% to 10% of epithelial ovarian tumors.** They may reach enormous size, filling the entire abdominal cavity (2).

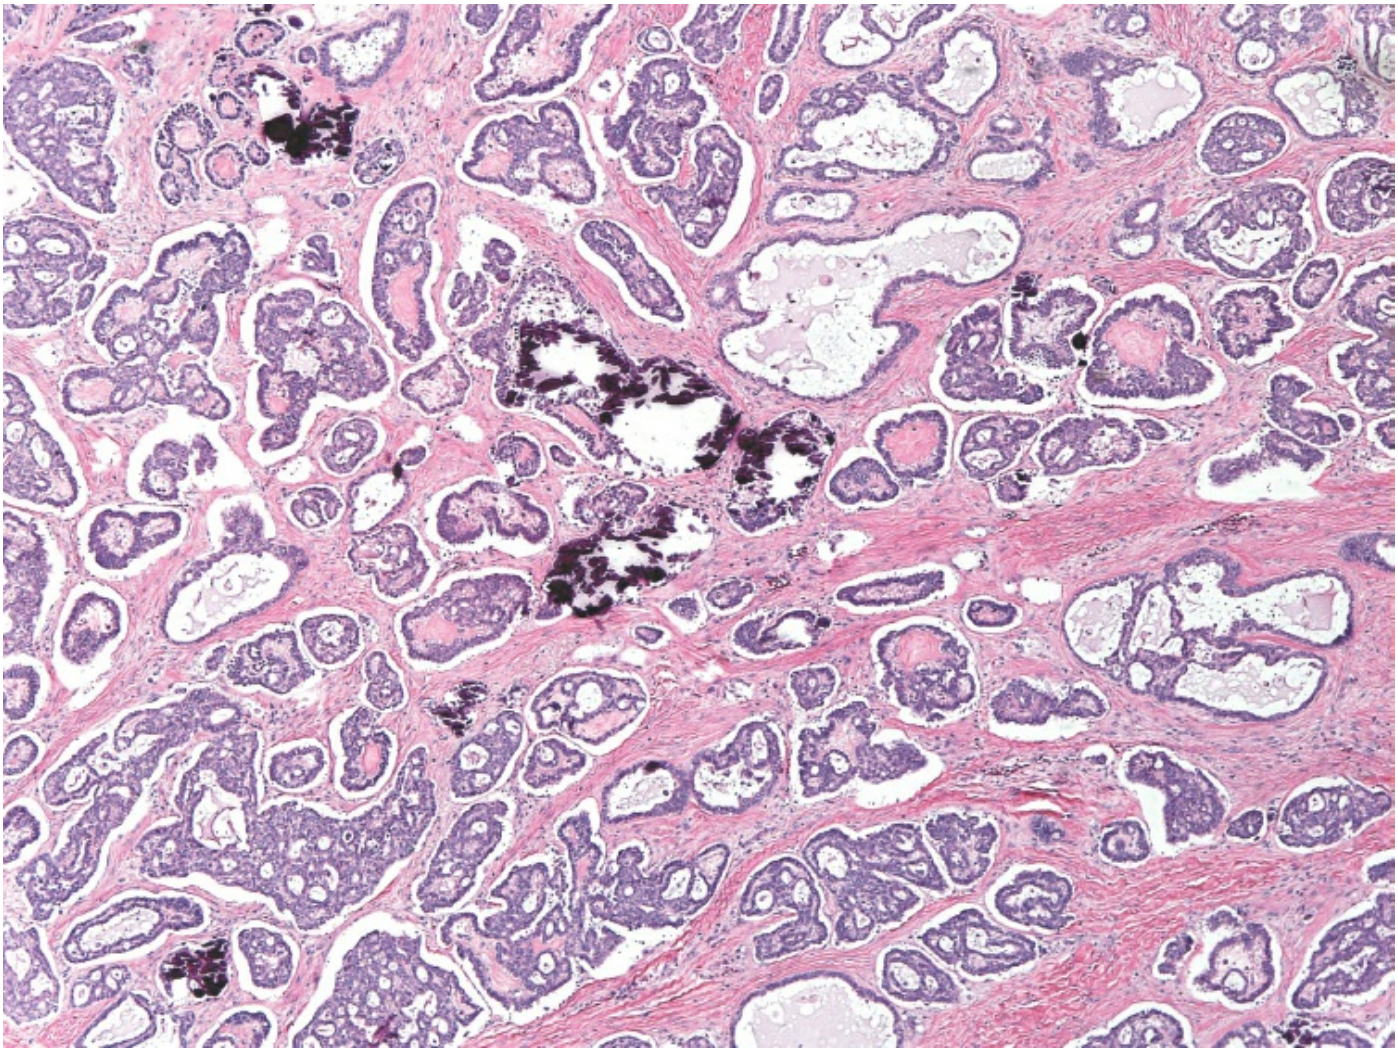

FIGURE 39-3 Low-grade serous adenocarcinoma of the ovary. Clusters and papillae of malignant cells are in direct contact with fibrous stroma indicative of stromal invasion.

Borderline Mucinous Tumors

The mucinous tumor of low malignant potential is often difficult to diagnose. Although it is common to find a rather uniform pattern from section to section in the serous borderline tumor, this is not true in the mucinous tumors. **Well-differentiated mucinous epithelium may be seen immediately adjacent to a poorly differentiated focus. It is important to take multiple sections from many areas in the mucinous tumor to identify the most malignant alteration** (2).

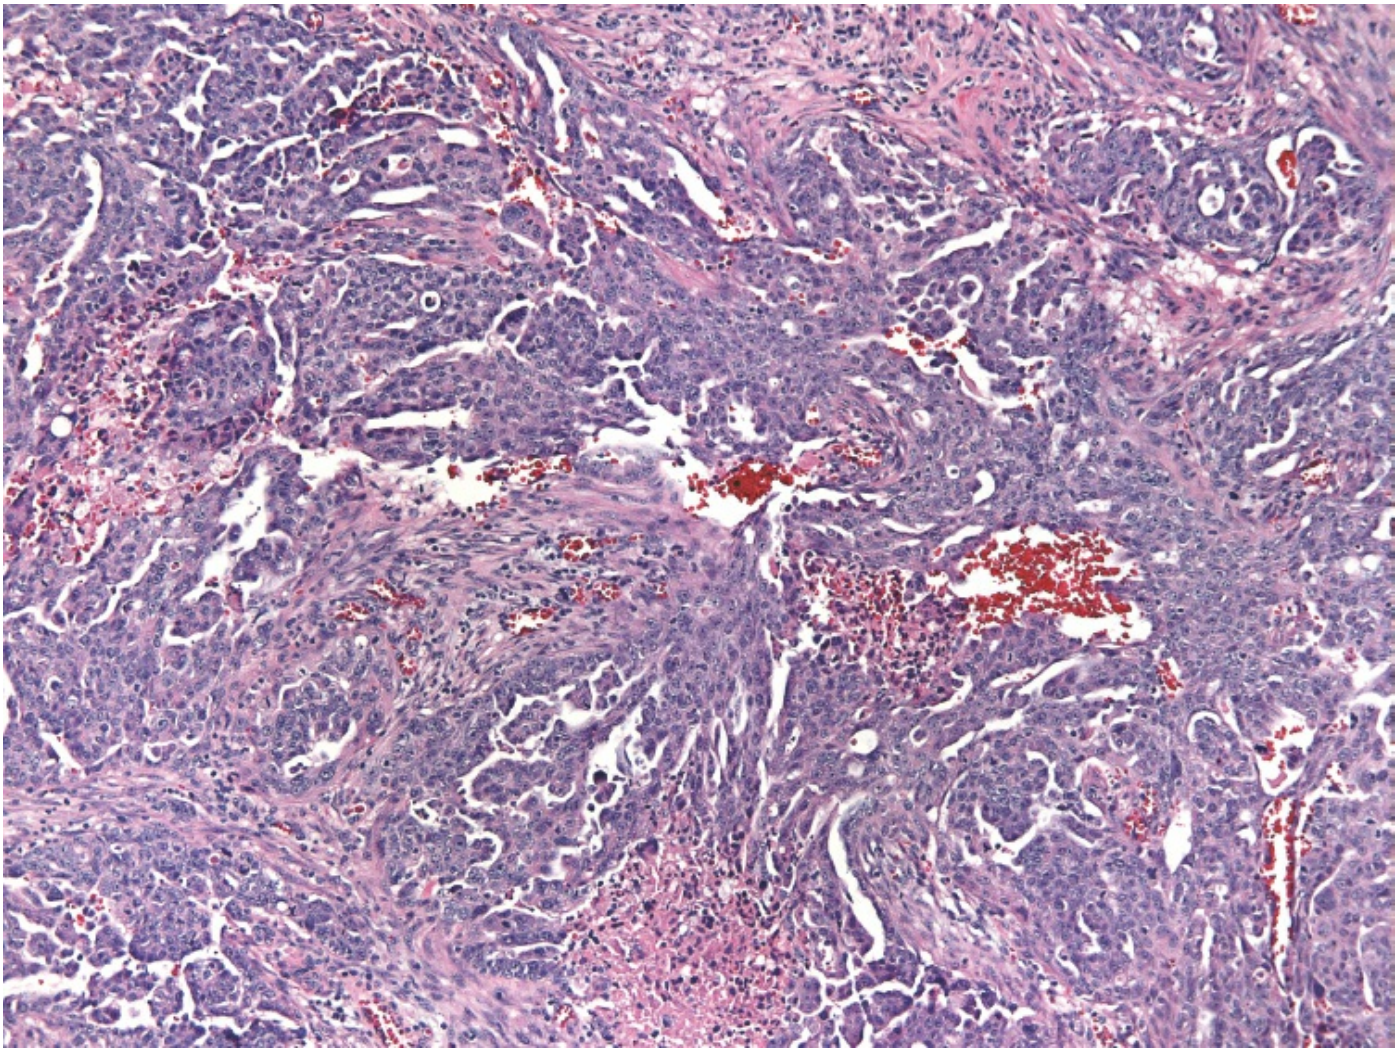

FIGURE 39-4 High-grade serous adenocarcinoma. Papillae lined by sheets of cytologically malignant cells invade stroma, often with associated necrosis.

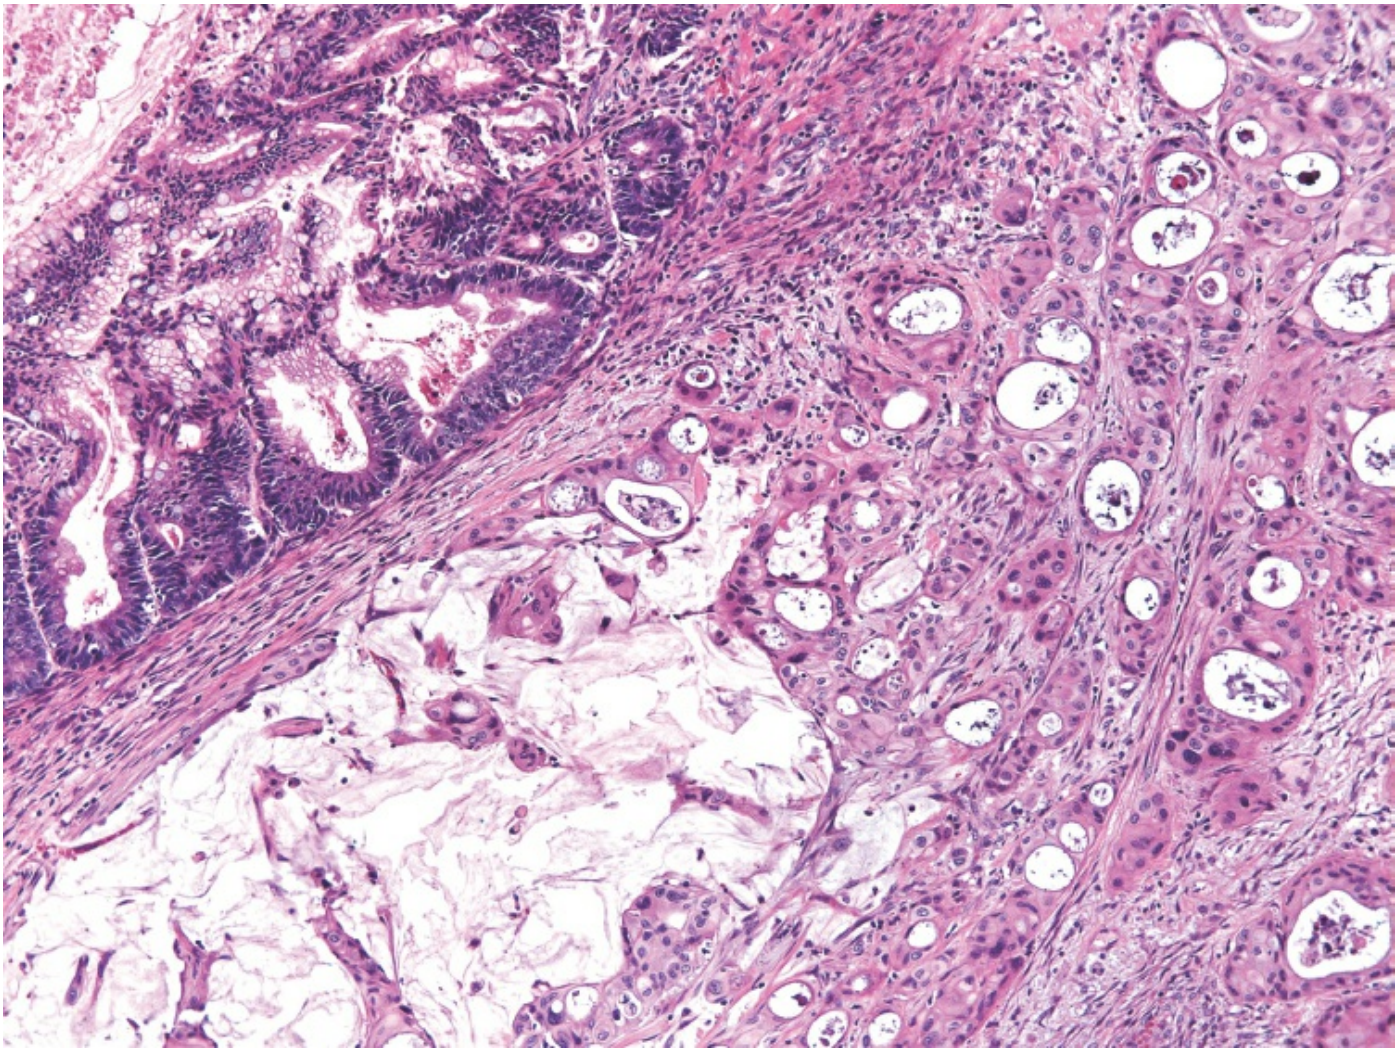

FIGURE 39-5 Mucinous adenocarcinoma of the ovary. Irregular glandular spaces are lined with a layer of tall columnar cells with abundant mucinous cytoplasm, resembling intestinal epithelium at the left. At the right, there is destructive invasion into the ovarian stroma.

Mucinous Carcinomas

Bilateral tumors occur in 8% to 10% of cases. The mucinous lesions are confined to the ovary in 95% to 98% of cases **(Fig. 39-5)**. Because most ovarian mucinous carcinomas contain enteric-type cells, they cannot be distinguished from metastatic carcinoma of the gastrointestinal tract on the basis of histology alone. Primary ovarian neoplasms rarely metastasize to the mucosa of the bowel, although they commonly involve the serosa, whereas gastrointestinal lesions frequently involve the ovary by direct extension or lymphatic spread (2).

Pseudomyxoma Peritonei

Pseudomyxoma peritonei is a clinical term used to describe the finding of abundant mucoid or gelatinous material in the pelvis and abdominal cavity surrounded by fibrous tissue. It is **most commonly secondary to a well-differentiated appendiceal mucinous neoplasm** or other gastrointestinal primary; rarely, mucinous tumors arising in an

ovarian mature teratoma are associated with pseudomyxoma peritonei.

Endometrioid Tumors

Endometrioid lesions constitute 6% to 8% of epithelial tumors. Endometrioid neoplasia includes all the benign demonstrations of endometriosis. In 1925, Sampson suggested that certain cases of adenocarcinoma of the ovary probably arose in areas of endometriosis (20). The adenocarcinomas are similar to those seen in the uterine corpus. The malignant potential of endometriosis is very low, although a transition from benign to malignant epithelium may be demonstrated.

Borderline Endometrioid Tumors

The endometrioid tumor of low malignant potential has a wide morphologic spectrum. Tumors may resemble an endometrial polyp or complex endometrial hyperplasia with glandular crowding. When there are back-to-back, architecturally complex glands with no intervening stroma, the tumor is classified as a well-differentiated endometrioid carcinoma. Some borderline endometrioid tumors have a prominent fibromatous component. In such cases, the term *adenofibroma* is used to describe them (2).

Endometrioid Carcinomas

Endometrioid tumors are characterized by a markedly complex glandular pattern with all the potential variations of epithelia found in the uterus **(Fig. 39-6)**.

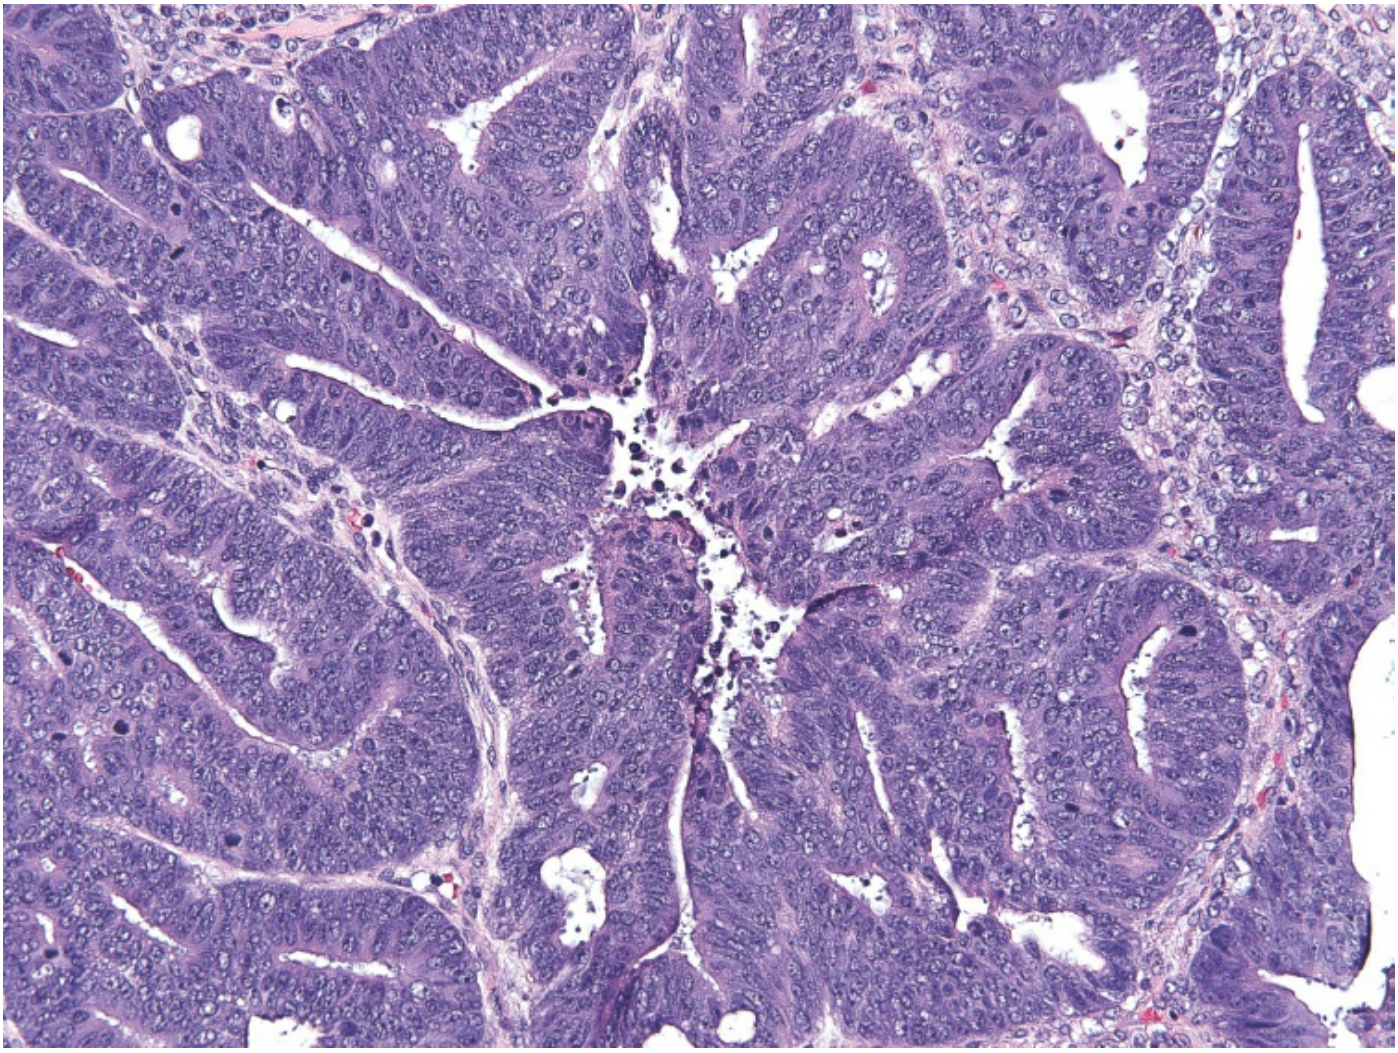

FIGURE 39-6 Endometrioid cancer. Round to tubular glands lined by stratified columnar cells with a confluent growth pattern.

Multifocal Disease

The endometrioid tumors afford the greatest opportunity to evaluate multifocal disease. **Endometrioid carcinoma of the ovary is associated in 15% to 20% of the cases with carcinoma of the endometrium. Identification of multifocal disease is important because patients with disease metastatic from the uterus to the ovaries have a 30% to 40% 5-year survival, whereas those with synchronous multifocal disease have a 75% to 80% 5-year survival** (21). When the histologic appearance of endometrial and ovarian tumors is different, the two tumors most likely represent two separate primary lesions. When they appear similar, the endometrial tumor can be considered a separate primary tumor if it is well differentiated and only superficially invasive.

Clear Cell Carcinomas

Several basic histologic patterns are present in the clear cell adenocarcinoma (i.e.,

tubulocystic, papillary, reticular, and solid). The tumors are made up of clear and hobnail cells that project their nuclei into the apical cytoplasm. The clear cells have abundant clear or vacuolated cytoplasm, hyperchromatic irregular nuclei, and nucleoli of various sizes **(Fig. 39-7)**. **Focal areas of endometriosis are common and mixed clear cell and endometrioid carcinoma may occur** (21). The clear cell carcinoma seen in the ovary is histologically identical to that seen in the uterus or vagina of the young patient who has been exposed to *diethylstilbestrol* (DES) *in utero.* **Almost invariably high-grade nuclei are identified. Hence, clear cell carcinomas are not graded.**

Transitional (Brenner) Tumors

Borderline Brenner Tumors

Proliferative Brenner tumors were previously subclassified as proliferating tumors (those tumors that resemble low-grade papillary urothelial carcinoma of the urinary bladder) and borderline tumors (those tumors that resemble high-grade papillary urothelial carcinoma), these groups of tumors are now classified as borderline Brenner tumors (22). Complete surgical removal usually results in cure.

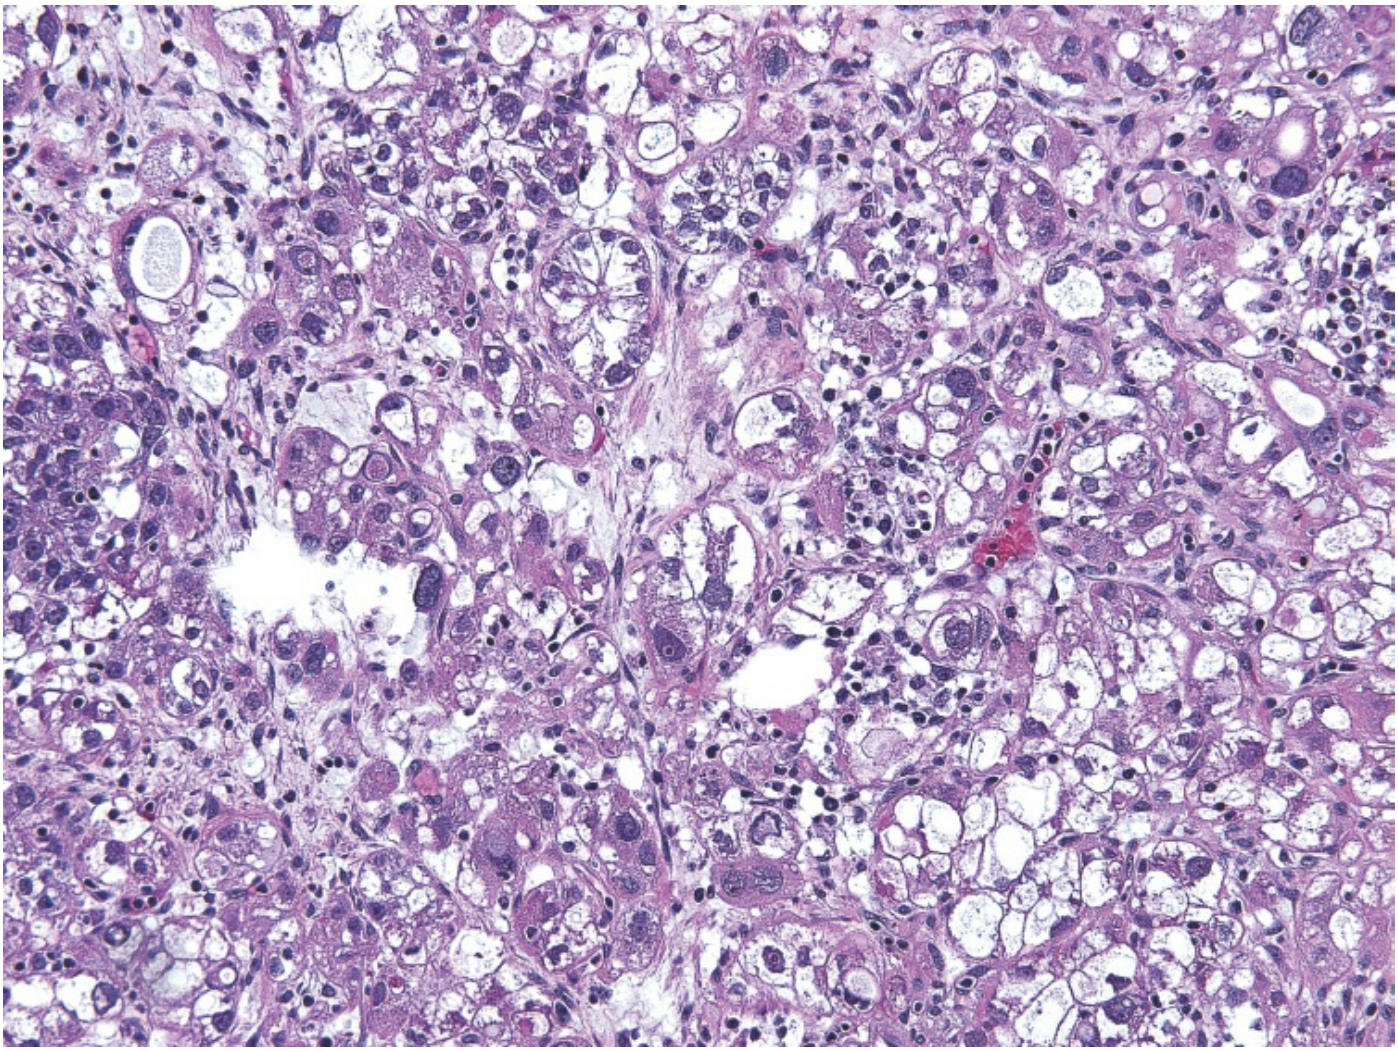

FIGURE 39-7 Clear cell carcinoma of the ovary. Note the solid variant of clear cell carcinoma with sheets of cells that have clear cytoplasm ("hobnail" cells).

Malignant Brenner Tumors

These rare tumors are defined as benign or borderline Brenner tumors coexisting with invasive transitional cell carcinoma.

Transitional Cell Carcinoma

The designation *transitional cell carcinoma* has been attributed to primary ovarian carcinoma resembling transitional cell carcinoma of the urinary bladder without a recognizable Brenner tumor. It is now thought that these are a variant of high-grade serous carcinoma and do not represent a distinct epithelial subtype of carcinoma (23,24). Unlike malignant Brenner tumors these tumors are more frequently diagnosed in an advanced stage and are associated with a survival rate similar to that of high-grade serous carcinoma (25).

Peritoneal Carcinomas

Peritoneal tumors are histologically indistinguishable from ovarian and fallopian tube serous tumors. In the case of ***borderline serous peritoneal tumors*** and ***serous peritoneal carcinomas*****,** the ovaries are normal or minimally involved, and the tumors affect predominantly the uterosacral ligaments, pelvic peritoneum, or omentum. The overall prognosis for borderline serous peritoneal tumors is excellent and comparable to that of ovarian borderline serous tumors (26–28). In the review of 38 cases of peritoneal borderline serous tumors from the literature, 32 women had no persistent disease, 4 were well after resection of recurrence, 1 developed an invasive serous carcinoma, and 1 died from the effects of the tumor (26).

Carcinomas that appear to be predominantly peritoneal without appreciable ovarian or fallopian tube enlargement have traditionally been called *peritoneal carcinoma,* when tumors spread from the breast, gastrointestinal tract, and other organs of non-müllerian origin are excluded. Most are *peritoneal serous carcinomas*, and have the appearance of a moderately to poorly differentiated serous ovarian carcinoma. Peritoneal endometrioid carcinoma also occurs, but is less common; peritoneal clear cell carcinoma is rare.

[15] Peritoneal serous carcinoma should be considered clinically the same as ovarian and fallopian tube cancers, as all these cancers share a similar pathogenesis and clinical behavior and treatment. Patients in whom exploratory surgery is performed, there may be microscopic or small macroscopic cancer on the surface of the ovary and extensive disease in the upper abdomen, particularly in the omentum (29).

Mesotheliomas

Peritoneal malignant mesotheliomas may be epithelial, sarcomatous, or biphasic (2,30). Deciduoid peritoneal mesothelioma is an unusual variant that resembles exuberant, ectopic decidual reaction of the peritoneum. Asbestos exposure is not correlated with peritoneal mesotheliomas in women. These lesions typically appear as multiple intraperitoneal (IP) masses, often coating the entire peritoneum and can develop after hysterectomy and bilateral salpingo-oophorectomy for benign disease. Malignant mesotheliomas should be distinguished from benign multicystic peritoneal mesothelioma (multilocular peritoneal inclusion cyst), and ovarian tumor implants and primary peritoneal müllerian neoplasms.

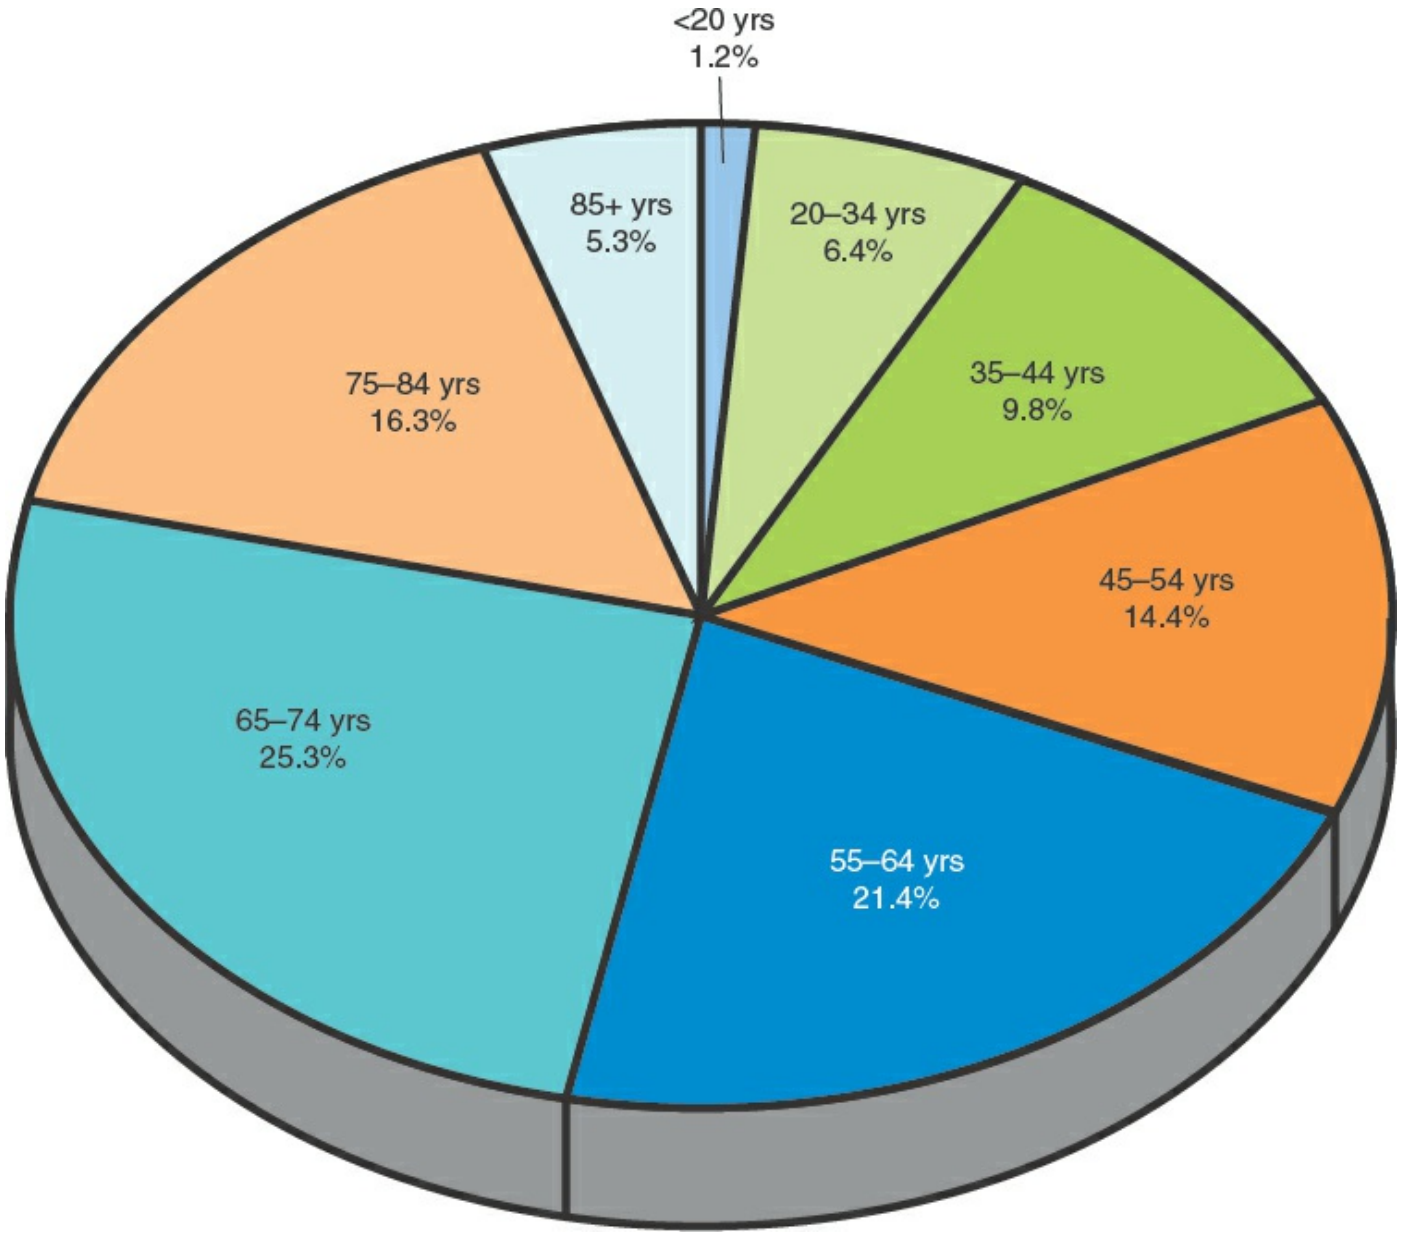

FIGURE 39-8 Ovarian cancer incidence: distribution by age. (From **Nagy K.** The side effects of managed care on the drug industry. J Natl Cancer Inst 1995;87:1280, with permission.)

Clinical Features

More than 80% of epithelial ovarian cancers are found in postmenopausal women **(Fig. 39-8)**. **The peak incidence of invasive epithelial ovarian cancer is at 56 to 60 years of age** (2,3). The age-specific incidence of ovarian epithelial cancer rises precipitously from 20 to 80 years of age and subsequently declines. These cancers are relatively uncommon in women younger than age 45. Fewer than 1% of epithelial ovarian cancers occur before the age of 21 years, two-thirds of ovarian malignancies in such patients being germ cell tumors (2,31). **[1] About 30% of ovarian neoplasms in women are malignant, whereas only about 7% of ovarian epithelial tumors in premenopausal patients are malignant** (2,3).

The average age of patients with borderline tumors is approximately 46 years (2,3,9). Eighty percent to 90% of ovarian cancers, including borderline forms, occur after the age of 40 years, whereas 30% to 40% of malignancies occur after the age of 65 years. The chance that a primary epithelial tumor will be of borderline or invasive malignancy in a patient younger than 40 years is approximately 1 in 10, but after that age it rises to 1 in 3 (2,3). Less than 1% of epithelial ovarian cancers occur before the age of 20 years, with two-thirds of ovarian malignancies in such patients being germ cell tumors (31).

Etiology

[2] Ovarian cancer is associated with low parity and infertility (32). Although there are a variety of epidemiologic variables correlated with ovarian cancer, such as talc use, galactose consumption, and tubal ligation, none is as strongly correlated as prior reproductive history and duration of the reproductive career (32,33). Early menarche and late menopause increase the risk of ovarian cancer (33). These factors and the relationship of parity and infertility to the risk of ovarian cancer led to the hypothesis that suppression of ovulation may be an important factor.

Prevention

[2] Because parity is inversely related to the risk of ovarian cancer, having at least one child is protective for the disease, with a risk reduction of 0.3 to 0.4. Oral contraceptive use reduces the risk of epithelial ovarian cancer [3] (32). **Women who use oral contraceptives for 5 or more years reduce their relative risk to 0.5 (i.e., there is a 50% reduction in the likelihood of development of ovarian cancer).** Women who had two children and used oral contraceptives for 5 or more years have a relative risk of ovarian cancer as low as 0.3, or a 70% reduction (34). **The oral contraceptive pill is the only documented method of chemoprevention for ovarian cancer, and it should be recommended to women for this purpose. When counseling**

patients regarding birth control options, this important benefit of oral contraceptive use should be emphasized. This is important for women with a strong family history of ovarian cancer.

The performance of a prophylactic salpingo-oophorectomy significantly reduces, but does not totally eliminate, the risk of nonuterine pelvic cancers; because the entire peritoneum is at risk, peritoneal carcinomas can occur in 2% to 3% of women even after prophylactic bilateral salpingo-oophorectomy (26,29).

A thorough discussion of the risks and benefits of oophorectomy should be undertaken in premenopausal women who are undergoing a hysterectomy for benign disease, do not carry germline mutations, and do not have a family history that suggests that they are at higher than average risk for ovarian cancer (35). **The ovaries may provide protection from cardiovascular disease and osteoporosis, and long-term mortality may not be decreased by the performance of prophylactic oophorectomy in women at population risk of ovarian cancer** (36).

Screening

CA-125 is useful for monitoring epithelial ovarian cancer patients during their chemotherapy; and is elevated in 50% of patients with stage I disease and in 80% to 90% of patients with advanced serous cancers **(**37–46). Transvaginal ultrasonography is useful to characterize the morphology of ovarian tumors (47,48). However, **the value of tumor markers and ultrasonography to screen for epithelial ovarian cancer is not established by prospective studies** (49). **[4] The use of transvaginal ultrasound alone or in combination with CA-125 for early ovarian cancer detection has not proven effective in average-risk women to decrease mortality from ovarian cancer, instead there are harms to this strategy, including false-positive results and more invasive procedures being performed such as surgery** (50). The inability to use these modalities for screening is discussed in the American College of Obstetricians and Gynecologists (ACOG) committee opinion (51).

The U.S. Preventative Services Task Force (USPSTF) recommends against screening asymptomatic women for ovarian cancer with pelvic examination, pelvic ultrasound, or serum tumor marker measurements (52). **The USPSTF concluded that there is adequate evidence that there is no mortality benefit to routine screening for ovarian cancer with transvaginal ultrasonography or single-threshold serum CA-125 testing and that the harms of such screening are at least moderate. There is no effective strategy for early detection of ovarian cancer that translates to a reduction in ovarian cancer mortality** (52). **Ultrasonography, despite being able to detect changes in size and morphology of the ovaries, has not been shown be effective for ovarian cancer screening** (2,5).

Final results from United Kingdom Collaborative Trial of Ovarian Cancer Screening (UKCTOCS), which is fully accrued and follow-up is pending, should provide more information about the relative benefits and harms of an algorithm-based approach to screening for ovarian cancer. In the **UKCTOCS study**, 202,638 healthy average-risk postmenopausal patients in the age range 50 to 74 years were randomized to receive no screening, annual pelvic ultrasound or multimodal screening using a combination of CA-125 testing (interpreted using risk of ovarian cancer algorithm [ROCA]) and ultrasound triggered by a ROCA score signifying increased risk. Multimodal screening with the ROCA was superior to using fixed CA-125 cut-off values in combination with ultrasound screening (positive predictive value = 35.1%). Ten women had surgical intervention because of a false-positive screening result, demonstrating that the harm related to unnecessary surgical procedures as a consequence of a false-positive test can occur (50,53). Thus far, follow-up data has not shown a significant reduction of ovarian cancer mortality with multimodal screening when compared with no screening (50,54).

The **ROCA** uses serially measured CA-125 and mathematical modeling to determine whether an increase in levels should prompt referral for ultrasound and has a better predictive performance for detecting ovarian cancer than using a fixed CA-125 value cut-off (55,56–59). The U.S. Food and Drug Administration (FDA) has warned that early detection tests, including the ROCA test, are unreliable (60).

Other large prospective randomized trials in the United States and the United Kingdom sought to address the utility of a multimodality assessment for early detection of ovarian cancer. In the US-based **Prostate, Lung, Colorectal, and Ovarian (PLOC) Cancer Screening Trial,** 78,216 healthy average-risk women between age 55 and 74 years were randomized to have either annual CA-125 testing for 6 years and transvaginal ultrasound examination for 4 years (tested group) versus the "usual care" who were patients not offered this testing, many of these patients did have annual pelvic examinations. There was an ovarian cancer mortality rate of 3.1 deaths per 10,000 person-years versus 2.6 deaths per 10,000 person-years in the tested group versus usual care group respectively, after a median follow-up period of 12.4 years. **This study also showed that using a baseline and annual measurement of CA-125 with a cut-off (35 U/mL) in combination with pelvic ultrasound as a way for early assessment does not result in decreased ovarian cancer mortality** (45,61). **Thus far, this large trial showed that screening women at average risk with annual transvaginal ultrasound provided no mortality benefit when compared with no screening.**

In the future, new markers or technologies may improve the specificity of ovarian cancer screening, but proof of this will require a large, prospective study (41,42).

Screening in women who have a familial risk may provide a better yield, but **there is no evidence to demonstrate a benefit of screening high-risk women,** even with

active investigation (62,63). The findings of two prospective studies of annual transvaginal ultrasound and CA-125 screening in 888 *BRCA1* and *BRCA2* mutation carriers in the Netherlands and 279 mutation carriers in the United Kingdom are not encouraging and suggest a very limited benefit of screening in high-risk women (62,64). Despite annual gynecologic screening, Hermsen et al. reported that a high proportion of ovarian cancers in *BRCA1* and *BRCA2* carriers were interval cancers and the large majority of all cancers diagnosed were at advanced stages; similar results were reported by Woodward et al. (62,64).

Women with particular genetic syndromes are at increased risk of ovarian cancer, for example patients with a BRCA gene mutation or Lynch syndrome (hereditary nonpolyposis colorectal cancer). These patients should be referred to genetic counseling to have an evaluation in order to properly quantify their level of risk and have a discussion about the available risk reduction strategies.

Genetic Risk for Epithelial Ovarian Cancer

The lifetime risk of ovarian carcinoma for women in the United States is about 1.4% (2,4,65). The risk of ovarian cancer is higher than that in the general population in women with certain family histories (55,62–64,66–71). **[5] Most epithelial ovarian cancer is sporadic, with causes accounting for up to 24% of invasive epithelial ovarian cancer** (14).

Hereditary Ovarian Cancer

BRCA1 and BRCA2

Most hereditary ovarian cancers result from pathogenic mutations in either the *BRCA1* or *BRCA2* genes. Many studies have found that at least 15% of women with high-grade nonmucinous ovarian cancers have germline mutations in *BRCA1*/*BRCA2* and almost 40% of these women do not have a family history of breast/ovarian cancer (71). There are other low-to-moderate–penetrance genes that predispose to ovarian cancer, and this is an area of intense research interest (65,72,73). Norquist et al. used next-generation sequencing of constitutional DNA samples from over 1,900 women with ovarian cancer to identify germline mutations in a panel of 20 genes, including *BRCA1* and *BRCA2*, DNA mismatch repair genes, double-stranded DNA break repair genes such as CHEK2 and ATM, and the *BRCA1*-associated complex or the *BRCA2*/Fanconi Anemia pathway genes (including *BRIP1, BARD1, PALB2, RAD50, RAD51C, RAD51D* among others). About 80% of mutations were in *BRCA1* or *BRCA2*. Approximately 3% of patients carried mutations in the Fanconi Anemia pathway genes, while only 0.4% had mutations in mismatch repair genes (74).

[6] The mutations are inherited in an autosomal dominant fashion, and therefore a full pedigree analysis (i.e., maternal and paternal sides of the family) is essential

when taking a family history. All women with high-grade invasive ovarian cancers should be offered genetic testing, even if they do not have a family history of breast/ovarian cancer (75). A very large study that followed women enrolled in familial cancer registries primarily in the United Kingdom, Holland, and France provides the most comprehensive data on the risk of ovarian cancer and breast cancer in BRCA mutation carriers. Women were recruited into this cohort from 1997 to 2011 and had not undergone risk-reducing breast or gynecologic surgery; follow-up continued until 2013 (median, 5 years). A total of 6,036 *BRCA1* and 3,820 *BRCA2* mutation carriers were followed (median age at study entry, 38). The cumulative risk for breast cancer by age 80 was 72% in *BRCA1* carriers and 69% in *BRCA2* carriers. For ovarian cancer, the cumulative risk was 44% and 17%, respectively. The peak breast cancer incidence occurred at age 41 to 50 for *BRCA1* carriers and age 51 to 60 for *BRCA2* carriers. The incidence of ovarian cancer was 3.6 times higher among *BRCA1* than *BRCA2* carriers.

[5] Hereditary ovarian cancers occur in women who are approximately 10 years younger than those with nonhereditary tumors (i.e., closer to age 50 compared to age 60 for those with sporadic cancer) (70). A woman with a first- or second-degree relative who had premenopausal ovarian cancer may have a higher probability of being a BRCA carrier. Women with BRCA germline mutations tend to be diagnosed at a younger age than women with sporadic ovarian cancers. In women with *BRCA1* mutations, less than 2% to 3% of carriers develop ovarian cancer by the age of 40 which increases to 10% to 21% by the age of 50. In women with *BRCA2* mutations, less than 3% of carriers develop ovarian cancer by the age of 50 and most develop after age 50. Most BRCA ovarian cancers are high-grade serous carcinomas **(Fig. 39-9)**.

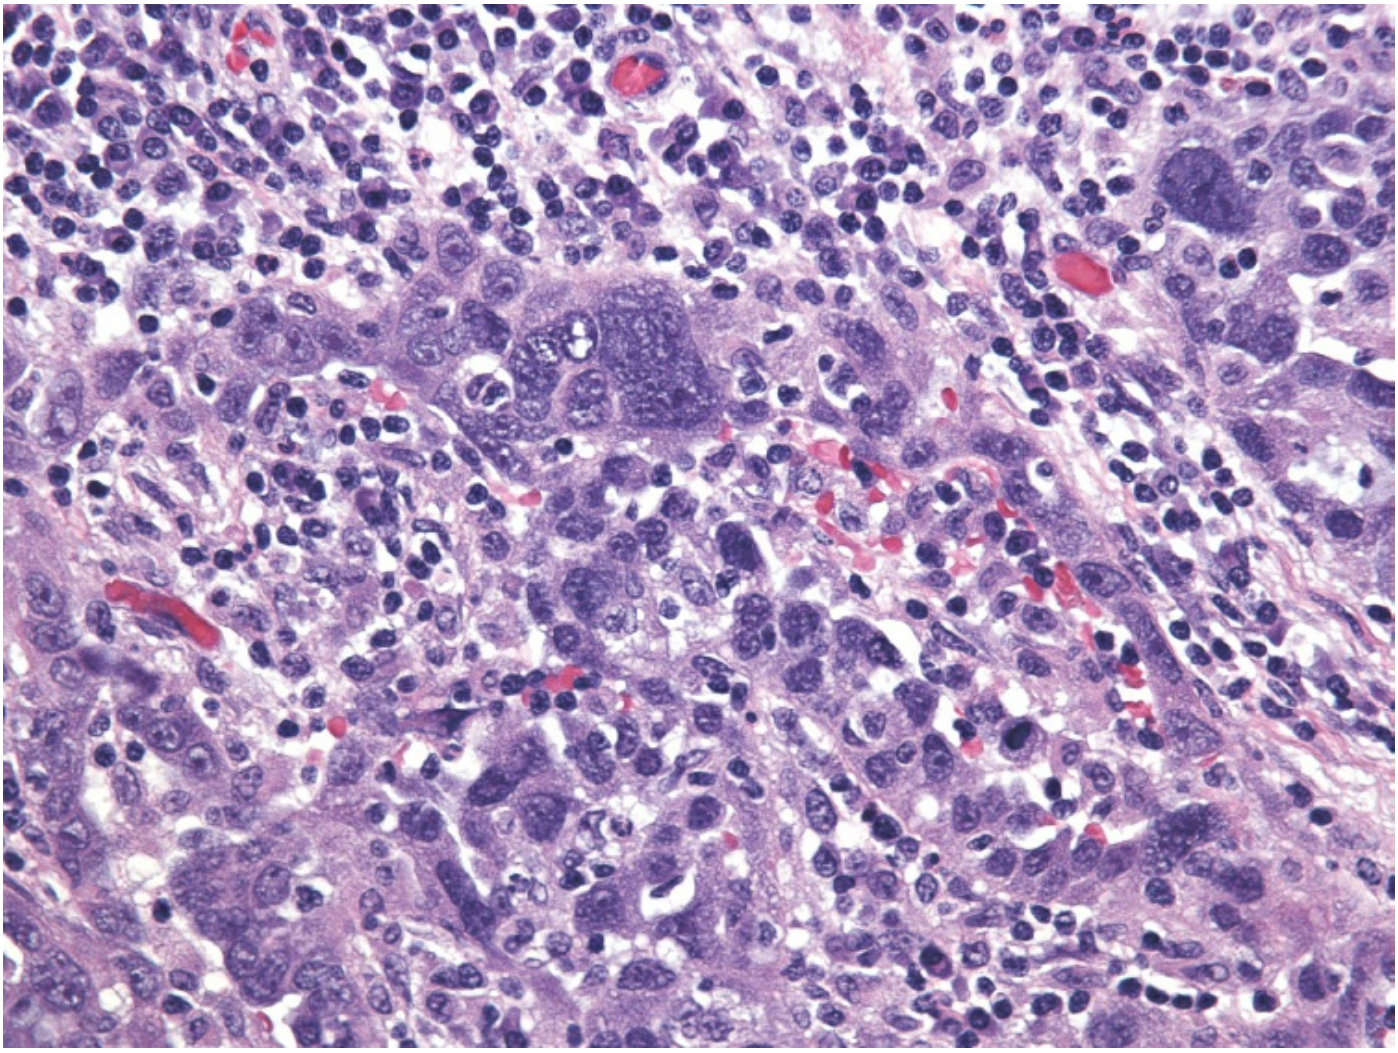

FIGURE 39-9 *BRCA1*-associated ovarian carcinoma is typically a high-grade serous adenocarcinoma with numerous mitotic figures and marked nuclear pleomorphism. A brisk lymphocytic infiltrate with tumor-infiltrating lymphocytes is not uncommon in these tumors.

Founder Effect

There is a higher carrier rate of *BRCA1* and *BRCA2* mutations in women of Ashkenazi Jewish descent, Icelandic women, and many other ethnic groups (76–81). There are three specific founder mutations carried by the Ashkenazi population, 185delAG and 5382insC on *BRCA1*, and 6174delT on *BRCA2*. **Individuals of Ashkenazi Jewish descent have a 1 in 40, or 2.5%,** chance of having a mutation in *BRCA1* or *BRCA2*, in contrast to a 1 in 500 risk in the Caucasian population (82). The increased risk is a result of the *founder effect*, in which a higher rate of specific mutations occurs in an ethnic group from a defined geographic area. These founder mutations generated considerable interest, because they facilitate studies of prevalence and penetrance and can be used to quantify the degree of homogeneity within a population.

Pedigree Analysis

[6] The risk of carrying a germline mutation that predisposes to ovarian cancer depends on the number of first- or second-degree relatives (or both) with a history of epithelial ovarian carcinoma or breast cancer (or both) and on the number of malignancies that occur at an earlier age. The degree of risk is difficult to determine precisely without performing a full pedigree analysis. It is important to be aware that 40% of women with BRCA-related ovarian cancer do not have a family history.

Lynch Syndrome or Hereditary Nonpolyposis Colon Cancer

Lynch syndrome (HNPCC), which includes multiple adenocarcinomas, involves a combination of colon cancer and endometrial or ovarian cancer and other malignancies of the gastrointestinal and genitourinary systems (83). **The chief gene mutations that are associated with this syndrome include *MSH2*, *MLH1*, *MSH6*, and *PMS2* or the *EPCAM* gene.** The risk that a woman who is a member of one of these families will develop epithelial ovarian cancer depends on the frequency of this disease in first- and second-degree relatives, although these women appear to have at least three times the relative risk of the general population. A full pedigree analysis of such families should be performed by a geneticist to more accurately determine the risk.

Management of Women at High Risk for Ovarian Cancer

The management of an unaffected woman with a germline BRCA (gBRCA) mutation or a strong family history of epithelial ovarian cancer where a mutation has not been found must be individualized and depends on her age, reproductive plans, and the estimated risk. All these women should be seen by a geneticist in a high-risk clinic. Decisions about management are best made after careful study and, whenever possible, verification of the histologic diagnosis of the family members' ovarian cancer.

The value of testing for *BRCA1* and *BRCA2* is well **established, and there are guidelines for testing** (75,82,84,85). Essentially all women with epithelial ovarian cancer, excluding mucinous cancers, should be offered testing irrespective of whether she has a family history of breast/ovarian cancer. The American Society of Clinical Oncology offered guidelines that emphasize careful evaluation by geneticists, careful maintenance of medical records, and a genetic screening clinic with an understanding of how to effectively counsel and manage these patients. Concerns remain over the use of the information, impact on insurability, interpretation of the results, and how the information will be used within a specific family (e.g., to counsel children).

Although there are some conflicting data, the behavior of breast cancers arising in women with germline mutations in *BRCA1* or *BRCA2* is comparable to the behavior of sporadic tumors (86,87). **Women with breast cancer who carry these mutations are at a greatly increased risk of ovarian cancer and a second breast cancer: the**

lifetime risk of ovarian cancer is 54% for women who have a *BRCA1* mutation and 23% for those with a *BRCA2* mutation, and for the two groups together, there is an 82% lifetime risk of breast cancer (87).

[4] Despite recommendation by the National Institutes of Health Consensus Conference on Ovarian Cancer, the value of screening with transvaginal ultrasonography, CA-125 levels, or other procedures is not established in women at high risk (88). Bourne and coworkers showed that, using this approach, tumors can be detected approximately 10 times more often than in the general population, and they recommend screening in high-risk women, but other groups have not confirmed these findings, and bilateral salpingo-oophorectomy remains the most effective way to reduce the risk (89).

Data derived from a multicenter consortium of genetic screening centers indicate that the use of the oral contraceptive pill is associated with a lower risk for development of ovarian cancer in women who have a mutation in either *BRCA1* or *BRCA2* (90,91). The risk reduction is significant: in women who take oral contraceptives for 5 or more years, the relative risk of ovarian cancer is 0.4, or a 60% reduction in the incidence of the disease (92).

Prophylactic Salpingo-oophorectomy in High-Risk Women

[6] The value of prophylactic salpingo-oophorectomy in these patients is well established (93–99). Women at high risk for ovarian cancer who undergo prophylactic salpingo-oophorectomy have a risk of harboring occult neoplasia: in one series of 98 such operations, 3 (3.1%) patients were found to have an ovarian cancer or early invasive cancer in a fallopian tube (96). **[6] The protection against ovarian cancer is high: the performance of a prophylactic salpingo-oophorectomy reduced the risk of BRCA-related gynecologic cancer by 96%** (96). In a series of 42 such operations, 4 patients (9.5%) had a malignancy, 1 of which was noted at surgery and 3 that were microscopic; all were smaller than 5 mm (94). Although the risk of ovarian cancer is significantly diminished, there remains the small risk of peritoneal carcinoma. In these series, the subsequent development of peritoneal carcinoma was reported to be 0.8% and 1%, respectively (78,79). **The risk of developing subsequent breast cancer may be reduced by 50% to 80% in BRCA carriers. However, this has been challenged by a prospective study.** In an analysis stratified by BRCA mutation status and age at diagnosis, they found that oophorectomy was associated with a significantly reduced risk of breast cancer in *BRCA2* carriers diagnosed at age <50 years (age-adjusted hazard ratio [HR], 0.18; $p = 0.007$) but not among *BRCA1* carriers diagnosed at <50 years (age-adjusted HR, 0.79; $p = 0.51$). These findings warrant further evaluation (100).

The role of hysterectomy is more controversial. Most studies show no increase in

the rate of uterine and cervical tumors, but there are rare reports of an increase of serous tumors of the endometrium. A large multicenter prospective cohort study concluded that the overall risk of uterine cancer after a risk-reducing bilateral salpingo-oophorectomy was not increased; however, the risk of serous and serous-like uterine cancer was increased in *BRCA1*-positive women, although still very low, and the benefit of a hysterectomy remains uncertain (101). Women on *tamoxifen* are at higher risk for benign endometrial lesions (e.g., polyps) and endometrial cancer. **It is reasonable to consider the performance of a prophylactic hysterectomy in conjunction with salpingo-oophorectomy in women with BRCA mutations who are potentially at increased risk of an endometrial cancer,** but this decision should be individualized. The progression-free survival (PFS) of women who have a *BRCA1* or *BRCA2* mutation and develop ovarian cancer is longer than that for those who do not have a mutation. In one study, the median PFS for mutation carriers was 60 months compared with 22 months for controls. There was no difference in the overall survival between BRCA mutation carriers and controls (102). **BRCA patients have increased sensitivity to platinum drugs and to the newer agents, poly(ADP-ribose) polymerase (PARP) inhibitors. [10] The advent of PARP inhibitors and their increased use for recurrent disease and maintenance therapy, particularly in BRCA mutation carriers may translate to an improvement in the PFS and overall survival for BRCA patients.**

Recommendations

Recommendations for the management of women at high risk for ovarian cancer are based on the ACOG practice bulletin no. 182 and summarized as follows:

1. **Genetic counseling is recommended for all women with ovarian/fallopian tube/peritoneal epithelial cancer and for individuals who have a personal or family history of breast cancer or ovarian cancer.** Genetic testing is recommended when the results of a detailed risks assessment that is performed as part of genetic counseling suggest the presence of an inherited cancer syndrome and when the results of testing are likely to influence medical management.
2. **Women who wish to preserve their reproductive capacity can undergo screening by transvaginal ultrasonography every 6 months or CA-125 measurement and this may be a reasonable short-term surveillance strategy for women at high risk of ovarian cancer starting at age 30 to 35 years until they decide to pursue definitive risk-reducing bilateral salpingo-oophorectomy.**
3. **Oral contraceptives should be recommended** to young women before they embark on an attempt to have a family.
4. **Women who do not wish to maintain their fertility or who have completed their families should be recommended to undergo prophylactic bilateral salpingo-**

oophorectomy after the age of 35, but by age 40 years. The risk of ovarian cancers under the age of 40 is very low but the decision regarding the age of surgery should be based on the age of onset of ovarian cancers in the family. Most *BRCA2*-related ovarian cancers tend to occur after the age of 50, whereas *BRCA1*-related cancers occur at an earlier age. **Typically, risk-reducing salpingo-oophorectomy is recommended at age 35 to 40 years for *BRCA1* carriers with the highest lifetime risk of ovarian cancer, whereas women with *BRCA2* may consider delaying until age 40 to 45 years because of later onset of ovarian cancer.** These women should be counseled that this operation does not offer absolute protection, because peritoneal carcinomas can occur after bilateral salpingo-oophorectomy (26,29,87).

5. **Women with BRCA mutations or who carry another actionable deleterious mutation that is predisposing to breast cancer should be offered risk-reducing bilateral mastectomy.** Women with BRCA mutations or who carry another actionable deleterious mutation that is predisposing to ovarian cancer should be offered risk-reducing bilateral salpingo-oophorectomy.
6. **For a risk-reducing bilateral salpingo-oophorectomy, all tissue from the ovaries and fallopian tubes should be removed.** Thorough visualization of the peritoneal surfaces should be done and pelvic washings taken. Complete serial sectioning of the ovaries and fallopian tubes is necessary with microscopic examination for occult cancer.
7. **For women aged 25 to 29 years with known BRCA mutations, recommended breast cancer surveillance includes clinical breast examination every 6 to 12 months and annual radiographic evaluation (preferably magnetic resonance imaging [MRI], with contrast). For women aged 30 years and older with known BRCA mutations or other actionable breast cancer mutations, recommended breast cancer surveillance includes annual mammography and annual breast MRI with contrast, often alternating every 6 months.**
8. **Women with a personal or family history of breast or ovarian cancer but who do not have a documented mutation in *BRCA1* or *BRCA2* or other hereditary breast- or ovarian-cancer–associated genes should be managed based on their family history.**
9. **Women with a documented Lynch syndrome (HNPCC) should undergo periodic colonoscopy every 1 to 2 years, starting at age 20 to 25 years or 2 to 5 years before the earliest colon cancer diagnosis in the family, depending on which is earlier. Endometrial biopsy every 1 to 2 years starting at age 30 to 35 years, is recommended for women with Lynch syndrome, prophylactic hysterectomy, and bilateral salpingo-oophorectomy is a risk-reducing option after the completion of childbearing. In general, risk-reducing hysterectomy and salpingo-**

oophorectomy should be discussed with patients by their early to mid-40s (103,104).

Symptoms

The majority of women with epithelial ovarian cancer have vague and nonspecific symptoms (4,105). In the early-stage disease, if the patient is premenopausal, she may experience irregular menses. If a pelvic mass is compressing the bladder or rectum, she may report urinary frequency or constipation (105–107). Occasionally, she may perceive lower abdominal distention, pressure, or pain, such as dyspareunia. Acute symptoms, such as pain secondary to rupture or torsion, shortness of breath from a malignant pleural effusion, or symptoms of a bowel obstruction are possible reasons for presentation.

In advanced-stage disease, patients have symptoms related to the presence of ascites, omental metastases, or bowel metastases. The symptoms include abdominal distention, bloating, constipation, nausea, anorexia, or early satiety. Premenopausal women may report irregular or heavy menses, whereas vaginal bleeding may occur in postmenopausal women but this is not a typical presentation of ovarian cancer unless the ovarian tumors are estrogen producing (107).

Traditionally, ovarian cancer was considered a "silent killer" that did not produce symptoms until far advanced. Some patients with ovarian cancers confined to the ovary are asymptomatic, but the majority will have nonspecific symptoms that do not necessarily suggest an origin in the ovary (107,108–110). In one survey of 1,725 women with ovarian cancer, 95% recalled symptoms before diagnosis, including 89% with stages I and II disease and 97% with stages III and IV disease (107). Some 70% had abdominal or gastrointestinal symptoms, 58% pain, 34% urinary symptoms, and 26% pelvic discomfort. At least some of these symptoms could have reflected pressure on the pelvic viscera from the enlarging ovary. Goff et al. developed an ovarian cancer symptom index and reported that symptoms associated with ovarian cancer, when present for less than 1 year and occurring longer than 12 days a month, were pelvic/abdominal pain, urinary frequency/urgency, increased abdominal size or bloating, and difficulty eating or feeling full (108). The index had a sensitivity of 56.7% for early ovarian cancer and 79.5% for advanced-stage disease. This study and others suggest that women and their obstetrician–gynecologist should maintain an appropriate level of suspicion for further investigation when potential symptoms and signs of ovarian, fallopian tube, or peritoneal cancer may be present.

A population-based study from Australia found that there did not appear to be a significant difference in the duration of symptoms or the nature of symptoms in patients with early as opposed to advanced-stage ovarian cancer, reinforcing the concept that they are biologically different entities and arguing against the widely held

misconception that early-stage ovarian cancers are at an early stage because they were diagnosed earlier than patients with more advanced-stage cancers (109). For fallopian tube carcinoma, the classic triad of symptoms that have been reported include clear or blood-tinged vaginal discharge, pelvic pain, and a finding of a pelvic mass. The vaginal discharge termed *hydrops tubae profluens* historically has been considered pathognomonic of fallopian tube cancer; however, in retrospect, these signs are uncommon.

Signs

The most important sign of epithelial ovarian cancer is the presence of a pelvic mass on physical examination. A solid, irregular, fixed pelvic mass is highly suggestive of an ovarian malignancy. If an upper abdominal mass or ascites is present, the diagnosis of ovarian cancer is almost certain. Because the patient usually reports abdominal symptoms, she may not have a pelvic examination, and a tumor may be missed.

In patients who are at least 1 year past menopause, the ovaries should be atrophic and not palpable. It was proposed that any palpable pelvic mass in these patients should be considered potentially malignant, a situation that was referred to as the postmenopausal palpable ovary syndrome (111). This concept was challenged, because subsequent authors reported that only about 3% of palpable masses measuring less than 5 cm in postmenopausal women are malignant (63). Atypical glandular cells on cervical pathology may signal an upper genital tract malignancy. This finding on a Papanicolaou (Pap) test should prompt further evaluation for cervical or endometrial carcinoma. If there are no findings to suggest these cancers, evaluation should continue for other malignancies of the female genital tract. In a systematic review of approximately 7,000 women with atypical glandular cells on a Pap test only 5.2% of patients had a malignancy. Among patients with a malignancy, there were 5.4% ovarian cancers and 1.0% fallopian tube cancers (112).

Women with ovarian cancer can rarely present with signs of a paraneoplastic syndrome, which may include disseminated intravascular coagulation, polyneuritis, dermatomyositis, hemolytic anemia, and cerebellar degeneration (113).

Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries. A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomas, can simulate ovarian cancer. Nongynecologic causes of a pelvic tumor, such as an inflammatory (e.g., diverticular) disease or neoplastic colonic mass, must be excluded (4). A pelvic kidney can simulate ovarian cancer.

Serum CA-125 levels are useful in distinguishing malignant from benign pelvic masses (114). **For a postmenopausal patient with an adnexal mass and a very high serum CA-125 level (>200 U/mL), there is a 96% positive predictive value for malignancy. For premenopausal patients, the specificity of the test is low because the CA-125 level tends to be elevated in common benign conditions.**

For the premenopausal patient, a period of observation is reasonable, provided the adnexal mass does not have characteristics that suggest malignancy (i.e., it is mobile, mostly cystic, unilateral, and of regular contour). An interval of no more than 2 months is allowed, during which hormonal suppression with an oral contraceptive may be used. If the lesion is not neoplastic, it should regress, as measured by pelvic examination and pelvic ultrasonography. If the mass does not regress or if it increases in size, it must be presumed to be neoplastic and must be removed surgically.

The size of the lesion is important. If a cystic mass is greater than 8 cm in diameter, the probability is high that the lesion is neoplastic, unless the patient is taking *clomiphene citrate* or other agents to induce ovulation (115–118). **Premenopausal patients whose lesions are clinically suspicious (i.e., large, predominantly solid, relatively fixed, or irregularly shaped) should undergo laparoscopy or laparotomy with keen attention to avoid intraoperative rupture or spillage, as should postmenopausal patients with complex adnexal masses of any size. Image-guided biopsy is not performed for fear of rupture and seeding a potential malignancy.**

Ultrasonographic signs of malignancy include an adnexal pelvic mass with areas of complexity, such as irregular borders, multiple echogenic patterns within the mass, and dense multiple irregular septae. Bilateral tumors are more likely to be malignant, although the individual characteristics of the lesions are of greater significance. Transvaginal ultrasonography may have a somewhat better resolution than transabdominal ultrasonography for adnexal neoplasms (119–122). Doppler color flow imaging may enhance the specificity of ultrasonography for demonstrating findings consistent with malignancy (123–125).

In postmenopausal women with unilocular cysts measuring 8 to 10 cm or less and normal serial CA-125 levels, expectant management is acceptable, and this approach may decrease the number of surgical interventions (126–128).

The suspicion of ovarian cancer or the diagnosis of an ovarian cancer requires surgical exploration by a gynecologic oncologist, which may be by an exploratory laparotomy or a minimally invasive technique such as laparoscopy or a robotic platform. The preoperative evaluation of the patient with an adnexal mass is outlined in Figure 10.2 (see Chapter 10, page 201).

Before the planned exploration, the patient should undergo routine hematologic and biochemical assessments. A preoperative evaluation in a patient undergoing laparotomy should include a radiograph of the chest. Abdominal and pelvic computed tomography

(CT) or magnetic resonance imaging (MRI) are of limited value for a patient with a definite pelvic mass (129–131). A CT or MRI should be performed for patients with ascites and no pelvic mass to look for liver or pancreatic tumors. The findings only rarely preclude laparotomy (129). The value of PET scanning is still being evaluated (131–133). If the hepatic enzyme values are normal, the likelihood of liver disease is low. Liver–spleen scans, bone scans, and brain scans are unnecessary unless symptoms or signs suggest metastases to these sites.

The preoperative evaluation should exclude other primary cancers metastatic to the ovary. A barium enema or colonoscopy is indicated in selected patients with symptoms and signs suspicious for colon cancer. This study should be performed for any patient who has evidence of occult blood in the stool or has signs of lower intestinal obstruction. An upper gastrointestinal radiographic series or gastroscopy is indicated if there are upper gastrointestinal symptoms such as nausea, vomiting, or hematemesis (4,134). Bilateral diagnostic mammography is indicated if there is any breast mass, because breast cancer metastatic to the ovaries can simulate primary ovarian cancer.

A Pap test can be performed, although its value for the detection of ovarian cancer is very limited. Patients who have irregular menses or postmenopausal vaginal bleeding should have endometrial biopsy and endocervical curettage to exclude the presence of uterine or endocervical cancer metastatic to the ovary.

Differential Diagnosis

Ovarian epithelial cancers must be differentiated from benign neoplasms and functional cysts of the ovaries (126–128). **A variety of benign conditions of the reproductive tract, such as pelvic inflammatory disease, endometriosis, and pedunculated uterine leiomyomata, can simulate ovarian cancer.** Nongynecologic causes of a pelvic tumor, such as an inflammatory or neoplastic colonic mass, must be excluded. Gastrointestinal and breast cancers are the most common nongenital malignancies that metastasize to the ovary (135,136).

Patterns of Spread

Ovarian epithelial cancers spread primarily by exfoliation of cells into the peritoneal cavity, lymphatic dissemination, and hematogenous spread.

Transcoelomic

The most common and earliest mode of dissemination of ovarian epithelial cancer is by exfoliation of cells that implant along the surfaces of the peritoneal cavity. The cells tend to follow the circulatory path of the peritoneal fluid. The fluid moves with the forces of respiration from the pelvis, up the paracolic gutters, especially on the right, along the intestinal mesenteries, to the right hemidiaphragm. Metastases are typically seen on the posterior cul-de-sac, paracolic gutters, right hemidiaphragm, liver capsule,

the peritoneal surfaces of the intestines and their mesenteries, and the omentum. The disease seldom invades the intestinal lumen but progressively agglutinates loops of bowel, leading to a functional intestinal obstruction. This condition is known as carcinomatous ileus (4).

Lymphatic

Lymphatic dissemination to the pelvic and para-aortic lymph nodes is common, particularly in advanced-stage disease (137–139). Spread through the lymphatic channels of the diaphragm and through the retroperitoneal lymph nodes can lead to dissemination above the diaphragm, especially to the supraclavicular lymph nodes (137). Burghardt et al. reported that 78% of patients with stage III disease have metastases to the pelvic lymph nodes (139). In another series, the rate of para-aortic lymph nodes positive for metastasis was 18% in stage I, 20% in stage II, 42% in stage III, and 67% in stage IV (137).

Hematogenous

Hematogenous dissemination at the time of diagnosis is uncommon. Spread to vital organ parenchyma, such as the lungs and liver, occurs in only about 2% to 3% of patients. Most patients with disease above the diaphragm when diagnosed have a right pleural effusion (4). Systemic metastases appear more frequently in patients who survived for some years. Dauplat et al. reported that distant metastasis consistent with stage IV disease ultimately occurred in 38% of the patients whose disease was originally IP (140).

Prognostic Factors

The outcome of treatment can be evaluated in the context of prognostic factors, which can be grouped into pathologic, biologic, and clinical factors (141).

Pathologic Factors

The morphology and histologic pattern, including the architecture and grade of the lesion, are important prognostic variables (4). The histologic type was not believed to have prognostic significance, but several papers contained suggestions that clear cell carcinomas are associated with a prognosis worse than that of other histologic types (141,142).

Histologic grade, as determined either by the pattern of differentiation or by the extent of cellular anaplasia and the proportion of undifferentiated cells, seems to be of prognostic significance (143–146). Studies of the reproducibility of grading ovarian cancers show a high degree of intraobserver and interobserver variation (147,148). Baak et al. have presented a standard grading system based on the morphometric analysis, and the system seems to correlate with prognosis, especially in its ability to

distinguish low-grade or borderline patterns from other tumors (149).

Clinical Factors

In addition to the stage, the extent of residual disease after primary surgery, the volume of ascites, patient age, and performance status are all independent prognostic variables (150–159). Among patients with stage I disease, Dembo et al. showed, in a multivariate analysis, that tumor grade and dense adherence to the pelvic peritoneum had a significant adverse impact on prognosis, whereas intraoperative tumor spillage or rupture did not (156). Sjövall et al. confirmed that **ovarian cancers that undergo intraoperative rupture or spillage do not worsen prognosis, whereas tumors that are ruptured preoperatively do have a poorer prognosis** (157). A multivariate analysis of these and several other studies was performed by Vergote et al., who found that for **early-stage disease, poor prognostic variables were tumor grade, capsular penetration, surface excrescences, and malignant ascites, but not iatrogenic rupture** (159).

Table 39-2 2013 FIGO Staging for Primary Carcinoma of the Ovary, Fallopian Tube, or Primary Peritoneal Cancer

Stage I	**Growth Limited to the Ovaries or Fallopian Tubes**
IA	Growth limited to one ovary or fallopian; no ascites containing malignant cells
	No tumor on the external surface; capsule intact
IB	Growth limited to both ovaries or fallopian tubes; no ascites containing malignant cells
	No tumor on the external surfaces; capsules intact
IC	Tumor limited to one or both ovaries or fallopian tubes with any of the following:
IC1	Surgical spill
IC2	Capsule ruptured before surgery or tumor on ovarian or fallopian tube surface
IC3	Malignant cells in the ascites or peritoneal washings
Stage II	**Growth involving one or both ovaries or fallopian tubes with pelvic extension (below the pelvic brim)**
IIA	Extension and/or metastases to the uterus and/or fallopian tubes and/or ovaries
IIB	Extension to other pelvic tissues
Stage III	**Tumor involving one or both ovaries or fallopian tubes or peritoneal cancer with cytologically or histologically confirmed spread to the peritoneum outside the pelvis and/or metastasis to the retroperitoneal lymph nodes**
IIIA	Positive retroperitoneal lymph nodes and/or microscopic metastasis beyond pelvis

IIIA1(i)	Positive retroperitoneal lymph nodes with metastasis up to 10 mm in greatest dimension
IIIA1(ii)	Positive retroperitoneal lymph nodes with metastasis more than 10 mm in greatest dimension
IIIA2	Microscopic extrapelvic (above the pelvic brim) peritoneal involvement, with or without positive retroperitoneal lymph nodes
IIIB	Macroscopic peritoneal metastasis beyond pelvis up to 2 cm in greatest dimension, with or without positive retroperitoneal nodes
IIIC	Macroscopic peritoneal metastasis beyond pelvis more than 2 cm in greatest dimension (includes extension of tumor to capsule of liver and spleen without parenchymal involvement of either organ), with or without positive retroperitoneal nodes
IV	**Distant metastasis (excludes peritoneal metastasis)**
IVA	**Pleural effusion is present, there must be positive cytologic test results**
IVB	**Parenchymal metastases and metastases to extra-abdominal organs (including lymph nodes and lymph nodes outside the abdominal cavity)**

The histologic characteristics are to be considered in the staging, as are results of cytologic testing as far as effusions are concerned. It is desirable that a biopsy be performed on suspicious areas outside the pelvis.

FIGO, International Federation of Obstetrics and Gynecology.

[a]Dense adhesions with histologically proven tumor cells justify upgrading to stage II.

Transmural bowel infiltration or umbilical deposit are stage IVB.

Initial Surgery for Ovarian Cancer

Staging

Ovarian epithelial malignancies are staged according to the FIGO system listed in Table 39-2 (160). **The FIGO staging is based on findings at surgical exploration. A preoperative evaluation should exclude the presence of extraperitoneal metastases.**

[7] Thorough surgical staging and search for microscopic metastasis should be performed when there is no visible or palpable disease in the intra-abdominal space outside the ovaries and fallopian tubes. Subsequent treatment may be determined by the stage of the disease. In earlier series in which patients did not undergo careful surgical staging, the overall 5-year survival for patients with apparent stage I epithelial ovarian cancer was only about 60% (161). Survival rates of 90% to 100% are reported for patients who were properly staged and were found to have stage IA or IB disease.

Technique for Surgical Staging

In patients whose preoperative evaluation suggests a probable malignancy, a

vertical abdominal incision is recommended to allow adequate access to the upper abdomen (4,161). When a malignancy is unexpectedly discovered in a patient who has a lower transverse incision, the rectus muscles can be either divided or detached from the symphysis pubis to allow better access to the upper abdomen. If this is not sufficient, the incision can be extended on one side to create a "J" incision (4).

The ovarian tumor should be removed intact, if possible, and a frozen histologic section should be obtained. A thorough surgical staging should be performed. Staging involves the following steps (4,161):

1. **Any free fluid, especially in the pelvic cul-de-sac, should be submitted for cytologic evaluation.**
2. **If no free fluid is present, peritoneal washings should be performed by instilling and recovering 50 to 100 mL of saline from the pelvic cul-de-sac, each paracolic gutter, and beneath each hemidiaphragm.** Obtaining the specimens from under the diaphragms can be facilitated with the use of a rubber catheter attached to the end of a bulb syringe.
3. **A systematic exploration of all the intra-abdominal surfaces and viscera is performed,** proceeding in a clockwise fashion from the cecum cephalad along the paracolic gutter and the ascending colon to the right kidney, the liver and gallbladder, the right hemidiaphragm, the entrance to the lesser sac at the para-aortic area, across the transverse colon to the left hemidiaphragm, down the left gutter and the descending colon to the rectosigmoid colon. The small intestine and its mesentery from the Treitz ligament to the cecum should be inspected.
4. **Any suspicious areas or adhesions on the peritoneal surfaces should be biopsied.** If there is no evidence of disease, multiple IP biopsies should be performed. Tissue from the peritoneum of the pelvic cul-de-sac, both paracolic gutters, the peritoneum over the bladder, and the intestinal mesenteries should be taken for biopsy.
5. **The diaphragm should be sampled, either by biopsy or by scraping with a tongue depressor, and a sample obtained for cytologic assessment.** Biopsies of any irregularities on the surface of the diaphragm can be facilitated by the use of the laparoscope and the associated biopsy instrument.
6. **The omentum should be resected from the transverse colon, including from the hepatic and splenic flexure of the colon and separated from its attachment to the greater curvature of the stomach, including ligation of the left and right gastroepiploic and short gastric arteries, a procedure called *supracolic omentectomy*.** The procedure is initiated on the underside of the greater omentum, where the peritoneum is incised a few millimeters away from the transverse colon. The branches of the gastroepiploic vessels are clamped, ligated, and divided, along with all the small branching vessels that feed the infracolic omentum.

7. **The retroperitoneal spaces should be explored to evaluate the pelvic and para-aortic lymph nodes.** The retroperitoneal dissection is performed by incision of the peritoneum over the psoas muscles. Any enlarged lymph nodes should be resected and submitted for frozen section. If no metastases are present, a formal pelvic lymphadenectomy should be performed. The para-aortic area should be palpated and lymph nodes sampled if enlarged or suspicious.

Results

Metastases in apparent stages I and II epithelial ovarian cancer occur in as many as 3 in 10 patients whose tumors appear to be confined to the pelvis but who have occult metastatic disease in the upper abdomen or the retroperitoneal lymph nodes (138,162–169). In a literature review, occult metastases in such patients were found in biopsies of the diaphragm in 7.3%, biopsies of the omentum in 8.6%, the pelvic lymph nodes in 5.9%, the aortic lymph nodes in 18.1%, and in 26.4% of peritoneal washings (161).

The importance of careful initial surgical staging is emphasized by the findings of a cooperative national study in which 100 patients with apparent stages I and II disease were referred for subsequent therapy and underwent additional surgical staging (162). In this series, 28% of the patients initially believed to have stage I disease were upstaged and 43% of those believed to have stage II disease had more advanced lesions. **A total of 31% of the patients were upstaged as a result of additional surgery, and 77% were reclassified as having actual stage III disease. Histologic grade was a significant predictor of occult metastasis.** Sixteen percent of the patients with grade 1 lesions were upstaged, compared with 34% with grade 2 disease and 46% with grade 3 disease.

Borderline Tumors

The principal treatment of borderline (low malignant potential) ovarian tumors is surgical resection of the primary tumor. There is no evidence that either subsequent chemotherapy or radiation therapy improves survival. When a **frozen section determines that the histology is borderline, premenopausal patients who desire preservation of the ovarian function may undergo a conservative operation, a unilateral oophorectomy** (4,170). In a study of patients who underwent unilateral ovarian cystectomy for apparent stage I borderline serous tumors, Lim-Tan et al. found that this conservative operation was safe, with only 8% of the patients developing recurrences 2 to 18 years later, all with curable disease confined to the ovaries (170). Recurrence was associated with positive margins of the removed ovarian cyst. Thus, hormonal function and fertility can be maintained (4,170). For patients who had an oophorectomy or cystectomy and a borderline tumor is documented later in the permanent pathology, no additional immediate surgery is necessary.

Stage I

After a comprehensive staging laparotomy, only a minority of women will have local disease (FIGO stage I). There are over 20,000 women diagnosed yearly with epithelial ovarian cancer in the United States, and nearly 4,000 of these have disease confined to the ovaries (65,171). The prognosis for these patients depends on the clinical–pathologic features. Because of this emphasis on the importance of surgical staging, the rate of lymph node sampling increased in the United States, with a study showing that for women with stages I and II disease, the percentage having lymph nodes sampled increased from 38% to 59% from 1991 to 1996 (172).

The primary surgical treatment for stage I epithelial ovarian cancer is surgical, and patients should undergo total abdominal hysterectomy, bilateral salpingo-oophorectomy, and surgical staging (161,162). **In certain circumstances, a unilateral salpingo-oophorectomy may be performed as a part of fertility-sparing surgery.** Based on the findings at surgery and the pathologic evaluation, patients with stage I ovarian cancer can be grouped into low-risk and high-risk categories (Table 39-3).

Table 39-3 Prognostic Variables in Early-Stage Epithelial Ovarian Cancer

Low Risk	High Risk
Low grade	High grade
Intact capsule	Tumor growth through capsule
No surface excrescences	Surface excrescences
No ascites	Ascites
Negative peritoneal cytologic findings	Malignant cells in fluid
Unruptured or intraoperative rupture	Preoperative rupture
No dense adherence	Dense adherence
Diploid tumor	Aneuploid tumor

From **Berek JS, Friedlander ML, Hacker NF.** Epithelial ovarian, fallopian tube, and peritoneal cancer. In: Berek JS, Hacker NF. *Berek & Hacker's Gynecologic Oncology*. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:483.

Stage I Low Risk

Fertility Preservation in Early-Stage Ovarian Cancer

For patients who underwent a thorough staging laparotomy and who have no evidence of spread beyond the ovary, abdominal hysterectomy and bilateral salpingo-oophorectomy are appropriate therapy. The uterus and the contralateral ovary can be preserved in women with stage IA, grade 1 to 2 disease who desire to

preserve fertility. The women undergoing disease surveillance should be monitored carefully with routine periodic pelvic examinations and determinations of serum CA-125 levels. The other ovary and the uterus are removed at the completion of childbearing.

Guthrie et al. studied the outcome of 656 patients with early-stage epithelial ovarian cancer (169). No untreated patients who had stage IA, grade 1 cancer died of their disease; thus, adjuvant radiation and chemotherapy are unnecessary. The Gynecologic Oncology Group (GOG) carried out a prospective, randomized trial of observation versus *melphalan* for patients with stages IA and IB, grade 1 or 2 disease (142). Five-year survival for each group was 94% and 96%, respectively, confirming that no further treatment is needed for such patients.

Stage I High Risk

Patients who have more poorly differentiated disease or who have malignant cells either in ascites fluid or in peritoneal washings, must undergo complete surgical staging (4). Most patients require chemotherapy.

Advanced-Stage Ovarian Cancer

The management of all patients with advanced-stage disease is approached in a similar manner, with modifications made in response to the overall status and general health of the patient and the extent of residual disease present at the time treatment is initiated. A treatment scheme is outlined in Figure 39-10. Most patients subsequently receive combination chemotherapy for an empiric number of cycles.

Cytoreductive Surgery for Advanced-Stage Disease

If the patient is medically stable, she should undergo cytoreductive surgery to remove as much of the tumor and its metastases as possible (173–200). **The operation to remove the primary tumor and the associated metastatic disease is referred to as *debulking*** or cytoreductive surgery. The operation typically includes the performance of a total abdominal hysterectomy and bilateral salpingo-oophorectomy, along with a complete omentectomy and resection of any metastatic lesions from the peritoneal surfaces or from the intestines. The pelvic tumor often directly involves the rectosigmoid colon, the terminal ileum, and the cecum **(Fig. 39-11)**. In a minority of patients, most or all of the disease is confined to the pelvic viscera and the omentum, so that removal of these organs will result in extirpation of all gross tumor, a situation that is associated with a reasonable chance of prolonged PFS.

The paradigm of routine lymphadenectomy in patients with advanced ovarian cancer and clinically and radiographically negative nodes has been challenged with the reporting of the Lymphadenectomy in Ovarian Neoplasms (LION) study. This was a

prospective randomized trial of 647 patients with stage IIB to IV ovarian cancer with macroscopic complete resection and preoperative and intraoperative clinically negative lymph nodes randomized intraoperatively to systematic pelvic and para-aortic lymphadenectomy versus no lymphadenectomy. This trial showed that systematic pelvic and para-aortic lymphadenectomy in patients with advanced ovarian cancer with intra-abdominal complete resection and clinically negative lymph nodes does not provide a PFS or overall survival benefit, despite the detection and removal of subclinical lymph nodal metastases in approximately 56% of patients. The authors suggest that routine lymphadenectomy should be omitted in these patients to reduce postoperative morbidity and mortality (201).

The removal of bulky tumor masses may reduce the volume of ascites present. Often, ascites will disappear after removal of the primary tumor and a large omental "cake." Removal of the omental cake may alleviate the nausea and early satiety that many patients experience. Removal of intestinal metastases may restore adequate intestinal function and improve the overall nutritional status of the patient, thereby facilitating the patient's ability to tolerate subsequent chemotherapy.

A large, bulky tumor may contain areas that are poorly vascularized, and these areas will be exposed to suboptimal concentrations of chemotherapeutic agents. Similarly, these areas are poorly oxygenated, so that radiation therapy, which requires adequate oxygenation to achieve maximal cell kill, will be less effective. Surgical removal of these bulky tumors may eliminate areas that could be relatively resistant to radiation and chemotherapeutic treatment.

Larger tumor masses tend to be composed of a higher proportion of cells that are either nondividing or in the "resting" phase (i.e., G_0 cells, which are essentially resistant to the therapy). A low growth fraction is characteristic of bulky tumor masses, and cytoreductive surgery can result in smaller residual masses with a relatively higher growth fraction.

Goals of Cytoreductive Surgery

The principal goal of cytoreductive surgery is removal of all of the primary cancer and, if possible, all metastatic disease. If resection of all metastases is not feasible, the goal is to reduce the tumor burden by resection of all individual tumors to an optimal status (<1 cm of any single implant of residual disease). **Patients whose disease is completely resected to no macroscopic (microscopic only) residual disease have the best overall survival (Fig. 39-12)** (178). **Approximately 30% to 40% of patients in this category will be free of disease at 5 years.**

FIGURE 39-10 Treatment scheme for patients with advanced-stage ovarian cancer. *In selected cases of stage IIIC/IV disease, neoadjuvant chemotherapy may be given, and then an interval cytoreductive surgery is performed after three cycles. +Chemotherapy depends on whether platinum-sensitive or platinum-resistant. (Modified from **Berek JS, Friedlander ML, Hacker NF.** Epithelial ovarian, fallopian tube, and peritoneal cancer. In: Berek JS, Hacker NF. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:485.)

The resectability of the metastatic tumor is usually determined by the location of the disease. Optimal cytoreduction is difficult to achieve in the presence of extensive disease on the diaphragm, in the parenchyma of the liver, along the base of the small bowel mesentery, in the lesser omentum, or in the porta hepatis. **[7] Neoadjuvant chemotherapy is an option for patients with advanced ovarian/fallopian tube or peritoneal cancer who are determined to have a low likelihood of optimal cytoreduction or in women determined to have a high perioperative risk** (202).

In two published large randomized control trials, neoadjuvant chemotherapy was noninferior to upfront cytoreduction (203,204). There was no significant difference between the PFS or overall survival between the two groups. In one trial, the EORTC 55971, outcomes were found to vary by the stage of disease and tumor size. In particular, patients with stage IV disease and more extensive tumors greater than 45 mm had a better survival with neoadjuvant chemotherapy; however, patients with stage IIIC cancer and metastatic lesions less than 45 mm had a better survival with primary cytoreductive surgery (205). All randomized clinical trials have shown lower perioperative morbidity with neoadjuvant chemotherapy compared to primary cytoreductive surgery (202).

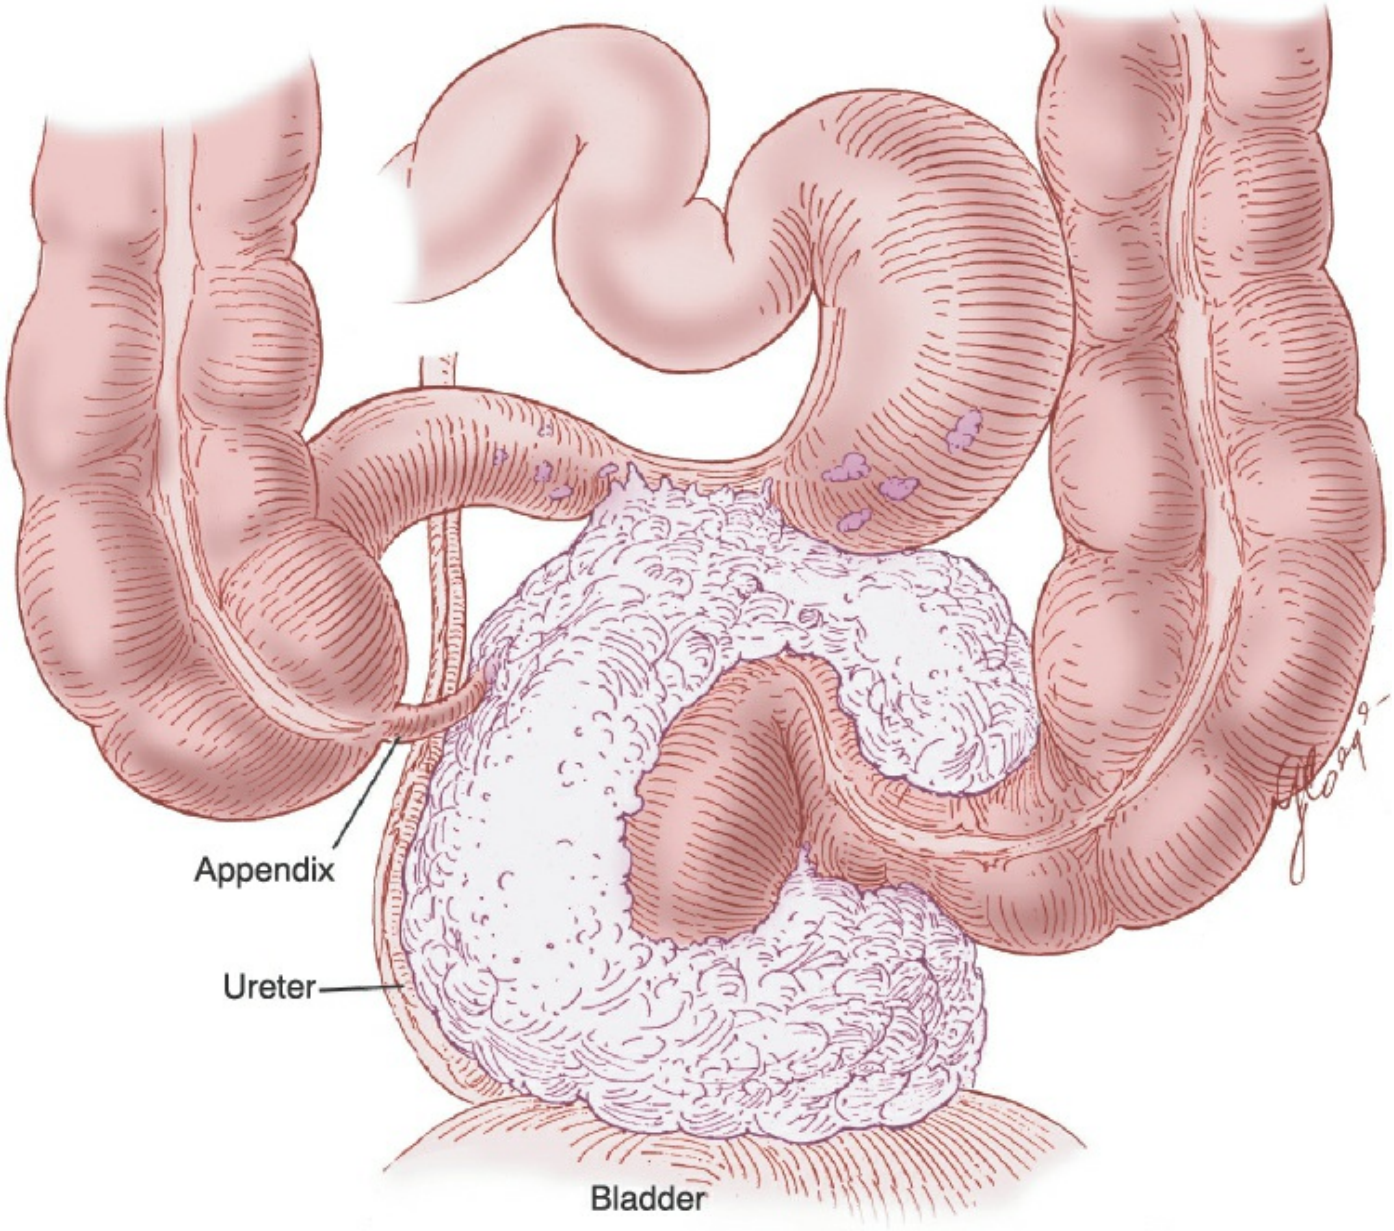

FIGURE 39-11 Extensive ovarian carcinoma involving the bladder, rectosigmoid, and ileocecal area. (Redrawn from **Heintz APM, Berek JS.** Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian Malignancies. Edinburgh, UK: Churchill Livingstone; 1987:134, with permission.)

(From **Heintz APM, Odicino F, Maisonneuve P, et al.** Carcinoma of the ovary. Twenty-sixth annual report of the results of treatment of gynaecological cancer. Int J Gynecol Oncol 2006;95(suppl 1): S161–S192, with permission.)

Exploration

The supine position on the operating table may be sufficient for surgical exploration of most patients. For patients with extensive pelvic disease and for whom a low resection of the colon may be necessary, the low lithotomy position should be used. Debulking operations should be performed through a vertical incision to gain adequate access to the upper abdomen and to the pelvis.

After the peritoneal cavity is opened, ascites fluid, if present, should be evacuated. In some centers, fluid is submitted for *in vitro* research studies, such as molecular analyses. In cases of massive ascites, careful attention must be given to hemodynamic monitoring, especially for patients with borderline cardiovascular function.

The peritoneal cavity and retroperitoneum are thoroughly inspected and palpated to assess the extent of the primary tumor and the metastatic disease. All abdominal viscera must be palpated to exclude the possibility that the ovarian disease is

metastatic, particularly from the stomach, colon, or pancreas. If optimal cytoreduction is not considered achievable, extensive bowel and urologic resections are not indicated, except to overcome a bowel obstruction. Removal of the primary tumor and omental cake is usually feasible and desirable.

Pelvic Tumor Resection

The essential principle of pelvic tumor removal is the retroperitoneal approach. To accomplish this, the retroperitoneum is entered laterally, along the surface of the psoas muscles, which avoids the iliac vessels and the ureters. If the uterus is present, the procedure is initiated by bilateral division of the round ligaments. The peritoneal incision is extended cephalad, lateral to the ovarian vessels within the infundibulopelvic ligament, and caudally toward the bladder. With careful dissection, the retroperitoneal space is explored, and the ureter and pelvic vessels are identified. The pararectal and paravesical spaces are identified and developed, as described in Chapter 38.

The peritoneum overlying the bladder is dissected to connect the peritoneal incisions anteriorly. The vesicouterine plane is identified, and with careful sharp dissection the bladder is mobilized from the anterior surface of the cervix. The ovarian vessels are isolated, doubly ligated, and divided.

Hysterectomy is performed. The ureters must be carefully displayed to avoid injury. During this procedure, the uterine vessels can be identified. Ligation of the uterine vessels and the remainder of the tissues within the cardinal ligaments completes the hysterectomy and resection of the contiguous tumor.

Because epithelial ovarian cancers tend not to invade the lumina of the colon or bladder, it is usually feasible to resect pelvic tumors without having to resect portions of the lower colon or the urinary tract (183,184). Resection of a small portion of the bladder may be required and, if so, a cystotomy should be performed to assist in resection of the disease (184).

Intestinal Resection

Resection of focal areas of disease involving the small or large intestine should be performed if that would permit the removal of all or most of the abdominal metastases and leave the patient with optimal cytoreduction at the end of surgery. Apart from the rectosigmoid colon, the most frequent sites of intestinal metastasis are the terminal ileum, the cecum, and the transverse colon. Resection of one or more of these segments of bowel may be necessary (183,185).

If the disease surrounds the rectosigmoid colon and its mesentery, that portion of the colon may have to be removed in order to clear the pelvic disease **(Fig. 39-13)** (183). After the pararectal space is identified, the proximal site of colonic involvement is identified, the colon and its mesentery are divided, and the rectosigmoid is removed

along with the uterus *en bloc.* A reanastomosis of the colon is performed.

Omentectomy

Advanced epithelial ovarian cancer often completely replaces the omentum, forming an "omental cake." This disease may be adherent to the parietal peritoneum of the anterior abdominal wall, making entry into the abdominal cavity difficult. After freeing the omentum from any adhesions to the parietal peritoneum, adherent loops of the small intestine are freed by sharp dissection. The omentum is lifted and pulled gently in the cranial direction, exposing the attachment of the infracolic omentum to the transverse colon. The peritoneum is incised to open the appropriate plane, which is developed by sharp dissection along the serosa of the transverse colon. Small vessels are ligated with hemoclips, suture, or a vessel-sealing device. The omentum is separated from the greater curvature of the stomach by ligation of the right and left gastroepiploic arteries and ligation of the short gastric arteries **(Fig. 39-14)**.

The disease in the gastrocolic ligament can extend to the hilus of the spleen and splenic flexure of the colon on the left and to the capsule of the liver and the hepatic flexure of the colon on the right. Usually, the disease does not invade the parenchyma of the liver or spleen, and a plane can be found between the tumor and these organs. It will occasionally be necessary to perform splenectomy to remove all the omental disease (186).

Resection of Other Metastases

Other large masses of tumor located on the parietal peritoneum should be removed, particularly if they are isolated masses and their removal will permit optimal cytoreduction. Resection of extensive disease from the surfaces of the diaphragm is neither practical nor feasible, although solitary metastases may be resected, the diaphragm sutured, and a chest tube placed for a few days if needed (186,187). The use of the Cavitron Ultrasonic Surgical Aspirator (CUSA) and the argon beam coagulator may facilitate resection of small tumor nodules, especially those on flat surfaces (188,189).

Feasibility and Outcome

There was no randomized prospective study performed to define the value of primary cytoreductive surgery, but all retrospective studies indicate that the diameter of the largest residual tumor nodule before the initiation of chemotherapy is significantly related to the PFS in patients with advanced ovarian cancer (190). The quality of life may be significantly enhanced by the removal of bulky tumor masses from the pelvis and upper abdomen (191).

An analysis of the retrospective data indicates that, when performed by gynecologic oncologists, successful operations are feasible in 70% to 90% of patients (181,182). Major morbidity is approximately 5% and operative mortality is

1% (185,192,193). Intestinal resection in these patients does not appear to increase the overall morbidity caused by the operation (185).

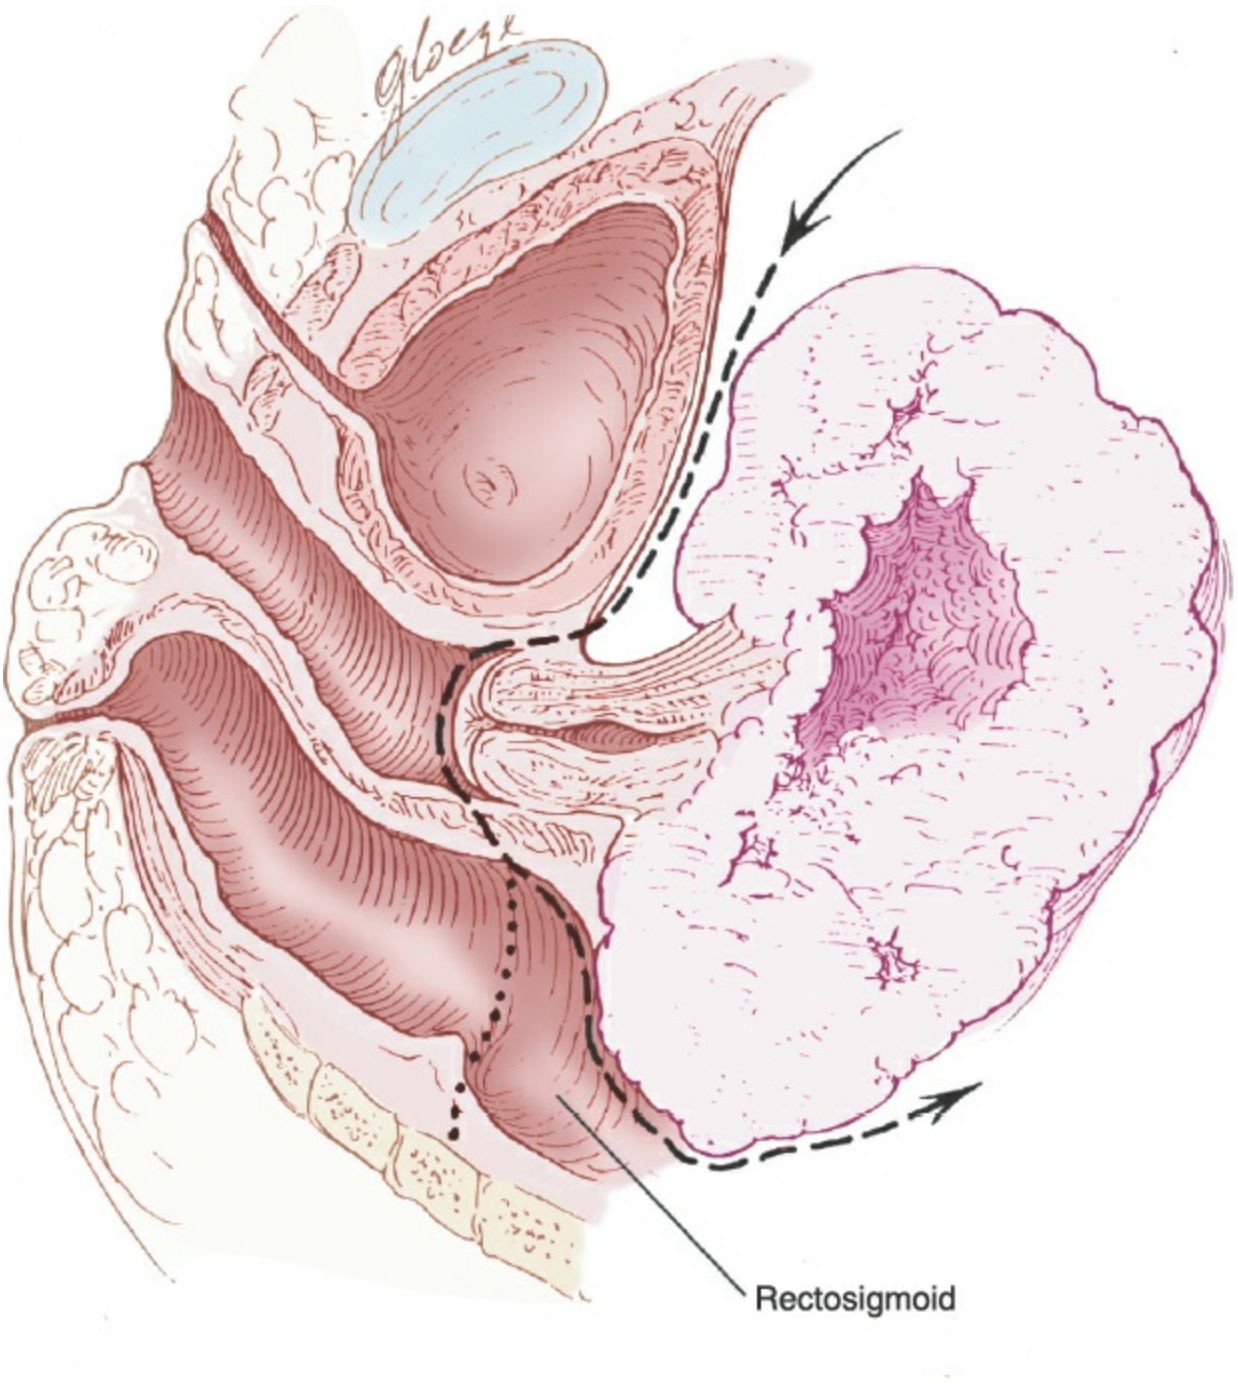

FIGURE 39-13 The resection of the pelvic tumor may include removal of the uterus, tubes, and ovaries, as well as portions of the lower intestinal tract. The *arrows* represent the plane of resection. (Modified from **Berek JS, Friedlander ML, Hacker NF.** Epithelial ovarian, fallopian tube, and peritoneal cancer. In: Berek JS, Hacker NF. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:490.)

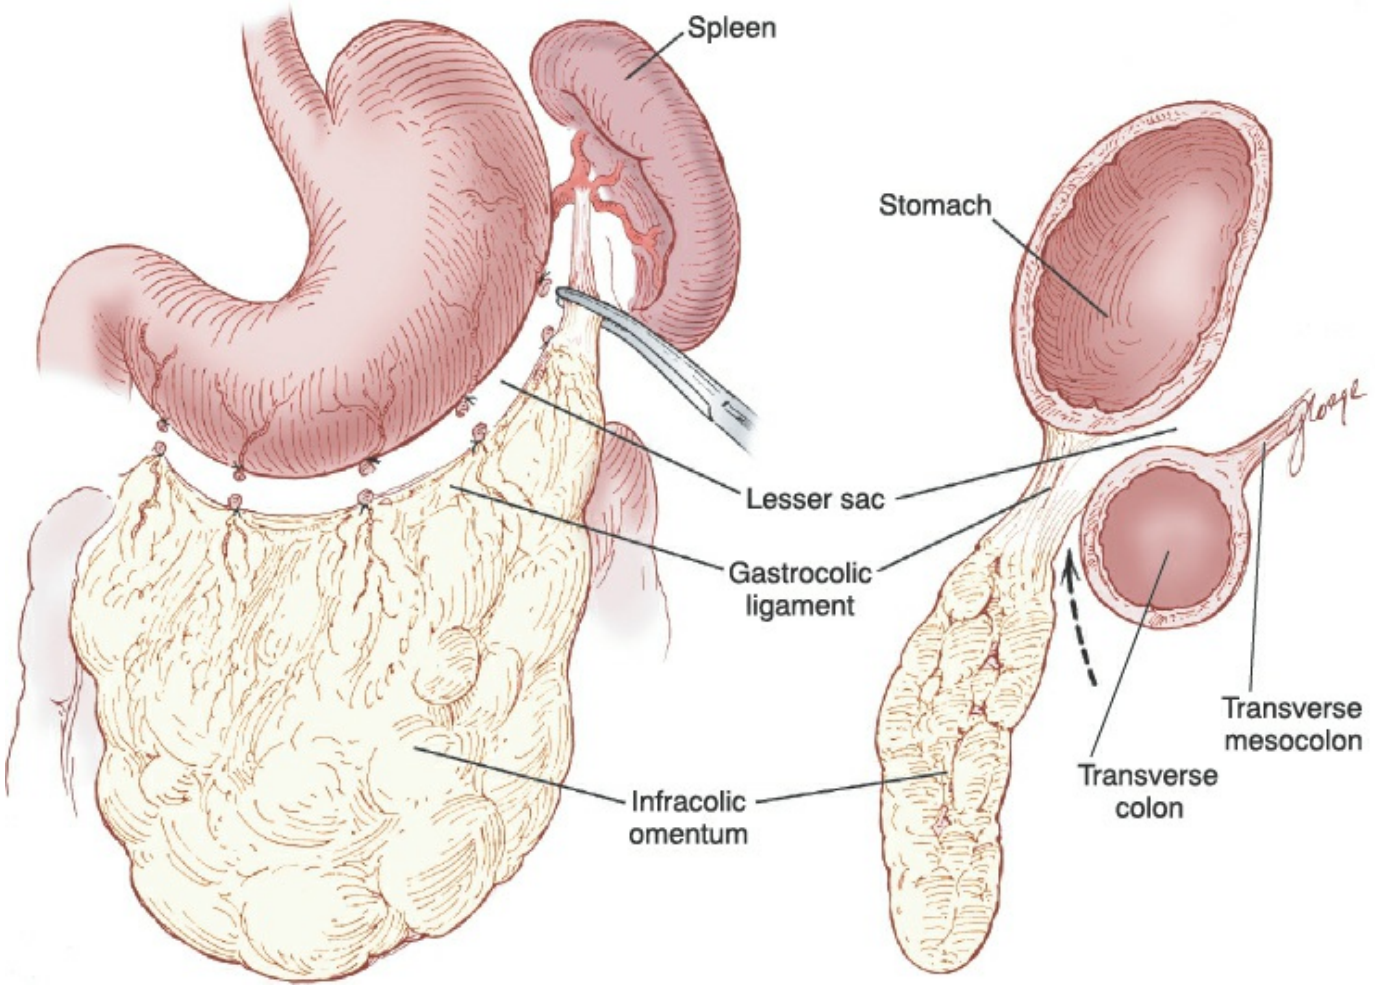

FIGURE 39-14 Separation of the omentum from stomach and transverse colon. *Arrow*, the direction of the initial surgical approach. (From **Heintz APM, Berek JS.** Cytoreductive surgery for ovarian carcinoma. In: Piver MS, ed. Ovarian Malignancies. Edinburgh, UK: Churchill Livingstone; 1987:134, with permission.)

In a meta-analysis of 81 studies of women who underwent cytoreductive surgery for advanced ovarian cancer, Bristow et al. documented that the extent of debulking correlated with incremental benefits in survival (i.e., the greater the percentage of tumor reduction, the longer the survival). Each 10% increase in cytoreduction equaled a 5.5% increase in median survival (190). **Women whose cytoreduction was greater than 75% of their tumor burden had a median survival of 33.9 months compared with 22.7 months for women whose tumors were cytoreduced less than 75%** (p <0.001). The performance of a pelvic and para-aortic lymphadenectomy in patients with stage III disease does not prolong survival, based on the results of a large prospective, randomized trial (194).

A prospective randomized study of "interval" cytoreductive surgery was carried out by the European Organization for the Research and Treatment of Cancer (EORTC). Interval surgery was performed after three cycles of *platinum*-combination chemotherapy in patients whose primary attempt at cytoreduction was suboptimal. The

initial surgery for most of these patients was not an aggressive attempt to debulk their tumors. Patients in the surgical arm of the study demonstrated a survival benefit when compared with those who did not undergo interval debulking (195). The risk of mortality was reduced by more than 40% in the group that was randomized to the debulking arm of the study. Based on these data, the performance of a debulking operation as early as possible in the course of the patient's treatment should be considered the standard of care (191).

A prospective phase III study of interval cytoreductive surgery was conducted by the GOG; the patients entered on the trial had a maximal attempt at tumor resection at their initial surgery (196). The randomized findings showed no difference between the patients who had an additional attempt at debulking after three cycles of chemotherapy compared with those who did not. The median survival of the 216 women who underwent interval cytoreduction was 32 months compared with 33 months for the 209 women who did not undergo surgical cytoreduction.

There is evidence that the survival of women with advanced ovarian cancer is improved when the surgeon is specifically trained to perform cytoreductive surgery and when there is centralization of care (197–200). **Whenever feasible, patients with advanced ovarian malignancy should be referred to a subspecialty unit for primary surgery, and every effort should be made to attain as complete a cytoreduction as possible.**

Chemotherapy

Stage I Epithelial Ovarian Cancer

Early Stage, Low Risk

Guthrie et al. studied the outcome of 656 patients with early-stage epithelial ovarian cancer (169). Patients who had stage IA, grade 1 cancer and did not receive radiation or chemotherapy did not die of their disease; indicating that adjuvant therapy is unnecessary. The GOG carried out a prospective, randomized trial of observation versus *melphalan* for patients with stages IA and IB, grades 1 and 2 disease (142). **Five-year survival for each group was 94% and 96%, respectively, confirming that adjuvant treatment did not improve survival. Therefore, no adjuvant chemotherapy is recommended for these patients.**

Early Stage, High Risk

In patients whose disease is high risk (e.g., high-grade serous or in whom there are malignant cells either in ascites fluid or in peritoneal washings), additional therapy is indicated. Chemotherapy is recommended for these patients to reduce recurrence risk (206–219).

Two large parallel randomized phase III clinical trials were conducted on women with early-stage disease more than 20 years ago and reported in 2003: the **International Collaborative Ovarian Neoplasm Trial 1 (ICON1)** and the **Adjuvant Chemotherapy Trial in Ovarian Neoplasia (ACTION)** (220,221).

In the ICON1 trial, 477 patients from 84 centers in Europe were entered. Patients of all stages were eligible for the trial if, in the opinion of the investigator, it was unclear whether adjuvant therapy would be of benefit. Most patients were considered to have stages I and IIA disease, but optimal **surgical staging was not required,** and it is likely that a significant number of these women had stage III disease. Adjuvant *platinum*-based chemotherapy was given to 241 patients, and no adjuvant chemotherapy was given to 236 patients. **The 5-year survival was 73% in the group who received adjuvant chemotherapy compared with 62% in the control group** (HR, 0.65; p = 0.01) (221).

In the ACTION trial, 440 patients from 40 European centers were randomized; 224 patients received adjuvant *platinum*-based chemotherapy, and 224 patients did not (220). **Patients with stages I and II, grades 2 and 3 were eligible.** Only about one-third of the total group was optimally staged (151 patients). **In the observation arm, optimal staging was associated with a better survival** (HR, 2.31; p = 0.03), **and in the suboptimally staged patients, adjuvant chemotherapy was associated with an improvement in survival** (HR, 1.78; p = 0.009). **In the ACTION trial, the initial trial results suggested that the benefit from adjuvant chemotherapy was limited to the patients with suboptimal staging. However, a long-term follow-up of the randomized trial after a median of 10.1 years showed that the overall survival after optimal staging was improved even among those who received adjuvant chemotherapy** (HR of death, 1.89; p = 0.05) (222).

When the data from the two trials were combined and analyzed, a total of 465 patients were randomized to receive *platinum*-based adjuvant chemotherapy and 460 to observation until disease progression (223). After a median follow-up of more than 4 years, the overall survival was 82% in the chemotherapy arm and 74% in the observation arm (HR, 0.67; p = 0.001). Recurrence-free survival was better in the chemotherapy arm: 76% versus 65% (HR, 0.64; p = 0.001). The results of this analysis must be interpreted with caution, because most of the patients did not undergo thorough surgical staging, but the **findings suggest that *platinum*-based chemotherapy should be given to patients who were not optimally staged.** It is generally accepted that high-risk early-stage ovarian cancer patients, including stage I, grade 3 endometrioid, stage IC, serous and carcinosarcoma, benefit from adjuvant chemotherapy just as advanced-stage ovarian cancer patients do. There remains uncertainty about the impact of chemotherapy in women with stage I clear cancers as these cancers are less chemosensitive than high-grade serous cancers.

A randomized phase III trial of three versus six cycles of adjuvant *carboplatin* and *paclitaxel (CP)* in 457 patients with early-stage epithelial ovarian carcinoma was conducted by the GOG (224). An unexpectedly large number of patients (126 patients, 29%) had incomplete or inadequately documented surgical staging in this study. The recurrence rate for six cycles was 24% lower (HR, 0.76; confidence interval [CI], 0.5–1.13; $p = 0.18$) versus three cycles, but this was not statistically significant. The estimates of probability of recurrence at 5 years were 20.1% for six cycles and 25.4% for three cycles (225). An exploratory analysis of high-risk early-stage epithelial ovarian cancer patients from this trial reported by Chan et al., suggested that six cycles rather than three cycles may decrease risk of recurrence, particularly in patients with serous ovarian tumors (226).

The recommendations for therapy follow:

- **Patients with high-grade, high-risk stage I epithelial ovarian cancer should be offered adjuvant chemotherapy depending on the patient's overall health and medical comorbidities.**
- **Treatment with *CP* chemotherapy for three to six cycles is used in these patients, whereas single-agent *carboplatin* may be preferable for older women and patients with other medical comorbidities.**

Advanced-Stage Epithelial Ovarian Cancer

Systemic multiagent chemotherapy is the standard treatment for metastatic epithelial ovarian cancer (227–251). After the introduction of *cisplatin* in the latter half of the 1970s, *platinum*-based combination chemotherapy became the most frequently used treatment regimen in the United States. **The second-generation *platinum* analogue, *carboplatin*, was developed to have less toxicity than its parent compound, *cisplatin*** (238). Fewer gastrointestinal side effects, especially nausea and vomiting, were observed than with *cisplatin*, and there was less nephrotoxicity, neurotoxicity, and ototoxicity. *Carboplatin* is associated with a higher degree of myelosuppression (240). **The dose of *carboplatin* is calculated by using the area under the curve (AUC) and the glomerular filtration rate (GFR) according to the *Calvert formula*** (241). **The target AUC is 5 to 6 for previously untreated patients with ovarian cancer.**

A **major advance in the treatment of advanced-stage disease was the incorporation of *paclitaxel* into the chemotherapeutic regimens in the late 1990s** (224,227–230). **Based on two studies** (228,229), ***paclitaxel* is included in the primary treatment of all women with advanced-stage epithelial ovarian cancer, unless there are contraindications to *paclitaxel*, such as preexisting peripheral neuropathy.**

Carboplatin and Paclitaxel

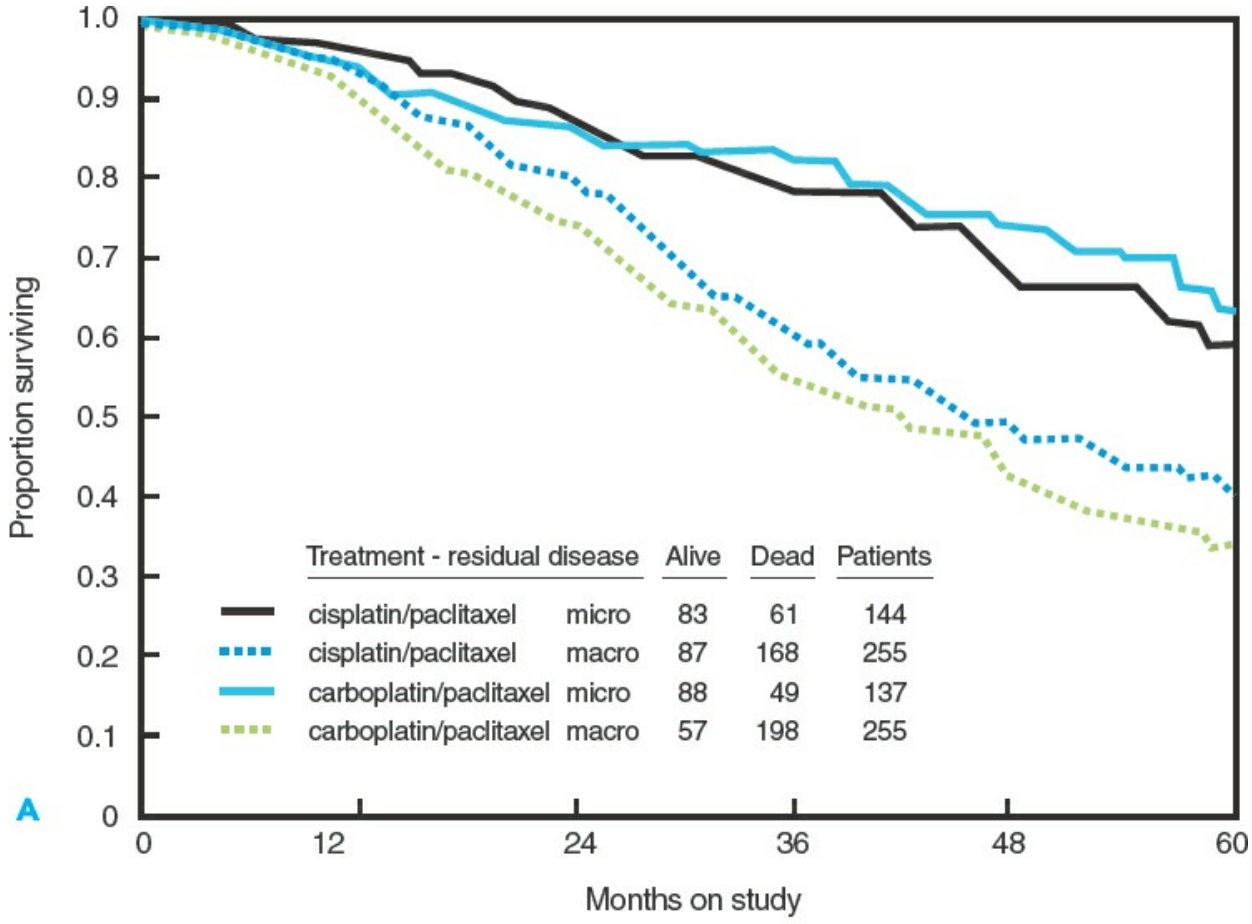
A series of randomized, prospective clinical trials with *paclitaxel*-containing arms defined *CP* as the standard treatment protocol in advanced epithelial ovarian cancer, although there are data to support IP chemotherapy in selected patients (228,229,235,236). **[8]** Two randomized, prospective clinical studies compared the combination of *paclitaxel* and *carboplatin* to *paclitaxel* and *cisplatin* (235,236). In both studies, the efficacy and survivals were similar, but the toxicity was more acceptable with the carboplatin-containing regimen **(Fig. 39-15)** (237).

Carboplatin and Docetaxel

Docetaxel* has a different toxicity profile from *paclitaxel. The SCOT-ROC (Scottish Gynaecological Cancer Trials Group) study randomly assigned 1,077 women with stages IC to IV epithelial ovarian cancer to *carboplatin* with either *paclitaxel* or *docetaxel* (244). **The efficacy of *docetaxel* appeared to be similar to *paclitaxel:*** The median PFS was 15.1 months versus 15.4 months, and the ***docetaxel* group had fewer neurologic effects, arthralgias, myalgias, and extremity weakness than the *paclitaxel* group.** The *docetaxel* plus *carboplatin* regimen was associated with significantly more myelosuppression and its consequences (i.e., serious infections and prolonged grade 3 to 4 neutropenia). *Docetaxel* is not widely used, but is an option in patients who have had a significant allergic reaction to *paclitaxel* or who develop early sensory neuropathy.

Five-Arm Trial

An Intergroup, international trial—GOG 182/Southwest Oncology Group (SWOG) 182/ICON5—compared the standard combination of *CP* with these drugs in combination with *gemcitabine*, *topotecan*, or *liposomal doxorubicin* in sequential doublets or triplets (245). The study showed that the addition of any these three drugs to the standard chemotherapy with *CP* did not improve the PFS or overall survival.



Intraperitoneal Chemotherapy

A randomized, prospective GOG study (Protocol 104) of IP *cisplatin* versus intravenous (IV) *cisplatin* (100 mg/m^2), each given with 750 mg/m^2 *cyclophosphamide*, was performed jointly by the SWOG and the GOG in patients with minimal residual disease (246). **[8]** **The IP *cisplatin* arm had a somewhat longer overall median survival than the IV arm, 49 months versus 41 months** (p = 0.03). In the patients with minimal residual disease (<0.5 cm maximal residual), paradoxically, there was no difference between the two treatments, 51 **months** versus 46 months (p = 0.08).

In a follow-up GOG study (Protocol 114), the dose-intense arm was initiated by giving a moderately high dose of *carboplatin* (dose AUC = 9) for two induction cycles, followed by IP *cisplatin* 100 mg/m^2 and IV *paclitaxel* 135 mg/m^2 over 24 hours, versus IV *cisplatin* 75 mg/m^2 and IV *paclitaxel* 135 mg/m^2 (247). The dose-intense arm results

were slightly better—the disease progression-free median survival was 27.6 months compared with 22.5 months for the control arm ($p = 0.02$). There was no difference in overall survival (52.9 months vs. 47.6 months, $p = 0.056$). Based on this study, it was unclear whether dose intensification with IP *cisplatin* has a sustained long-term impact on the survival of these patients.

A third randomized prospective GOG study (Protocol 172) compared IP *cisplatin* and *paclitaxel* versus IV *cisplatin* and *paclitaxel* (248). The combination of *cisplatin* 75 mg/m^2 and *paclitaxel* 135 mg/m^2 given IV every 3 weeks was compared with *paclitaxel* 135 mg/m^2 IV day 1, followed by *cisplatin* 100 mg/m^2 IP day 2, and *paclitaxel* 60 mg/m^2 IP day 8 every 3 weeks, each given for six cycles. **Although 83% of the patients randomized to IV chemotherapy completed all six cycles of therapy, only 42% of those treated with IP chemotherapy completed the six cycles, principally because of catheter-related complications. For patients in either group who could not complete the therapy because of *cisplatin*-related toxicity, the chemotherapy was switched to IV *carboplatin*.** Comparing the IV and IP arms, the median duration of the PFS was 18.3 and 23.8 months, respectively ($p = 0.05$). **[8] The median duration of the overall survival in the IV-therapy and IP-therapy groups was 49.7 and 65.6 months, respectively** ($p = 0.03$) (248). The **quality of life was significantly worse in the IP-therapy group before cycle four and 3 to 6 weeks after treatment but not 1 year after treatment.** A summary of the IP-catheter–related issues in this trial was presented (249).

FIGURE 39-15 Survival of patients with stage III epithelial ovarian cancer treated with *carboplatin* and *paclitaxel* versus *cisplatin* and *paclitaxel:* a Gynecologic Oncology Group study. **A:** Survival by treatment. **B:** Survival by treatment group (micro vs. macro). (From **Ozols RF, Bundy BN, Greer BE, et al.** Phase III trial of carboplatin and paclitaxel compared with cisplatin and paclitaxel in patients with optimally resected stage III ovarian cancer: a Gynecologic Oncology Group Study. J Clin Oncol 2003;21:3194–3200, with permission.)

In GOG 252, 1,560 patients with stage II to IV epithelial ovarian, fallopian tube, or peritoneal carcinoma were randomized to receive six cycles of chemotherapy. There were three treatment arms: Arm 1, IV *carboplatin* AUC 6/IV weekly *paclitaxel* at 80 mg/m^2; Arm 2, IP *carboplatin* AUC 6/IV weekly *paclitaxel* at 80 mg/m^2; Arm 3, IV *paclitaxel* at 135 mg/m^2 on day 1/IP *cisplatin* at 75 mg/m^2 on day 2/IP *paclitaxel* 60 mg/m^2 on day 8. Each arm received IV *bevacizumab* at 15 mg/kg with cycles 2 through 6 of chemotherapy and then single-agent *bevacizumab* for cycles 7 through 22. The trial results showed a median PFS of 27 to 29 months in patients with optimal stage II to III disease treated with regimens consisting of different combinations of IV and IP *cisplatin*, *carboplatin*, and *paclitaxel*, in combination with *bevacizumab.* An analysis limited to patients with optimal stage III tumors and no gross residual disease found a median PFS of 31 to 34 months. By comparison, the GOG 172 trial comparing IP and IV chemotherapy regimens in ovarian cancer had a median PFS of 23.8 months with IP *cisplatin* (vs. 18.3 months with IV) with an improvement in OS in favor of IP (252). Differences in the *cisplatin* arm from the GOG 172 study include a dose reduction from 100 to 75 mg and a shorter infusion time from 24 to 3 hours. If IP is used, it would be appropriate to follow the GOG 172 protocol rather than the modified protocol with a lower dose of *cisplatin*. Investigators at the Mayo Clinic reported in 2009 at the SGO that only 20% of the 105 patients they treated in the clinic could complete 3 or more cycles of the 172 protocol because of toxicity. However, the GOG 172 study did find a significant survival advantage for IP therapy and there is still support for IP chemotherapy in some centers.

[8] Based on these randomized trials, the IP route of administration for *carboplatin* or *cisplatin* and *paclitaxel* chemotherapy in the primary treatment of optimally resected stage III ovarian cancer is an acceptable therapeutic alternative to IV chemotherapy with *CP* (250). IP chemotherapy is best suited to patients who have optimally resected tumors, a good performance status, and are in overall good health. Because IP chemotherapy is more cumbersome and has a higher morbidity than IV therapy, this technique of drug delivery should be individualized after thorough discussion with the patient.

Dose-Dense Intravenous Chemotherapy

The Japanese GOG randomized 637 patients with ovarian cancer to receive

carboplatin AUC 6 and *paclitaxel* 180 mg/m^2 every 3 weeks, or the same dose of *carboplatin* and 80 mg/m^2 *paclitaxel* every week for at least six cycles (251). The median PFS was 28 months in the dose-dense arm and 17 months in the control group, and the median overall survival was 100.5 months for those patients receiving dose-dense therapy, versus 62 months for the every-3-weeks arm. They reported relatively little difference in toxicity between the two arms and that grade 3 to 4 neurotoxicity in particular was very low. In the 417 patients who had stage III disease, about half had less than 1 cm maximum residual disease, similar to the patients in GOG 172. Women with at least 1 cm of residual disease following cytoreductive surgery appeared to benefit the most from dose-dense therapy compared to every 3 weeks therapy. In this analysis, the median PFS was 17.6 months versus 12 months and the median overall survival was 51 months versus 33 months, respectively. **There is good evidence that weekly *paclitaxel* is more effective than *paclitaxel* every 3 weeks in breast cancer and the Japanese GOG study suggests that the same may apply to ovarian cancer.** Other studies have led to questioning this treatment approach in the United States. In GOG 262, patients with stage II to IV epithelial ovarian cancer were randomly assigned to *CP* every 3 weeks versus dose-dense chemotherapy (*carboplatin* every 3 weeks and weekly *paclitaxel*). *Bevacizumab* administration was optional in both arms and 84% of the patients were treated with *bevacizumab*. Sixty-three percent had gross residual disease, 24% had microscopic residual disease, and in 13% the amount of residual disease was not noted.

At a median follow-up of 28 months, no difference in PFS was found between the two groups. The subset analysis suggested a difference based on whether or not *bevacizumab* was received. **In patients who did not receive *bevacizumab*, dose-dense treatment prolonged PFS versus the every 3-week chemotherapy** (median of 14 months vs. 10 months). Among patients treated with chemotherapy and *bevacizumab,* there was no significant difference among the every 3-week chemotherapy versus dose-dense patients (median of 15 months in both arms) (253).

The Multicenter Italian Trial in Ovarian Cancer (MITO-7), compared every 3-week *CP* to a modified dose-dense regimen where *CP* were delivered on a weekly schedule (*carboplatin* AUC 2 and *paclitaxel* 60 mg/m^2 on days 1, 8, 15 every 3 weeks) in stage 1C to IV epithelial ovarian cancer.

In this study, there was a similar PFS between the two regimens with the weekly regimen having better quality-of-life scores. Severe myelosuppression and neuropathy were less common in the weekly regimen (254).

[9] More convincing evidence that the dose-dense therapy may be not superior to every 3-week chemotherapy of the JCOG study can be found in the results from the ICON8 trial. In this trial, 1,566 predominantly European patients were randomized to receive one of three regimens: Arm 1, *carboplatin* AUC 5/6 and *paclitaxel* 175

mg/m^2 every 3 weeks; Arm 2, *carboplatin* AUC 5/6 every 3 weeks and *paclitaxel* 80 mg/m^2 weekly; Arm 3, *carboplatin* AUC 2 and *paclitaxel* 80 mg/m^2 weekly. All patients had received neoadjuvant chemotherapy with planned interval debulking or received chemotherapy after initial primary cytoreductive surgery. **There was no benefit found for the dose-dense regimens. The PFS was 24.4 months with every 3-week dosing, compared to 24.9 and 25.3 months in arms 2 and 3, respectively** (255).

Neoadjuvant Chemotherapy

[7] Neoadjuvant chemotherapy may be considered for patients with advanced ovarian/fallopian tube/peritoneal carcinoma who are thought to have a low likelihood of upfront optimal cytoreduction or in women determined to have a high perioperative risk based on a poor performance status. A series performed by Schwartz et al. suggested that these patients treated with neoadjuvant or cytoreductive chemotherapy had survival that was comparable to those patients treated in the same institution with debulking surgery followed by conventional chemotherapy (256). It is accepted that two or three cycles of chemotherapy before cytoreductive surgery may be helpful in patients with massive ascites and large pleural effusions. The chemotherapy may decrease the effusions, improve the patient's performance status, and decrease postoperative morbidity, particularly chest morbidity (257,258).

The EORTC completed a large randomized trial in 718 patients with advanced ovarian cancer comparing initial surgery followed by six cycles of *CP* with three cycles of neoadjuvant chemotherapy followed by surgical debulking and another three cycles of chemotherapy. The study found that the PFS was identical in both arms (12 months) and the overall survival (30 months) was the same in both arms (203). The morbidity of surgery was significantly less in patients receiving neoadjuvant chemotherapy, suggesting that **in selected patients with very advanced (stages IIIC and IV) ovarian cancer and on average had a poor performance status, two to three cycles of neoadjuvant chemotherapy prior to surgical debulking is a reasonable option.** There have been other studies in support of neoadjuvant chemotherapy as an option for advanced ovarian/ fallopian tube/peritoneal carcinoma including the CHORUS trial. This phase III randomized, noninferiority, controlled trial was done across 87 hospitals in New Zealand and the United Kingdom and enrolled patients with suspected stage III or IV cancer. Patients were randomly assigned to either primary surgery followed by six cycles of chemotherapy versus three cycles of primary chemotherapy followed by surgery, then three additional cycles of completion chemotherapy. Patients could receive *CP* or another *carboplatin* combination regimen or single-agent carboplatin. There was no difference in the median overall survival comparing primary surgery to the primary chemotherapy group. **The CHORUS trial also concluded that in women with very advanced stage III or IV ovarian cancer**

and a poor performance status, survival with primary chemotherapy is noninferior to primary surgery (204).

Chemotherapy and Bevacizumab

Inhibition of angiogenesis with drugs such as *bevacizumab* demonstrated activity and benefit in women with recurrent ovarian cancer. There is evidence in other tumor types such as breast cancer and colon cancer that the addition of *bevacizumab* to chemotherapy increases response rates, PFS, and survival in some studies (259–261). Two large randomized trials (GOG 218 and ICON7) investigating the impact of the addition of *bevacizumab* to standard *CP* in patients with advanced ovarian cancer were carried out to address this question (262,263). GOG 218 was a phase III three-arm randomized double-blind placebo-controlled trial. Patients in arm one received six cycles of *CP* and placebo starting with the second cycle and continuing for 16 additional cycles after the completion of chemotherapy. Patients in arm two received six cycles of chemotherapy with *bevacizumab* starting with cycle two and administered with chemotherapy followed by 16 cycles of placebo, and in arm three patients received *bevacizumab* starting with cycle two of chemotherapy and then received 16 additional cycles after the completion of chemotherapy. This study was designed to investigate the benefit of *bevacizumab* in combination with chemotherapy and as a maintenance therapy. The *bevacizumab* was administered at a dose of 15 mg/kg, starting with the second cycle of chemotherapy, to decrease the risk of gastrointestinal perforation, which is a rare complication of this agent. The GOG 218 reported a modest improvement of 3.8 months in the PFS in patients randomized to receive *bevacizumab* in combination with *CP* every 3 weeks and then as a maintenance therapy every 3 weeks for an additional 16 cycles for a total of 15 months' treatment (262). The toxicity of *bevacizumab* was acceptable and the risk of bowel perforation low (below 2%). The study did not find any improvement in the overall survival with *bevacizumab* in either arm receiving the drug. An unplanned subgroup analysis demonstrated that treatment with *bevacizumab* improved the PFS and overall survival particularly in patients with ascites but not in other patients. The ICON7 study is similar to the GOG study, although it was a two-arm study of *CP* plus or minus *bevacizumab* 7.5 mg/kg administered every 3 weeks with chemotherapy for six cycles and then as maintenance therapy for 12 additional cycles. The ICON7 results reported a longer median PFS at 42 months of follow-up for the arm including *bevacizumab* compared to the standard therapy arm (24 months vs. 22 months). There was no difference in the overall survival noted (263). In an exploratory analysis of a predefined subgroup of patients with poor prognosis/ high-risk disease, a significant difference in the overall survival was noted between women who received *bevacizumab* plus chemotherapy and those who received chemotherapy alone (restricted mean survival time, 34.5 months [95% CI, 32.0–37.0] with standard chemotherapy vs. 39.3 months [37.0–41.7] with *bevacizumab*; log-rank $p = 0.03$). In

non–high-risk patients, the restricted mean survival time did not differ significantly between the two treatment groups (49.7 months [95% CI, 48.3–51.1] in the standard chemotherapy group vs. 48.4 months [47.0–49.9] in the *bevacizumab* group; $p = 0.20$) (264). **The results of these studies support a potential role of *bevacizumab* in combination with chemotherapy in selected patients with advanced ovarian cancer. However, the cost of *bevacizumab* is very high and the improvement in PFS is short and no survival improvement was seen.**

Chemotherapeutic Recommendation in Advanced Epithelial Ovarian Cancer

For the treatment of advanced-stage epithelial ovarian cancer, the following treatment regimens should be considered (Table 39-4):

- **Combination chemotherapy or IV *CP every 3 weeks* or IP *carboplatin* or *cisplatin* and *paclitaxel* are the treatments of choice for patients with advanced disease. The advantages and disadvantages of the IV versus IP routes of administration of these drugs should be discussed with the patient.**
- **The recommended doses and schedule for IV chemotherapy are *carboplatin* (starting dose AUC = 5 to 6), and *paclitaxel* (175 mg/m^2), every 3 weeks for six cycles. Alternatively, the dose-dense regimen of *carboplatin* AUC 6 every 3 weeks for six cycles and weekly *paclitaxel* 80 mg/m^2 could be used, but is not superior to the 3-weekly regimen in non-Japanese women (251). There are no good data to show any benefit for treatment beyond six cycles but the number of cycles may need to be individualized based on time to response and toxicity. Ideally the CA-125 should have normalized by the end of chemotherapy.**
- **The recommended doses and schedule for IP chemotherapy are *paclitaxel* 135 mg/m^2 IV on day 1, followed by *carboplatin* AUC 5 or *cisplatin* 75 to 100 mg/m^2 IP on day 2, followed by *paclitaxel* 60 mg/m^2 IP on day 8, every 3 weeks for six cycles, as tolerated.**
- ***Bevacizumab* 7.5 to 15 mg/kg can be added to any of these IV or IP chemotherapy regimens.**
- **In patients who cannot tolerate combination chemotherapy, single-agent, IV-administered *carboplatin* (AUC 5 to 6) can be given.**
- **In patients who have a hypersensitivity to *paclitaxel* or *carboplatin*, an alternative active drug can be substituted (e.g., *docetaxel*, nanoparticle *paclitaxel*, *cisplatin*). In the case of *carboplatin* hypersensitivity, desensitization could be attempted.**

Table 39-4 Combination Chemotherapy for Advanced Epithelial Ovarian Cancer: Recommended Regimens

Drugs[a]	Dose (mg/m²)[b]	Route	Interval (weeks)	Treatments (cycles)
Standard Regimens				
Intraperitoneal chemotherapy				
Paclitaxel	135	IV	3, day 1	6
Cisplatin	50–100	IP	day 2	
Paclitaxel	60	IP	day 8	
Intravenous chemotherapy				
Paclitaxel	175	IV	3	6–8
Carboplatin	AUC = 5–6[a]	IV		
Paclitaxel	135	IV	3	6–8
Cisplatin	75	IV		
Alternative Drugs[c]				
Docetaxel	75	IV	3	
Doxorubicin, liposomal	35–50	IV	3–4	
Topotecan	1.0–1.25	IV	1	
	4.0	IV	3 (daily × 3–5 days)	
Etoposide	50	PO	3, days 14–21	

[a] *Bevacizumab* 7.5–15 mg/kg can be added to any of these regimens.

[b] Except for carboplatin dosing, where AUC—area under the curve—dose calculated by using the Calvert formula (**Calvert AH, Newell DR, Gumbrell LA, et al.** Carboplatin dosage: prospective evaluation of a simple formula based on renal function. *J Clin Oncol* 1989;7:1748–1756).

[c] Drugs that can be substituted for paclitaxel if hypersensitivity to that drug occurs; the number of treatments administered as tolerated.

The treatment of all patients with advanced-stage disease is approached in a similar manner, with modifications based on the overall status and general health of the patient and the extent of residual disease present at the time treatment is initiated.

Maintenance Therapy Following Response to First-Line Chemotherapy

Almost 80% of women with advanced-stage disease who respond to first-line chemotherapy will relapse. There have been several trials conducted to determine if there is a benefit of maintenance therapy in these patients immediately following their primary treatment in an effort to decrease the relapse rate.

Paclitaxel

In a study conducted by the GOG and SWOG, 277 women with advanced ovarian cancer who had a complete clinical remission to first-line chemotherapy were

randomized to receive 3 or 12 cycles of additional single-agent *paclitaxel* (175 or 135 mg/m^2 every 28 days) (265). Patients were excluded if they developed grade 2 or 3 neurotoxicity during their initial chemotherapy. Because of cumulative toxicity, the mean number of actual cycles of *paclitaxel* received by the group assigned to receive 12 cycles was 9. The treatment-related grade 2 to 3 neuropathy was more common with longer treatment, 24% versus 14% of patients, respectively. The study closed after a median follow-up of only 8.5 months, and an interim analysis showed a significant 7-month prolongation in the median PFS (28 months vs. 21 months) with 9 months versus 3 months of consolidation *paclitaxel*. There was no difference in the median overall survival and this study has not changed practice. It is improbable that a survival benefit will appear with longer follow-up, because patients assigned to three cycles were given the option of receiving an additional nine courses of *paclitaxel* after the study was discontinued (266). Another placebo-controlled, randomized trial using two formulations of *paclitaxel* was conducted by the GOG. A total of 1,157 patients with stage III to IV ovarian/fallopian tube/peritoneal cancer who achieved a clinical complete response after first-line treatment were randomized to surveillance, *paclitaxel* infusion every 28 days for 12 cycles, or CT-2103 (paclitaxel poliglumex) on the same schedule. After a median follow-up of 71 months, the median overall survival was not different between the groups. There was a small extension in the PFS with maintenance therapy compared to surveillance (267).

Topotecan

Four additional treatment courses of *topotecan* were administered to patients following six cycles of *CP* in two randomized trials, one conducted in Italy and the other in Germany (268,269). In the larger trial conducted in Germany, 1,059 evaluable patients were randomly assigned to six cycles of *paclitaxel* (175 mg/m^2 over 3 hours) and *carboplatin* (AUC 5) with (537 patients) or without (522 patients) four additional cycles of *topotecan* (1.25 mg/m^2 IV days 1 to 5 every 3 weeks) (269). In the Italian trial, 273 women were randomly assigned to receive four additional cycles (137 patients) of *topotecan* at a dose of 1 mg/m^2 on days 1 to 5 every 3 weeks or no further chemotherapy (136 patients) (268). No significant differences in either the PFS or overall survival in patients who received four to six cycles of consolidation *topotecan*.

Cisplatin

In a randomized clinical trial of IP *cisplatin* for consolidation versus observation, there was no difference in survival between the treatment arms (270). A meta-analysis concluded that maintenance chemotherapy was associated with increased toxicity but no significant improvement in the PFS or overall survival (271).

Biologic Therapies

Adding the monoclonal antibody (MonAb) *bevacizumab* to first-line *CP*

chemotherapy followed by maintenance *bevacizumab* for a year was associated with a modest improvement in the PFS (262,263).

There are a number of trials that addressed the role of oral angiogenesis inhibitors as maintenance therapy after completion of first-line therapy in women with advanced ovarian cancer. *Pazopanib* is an oral tyrosine kinase inhibitor of vascular endothelial growth factor receptors, platelet-derived growth factor receptors, and c-KIT. In the randomized double-blinded placebo-controlled phase III AGO-OVAR16/VEG110655 trial, maintenance *pazopanib* for up to 2 years after completion of first-line chemotherapy in women with advanced epithelial ovarian cancer improved the PFS over placebo (HR, 0.77; 95% CI, 0.64–0.91; $P = 0.0021$; median PFS 17.9 with PZ vs. 12.3 months with placebo) (272). However, there was a higher incidence of grade 3 and 4 adverse events in the *pazopanib* arm, which led to dose reductions in 58% of patients and early discontinuation caused by adverse events (AE) in 33% of patients. In view of the toxicity, the pharmaceutical company who sponsored the trial decided not to submit for regulatory approval. *Nintedanib* is a triple angiokinase inhibitor of VEGF, fibroblast growth factor, and platelet-derived growth factor. AGO-OVAR 12 randomized 1,366 patients 2:1 to maintenance *nintedanib* or placebo as maintenance therapy following first-line chemotherapy. The median PFS in *nintedanib* was 17.2 months vs. 16.6 months in placebo arm and this is not a reasonable therapeutic option (273).

Studies investigating MonAbs directed toward CA-125 (OvaRex) and toward the HMFG (human milk fat globulin) tumor–associated antigens were conducted (274–276). In a randomized, placebo-controlled trial of IV *oregovomab* (anti-CA-125 MonAb) as maintenance therapy, Berek et al. reported that *oregovomab* did not demonstrate a survival advantage as a maintenance therapy (275). A randomized trial of an IP-administered yttrium-labeled anti-mucin (HMFG) MonAb versus placebo was not associated with an improved overall survival after a negative second-look laparoscopy (276).

Treatment Assessment

Many patients who undergo optimal cytoreductive surgery and subsequent chemotherapy for epithelial ovarian cancer have no evidence of disease at the completion of treatment. Tumor markers and radiologic assessments are too insensitive to exclude the presence of subclinical disease. **Historically, a second-look surgery was performed to evaluate these patients, but that was abandoned, as there was no evidence of a meaningful benefit to patients** (161,277–286).

Tumor Markers

CA-125 is a surface glycoprotein associated with müllerian epithelial tissues, and is elevated in about 80% of patients with epithelial ovarian cancers, particularly those

with nonmucinous tumors (287–289). The CA-125 level frequently falls below the normal range after the initial surgical resection and one or two cycles of chemotherapy. Carcinoembryonic antigen (CEA) levels may be elevated in patients with ovarian cancer, but the test is too nonspecific and insensitive to be used in the management of these patients, apart from patients with a mucinous cancer of the ovary who may have an elevated CEA and CA19-9 (42).

Levels of CA-125 were correlated with findings at second-look operations. Elevated levels predicted the presence of residual disease, but levels within the normal range are an insensitive determinant of the absence of disease. In a prospective study, the predictive value of a positive test was 100%; if the level of CA-125 was elevated (>35 U/mL), the disease was always detectable in patients at the second-look procedure (287). The predictive value of a negative test was only 56%; if the level was less than 35 U/mL, disease was present in 44% of the patients at the time of the second-look surgery. **A literature review suggests that an elevated CA-125 level predicts persistent disease at second-look surgery in 97% of the cases, but the CA-125 level is not sensitive enough to exclude subclinical disease in many patients** (288).

Serum CA-125 levels can be used during chemotherapy to follow those patients whose levels were elevated at initial diagnosis and at the initiation of therapy (287). **The fall in the CA-125 correlates with response.** Those patients with persistently elevated levels after three cycles of treatment almost certainly will still have persistent disease. The majority of patients will have a CA-125 in the normal range following surgery and first-line chemotherapy and are typically followed with CA-125 levels every 3 to 4 months. There are well-accepted Gynecologic Oncology Intergroup (GCIG) criteria for CA-125 progression. Patients with an elevated CA-125 pretreatment and in the normal range following the completion of treatment must have a CA-125 greater than, or equal to, two times the upper normal limit on two occasions at least 1 week apart to be classified as having CA-125 progression (289).

Radiologic Assessment

CT can be used to assess the response in patients with measurable lesions at the start of therapy. In patients who have no or minimal residual disease following cytoreductive surgery, the value of these tests is limited, but they may be useful in follow-up, especially to document the site of recurrence in patients with CA-125 progression. Ascites can be readily detected, but other diseases can be missed on a CT scan in patients with recurrent disease (290). A CT scan and fine-needle aspiration (FNA) cytology, if appropriate, can diagnose persistent or recurrent disease, but the false-negative rate of a CT scan is about 45% (291). MRI can be used as an alternative to CT in patients with allergies to the contrast medium (131,133). PET/CT has high diagnostic accuracy in patients with recurrent ovarian cancer. The reported sensitivity, specificity, and accuracy range from 86% to 96%, 93% to 100%, and 85% to 100%,

respectively (292).

Second-Line Therapy

Secondary Cytoreductive Surgery

Secondary cytoreduction is defined as an attempt at cytoreductive surgery in patients with recurrent ovarian cancer. This is usually considered in patients with platinum-sensitive recurrent ovarian cancer with localized recurrence or limited number of sites of recurrence when it is considered possible to resect all disease (293–296). Patients with progressive disease on chemotherapy (platinum refractory) or with platinum-resistant ovarian cancer are not suitable candidates for secondary cytoreduction. Although there are no hard and fast rules, secondary debulking should be restricted to patients who have a disease-free interval of at least 12, but preferably 24 months or those in whom it is expected that all macroscopic disease can be resected, regardless of the disease-free interval (293–301). **The role of secondary debulking surgery has been addressed in the DESKTOP III trial.** This study included patients with a PFS OF >6 months after first-line chemotherapy and who were considered to be good candidates for surgery based on a positive AGO Study Group score, defined as an ECOG performance status score of 0, ascites of 500 mL or less, and complete resection at initial surgery. The PFS results have been presented at ASCO 2017 and DuBois reported that the median PFS **in 204 women who met these criteria and were randomized to undergo surgery followed by chemotherapy was 19.6 months, compared with 14 months in 203 women who were randomized to receive only second-line chemotherapy.** The primary endpoint of the study is overall survival which will be available in a few years (302).

Chemotherapy for Recurrent Ovarian Cancer

The majority of women who relapse will be offered more chemotherapy with the likelihood of benefit related to the initial response and the duration of response. **The goals of treatment include improving control of disease-related symptoms, maintaining or improving the quality of life, delaying the time to progression, and possibly prolonging survival, particularly in women with *platinum*-sensitive recurrences.** Many active chemotherapy agents (*platinum*, *paclitaxel, topotecan, liposomal doxorubicin, docetaxel, gemcitabine*, and *etoposide*) and targeted agents (*bevacizumab*) and PARP inhibitors are available, and the choice of treatment is based on many factors including the likelihood of benefit, potential toxicity, and patient convenience.

Women who relapse later than 6 months after primary chemotherapy are classified as *platinum*-sensitive and usually receive further *platinum*-based chemotherapy with response rates ranging from 27% to 65% and a median survival

of 12 to 24 months (303–307). **Patients who relapse within 6 months of completing first-line chemotherapy are classified as *platinum*-resistant and have a median survival of 6 to 9 months and a 10% to 30% likelihood of responding to chemotherapy. Patients who progress while on treatment are classified as having *platinum*-refractory disease.** Objective response rates to chemotherapy in patients with *platinum*-refractory ovarian cancer are low—less than 20% (308).

The potential adverse effects associated with chemotherapy in trials in women with recurrent ovarian cancer are well documented and should not be underestimated. The three most commonly used drugs are *paclitaxel, topotecan*, and *liposomal doxorubicin* (309–335). The reported adverse effects associated with *paclitaxel* include alopecia in 62% to 100%, neurotoxicity (any grade) in 5% to 42% of patients, and grade 3 to 4 leukopenia in 4% to 24% of patients. *Topotecan* is associated with significantly greater myelosuppression than *liposomal doxorubicin* or *paclitaxel* and is observed in 49% to 76% of patients. *Liposomal doxorubicin* is associated with palmar-plantar erythrodysesthesia (PPE) of any grade in over 50% of patients and is severe in 23% particularly in patients treated at higher doses such 50 mg/m^2. Severe stomatitis is reported in up to 10% of patients (309–312).

Platinum-Sensitive Disease

The use of combination *platinum* plus *paclitaxel* chemotherapy versus a single-agent *platinum* was tested in two multinational randomized phase III trials and a randomized phase II study (336,337). In a report of the ICON4 and AGO-OVAR-2.2 (AGO Studiengruppe Ovarialkarzinom) trials, 802 women with *platinum*-sensitive ovarian cancer, who relapsed after being treatment free for at least 6 to 12 months were randomized to *platinum*-based chemotherapy (72% *carboplatin* or *cisplatin* alone; 17% *CAP;* 4% *carboplatin* plus *cisplatin;* and 3% *cisplatin* plus *doxorubicin*) or *paclitaxel* plus *platinum*-based chemotherapy (80% *paclitaxel* plus *carboplatin;* 10% *paclitaxel* plus *cisplatin;* 5% *paclitaxel* plus both *carboplatin* and *cisplatin;* and 4% *paclitaxel* alone) (336). The AGO-OVAR-2.2 trial did not accrue its planned number of patients. **In both trials, a significant proportion of the patients did not receive *paclitaxel*** as **part of their initial chemotherapeutic regimen. Combining the trials for analysis, there was a significant survival advantage for the *paclitaxel*-containing therapy** (HR, 0.82) with a median follow-up of 42 months. **The absolute 2-year survival advantage was 7% (57% vs. 50%), and there was a 5-month improvement in median survival (29 months vs. 24 months).** The PFS was better with the *paclitaxel* regimen (HR, 0.76); there was a 10% difference in 1-year PFS (50% vs. 40%) and a 3-month prolongation in the median PFS (13 months vs. 10 months). The toxicities were comparable, except for a significantly higher incidence of neurologic toxicity and alopecia in the *paclitaxel* group, while myelosuppression was significantly

greater with the *non-paclitaxel*–containing regimens. **These data support the slight advantage of a second-line regimen containing both *paclitaxel* and a *platinum* agent compared with *platinum*-based therapy alone. There were two randomized trials comparing *carboplatin alone to carboplatin and gemcitabine or liposomal doxorubicin*** (338,339). There was a higher response rate with the combination therapy and a longer PFS, but the studies were not powered to look at the overall survival. In the GCIG study comparing *carboplatin* and *gemcitabine* with *carboplatin* alone, the response rate was 47.2% for the combination and 30.9% for *carboplatin*, with the PFS being 8.6 months and 5.8 months, respectively (338). **A large GCIG study (CALYPSO) compared *carboplatin and liposomal doxorubicin* (CD) with *CP* in 976 patients** (340). **The PFS for the CD arm was statistically superior to the *CP* arm with a median PFS of 11.3 months versus 9.4 months, respectively.** There was no statistically significant difference in the overall survival between the treatment groups. Median survival was 33 months versus 30.7 months for CP versus CD. **The CD arm was better tolerated with less severe toxicities, and this combination is now widely used** (340).

***Carboplatin, gemcitabine,* and *bevacizumab* have been shown in a phase III randomized control trial to be superior to *carboplatin* and *gemcitabine* alone for platinum-sensitive recurrent epithelial ovarian cancer.** In the OCEANS study, 484 with platinum-sensitive disease were randomly assigned to *carboplatin* (AUC 4 on day 1) and *gemcitabine* 1,000 mg/m^2 on days 1 and 8 with or without *bevacizumab* (15 mg/kg on day 1) with every 21-day cycles. *Bevacizumab* could be given concurrently with chemotherapy for a maximum of 10 cycles followed by *bevacizumab* alone until progression of disease or toxicity.

The addition of *bevacizumab* to *carboplatin* and *gemcitabine* resulted in an improvement in the PFS (12 months vs. 8 months; HR, 0.48; 95% CI, 0.39–0.61); however, there was no overall survival difference between the two arms. Treatment with *bevacizumab* was associated with higher rates of serious hypertension (17% vs. <1%), proteinuria grade 3 or higher (9% vs. 1%) and noncentral nervous system bleeding (6% vs. 1%) (341,342).

In GOG 213, patients with platinum-sensitive recurrent epithelial ovarian cancer were assigned randomly to secondary cytoreduction versus no secondary cytoreduction and separately to chemotherapy (*CP*) with or without *bevacizumab*. Patients treated with *bevacizumab* received the drug with chemotherapy and afterward it was continued as a single agent until disease progression.

Compared with chemotherapy alone, the addition of *bevacizumab* resulted in an improvement in the PFS (13.8 months vs. 10.4 months, respectively; HR, 0.61; 95% CI, 0.51–0.72). There was an improvement of the overall survival of 5 months with chemotherapy and *bevacizumab* versus chemotherapy alone; median overall survival

(42.6 months vs. 37.3 months, respectively; HR, 0.84; 95% CI, 0.69–1.01) (343). **These studies show that maintenance with *bevacizumab* can improve the PFS and may improve the overall survival in a subset of patients.**

PARP Inhibitors

PARP inhibitors, including *niraparib* and *olaparib,* have been approved by FDA for maintenance therapy in patients with platinum-sensitive disease following a partial or complete response to platinum-based chemotherapy. The PFS is improved with these agents regardless of the BRCA status, although the patients with BRCA germline/somatic mutations have a greater benefit than patients without mutations.

Niraparib

***Niraparib* has been approved by the U.S. FDA for maintenance therapy in patients with platinum-sensitive disease following a partial or complete response to platinum-based chemotherapy for both germline *BRCA1* and *BRCA2* carriers and nongermline carriers.**

In the NOVA study, a phase III trial, 553 patients with platinum-sensitive recurrent ovarian cancer were assigned randomly after completion of platinum-based chemotherapy in a 2:1 ratio to *niraparib* maintenance or placebo. Patients were stratified based on the presence or absence of a gBRCA mutation. The patients in the non-gBRCA mutation cohort were further classified by whether or not homologous recombination deficiency (HRD) was observed. *Niraparib* compared to placebo increased the PFS in all groups of patients. **In the gBRCA group, the PFS was 21 months versus 5.5 months** (HR, 0.27; 95% CI, 0.17–0.41) in contrast to the **non-gBRCA group, where the PFS was 9.3 months versus 3.9 months** (HR, 0.45; 95% CI, 0.34–0.61). This study also attempted to identify the subset of patients with tumors with HRD and reported that in the HRD-positive group of non-gBRCA patients, the PFS was 12.9 months versus 3.8 months (HR, 0.38; 95% CI, 0.24–0.59). An exploratory analysis of HRD-negative patients demonstrated an improvement in the median PFS in favor of *niraparib* (6.9 months vs. 3.8 months; HR, 0.58; 95% CI, 0.08–0.90) (344).

Olaparib

***Olaparib* is FDA approved for the treatment of patients with gBRCA-mutated recurrent ovarian cancer who have received three or more prior lines of chemotherapy.**

There are data in support of maintenance *olaparib* in women with platinum-sensitive recurrent high-grade serous ovarian cancer from Study 19. This was a randomized phase II controlled trial of approximately 300 women with platinum-sensitive recurrent high-grade ovarian cancer who had achieved a response to their most recent treatment regardless of their BRCA status. The patients were randomly

assigned to *olaparib* 400 mg twice daily or placebo. Compared with placebo, *olaparib* was shown to improve the PFS (8 months vs. 5 months; HR for progression or death, 0.35; 95% CI, 0.25–0.49) (345). A separate analysis of Study 19 evaluated outcomes for gBRCA patients and showed that the clinical benefit was greatest for these patients. The PFS was (11 months vs. 4 months; HR, 0.18; 95% CI, 0.10–0.31) for *olaparib* versus placebo, respectively (346,347).

A randomized, double-blind, placebo-controlled, phase 3 trial was of maintenance *olaparib* after first-line combination chemotherapy known as the SOLO1 study was conducted in 15 countries (348). Of the 391 patients who underwent randomization, 260 were assigned to receive *olaparib* and 131 to receive placebo. A total of 388 patients had a germline *BRCA1* or *BRCA2* mutation, and 2 patients had a somatic *BRCA1* or *BRCA2* mutation. After a median follow-up of 41 months, the risk of disease progression or death was 70% lower with *olaparib* than with placebo (at 3 years, 60% vs. 27%, HR = 0.30; 95% CI, 0.23 to 0.41; p <0.0001). Adverse events were consistent with the known toxic effects of *olaparib*. **The use of maintenance therapy with olaparib provided a substantial benefit in progression-free survival among women with newly diagnosed advanced ovarian cancer and a *BRCA1* or *BRCA2* mutations, and they had a 70% lower risk of disease progression or death with *olaparib* than with placebo**.

These results were confirmed in the much larger SOLO2 trial, which included 295 patients with gBRCA mutations and platinum-sensitive recurrent ovarian cancer who had responded to platinum-based chemotherapy. They were randomly assigned to receive *olaparib* (n = 196) or placebo (n = 99). The median PFS was significantly longer with *olaparib* (19.1 months [95% CI, 16.3–25.7]) than with placebo (5.5 months [5.2–5.8]; HR, 0.30; 95% CI, 0.22–0.41]; p <0.0001).

Rucaparib

***Rucaparib* is approved for treatment of BRCA-mutation–associated advanced ovarian cancer after completion of treatment with two or more chemotherapy regimens regardless of whether patients are platinum-sensitive or resistant.**

Ariel 3 included patients with platinum-sensitive, high-grade serous or endometrioid ovarian, fallopian tube, or peritoneal carcinoma, who had received at least two prior platinum-based chemotherapy regimens, complete or partial response to their last platinum-based regimen, and a CA-125 concentration of less than the upper limit of normal. They were randomized 2:1 to receive oral *rucaparib* 600 mg twice daily or placebo. The median PFS in patients with a BRCA-mutant carcinoma was 16.6 months (95% CI, 13.4–22.9; 130 [35%] patients) in the *rucaparib* group versus 5.4 months (3.4–6.7; 66 [35%] patients) in the placebo group (HR, 0.23 [95% CI, 0.16–0.34]; p <0.0001). Similar to the NOVA trial, the investigators analyzed all tumors for HRD using a different method. In patients with an HRD carcinoma (236 [63%] vs. 118

[62%]), the PFS was 13.6 months (10.9–16.2) versus 5.4 months (5.1–5.6; 0.32 [0.24–0.42]; p <0.0001).

In a phase II trial of 204 patients with recurrent platinum-sensitive, high-grade ovarian cancer treated with *rucaparib*, patients with BRCA mutations and high loss of heterozygosity (LOH) had a longer PFS compared to patients with low LOH. Patients were divided into three groups for the study; those with germline or somatic BRCA mutations, those who were BRCA-wild type but LOH high, and those who were BRCA-wild type and LOH low. The PFS was longer for patients with BRCA mutations (12.8 months; HR, 0.27; 95% CI, 0.16–0.44) and/or LOH high (5.7 months; HR, 0.62; 95% CI, 0.42–0.90) subgroups compared to those with LOH low (5.2 months) (349).

Other PARP Inhibitors

There are a number of other PARP inhibitors under investigation. *Veliparib* is another PARP inhibitor with encouraging results in a phase II trial of 50 women with BRCA mutations who were treated with *veliparib* monotherapy at a dose of 400 mg twice daily. There was a 26% overall response rate for platinum-sensitive and resistant patients and a 35% response rate among those with platinum-sensitive disease (350). *Veliparib* is being investigated in GOG-3005 in combination with chemotherapy in the frontline and maintenance setting.

Platinum-Resistant and Refractory Disease

Patients with *platinum*-refractory and resistant ovarian cancer are often treated with chemotherapy and may have a number of lines of therapy depending on the response and performance status. In *platinum*-refractory patients (i.e., those progressing on treatment), response rates to second-line chemotherapy are less than 10% and the median survival is short, around 3 to 5 months (304–308). **The management of women who are *platinum*-resistant (i.e., progressing within 6 months of completion of chemotherapy) is difficult and "non–cross-resistant agents" are selected, but there does not appear to be one best treatment.** Single-agent therapy is typically used because combination regimens are associated with more toxicity without any apparent additional benefit. High response rates of 48% to 64% were reported with dose-dense weekly *carboplatin* (AUC 2) plus *paclitaxel* (80 mg/m^2), and this deserves more study (351). There are a variety of potentially active drugs: *paclitaxel*, *docetaxel*, *topotecan*, *liposomal doxorubicin*, *gemcitabine*, *oral etoposide*, *tamoxifen*, and *bevacizumab* are the most frequently used. **Other agents include *vinorelbine* and newer drugs such as *trabectedin.***

Chemotherapy plus *bevacizumab* leads to improved responses in platinum-resistant disease. In the Aurelia study, 361 patients with platinum-resistant, *bevacizumab* naïve ovarian cancer (progression less than or equal to 6 months after 4 or more platinum-based cycles) were randomly assigned to treatment with chemotherapy with or without

bevacizumab at 15 mg/kg every 3 weeks. No more than two prior lines were allowed.

Chemotherapy options included the investigator's choice of *paclitaxel* 80 mg/m^2 on days 1, 8, 15, and 22 every 4 weeks, *or topotecan* 4 mg/m^2 on days 1, 8, 15 every 4 weeks or 1.25 mg/m^2 on days 1 through 5 every 3 weeks, or *Doxil* 40 mg/m^2 on day 1 every 4 weeks. Patients who received chemotherapy alone were allowed to crossover at time of disease progression to single-agent *bevacizumab*. The median follow-up was 13.5 months and compared to chemotherapy alone, the addition of chemotherapy to *bevacizumab* resulted in a reduction in the risk of disease progression. Median duration of response was 6.7 months versus 3.4 months (HR, 0.48; 95% CI, 0.38–0.60) in favor of *bevacizumab* and chemotherapy. There was no statistical improvement in overall survival. A planned subset analysis was performed and showed among those patients who received *paclitaxel*, the median PFS with or without *bevacizumab* was longer, 10 months versus 4 months, respectively; HR, 0.46; 95% CI, 0.30–0.71 (352).

The results of a study comparing *topotecan* with *liposomal doxorubicin* demonstrate the low response rates and poor prognosis among women with *platinum*-resistant ovarian cancer (309). There were two randomized trials comparing *liposomal doxorubicin* with either *topotecan* or *paclitaxel.* In a study of 237 women who relapsed after receiving one *platinum*-containing regimen, 117 of whom (49.4%) had *platinum*-refractory disease, *liposomal doxorubicin* 50 mg/m^2 over 1 hour every 4 weeks was compared with *topotecan* 1.5 mg/m^2/day for 5 days every 3 weeks (309). **The two treatments had a similar overall response rate** (20% vs. 17%), **time to progression** (22 weeks vs. 20 weeks), **and median overall survival** (66 weeks vs. 56 weeks). The myelotoxicity was significantly lower in the *liposomal doxorubicin*–treated patients than with those receiving *topotecan.* In a second study comparing *liposomal doxorubicin* with single-agent *paclitaxel* in 214 *platinum*-treated patients who had not received prior *taxanes*, the overall response rates for *liposomal doxorubicin* and *paclitaxel* were 18% versus 22%, respectively, and median survival durations were 46 and 56 weeks, respectively, and these were not significantly different (310). In practice, most patients are treated with a starting dose of 40 mg/m^2 of *liposomal doxorubicin* every 4 weeks, because of the toxicity associated with the higher dose and the need to dose reduce when 50 mg/m^2 is used. In a subset analysis of *platinum*-resistant patients, the median time to progression ranged from 9.1 to 13.6 weeks for *topotecan* and *liposomal doxorubicin*, respectively. The median survival (p = 0.455) was 35.6 weeks for pegylated *liposomal doxorubicin* and 41.3 weeks for *topotecan.* Objective response rates were recorded in 6.5% of patients who received *topotecan* and in 12.3% of those who received pegylated *liposomal doxorubicin* (p = 0.118). It is not known whether the treatment-improved symptom control or quality of life because this was not specifically addressed.

In another randomized trial of 195 patients with *platinum*-resistant ovarian cancer,

patients were randomized to receive either liposomal doxorubicin (PLD) or *gemcitabine* (353). In the *gemcitabine* and PLD groups, the median PFS was 3.6 months versus 3.1 months; the median overall survival was 12.7 months versus 13.5 months; the overall response rate was 6.1% versus 8.3%; and in the subset of patients with measurable disease, the overall response rate was 9.2% versus 11.7%, respectively. None of the efficacy end points showed a statistically significant difference between treatment groups. The PLD group experienced significantly more hand–foot syndrome and mucositis; the *gemcitabine* group experienced significantly more constipation, nausea or vomiting, fatigue, and neutropenia.

Taxanes

Single-agent *paclitaxel* shows objective responses in 20% to 30% in phase II trials of women with *platinum*-resistant ovarian cancer (313–318). The main toxicities are fatigue and peripheral neuropathy. **Weekly *paclitaxel* appears to be more active than 3-weekly administration in patients with platinum-resistant ovarian cancer.** In a study of 53 women with *platinum*-resistant ovarian cancer, weekly *paclitaxel* (80 mg/m^2 over 1 hour) had an objective response of 25% in patients with measurable disease, and 27% of patients without measurable disease had a 75% decline in serum CA-125 levels (313).

Docetaxel has some activity in these patients (354–356). The GOG studied 60 women with *platinum*-resistant ovarian or primary peritoneal cancer (356). Although there was a 22% objective response rate, the median response duration was only 2.5 months, and therapy was complicated by severe neutropenia in three-quarters of the patients.

Topotecan

Topotecan is a relatively active second-line treatment for patients with *platinum*-sensitive and *platinum*-resistant disease (321–335). In a study of 139 women receiving *topotecan* 1.5 mg/m^2 daily for 5 days, response rates were 19% and 13% in patients with *platinum*-sensitive and *platinum*-resistant disease, respectively (331). **The predominant toxicity of *topotecan* is hematologic, especially neutropenia.** With the 5-day dosing schedule, approximately 70% to 80% of patients have severe neutropenia, and 25% have febrile neutropenia with or without infection. In some studies, regimens of 5 days produce better response rates than regimens of shorter duration, but in others, reducing the dose to 1.0 mg/m^2 per day for 3 days is associated with similar response rates but lower toxicity (324,334). In a study of 31 patients, one-half of whom were *platinum* refractory, *topotecan* 2 mg/m^2 per day for 3 days every 21 days had a 32% response rate (329). Continuous infusion *topotecan* (0.4 mg/m^2 per day for 14 to 21 days) had a 27% to 35% objective response rate in *platinum*-refractory patients (328).

Weekly *topotecan* administered at a dose of 4 mg/m^2 per week for 3 weeks with a week off every month produced a response rate similar to the 5-day regimen with considerably less toxicity, and this dose schedule is commonly used in the recurrent setting (334).

Oral *topotecan*, not available in the United States, **results in similar response rates with less hematologic toxicity** (330). The IV and oral formulations of *topotecan* were compared in a randomized trial of 266 women as a third-line regimen after an initial *platinum*-based regimen (335). Compared with IV *topotecan* (1.5 mg/m^2 daily for 5 days every 3 weeks), oral *topotecan* (2.3 mg/m^2 per day for 5 days every 3 weeks) produced a similar response rate (13% vs. 20%), less severe myelosuppression, and only a slightly shorter median survival (51 weeks vs. 58 weeks).

Liposomal Doxorubicin

Liposomal doxorubicin (*Doxil* in the United States and *Caelyx* in Europe) has activity in *platinum*- and *taxane*-refractory disease (309–312,339). One of the **most important side effects of *liposomal doxorubicin* is the hand–foot syndrome, also known as palmar-plantar erythrodysesthesia or acral erythema, which occurs in 20% of patients who receive 50 mg/m^2 every 4 weeks** (310). Most oncologists administer 40 mg/m^2 and escalate only if there are no side effects. *Liposomal doxorubicin* has a low rate of alopecia. In a study of 89 patients with *platinum*-refractory disease, including 82 *paclitaxel*-resistant patients, *liposomal doxorubicin* (50 mg/m^2 every 3 weeks) produced a response in 17% (1 complete and 14 partial responses) (312). In another study, an objective response of 26% was reported, although there were no responses in women who progressed during first-line therapy (309).

Gemcitabine

Gemcitabine is associated with response rates of 20% to 50%, with 15% to 30% in patients who are *platinum*-resistant (357–361). **The principal toxicity is myelosuppression.**

Oral Etoposide

The most common toxicities with oral *etoposide* are myelosuppression and gastrointestinal issues: grade 4 neutropenia is observed in about one-fourth of patients, and 10% to 15% have severe nausea and vomiting (362,363). A study of oral *etoposide* given for a prolonged treatment (50 mg/m^2 daily for 21 days every 4 weeks) had a 27% response rate in 41 women with *platinum*-resistant disease, 3 of whom had durable complete responses (363). In 25 patients with *platinum* and *taxane*-resistant disease, 8 objective responses (32%) were reported.

Hormonal Therapy

***Tamoxifen* is associated with CA-125 response rates of 15% to 20% in small studies of patients with recurrent ovarian cancer** (364–370). The efficacy of tamoxifen was analyzed in a Cochrane review which included 623 women with recurrent epithelial ovarian cancer across several studies. Overall, 10% achieved an objective response, although the range within individual studies was 0% to 56%. The duration of response is short-lived for patients with high-grade ovarian cancer (366). Aromatase inhibitors (e.g., *letrozole*, *anastrozole*, and *exemestane*), which have activity in metastatic breast cancer, are being studied in relapsed ovarian cancer (371). One of the principal advantages of this class of agents is its very low toxicity (372).

Bevacizumab

***Bevacizumab* was the first targeted drug to show significant single-agent activity in ovarian cancer.** It is a humanized MonAb that targets angiogenesis by binding to VEGF-A, thereby blocking the interaction of VEGF with its receptor. There are a number of phase II studies reported using *bevacizumab* in patients with *platinum*-sensitive and *platinum*-resistant ovarian cancer with response rates ranging from 16% to 22% in *platinum*-sensitive and refractory patients (373). Up to 40% of patients had stabilization of disease for at least 6 months. A study of low-dose metronomic chemotherapy with 50 mg of *cyclophosphamide* daily and *bevacizumab* 10 mg/kg IV every 2 weeks showed significant activity in a study of 70 patients with recurrent ovarian cancer (374). The primary end point was PFS at 6 months. The probability of being alive and progression free at 6 months was 56%. A partial response was achieved in 17 patients (24%). The median time to progression and survival were 7.2 and 16.9 months, respectively. The use of *bevacizumab* brings potential toxicity. The side effects of *bevacizumab* are well recognized and include hypertension, fatigue, proteinuria, gastrointestinal perforation or fistula, and uncommonly, vascular thrombosis and central nervous system ischemia, pulmonary hypertension, and bleeding and wound-healing complications. The most common side effects are hypertension that is grade 3 in 7% of patients but is manageable in most patients. The most concerning side effect is bowel perforation and the study by Cannistra et al. was stopped after recruiting 44 patients because of an 11% incidence of perforation of the bowel (375). The bowel perforation complication could be minimized by carefully screening patients. Simpkins et al. limited *bevacizumab* treatment to patients without clinical symptoms of bowel obstruction or evidence of rectosigmoid involvement on pelvic examination or bowel involvement on CT scan (376). Their study included 25 patients with *platinum*-resistant ovarian cancer who were heavily pretreated, and they observed a response rate of 28% without any bowel perforations or other grade 3 or 4 toxicities. This highlights the importance of patient selection.

Radiation Therapy

Whole-abdominal radiation therapy was given as a treatment for recurrent or persistent disease but is associated with high morbidity and is not used. The principal problem with this approach is the development of acute and chronic intestinal morbidity. As many as 30% of patients receiving this treatment develop intestinal obstruction, which necessitated exploratory surgery with potential morbidity (377).

Intestinal Obstruction

Patients with epithelial ovarian cancer often develop intestinal obstruction, either at the time of initial diagnosis or in association with recurrent disease (378–393). Obstruction may be related to a mechanical blockage or to carcinomatous ileus.

The intestinal blockage can be corrected in most patients with obstruction at initial diagnosis. The decision to perform an exploratory procedure to ease intestinal obstruction in patients with recurrent disease is more difficult. For patients whose life expectancy is very short (e.g., less than 2 months), surgical relief of the obstruction is not indicated (378–383). **In those patients with a longer projected lifespan, features predicting a reasonable likelihood of correcting the obstruction include young age, good nutritional status, and the absence of rapidly accumulating ascites** (379).

For most patients with recurrent ovarian cancer and intestinal obstruction, particularly small bowel obstruction, initial management should include proper radiographic documentation of the obstruction, hydration, correction of any electrolyte disturbances, parenteral alimentation, and intestinal intubation. For some patients, the obstruction may be alleviated by this conservative approach. A preoperative upper gastrointestinal radiographic series and a barium enema will define possible sites of obstruction.

If exploratory surgery is deemed appropriate, the type of operation to be performed will depend on the site and the number of obstructions. **Multiple sites of obstruction are not uncommon in patients with recurrent epithelial ovarian cancer.** More than one-half of the patients have small bowel obstruction, one-third have colonic obstruction, and one-sixth have both (380–384). If the obstruction is principally contained in one area of the bowel (e.g., the terminal ileum), this area can be either resected or bypassed, depending on what is easier to accomplish safely. Intestinal bypass is less morbid than resection, and in patients with progressive cancer, the survival time after these two operations is the same (385–390).

If multiple obstructions are present, resection of several segments of intestine is usually not indicated, and intestinal bypass and/or colostomy should be performed. A gastrostomy may be useful in this circumstance, and this can usually be placed percutaneously (389,392).

Surgery for bowel obstruction in patients with ovarian cancer carries an operative mortality of about 10% and a major complication rate of about 30% (378–390). The need for multiple reanastomoses and poor nutrition increases the

morbidity, which consists primarily of sepsis and enterocutaneous fistulae. The median survival ranges from 3 to 12 months, although about 20% of these patients survive longer than 12 months (390–393).

Survival

The prognosis for patients with epithelial ovarian cancer is related to several clinical variables. Survival analyses based on prognostic variables are presented (4,65,151–155,160). Including patients at all stages, patients younger than 50 years of age have a 5-year survival rate of about 40%, compared with about 15% for patients older than 50 years.

The 5-year survival rate for carefully and properly staged patients with stage I disease is as high as 94%, for stage II is 73%, for stage III or IV 28% (65). **The 5-year survival rate for stage IIIA is 41%, for stage IIIB about 25%, for stage IIIC 23%, and for stage IV disease 11% (Fig. 39-16). An analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) database reveals a trend toward improved survival for ovarian cancer in the United States. In this cohort, the survival for stage I was 93%, for stage II 70%, for stage III 37%, and for stage IV 25%** (394).

Survival of patients with borderline tumors is excellent, with stage I lesions having a 98% 15-year survival (160). When all stages of borderline tumors are included, the 5-year survival rate is about 86% to 90%.

Patients with stage III disease with microscopic residual disease at the start of treatment have a 5-year survival rate of about 40% to 75%, compared with about 30% to 40% for those with optimal disease, and only 5% for those with suboptimal disease (154,155,178). Patients whose Karnofsky index (KI) is low (<70) have a significantly shorter survival than those with a KI greater than 70 (160).

NONEPITHELIAL OVARIAN CANCERS

Compared with epithelial ovarian cancers, other malignant tumors of the ovary are uncommon. **Nonepithelial malignancies of the ovary account for about 10% of all ovarian cancers** (2,3,395). Nonepithelial ovarian cancers include malignancies of germ cell origin, sex cord–stromal cell origin, metastatic carcinomas to the ovary, and a variety of extremely rare ovarian cancers (e.g., sarcomas). Although there are similarities in the presentation, evaluation, and management of these patients, the tumors have unique qualities that require a special approach (2,395–398).

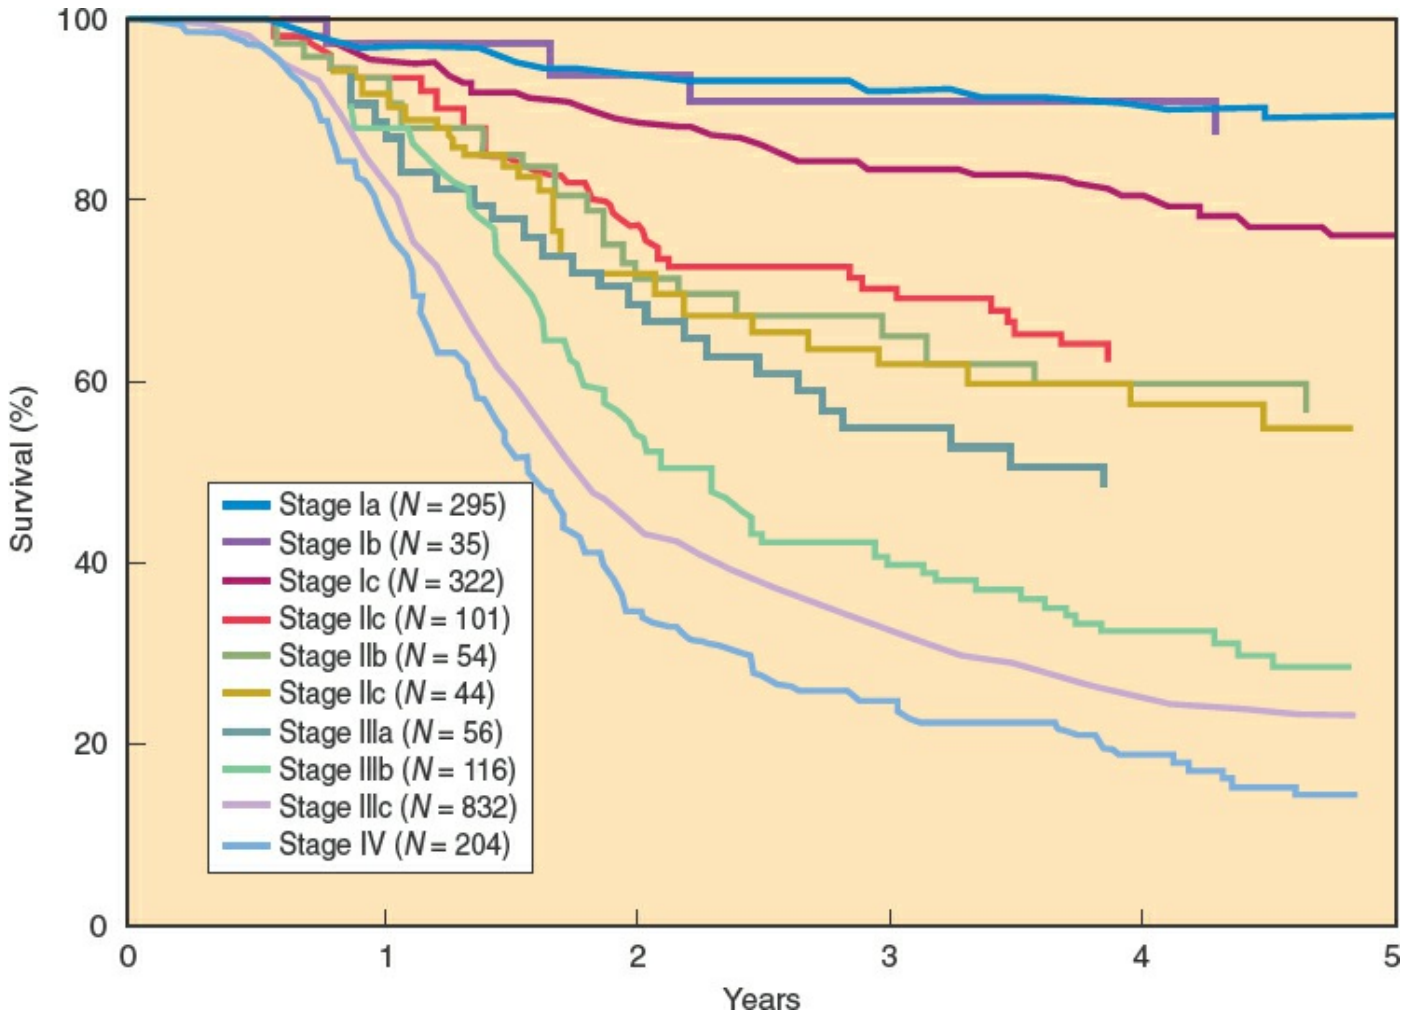

FIGURE 39-16 Survival of patients with epithelial ovarian cancer by substage. (Adapted from **Heintz APM, Odicino F, Maisonneuve P, et al.** Carcinoma of the ovary. In Twenty-sixth annual report of the results of treatment of gynaecological cancer. Int J Gynecol Oncol. 2006;95(suppl 1): S161–S192.)

Germ Cell Malignancies

Germ cell tumors are derived from the primordial germ cells of the ovary. Their incidence is about one-tenth the incidence of malignant germ cell tumors of the testis, so

most of the advances in the management of these tumors are extrapolations from experience with the corresponding testicular tumors. Although malignant germ cell tumors can arise in extragonadal sites such as the mediastinum and the retroperitoneum, most germ cell tumors arise in the gonad from undifferentiated germ cells. The variation in the site of these cancers is explained by the embryonic migration of the germ cells from the caudal part of the yolk sac to the dorsal mesentery before their incorporation into the sex cords of the developing gonads (2,4,395).

Table 39-5 Histologic Typing of Ovarian Germ Cell Tumors

1. Primitive germ cell tumors
- A. Dysgerminoma
- B. Yolk sac tumor
- C. Embryonal carcinoma
- D. Polyembryoma
- E. Nongestational choriocarcinoma
- F. Mixed germ cell tumor

2. Biphasic or triphasic teratoma
- A. Immature teratoma
- B. Mature teratoma
  1. Solid
  2. Cystic
     a. Dermoid cyst
     b. Fetiform teratoma (homunculus)

3. Monodermal teratoma and somatic-type tumors associated with dermoid cysts
- A. Thyroid tumor
  1. Struma ovarii
     a. Benign
     b. Malignant
- B. Carcinoid
- C. Neuroectodermal tumor
- D. arcinoma
- E. Melanocytic

Classification

A histologic classification of ovarian germ cell tumors is presented in Table 39-5 (4,395). **Both α-fetoprotein (AFP) and human chorionic gonadotropin (hCG) are secreted by some germ cell malignancies and can be clinically useful in the diagnosis of a pelvic mass and monitoring patients after surgery. Placental alkaline phosphatase (PLAP) and lactate dehydrogenase (LDH) are elevated to 95% of dysgerminomas, and serial measurements of LDH may be useful for monitoring the disease.** A classification of germ cell tumors is based on the histologic and immunocytochemical feature which include AFP and β-hCG **(Fig. 39-17)** (399).

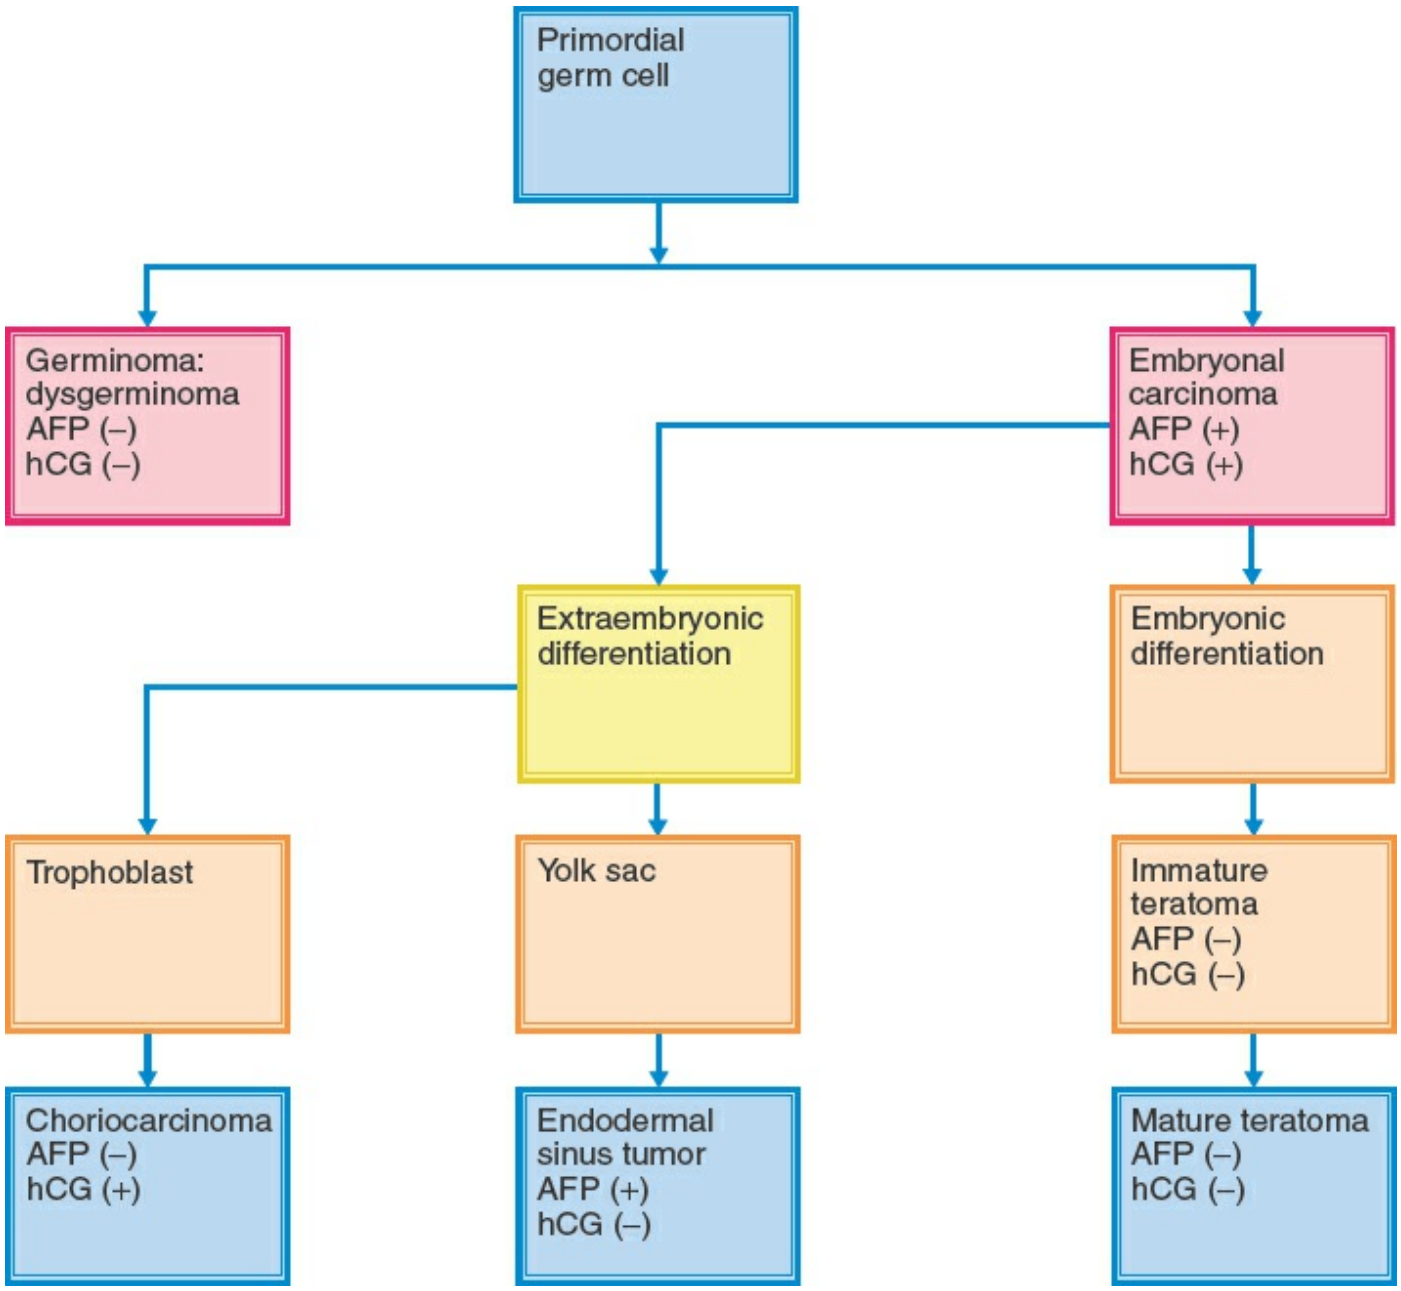

FIGURE 39-17 Relationship between types of pure malignant tumors. Germ cell tumors and their secreted marker substances. (From **Berek JS, Friedlander ML, Hacker NF.** Germ cell and nonepithelial ovarian cancer. In: Berek JS, Hacker NF. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:532.)

In this scheme, **embryonal carcinoma (a cancer composed of undifferentiated cells) synthesizes both hCG and AFP,** and this lesion is the progenitor of several other germ cell tumors (399–401). More differentiated germ cell tumors, such as the endodermal sinus tumor, which secretes AFP, and the choriocarcinoma, which secretes hCG, are derived from the extraembryonic tissues; the immature teratomas derived from the embryonic cells have lost the ability to secrete these substances. Pure germinomas do not secrete these markers.

Epidemiology

Although 20% to 25% of all benign and malignant ovarian neoplasms are of germ cell origin, only about 3% of these tumors are malignant (2,4). Germ cell malignancies account for fewer than 5% of all ovarian cancers in Western countries. Germ cell malignancies represent up to 15% of ovarian cancers in Asian and African American societies, where epithelial ovarian cancers are much less common.

[11] In the first two decades of life, almost 70% of ovarian tumors are of germ cell origin, and one-third of these are malignant (2,4,395). Germ cell cancers are seen in the third decade, but thereafter they become quite rare.

Clinical Features

Symptoms

[11] In contrast to the slower-growing epithelial ovarian tumors, germ cell malignancies grow rapidly and commonly present with acute/subacute pelvic pain related to capsular distention, hemorrhage, or necrosis. The rapidly enlarging pelvic mass may produce pressure symptoms on the bladder or rectum, and menstrual irregularities may occur in menarcheal patients. Some young patients misinterpret the early symptoms of a neoplasm as those of pregnancy, which can lead to a delay in the diagnosis. Acute symptoms associated with torsion or rupture of the adnexa can develop. These symptoms may be confused with acute appendicitis. In more advanced cases, ascites may develop, and the patient can have abdominal distention (389).

Signs

For a patient with a palpable adnexal mass, the evaluation can proceed as outlined. Some patients with germ cell tumors will be premenarcheal and may require examination under anesthesia. **If the lesions are principally solid or a combination of solid and cystic, as might be noted on an ultrasonographic evaluation, a neoplasm is probable and a malignancy is possible** (see Fig. 9.8 and Chapter 9). During the remainder of the physical examination, effort should be directed to searching for signs of ascites, pleural effusion, and organomegaly.

Diagnosis

Adnexal masses measuring 2 cm or larger in premenarcheal girls or 8 cm or larger in other premenopausal patients will usually require surgical exploration. For young patients, blood tests should include serum hCG and AFP and LDH. A CT scan of the chest is important because germ cell tumors can metastasize to the lungs or mediastinum. **A karyotype should be obtained preoperatively for all premenarcheal girls, particularly those with dysgerminomas, because they may arise in dysgenetic gonads** (396,402). A preoperative CT scan or MRI may document the presence and extent of retroperitoneal lymphadenopathy or liver metastases; however, because these

patients require surgical exploration, preoperative imaging may not impact initial surgical management. If postmenarcheal patients have predominantly cystic lesions up to 8 cm in diameter, they may be observed or given oral contraceptives for two menstrual cycles, which may reduce new ovarian cyst formation (403).

Dysgerminoma

[12] Dysgerminoma is the most common malignant germ cell tumor, accounting for about 30% to 40% of all ovarian cancers of germ cell origin (2,4,399). The tumors represent only 1% to 3% of all ovarian cancers, but they represent as many as 5% to 10% of ovarian cancers in patients younger than 20 years. Seventy-five percent of dysgerminomas occur between the ages of 10 and 30 years, 5% occur before the age of 10 years, but they rarely occur after 50 years of age (2,4,389). Because these malignancies occur in young women, 20% to 30% of ovarian malignancies associated with pregnancy are dysgerminomas.

Germinomas are found in both sexes and may arise in gonadal or extragonadal sites. The latter includes the midline structures from the pineal gland to the mediastinum and the retroperitoneum. Histologically, they represent abnormal proliferations of the basic germ cell. In the ovary, the germ cells are encapsulated at birth (the primordial follicle), and the unencapsulated or free cells die. If either of the latter processes fails, it is possible that the germ cell could free itself of its normal control and multiply indiscriminately.

The size of dysgerminomas varies widely, but they are usually 5 to 15 cm in diameter (2,4). The capsule is slightly bosselated, and the consistency of the cut surface is fleshy and pale tan to gray-brown in color **(Fig. 39-18)**.

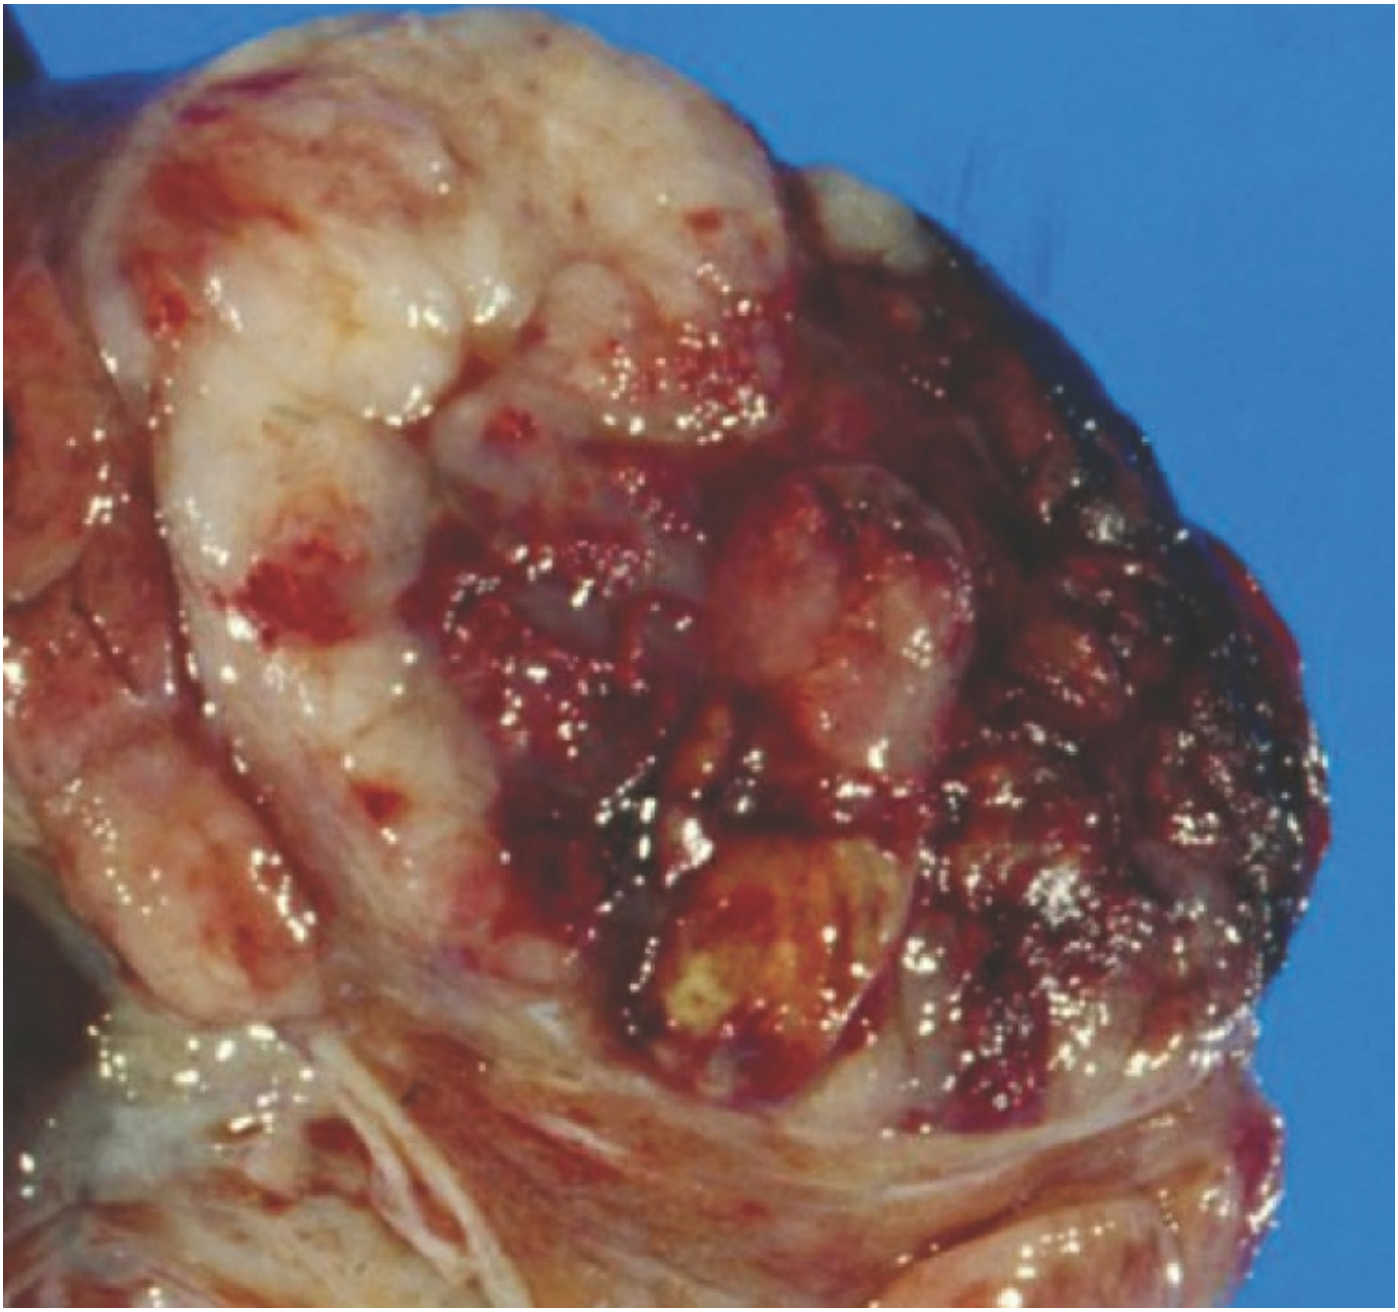

FIGURE 39-18 Dysgerminoma of the ovary. Note that the lesion is principally solid with some cystic areas and necrosis.

The histologic characteristics of the dysgerminoma are very distinctive. The large round, ovoid, or polygonal cells have abundant, clear, very-pale–staining cytoplasm, large and irregular nuclei, and prominent nucleoli (Fig. 39-19). Mitotic figures are seen in varying numbers, although they are usually numerous. Another characteristic feature is the arrangement of the elements in lobules and nests separated by fibrous septa, which are often extensively infiltrated with lymphocytes, plasma cells, and granulomas with epithelioid cells and multinucleated giant cells. When necrosis is extensive, the lesion may be confused with tuberculosis. Dysgerminomas may contain

syncytiotrophoblastic giant cells and may be associated with precocious puberty or virilization. The presence of these cells does not seem to alter prognosis (2,4). The presence of calcifications should prompt a search for a possible underlying gonadoblastoma.

Because the dysgerminoma is a germ cell tumor and parthenogenesis (stimulation of the basic germ cell to atypical division) is the accepted genesis for the more immature teratomas, it is logical that these two tumors may coexist. Choriocarcinoma, endodermal sinus tumor, and other extraembryonal lesions may be associated with the dysgerminoma.

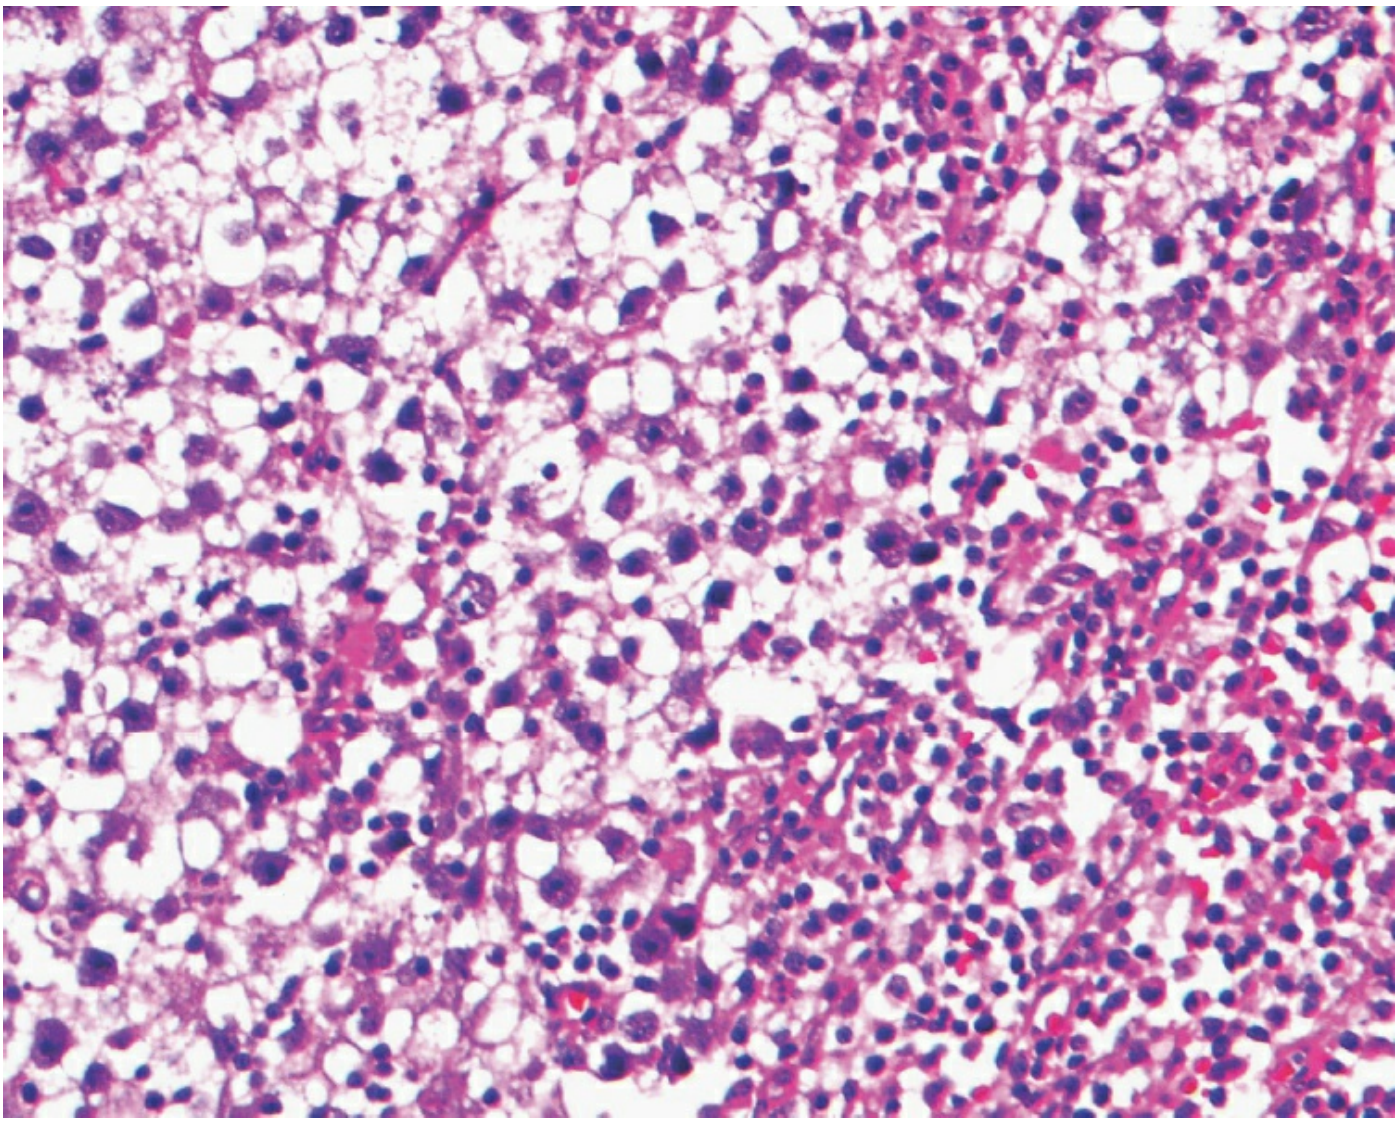

FIGURE 39-19 Dysgerminoma of the ovary. Primitive germ cells are divided into clusters and lobules by fibrous septa rich in lymphocytes.

Approximately 5% of dysgerminomas are discovered in phenotypic women with abnormal gonads (2,402,404). This malignancy can be associated with patients who have pure gonadal dysgenesis (46,XY, bilateral streak gonads), mixed gonadal

dysgenesis (45,X/46,XY, unilateral streak gonad, contralateral testis), and the androgen insensitivity syndrome (46,XY, testicular feminization). For premenarcheal patients with a pelvic mass, the karyotype should be determined (see Chapter 34).

For most patients with gonadal dysgenesis, dysgerminomas arise in gonadoblastomas, which are benign ovarian tumors that are composed of germ cells and sex cord stroma. If gonadoblastomas are left *in situ* in patients with gonadal dysgenesis, more than 50% will develop into ovarian malignancies (404).

About 65% of dysgerminomas are stage I (i.e., confined to one or both ovaries) at diagnosis (2,4,405–409). **About 85% to 90% of stage I tumors are confined to one ovary; 10% to 15% are bilateral. Dysgerminoma is the only germ cell malignancy that has this significant rate of bilaterality. Other germ cell tumors are rarely bilateral.**

For patients whose contralateral ovary is preserved, disease can develop in 5% to 10% of the retained gonads over the next 2 years (2). This figure includes those not given additional therapy and patients with gonadal dysgenesis.

In the 25% of patients who are diagnosed initially with metastatic disease, the tumor commonly spreads via the lymphatic system. It can spread hematogenously or by direct extension through the capsule of the ovary with exfoliation and dissemination of cells throughout the peritoneal surfaces. Metastases to the contralateral ovary may be present when there is no other evidence of spread. An uncommon site of metastatic disease is bone; when metastasis to this site occurs, the lesions are principally in the lower vertebrae. Metastases to the lungs, liver, and brain are often in patients with longstanding or recurrent disease. Metastasis to the mediastinum and supraclavicular lymph nodes is usually a late manifestation of disease (405,406).

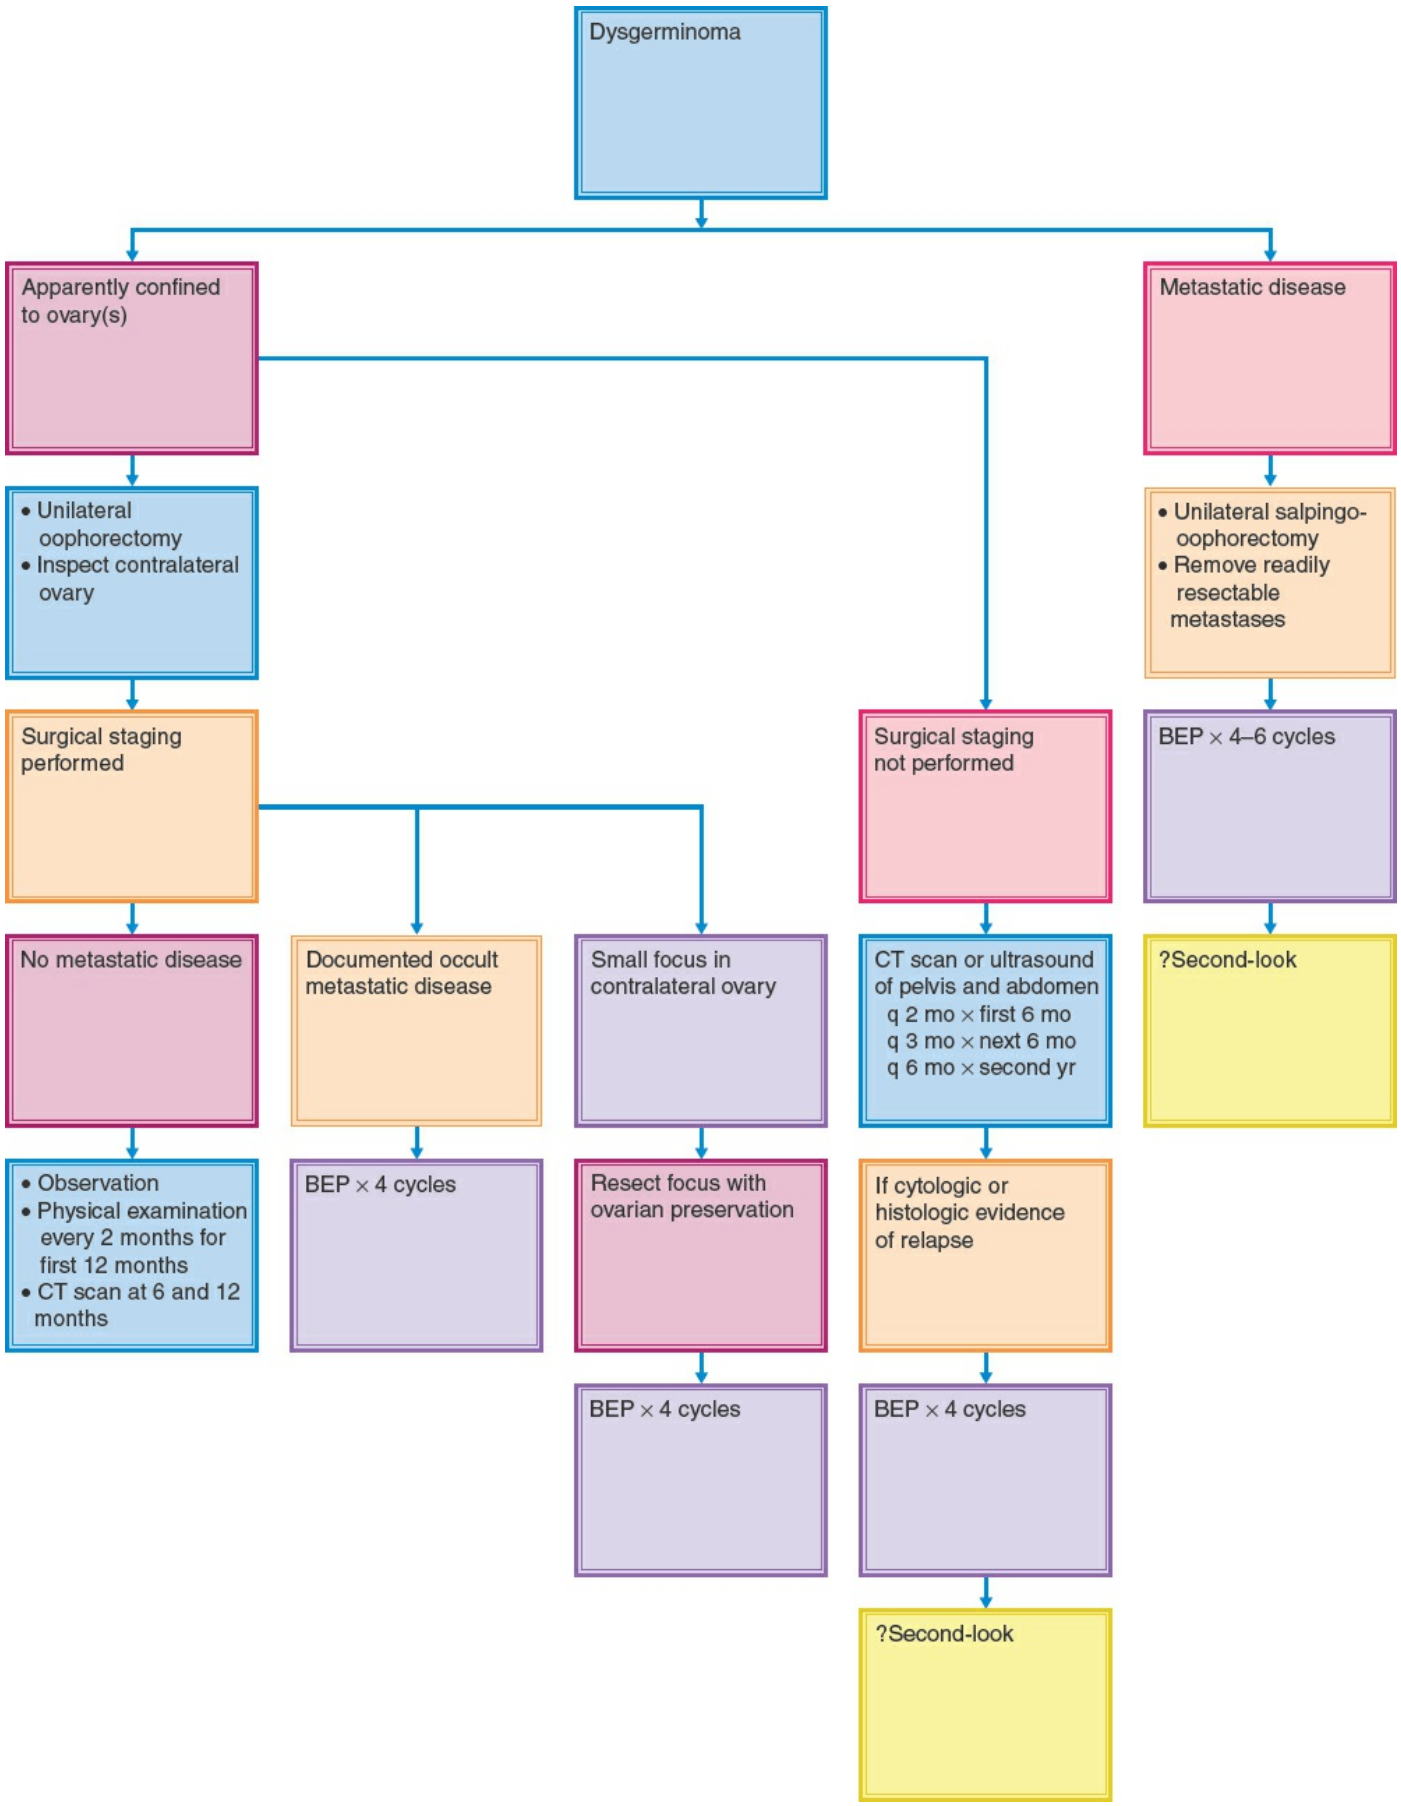
Treatment

The treatment of patients with early dysgerminoma is primarily surgical, including resection of the primary lesion and proper surgical staging. Chemotherapy is administered to patients with metastatic disease. [12] Because the disease principally affects girls and young women, special consideration must be given to the preservation of fertility whenever possible. An algorithm for the management of ovarian dysgerminoma is presented in **Figure 39-20**.

Surgery

The minimal surgical operation for ovarian dysgerminoma is a unilateral oophorectomy (407). **If there is a desire to preserve fertility, as there almost always is, the contralateral ovary, fallopian tube, and uterus should be left *in situ*, even in the presence of metastatic disease, because of the sensitivity of the tumor to chemotherapy.** If fertility need not be preserved, it may be appropriate to perform a total abdominal hysterectomy and bilateral salpingo-oophorectomy for patients with

advanced disease (409). For patients whose karyotype analysis reveals a Y chromosome, both ovaries should be removed, although the uterus may be left *in situ* for possible future embryo transfer (404). Whereas cytoreductive surgery is of unproved value, bulky disease that can be readily resected (e.g., an omental cake) should be removed during the initial operation.



Dysgerminoma
Apparently confined to ovary(s)
Metastatic disease
• Unilateral oophorectomy
• Inspect contralateral ovary
• Unilateral salpingo-oophorectomy
• Remove readily resectable metastases
Surgical staging performed
Surgical staging not performed
BEP × 4–6 cycles
No metastatic disease
Documented occult metastatic disease
Small focus in contralateral ovary
CT scan or ultrasound of pelvis and abdomen
q 2 mo × first 6 mo
q 3 mo × next 6 mo
q 6 mo × second yr
?Second-look
• Observation
• Physical examination every 2 months for first 12 months
• CT scan at 6 and 12 months
BEP × 4 cycles
Resect focus with ovarian preservation
If cytologic or histologic evidence of relapse
BEP × 4 cycles
BEP × 4 cycles
?Second-look

FIGURE 39-20 Management of dysgerminoma of the ovary. BEP, *bleomycin, etoposide*, and *cisplatin;* CT, computed tomogram. (From **Berek JS, Friedlander ML, Hacker NF.** Germ cell and nonepithelial ovarian cancer. In: Berek JS, Hacker NF. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:536.)

In patients in whom the neoplasm appears on inspection to be confined to the ovary, a careful staging operation should be undertaken to determine the presence of any occult metastatic disease. All peritoneal surfaces should be inspected and palpated, and any suspicious lesions should be sampled for biopsy. Unilateral pelvic lymphadenectomy and careful palpation and biopsy of enlarged para-aortic nodes are particularly important parts of the staging. These tumors may metastasize to the para-aortic nodes around the renal vessels. Dysgerminoma is the only germ cell tumor that tends to be bilateral, excisional biopsy of any suspicious masses is desirable (407–409). If a small contralateral tumor is found, it may be possible to resect it and preserve some normal ovary.

Many patients with a dysgerminoma will have a tumor that is apparently confined to one ovary and will be referred after unilateral salpingo-oophorectomy without surgical staging. Recommended options depend on the pathologic findings, the results of imaging and tumor markers (BHCG and LDH), the age of the patient and whether she desires fertility preservation.

The options include (i) completion of surgical staging as stage 1 dysgerminomas do not require adjuvant chemotherapy, (ii) close surveillance with pelvic and abdominal CT scans and tumor markers, or (iii) adjuvant chemotherapy if capsular rupture or more advanced stage. Tumor markers (LDH, AFP, and β-hCG) should be monitored in case occult mixed germ cell elements are present.

Radiation Therapy

Dysgerminomas are very sensitive to radiation therapy, and doses of 2,500 to 3,500 cGy may be curative, even for gross metastatic disease. Loss of fertility is a problem with radiation therapy, and radiation is rarely used as first-line treatment.

Chemotherapy

There is very good evidence to demonstrate the effectiveness of *platinum*-based chemotherapy, which is regarded as the treatment of choice (409–420). **The obvious advantage is the preservation of fertility** (421).

[12] The most frequently used chemotherapeutic regimen for germ cell tumors is *BEP* (*bleomycin*, *etoposide*, and *cisplatin*), EP (*etoposide* and *cisplatin*), or EC (*etoposide* and *carboplatin*) (**Table 39-6**) (409–426).

Table 39-6 Combination Chemotherapy for Germ Cell Tumors of the Ovary

Regimen and Drugs	Dose and Schedule[a]

BEP	
Bleomycin	30,000 IU on days 1, 8, and 15 every 3 wks
Etoposide	100 mg/m^2/day × 5 days every 3 wks
Cisplatin	20 mg/m^2/day × 5 days, or 100 mg/m^2/day × 1 day every 3 wks
VBP	
Vinblastine	0.15 mg/kg days 1 and 2 every 3 wks
Bleomycin	15 units/m^2/wk × 5; then on day 1 of course 4
Cisplatin	100 mg/m^2 on day 1 every 3 wks
VAC	
Vincristine	1–1.5 mg/m^2 on day 1 every 4 wks
Actinomycin D	0.5 mg/day × 5 days every 4 wks
Cyclophosphamide	150 mg/m^2/day × 5 days every 4 wks

[a]All doses given intravenously.

The GOG studied three cycles of the EC regimen, consisting of *etoposide* (120 mg/m^2 IV on days 1, 2, and 3 every 4 weeks) and *carboplatin* (400 mg/m^2 IV on day 1 every 4 weeks) for patients with completely resected ovarian dysgerminoma, stage IB, IC, II, or III (417). The results showed a sustained disease-free remission rate of 100%. This study was carried out many years ago when *carboplatin* dose was based on surface area, but it is now based on AUC.

For patients with advanced, incompletely resected germ cell tumors, the GOG studied *cisplatin*-based chemotherapy in two consecutive protocols (410,411). In the first study, patients received four cycles of *vinblastine* (12 mg/m^2 every 3 weeks), *bleomycin* (20 units/m^2 IV every week for 12 weeks), and *cisplatin* (20 mg/m^2 per day IV for 5 days every 3 weeks). Patients with persistent or progressive disease at second-look laparotomy were treated with six cycles of *VAC* (*vincristine*, *actinomycin D*, and *cyclophosphamide*). In the second trial, patients received three cycles of *BEP* initially, followed by consolidation with *VAC*, which was later discontinued in patients with dysgerminomas (411). The *VAC* consolidation after *BEP* is no longer used. A total of 20 evaluable patients with stages III and IV dysgerminoma were treated in these two protocols, and 19 were alive and free of disease after 6 to 68 months (median = 26 months). Fourteen of these patients had a second-look laparotomy, and all findings were negative. Another study at MD Anderson Cancer Center used *BEP* in 14 patients with

residual disease, and all patients were free of disease during long-term follow-up (414). **These results demonstrate that patients with advanced-stage, incompletely resected dysgerminoma have an excellent prognosis when treated with *EP*-based combination chemotherapy. [12] The standard regimen is three to four cycles of *BEP*, depending on assigned risk based on the data from testicular cancers, including advanced-stage seminomas which are the male equivalent of dysgerminoma** (425,429).

Recurrent Disease

About 75% of recurrences occur within the first year after initial treatment, the most common sites being the peritoneal cavity and the retroperitoneal lymph nodes (2,388,389). These patients should be treated with chemotherapy. Patients with recurrent disease who had no therapy other than surgery should be treated with chemotherapy as described above. If prior chemotherapy with *BEP* was given, there are a number of second-line options including *TIP* (*paclitaxel*, *ifosfamide*, *cisplatin*) or *VIP* (*vinblastine*, *ifosfamide*, *cisplatin*) (Table 35-7), and consideration should be given to the use of high-dose chemotherapy in selected patients. Patients with recurrent dysgerminomas following *BEP* should be managed in specialized centers. Radiation therapy may be an option in very selected subsets, with the major disadvantage being loss of fertility if pelvic and abdominal irradiation is required.

Table 39-7 POMB-ACE Chemotherapy for Germ Cell Tumors of the Ovary

POMB	
Day 1	*Vincristine* 1 mg/m^2 IV; *methotrexate* 300 mg/m^2 as a 12-hr infusion
Day 2	*Bleomycin* 15 mg as a 24-hr infusion: *folinic acid* rescue started at 24 hr after the start of *methotrexate* in a dose of 15 mg every 12 hrs for 4 doses
Day 3	*Bleomycin* infusion 15 mg as a 24-hr infusion
Day 4	*Cisplatin* 120 mg/m^2 as a 12-hr infusion, given with hydration and 3-g magnesium sulfate supplementation
ACE	
Days 1–5	*Etoposide* (VP16–213) 100 mg/m^2 IV, days 1–5
Days 3–5	*Actinomycin D* 0.5-mg IV, days 3, 4, and 5
Day 5	*Cyclophosphamide* 500 mg/m^2 IV, day 5

OMB	
Day 1	*Vincristine* 1 mg/m^2 IV; *methotrexate* 300 mg/m^2 as a 12-hr infusion
Day 2	*Bleomycin* 15 mg as a 24-hr infusion; *folinic acid* rescue started at 24 hrs after the start of *methotrexate* in a dose of 15 mg every 12 hrs for 4 doses
Day 3	*Bleomycin* 15 mg as a 24-hr infusion

IV, intravenous.

The sequence of treatment schedules is two courses of POMB followed by ACE. POMB is then alternated with ACE until patients are in biochemical remission as measured by human chorionic gonadotropin (hCG) and α-fetoprotein (AFP), placental alkaline phosphatase (PLAP), and lactate dehydrogenase (LDH). The usual number of courses of POMB is three to five. Following biochemical remission, patients alternate ACE with OMB until remission has been maintained for approximately 12 weeks. The interval between courses of treatment is kept to the minimum (usually 9 to 11 days). If delays are caused by myelosuppression after courses of ACE, the first 2 days of etoposide are omitted from subsequent courses of ACE.

From **Newlands ES, Southall PJ, Paradinas FJ, et al.** Management of ovarian germ cell tumours. In: Williams CJ, Kaikorian JG, Green MR, et al., eds. *Textbook of Uncommon Cancer*. New York: John Wiley & Sons; 1988:47, with permission.

Pregnancy

Because dysgerminomas tend to occur in young patients, they may coexist with pregnancy. When a stage IA cancer is found, the tumor can be removed intact and the pregnancy continued. For patients with more advanced disease, continuation of the pregnancy depends on the gestational age of the fetus. Chemotherapy can be given safely in the second and third trimesters in the same dosages as given for the nonpregnant patient without apparent detriment to the fetus (421).

Prognosis

For patients whose initial disease is stage IA (i.e., a unilateral encapsulated dysgerminoma), unilateral oophorectomy alone results in a 5-year disease-free survival rate of greater than 95% (408). The features associated with a higher tendency to recur, include lesions larger than 10 to 15 cm in diameter, age younger than 20 years, and a microscopic pattern that includes numerous mitoses, anaplasia, and a medullary pattern (2,399,409–426,430–432).

Immature Teratomas

Immature teratomas contain elements that resemble tissues derived from the embryo. Immature teratomatous elements may occur in combination with other germ cell tumors as mixed germ cell tumors. [12] The pure immature teratoma accounts for fewer than 1% of all ovarian cancers, but it is the second most common germ cell malignancy and accounts for 10% to 20% of all ovarian

malignancies seen in women younger than 20 years (2). About 50% of pure immature teratomas of the ovary occur in women between the ages of 10 and 20 years, and they rarely occur in postmenopausal women.

Pathology and Grading

Of fundamental importance in the understanding of the teratoma is recognition of the maturation of the various elements. If maturation continues along normal lines, it results in a mature teratoma, and the prognosis is excellent as these are benign tumors with the rare exception of other tumors arising from mature elements, such as squamous cell carcinomas. Conversely, abnormal maturation of these elements can result in an immature teratoma that has metastatic potential. Teratomas containing immature elements, although relatively rare, are recognized more often as pathologists are aware of the importance of differentiating them from mature teratomas **(Fig. 39-21)**. Among the tumors with embryonal elements, those containing neural tissues demonstrate the ability to mature.

Semiquantification of immature neuroepithelium correlates with survival in ovarian immature teratoma and is the basis for grading of these tumors (433–435). **Those with less than one low-power field (X 4) of immature neuroepithelium on the slide with the greatest amount of such tissue (grade 1) have a survival of at least 95%, whereas greater amounts of immature neuroepithelium (grades 2 and 3) appear to have a higher risk of recurrence and a lower overall survival (approximately 85%)** (435). This may not apply to immature teratomas of the ovary in children because they have a good outcome with surgery alone, regardless of the degree of immaturity (436,437). The significant inter- and intraobserver difficulty with a three-tier system led some authorities to recommend the two-tier grading system in use, with immature teratomas categorized as either low grade or high grade (433). Immature ovarian teratomas may be associated with gliomatosis peritonei, a favorable prognostic finding if composed of completely mature tissues; molecular analyses suggest that these glial implants are not tumor derived but rather represent teratoma-induced metaplasia of pluripotent müllerian stem cells in the peritoneum (438,439).

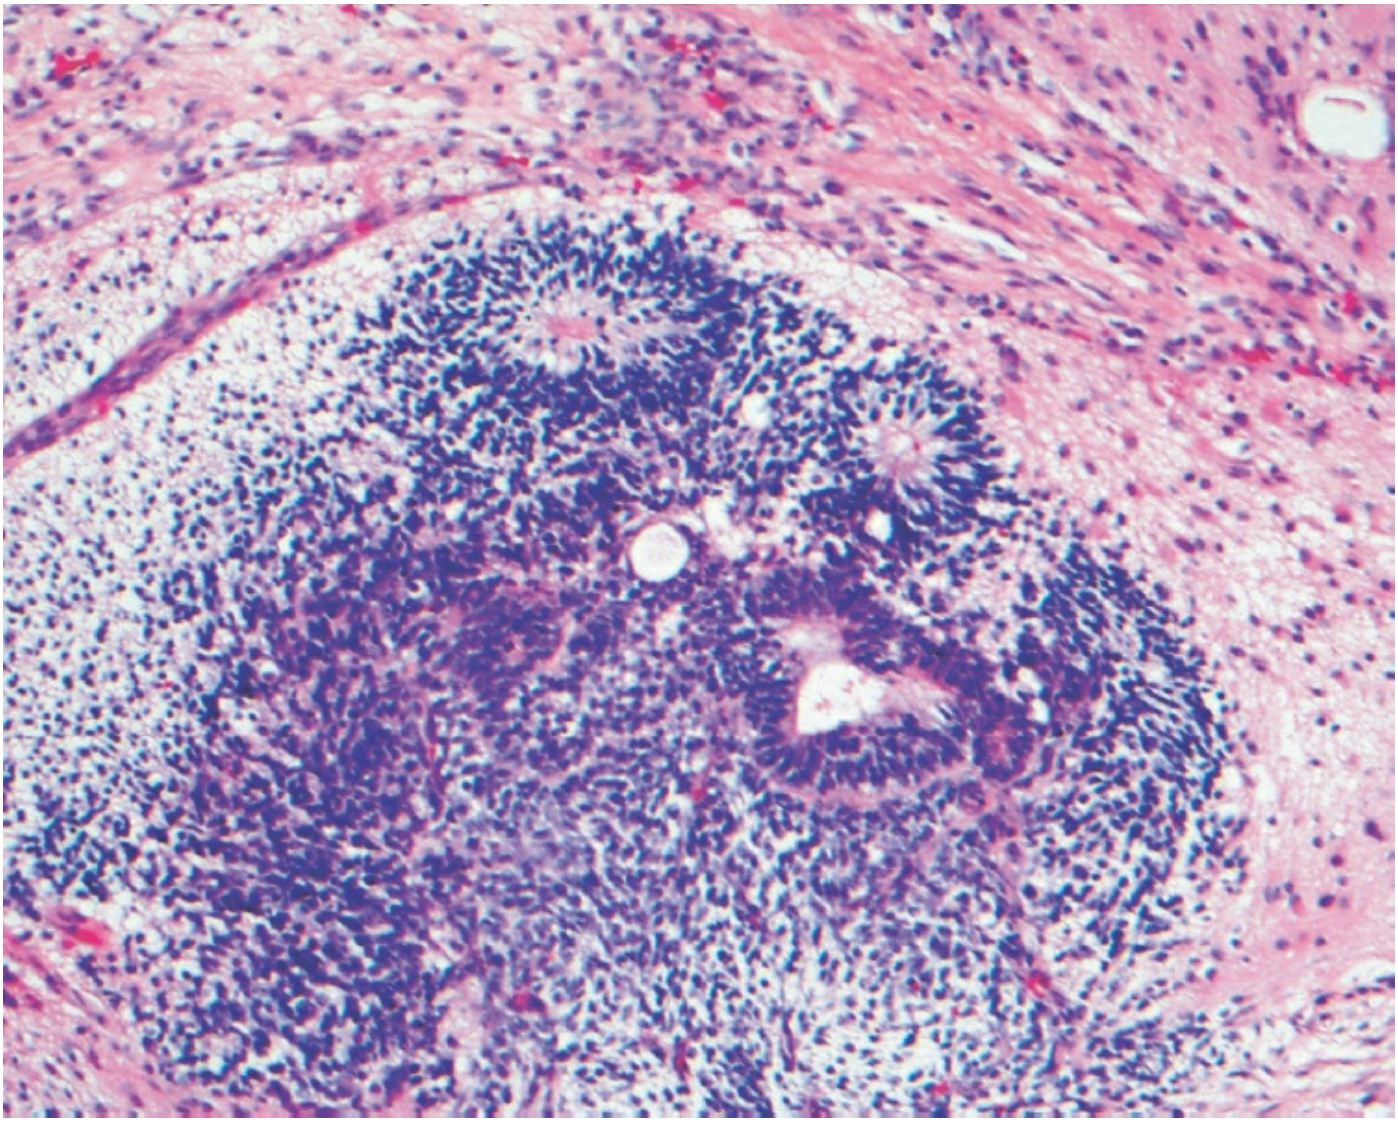


FIGURE 39-21 Ovarian teratoma. This tumor contains both mature and immature neural elements with a neural tube-like structure near its center.

Somatic malignant change in benign cystic teratomas was recorded as occurring in 0.5% to 2% of cases, usually in patients older than 40 years of age (433). **The most common malignancy that develops in the initially benign teratoma is squamous cell carcinoma.** Other neoplasms were reported (e.g., adenocarcinomas, melanomas, which may arise from the skin or retinal anlage, and sarcomas, including leiomyosarcomas and mixed mesodermal tumors) (2). Carcinomas may arise from any of the epithelial elements.

Diagnosis

The preoperative evaluation and differential diagnosis of immature teratomas are the same as for other germ cell tumors. Some of these tumors will contain calcifications similar to those of mature teratomas, which can be detected by a radiograph of the abdomen or by ultrasonography. Rarely they are associated with the production of

steroid hormones and can be accompanied by sexual pseudoprecocity (395). Tumor markers are negative unless a mixed germ cell tumor is present. Immature teratoma may contain embryonal hepatic or intestinal differentiation, and the presence of these elements in a tumor with high AFP levels. It is possible to have a slightly elevated AFP in a pure IT if they have evidence of hepatic or intestinal differentiation, but high levels would be associated with a mixed germ cell tumor.

Treatment

Surgery

In a premenopausal patient, immature teratomas are typically confined to a single ovary, and therefore unilateral oophorectomy and fertility-sparing surgical staging should be performed. For a postmenopausal patient, a total abdominal hysterectomy and bilateral salpingo-oophorectomy may be performed along with complete staging. Contralateral involvement is rare, and routine resection or wedge biopsy of the contralateral ovary is unnecessary (4,434,435). Any lesions on the peritoneal surfaces should be sampled and submitted for histologic evaluation. The most frequent site of dissemination is the peritoneum and, much less commonly, the retroperitoneal lymph nodes. Blood-borne metastases to organ parenchyma, such as the lungs, liver, or brain, are uncommon. When present, they are usually seen in patients with late or recurrent disease and most often in tumors that are poorly differentiated (i.e., grade 3).

It is unclear whether extensive debulking enhances the response to combination chemotherapy (440–442). These are chemosensitive tumors and the cure depends on the prompt delivery of chemotherapy. Therefore, any surgical resection that is potentially morbid and could delay chemotherapy should be resisted.

Chemotherapy

Patients with IA, grade 1 tumors have an excellent prognosis, and no adjuvant therapy is required. For patients whose tumors are stage IA, high-grade, adjuvant chemotherapy has been generally recommended, although there is evidence to support close surveillance (412–414,430–434). Chemotherapy is indicated for patients who have ascites, regardless of tumor grade. The standard approach is *BEP* (412,413,443–449). The GOG investigated three cycles of *BEP* for patients with completely resected stages I, II, and III ovarian germ cell tumors (412,413,449). Overall, the toxicity was acceptable, and 91 of 93 patients treated were clinically free of disease. **The *BEP* regimen, which is the standard of care for testicular cancer, is the most appropriate chemotherapy regimen for nondysgerminomatous germ cells tumors of the ovary.** As these tumors can progress rapidly, treatment should be initiated as soon as possible after surgery, preferably within 7 to 10 days (450). The combined *BEP* regimen is the international standard of care, usually administered for

three cycles in completely resected disease or in the adjuvant setting and four cycles for macroscopic residual disease.

The switch from *VBP* to *BEP* was prompted by the experience in patients with testicular cancer, in which the replacement of *vinblastine* with *etoposide* was associated with a better therapeutic index (i.e., equivalent efficacy and lower morbidity), especially less neurologic and gastrointestinal toxicity. The inclusion of *bleomycin* is particularly important those patients with nondysgerminomatous germ cell tumors. In a randomized study of three cycles of *EP* with or without *bleomycin* (*EP* vs. *BEP*) in 166 patients with germ cell tumors of the testes, the *BEP* regimen had a relapse-free survival rate of 84% compared with 69% for the *EP* regimen ($p = 0.03$) (425). *Cisplatin* appears to be superior to *carboplatin* in the setting of metastatic germ cell tumors. One hundred ninety-two patients with germ cell tumors of the testes were entered into a study of four cycles of *EP* versus four cycles of EC. There were three relapses with the *EP* regimen versus seven with the EC regimen, although the overall survival of the two groups is identical (426). In view of these results, ***BEP* is the preferred treatment regimen for patients with ovarian germ cell tumors.**

It is unclear whether adjuvant chemotherapy is indicated or required for all patients with resected immature teratomas. Several reports support the successful management of these patients with surgery alone and close surveillance (442,451). In the largest series, an Intergroup study from the Pediatric Oncology Group and the Children's Cancer Group, 73 children with immature teratoma (44 of ovarian origin) underwent surgery followed by surveillance. With a median follow-up of 35 months, the overall 3-year event-free survival rates for all patients and those with ovarian teratomas were 93% and 100%, respectively. Thirteen of the 44 girls with an immature ovarian teratoma had microscopic foci of yolk sac tumor in the teratoma; one developed recurrent disease and was successfully treated with *cisplatin*-based chemotherapy. Eighty-two percent of the tumors were grade 1 or 2; however, 92% of those with foci of yolk sac tumor were grade 2 or 3.

Second-Look Laparotomy or Laparoscopy

Second-look operation is not justified in patients who received adjuvant chemotherapy, because chemotherapy in these patients is effective (431,432). In the absence of any residual disease, there is no indication for second-look laparotomy or laparoscopy. In patients with radiographic evidence of residual tumor after surgery and chemotherapy, this may represent residual germ cell tumor, benign teratoma or more commonly, necrotic tissue in a patient whose tumor markers have normalized.

Second-look laparotomy or laparoscopy in patients with macroscopic residual disease at the start of chemotherapy should be considered, as patients with residual mature teratoma and are at risk of growing teratoma syndrome, an uncommon complication of immature teratomas (452,453). Cancers can arise at a later date in

residual mature teratoma. It is important to resect or biopsy any residual mass and exclude persistent disease because further chemotherapy may be indicated. The principles of surgery are based on the much larger experience of surgery in males with residual masses following chemotherapy for germ cell tumors with a component of immature teratoma (454). Mathew et al. reported their experience of laparotomy in assessing the nature of postchemotherapy residue in ovarian germ cell tumors. Sixty-eight patients completed combination chemotherapy with *cisplatin* regimes, and 35 had radiologic residual masses. Twenty-nine of these 35 patients underwent laparotomy and 3 patients had viable tumor, 7 immature teratomas, 3 mature teratoma, and 16 necrosis or fibrosis. None of the patients with dysgerminoma, embryonal carcinoma, absence of teratoma element in the primary tumor, and radiologic residual mass of less than 5 cm had viable tumor, whereas all patients with tumors containing the teratoma component initially had residual tumor, strengthening the case for surgery in patients with immature teratoma and any residual mass (455,456).

Prognosis

The most important prognostic feature of the immature teratoma is the grade (2,423). The stage of disease and the extent of tumor at the initiation of treatment have an impact on the curability of the lesion. Overall, the 5-year survival rate for patients with all stages of pure immature teratomas is 70% to 80%, and it is 90% to 95% for patients with surgically staged, stage I lesions (430,433,457).

Endodermal Sinus Tumors

[12] Endodermal sinus tumors (EST) are also referred to as *yolk sac carcinomas* because they are derived from the primitive yolk sac (2,4). **They are the third most frequent malignant germ cell tumors of the ovary.** ESTs occur in patients with a median age of 16 to 18 years (2,4,458). About one-third of the patients are premenarcheal at the time of diagnosis. Abdominal or pelvic pain is the most frequent initial symptom, occurring in about 75% of patients, whereas an asymptomatic pelvic mass is documented in 10% of patients (396).

Pathology

The gross appearance of an EST is soft grayish-brown. Cystic areas caused by degeneration or necrosis are present in these rapidly growing lesions. The capsule is intact in most cases.

The EST is unilateral in 100% of cases; thus, biopsy of the opposite ovary is contraindicated. The association of such lesions with gonadal dysgenesis must be appreciated, and chromosomal analysis should be performed preoperatively in premenarcheal patients (4).

Microscopically, the characteristic feature is the endodermal sinus, or the *Schiller–Duval body* (Fig. 39-22). The cystic space is lined with a layer of flattened or

irregular endothelium into which projects a glomerulus-like tuft with a central vascular core. These structures vary throughout the tumor, and the reticular, myxoid elements simulate undifferentiated mesoblast. The lining of the papillary infolding and the cavity is irregular, with an occasional cell containing clear, glassy cytoplasm, simulating the hobnail appearance of the epithelium in clear cell tumors. There is a possible association of EST with dysgerminoma in mixed germ cell tumors (2,4).

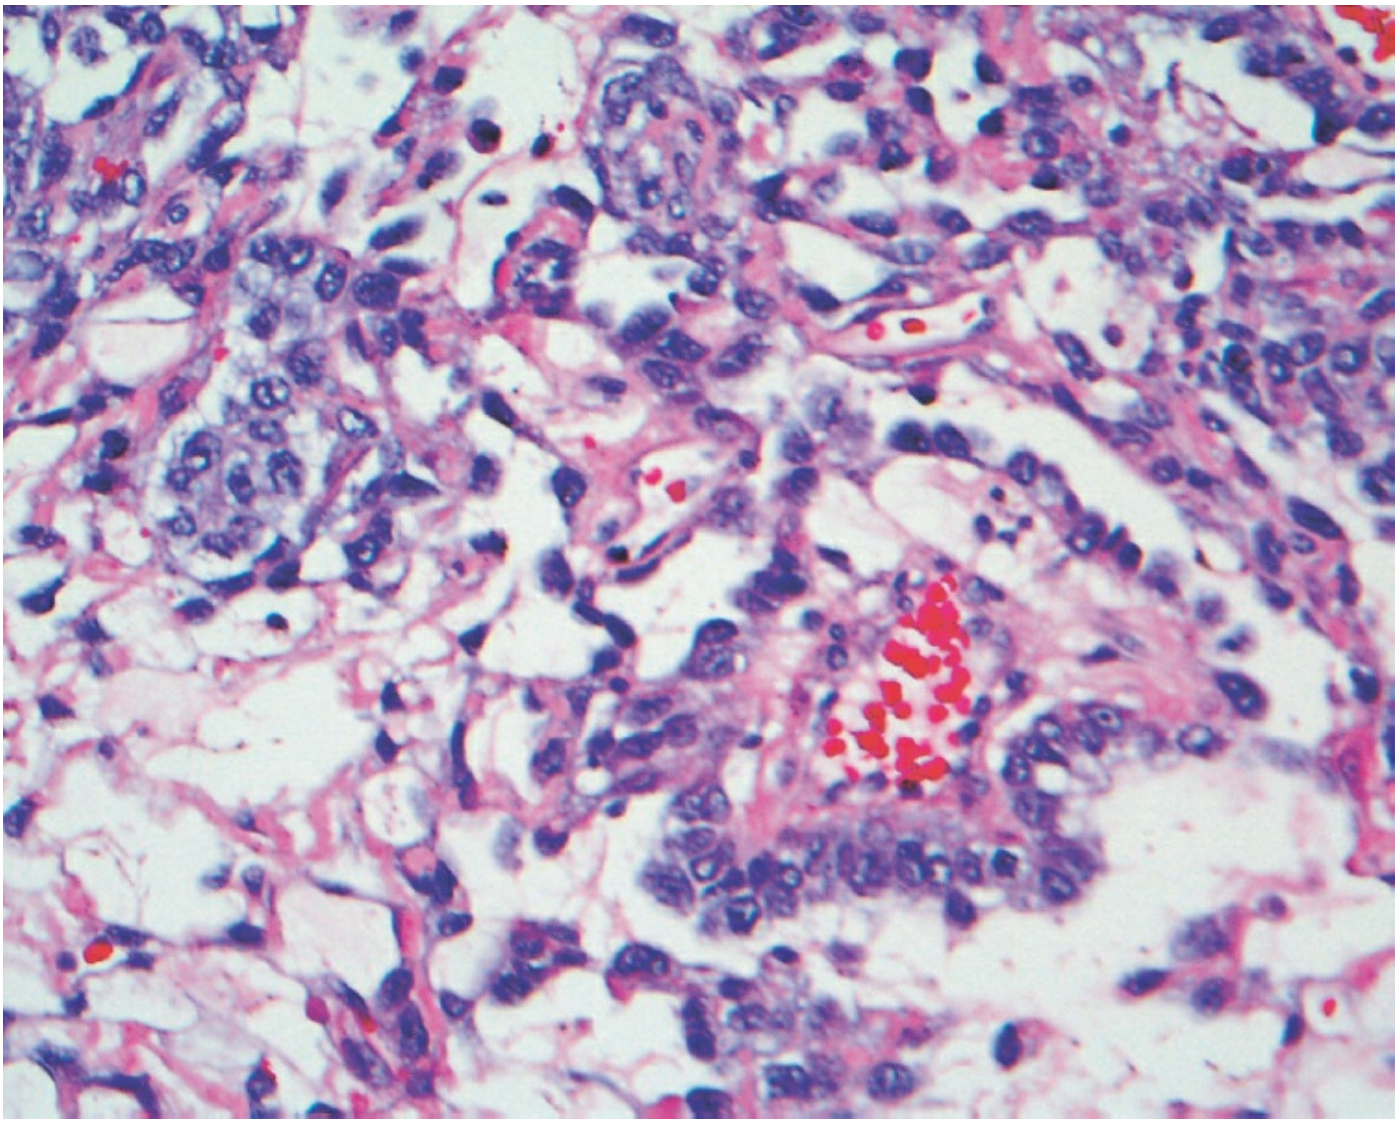

FIGURE 39-22 Yolk sac tumor of the ovary. Note the classic Schiller–Duval body with its central vessel and mantle of endoderm.

Most EST secrete AFP and, rarely, alpha-1 antitrypsin (AAT). AFP can be demonstrated in the tumor by immunohistochemistry. There is a good correlation between the extent of disease and the level of AFP, although discordance can occur. The serum level of these markers, particularly AFP, is useful in monitoring the patient's response to treatment (458–462).

Treatment

Surgery

The treatment of the EST consists of surgical exploration, unilateral salpingo-oophorectomy, and a frozen section for diagnosis. The addition of a hysterectomy and contralateral salpingo-oophorectomy does not alter the outcome and is not indicated (460). Any gross metastases should be removed, if possible, but thorough surgical staging may be omitted because all patients need chemotherapy. At surgery, the tumors tend to be solid and large, ranging in size from 7 to 28 cm (median, 15 cm) in the GOG series (449). Bilaterality does not occur, and the other ovary is involved with metastatic disease only when there are other metastases in the peritoneal cavity. Most patients have early-stage disease: 71%, stage I; 6%, stage II; and 23%, stage III (462).

Chemotherapy

All patients with ESTs are treated with either adjuvant or therapeutic chemotherapy. Before the routine use of combination chemotherapy for this disease, the 2-year survival rate was only about 25%. The introduction of the *VAC* regimen, improved survival rates to 60% to 70%, indicating the chemosensitivity of most of these tumors (444,445). With conservative surgery and adjuvant chemotherapy, fertility can be preserved as with other germ cell tumors.

***Cisplatin*-containing combination chemotherapy with three to four cycles of *BEP* should be used as primary chemotherapy for EST.** The GOG protocols used three to four treatment cycles given every 3 weeks (449,463). The number of cycles is dependent on prognostic factors including whether there is bulky residual disease after surgery and the site of metastases.

Rare Germ Cell Tumors of the Ovary

Embryonal Carcinoma

[12] Embryonal carcinoma of the ovary is an extremely rare tumor that is distinguished from a choriocarcinoma of the ovary by the absence of syncytiotrophoblastic and cytotrophoblastic cells. The patients are very young; ages ranged between 4 and 28 years (median, 14 years) in two series (464). Older patients were reported (465). Embryonal carcinomas may secrete estrogen, with the patient exhibiting symptoms and signs of precocious pseudopuberty or irregular bleeding (2). The clinical picture is otherwise similar to that of the EST. The primary lesions tend to be large, and about two-thirds are confined to one ovary at the time of diagnosis. These lesions frequently secrete AFP and hCG, which are useful for following the response to subsequent therapy (461). **The treatment of embryonal carcinomas is the same as for the EST (i.e., a unilateral oophorectomy followed by combination chemotherapy with *BEP*)** (413,449).

Choriocarcinoma of the Ovary

Pure nongestational choriocarcinoma of the ovary is an extremely rare tumor. Histologically, it has the same appearance as gestational choriocarcinoma metastatic to the ovaries (466). Most patients with this cancer are younger than 20 years. The presence of hCG can be useful in monitoring the patient's response to treatment. **In the presence of high hCG levels, isosexual precocity occurs in about 50% of patients whose lesions appear before menarche** (466,467).

There are only limited reports on the use of chemotherapy for nongestational choriocarcinomas, but complete responses were reported with the *MAC* (*methotrexate*, *actinomycin D*, and *cyclophosphamide*) regimen used in a manner described for gestational trophoblastic disease (see Chapter 41) (435). Alternatively, the *BEP* regimen can be used. The prognosis of ovarian choriocarcinomas is poor, with most patients having metastases to organ parenchyma at the time of diagnosis.

Polyembryoma

Polyembryoma of the ovary is another extremely rare tumor, which is composed of embryoid bodies. This tumor replicates the structures of early embryonic differentiation (i.e., the three somatic layers: endoderm, mesoderm, and ectoderm) (2,399). They tend to occur in very young, premenarcheal girls with signs of pseudopuberty and elevated AFP and hCG levels. The same principles of management apply (399,468).

Mixed Germ Cell Tumors

Mixed germ cell malignancies of the ovary contain two or more elements of the lesions described above. In one series, the most common component of a mixed malignancy was dysgerminoma, which occurred in 80%, followed by EST in 70%, immature teratoma in 53%, choriocarcinoma in 20%, and embryonal carcinoma in 16% (468). **The most frequent combination is a dysgerminoma and an EST. The mixed germ cell tumors may secrete either AFP, hCG, both, or neither of these markers, depending on the components.**

These tumors should be managed with *BEP* combination chemotherapy. The serum marker, if positive initially, may become negative during chemotherapy, but this finding may reflect regression of only a particular component of the mixed lesion.

The most important prognostic features are the size of the primary tumor and the relative size of its most malignant component (469). For stage IA tumors smaller than 10 cm, survival is 100%. Tumors composed of less than one-third EST, choriocarcinoma, or grade 3, immature teratoma have an excellent prognosis, but it is less favorable when these components constitute most of the mixed lesions.

Late Effects of Treatment of Malignant Germ Cell Tumors of the Ovary

Although there are substantial data regarding late effects of *cisplatin*-based therapy in men with testicular cancer, there is much less information available for women with

ovarian germ cell tumors. However, it is likely that the late effects will be similar to men treated with BEP and include renal and gonadal dysfunction, neurotoxicity, cardiovascular toxicity, and secondary malignancies.

Gonadal Function

An important cause of infertility in patients with ovarian germ cell tumors is unnecessary bilateral salpingo-oophorectomy and hysterectomy. **Although temporary ovarian dysfunction or failure is common with *platinum*-based chemotherapy, most women will resume normal ovarian function, and childbearing is usually preserved** (402,408). In one representative series of 47 patients treated with combination chemotherapy for germ cell malignancies, 91.5% resumed normal menstrual function, and there were 14 healthy live births and no birth defects (423). Factors such as older age at the initiation of chemotherapy, greater cumulative drug dose, and longer duration of therapy all have an adverse effect on future gonadal function.

Secondary Malignancies

An important cause of late morbidity and mortality in patients receiving chemotherapy for germ cell tumors is the development of secondary tumors. ***Etoposide* in particular was implicated in the development of treatment-related leukemias** (470,471).

The chance of developing treatment-related leukemia following *etoposide* is dose related. **The incidence of leukemia is approximately 0.4% to 0.5%** (representing a 30-fold increased likelihood) in patients receiving a cumulative *etoposide* dose of less than 2,000 mg/m^2, compared with as much as 5% (representing a 336-fold increased likelihood) in those receiving more than 2,000 mg/m^2 (470). In a typical three- or four-cycle course of *BEP*, patients receive a cumulative *etoposide* dose of 1,500 or 2,000 mg/m^2, respectively.

Despite the risk of secondary leukemia, risk–benefit analyses concluded that *etoposide*-containing chemotherapy regimens are beneficial in advanced germ cell tumors; one case of treatment-induced leukemia would be expected for every 20 additionally cured patients who receive *BEP* as compared with *platinum, vincristine, bleomycin* (*PVB*). The risk–benefit balance for low-risk disease, or for high-dose *etoposide* in the recurrence setting, is less clear (471–473).

Surveillance Versus Immediate Adjuvant Chemotherapy in Stage I Germ Cell Tumors

Close surveillance is a well-accepted and standard approach to the management of young men with apparent stage I testicular germ cell tumors. There is a large body of evidence to support this approach, and guidelines on surveillance protocols (474). **Although as many as 20% to 30% of patients will relapse, almost all will be cured using second-line chemotherapy with *BEP*,** and the potential adverse effects of chemotherapy can therefore be avoided in most patients. Although this is a very common

approach to management of young men with stage I testicular germ cell tumors, it has not been widely adopted in females with ovarian germ cell tumors in the United States. In the United Kingdom, all women with stage IA malignant ovarian germ cell tumors are offered surveillance regardless of histologic subtype. However, prior to making this recommendation there is close scrutiny of operative findings, central pathologic review, measurement of tumor markers, and whole-body imaging to ensure that the staging is correct. Surveillance includes regular clinical review, physical examination, interval imaging, and tumor marker assessments (hCG, AFP, and LDH). The frequency of surveillance with tumor marker monitoring is highest early on, as most relapses occur within 2 years.

The Charing Cross Group initially reported a prospective study of 24 patients with stage IA ovarian germ cell tumors who were also enrolled in a surveillance program. The group consisted of nine patients (37.5%) with dysgerminoma, nine (37.5%) with pure immature teratoma, and six (25%) with EST (with or without immature teratoma). Treatment consisted of surgical resection without adjuvant chemotherapy, followed by a surveillance program of clinical, serologic, and radiologic review. A second-look operation was performed, and **all patients, but one, were alive and in remission after a median follow-up of 6.8 years.** The 5-year overall survival was 95%, and the 5-year disease-free survival was 68%. Eight patients required chemotherapy for recurrent disease or second primary ovarian germ cell tumor. This included three patients with grade II immature teratoma, three patients with dysgerminoma, and two patients with dysgerminoma who developed a contralateral dysgerminoma 4.5 and 5.2 years after their first tumor. All but one, who died of a pulmonary embolus, were successfully salvaged with chemotherapy. The same group updated its experience and reported on the safety of the ongoing surveillance program of all stage IA female germ cell tumors (474). Thirty-seven patients (median age 26, range 14 to 48 years) with stage I disease were referred to Mount Vernon and Charing Cross Hospitals between 1981 and 2003. Patients underwent surgery and staging followed by intense surveillance, which included regular tumor markers and imaging. The median period of follow-up was 6 years. **Relapse rates for stage IA nondysgerminomatous tumors and dysgerminomas were 8 of 22 (36%) and 2 of 9 (22%), respectively.** In addition, one patient with mature teratoma and glial implants relapsed. Ten of these 11 patients (91%) were successfully cured with platinum-based chemotherapy. Only one patient died from chemoresistant disease. **All relapses occurred within 13 months of initial surgery.** The overall disease-specific survival of malignant ovarian germ cell tumors was 94%. If this approach is considered, then the Charing Cross surveillance protocol should be followed.

Sex Cord–Stromal Tumors

Sex cord–stromal tumors of the ovary account for about 5% to 8% of all ovarian malignancies (2,4,395,396,475–481). This group of ovarian neoplasms is derived from the sex cords and the ovarian stroma or mesenchyme. The tumors usually are composed of various combinations of elements, including the "female" cells (i.e., granulosa and theca cells) and "male" cells (i.e., Sertoli and Leydig cells), and morphologically indifferent cells. A classification of this group of tumors is presented in Table 39-8.

Granulosa–Stromal Cell Tumors

[13] Granulosa cell tumors are the most common type of malignant ovarian sex cord–stromal tumor and make up 2% to 5% of all ovarian malignancies Granulosa–stromal cell tumors include granulosa cell tumors, thecomas, and fibromas. They account for 70% of ovarian sex cord–stromal tumors. Granulosa cell tumors are considered to be a low-grade malignancy.

The majority of granulosa cell tumors are adult (95%) with juvenile granulosa cell tumors being much less common (5%). Adult granulosa cell tumors almost always occur in postmenopausal women while juvenile granulosa cell tumors are diagnosed in women under 30 years of age and may be seen in prepubertal girls in 5% of cases (478). **[13]** Granulosa cell tumors are bilateral in only 2% of patients (482).

C. Poorly differentiated (sarcomatoid)
D. With heterologous elements

3. Gynandroblastoma
4. Sex cord tumor with annular tubules
5. Sex cord–stromal tumors, unclassified
6. Steroid cell tumors
A. Stromal luteoma
B. Leydig cell tumor
C. Steroid cell tumor, not otherwise classified

Pathology

Granulosa cell tumors range from a few millimeters to 20 cm or more in diameter. **The tumors are rarely bilateral** and have a smooth, lobulated surface. The solid portions of the tumor are granular, frequently trabeculated, and yellow or gray-yellow in color. After clear cell carcinoma, the granulosa-theca cell tumor is probably the most inaccurately diagnosed tumor of the female gonad. Of 477 ovarian tumors from the Emil Novak Ovarian Tumor Registry diagnosed initially as granulosa-theca cell tumors, almost 15% were reclassified after histologic review. The FOXL2 gene is mutated in almost all adult granulosa cell tumors. It plays a role in the development of normal granulosa cells and mutations in this gene have been found in up to 97% of adult granulomas cell tumors. Molecular testing for mutations in the FOXL2 gene may help to improve the diagnostic accuracy among patients with sex cord–stromal tumors (483,484). Tumors misdiagnosed as granulosa cell tumors included primary or metastatic carcinomas, teratoid tumors, and poorly differentiated mesothelial tumors (475). A Norwegian study found that almost 30% of adult granulosa cell tumors had been misdiagnosed after reviewing the pathology and testing for FOXL2 mutations, which raises questions about the reliability of historical series.

Juvenile granulosa cell tumors, so named because of their tendency to occur in younger patients, feature rounder, more hyperchromatic nuclei, and may contain numerous mitotic figures. The presence of large, irregular follicle spaces is an additional distinguishing feature of the juvenile granulosa cell tumor.

The classic adult granulosa cell is round or ovoid with scant cytoplasm. The nucleus contains compact, finely granular chromatin and is either euchromatic or hypochromatic (4). Better-differentiated granulosa cell tumors may have a variety of patterns including macrofollicular, microfollicular, trabecular, solid-trabecular, and insular while less-differentiated tumors have a more diffuse pattern described as sarcomatoid. “Coffee bean” grooved nuclei are characteristic; mitotic figures may be present, but numerous mitotic figures should prompt consideration for poorly differentiated or undifferentiated carcinoma. **In the most common variety, the adult granulosa cells show a tendency to arrange themselves in small clusters or rosettes around a central cavity, so there**

is a resemblance to primordial follicles (i.e., *Call–Exner bodies*) (Fig. 39-23). The stroma is similar to the theca and may be luteinized. In children and adolescents, the granulosa cell tumors are often cystic, contain luteinized cells, and can be associated with precocious puberty. The adult granulosa cell tumor tends to occur in older women and the juvenile tumor in children and young women, with the diagnosis not being based on age of presentation, but on histology. Adult granulosa cell tumors, but not juvenile granulose cell tumors, harbor a somatic mutation in the *FOXL2* gene (483).

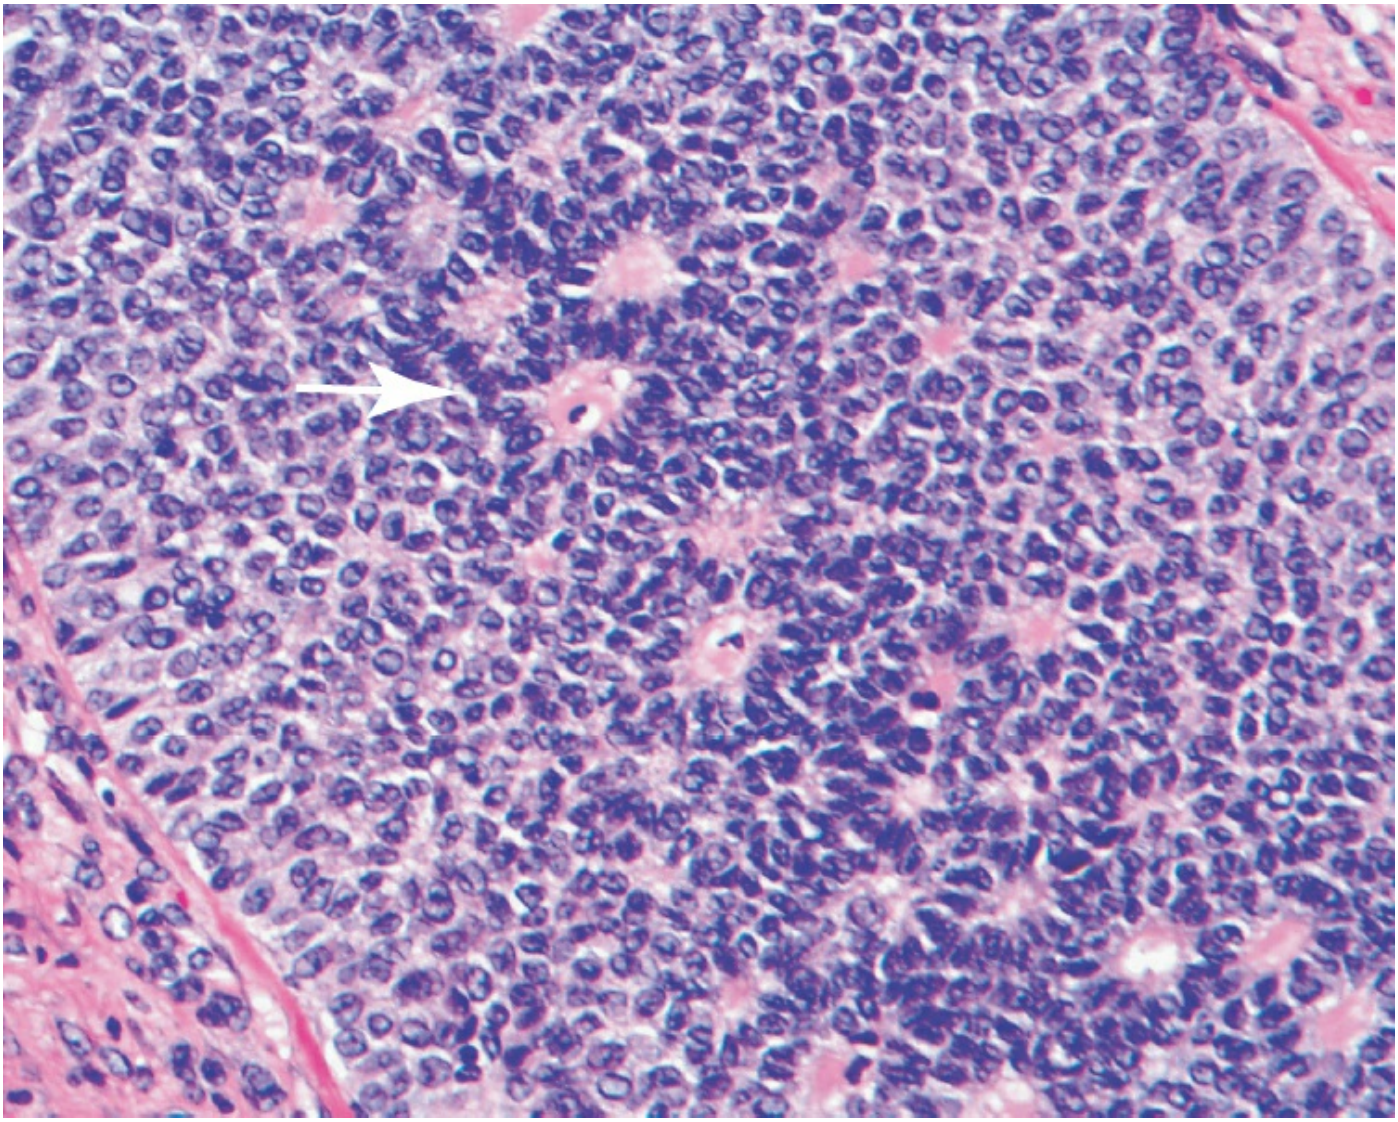

FIGURE 39-23 Granulosa cell tumor of the ovary. Note the classic Call–Exner bodies with a minimal stromal component in this tumor of folliculoid pattern (*arrow* points to an example).

Diagnosis

About 70% of granulosa cell tumors secrete estrogen or androgens.

Inhibin is secreted by some adult granulosa cell tumors and is a useful marker for the disease (485–489). Inhibin is a peptide hormone that is produced by granulosa cells

and plays a role in regulation of FSH secretion. **Inhibin exists in two different isoforms: inhibin A and inhibin B. Although some laboratories only perform testing for inhibin A, serum levels of inhibin B are more frequently elevated** (490).

Inhibin levels can be used to monitor patients during follow-up or to assess response to treatment. The lead-time between inhibin levels rising and documented recurrence is about 12 months.

An elevated serum inhibin level in a premenopausal woman presenting with amenorrhea and infertility is suggestive of a granulosa cell tumor (491). Seventy-five percent of women with AGCT's also have an elevated anti-müllerian hormone preoperatively and AMH has a >90% sensitivity in detecting recurrence.

Juvenile Granulosa Cell Tumors

Juvenile granulosa cell tumors of the ovary are rare and constitute less than 5% of ovarian tumors in childhood and adolescence (492). Most juvenile granulosa cell tumors are clinically benign; only about 10% recur and when they do, it is generally within 5 years of the initial diagnosis. **Of the rare prepubertal juvenile GCTs, 75% are associated with sexual pseudoprecocity because of the estrogen secretion** (477).

About 90% are diagnosed in stage I, and they have a favorable prognosis. The juvenile subtype behaves less aggressively than the adult type. Only about 10% of juvenile granulosa cell tumors are malignant and late relapse is unusual. Advanced-stage tumors can be treated with *platinum*-based combination chemotherapy (e.g., *BEP*) (493,494).

Adult Granulosa Cell Tumors

Low-grade endometrial cancer occurs in association with adult granulosa cell tumors in at least 5% of cases, and 25% to 50% are associated with endometrial hyperplasia (2,466,475–478,483). Most reproductive-age patients have menstrual irregularities or secondary amenorrhea, and, frequently, cystic hyperplasia of the endometrium. Abnormal uterine bleeding is often the initial symptom for postmenopausal women. The estrogen secretion in these patients can be sufficient to stimulate the development of endometrial cancer.

The other symptoms and signs of granulosa cell tumors are nonspecific and the same as most ovarian malignancies. Ascites is present in about 10% of cases, and, rarely, a pleural effusion is present (475–478). Granulosa tumors tend to be hemorrhagic; occasionally, they rupture and produce a hemoperitoneum.

Adult granulosa cell tumors are stage I at diagnosis in 90% of patients and are associated with a very good prognosis, but may recur 5 to 30 years after initial diagnosis (477). The tumors may spread hematogenously, and metastases can develop in the lungs, liver, and brain years after initial diagnosis. Malignant thecomas are

extremely rare, and their signs and symptoms, management, and outcome are similar to those of the granulosa cell tumors (475).

Treatment

The treatment of granulosa cell tumors depends on the age of the patient and the extent of disease. For most patients, surgery alone is sufficient primary therapy; radiation and chemotherapy are reserved for the treatment of recurrent or metastatic disease (478–481,483,485–487,492,495–497).

Surgery

Because granulosa cell tumors are bilateral in only about 2% of patients, a unilateral salpingo-oophorectomy is appropriate therapy for stage IA tumors in children or in women of reproductive age (476). At the time of laparotomy or laparoscopy, if a granulosa cell tumor is identified by frozen section, a staging operation is performed, including an assessment of the contralateral ovary. If the opposite ovary appears enlarged, it should be sampled for biopsy. For perimenopausal and postmenopausal women for whom ovarian preservation is not important, a hysterectomy and bilateral salpingo-oophorectomy should be performed. **For premenopausal patients in whom the uterus is left *in situ*, an endometrial biopsy should be performed because of the possibility of a coexistent adenocarcinoma of the endometrium** (478).

Radiation Therapy

There is no evidence to support the use of adjuvant radiation therapy for granulosa cell tumors, although pelvic irradiation may help to palliate isolated pelvic recurrences (478,495).

Chemotherapy

[13] There is no evidence that adjuvant chemotherapy will prevent recurrence of disease and improve prognosis (497–500). Patients with metastatic disease at initial presentation or with recurrent disease may benefit from chemotherapy. Although the data are inconclusive, *BEP* or *CP* are the most commonly used regimens in selected patients with stage III or IV tumors or recurrent disease (493). In a GOG study, 37% (14 of 30) patients treated with *BEP* had a negative second-look laparotomy, and these patients had a median time to progression of 24.4 months (494). The GOG is performing a randomized phase II trial comparing *BEP* with the combination of paclitaxel and carboplatin for patients with newly diagnosed and chemo-naïve recurrent/metastatic sex cord–stromal tumors of the ovary. Taxanes and *bevacizumab* are active in AGCT's. The Alienor trial has recently completed recruitment and randomized patients with recurrent/metastatic sex cord–stromal tumors to either *paclitaxel* alone or in combination with *bevacizumab* and the results are eagerly awaited. Granulosa cell tumors are potentially hormonally responsive, with about 30% of granulosa tumors

expressing estrogen receptors and almost 100% expressing progesterone receptors. Hormonal agents such as progestins or luteinizing hormone–releasing hormone agonists or aromatase inhibitors have been used to treat these patients (501–505). There are case reports of durable response to aromatase inhibitors in patients with metastatic granulosa cell tumors who received multiple prior treatment (503). Small clinical series and case reports indicated that luteinizing hormone– releasing hormone agonists had a 50% response rate in 13 patients, while 4 of 5 patients in the literature responded to a progestational agent. Two case series reported durable responses in a total of 6 patients receiving aromatase inhibitors among those who progressed on or were intolerant of chemotherapy (502–505). There are fewer than 100 patients reported in the literature who have received hormonal therapies and typically these have been individual case reports or small retrospective series that are subject to bias. The role of hormonal therapy remains uncertain.

Adult granulosa cell tumors have a prolonged natural history and a tendency toward late relapse, reflecting their low-grade biology. Ten-year survival rates of about 90% are reported, with 20-year survival rates dropping to 75% (476–478,491,493). Most histologic types have the same prognosis, but patients with the more poorly differentiated diffuse or sarcomatoid type tend to do worse (475).

The DNA ploidy of the tumors is correlated with survival. Holland et al. reported DNA aneuploidy in 13 of 37 patients (35%) with primary adult granulosa cell tumors (498). The presence of residual disease is the most important predictor of PFS, but DNA ploidy is an independent prognostic factor. **Patients with residual-negative DNA diploid tumors had a 10-year PFS of 96%.**

Sertoli–Leydig Tumors

Sertoli–Leydig tumors occur most frequently in the third and fourth decades of life; 75% of these tumors are seen in women younger than 40 years. These neoplasms are extremely rare and account for less than 0.2% of ovarian cancers (2,506,507). Sertoli–Leydig cell tumors are most frequently low-grade malignancies; a poorly differentiated variety may behave more aggressively **(Fig. 39-24)** (506–508).

The tumors typically produce androgens, and clinical virilization is noted in 70% to 85% of patients (508). Signs of virilization include oligomenorrhea followed by amenorrhea, breast atrophy, acne, hirsutism, clitoromegaly, deepening of the voice, and a receding hairline. Measurement of plasma androgens may reveal elevated testosterone and androstenedione, with normal or slightly elevated dehydroepiandrosterone sulfate (2,509). Rarely, the Sertoli–Leydig tumor is associated with manifestations of estrogenization (i.e., isosexual precocity, irregular or postmenopausal bleeding). Sertoli–Leydig tumors are associated with somatic mutations in the *DICER1* gene (510).

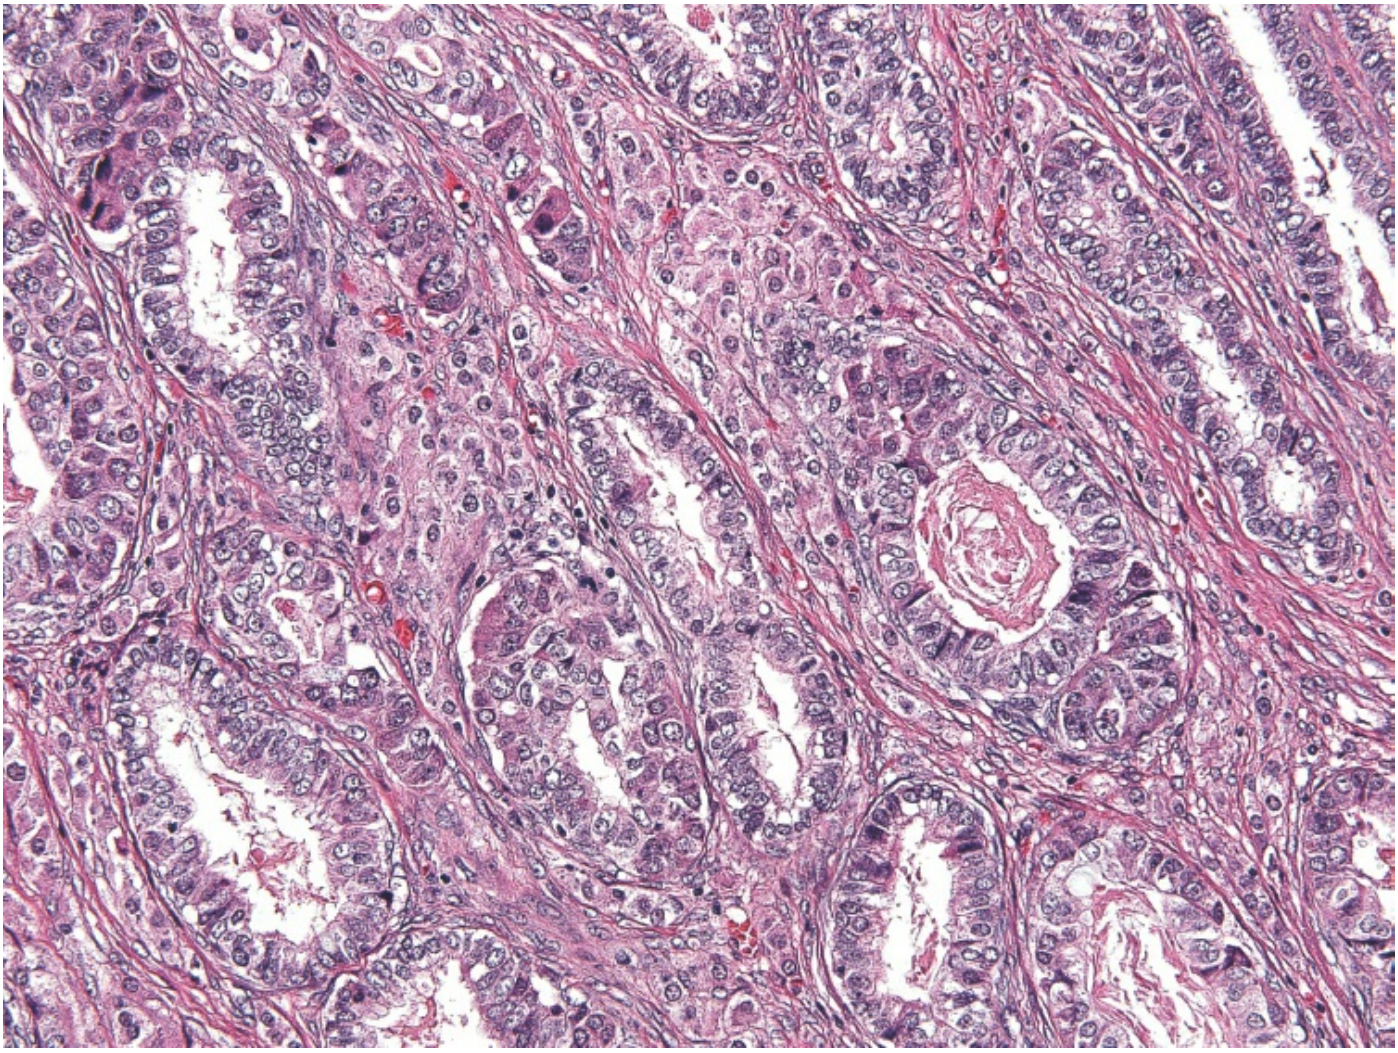

FIGURE 39-24 Sertoli–Leydig cell tumor of the ovary. Note the aggregates of eosinophilic Leydig cells in the stroma adjacent to Sertoli cell tubules.

Treatment

Because these low-grade lesions are rarely bilateral (<1%), the usual treatment is unilateral salpingo-oophorectomy and evaluation of the contralateral ovary for patients who are in their reproductive years (4,478). For older patients, hysterectomy and bilateral salpingo-oophorectomy are appropriate (506,507).

There are insufficient data to document the utility of radiation or chemotherapy for patients with persistent disease, but some responses in patients with measurable disease were reported with pelvic irradiation and the VAC chemotherapy regimen (4,511–515).

Prognosis

The 5-year survival rate is 70% to 90%, and recurrences thereafter are uncommon (4,509,511–515). **Most fatalities occur in the presence of poorly differentiated tumors.**

Uncommon Ovarian Cancers

There are several varieties of malignant ovarian tumors that together constitute only 0.1% of ovarian malignancies (2). Two of these lesions are the lipoid (or lipid) cell tumors and the primary ovarian sarcomas.

Steroid Cell Tumors

Steroid cell tumors account for less than 1% of ovarian neoplasms (2). Most are associated with virilization and, occasionally, with obesity, hypertension, and glucose intolerance, reflecting corticosteroid secretion. Rare cases of estrogen secretion and isosexual precocity have been reported.

Most of these tumors have benign or low-grade behavior, but about 20%, most of which are initially larger than 8 cm in diameter, may metastasize. Metastases are usually in the peritoneal cavity but can occur at distant sites, including the liver. The primary treatment is surgical removal of the ovary. There are no data regarding the effectiveness of radiation or chemotherapy for this disease.

Sarcomas

Carcinosarcomas (malignant mixed mesodermal tumors) of the ovary are uncommon. Clinical, morphologic, and molecular data suggest that they are monoclonal and that both epithelial and mesenchymal components are derived from a single uncommitted, totipotent cell which, after transformation, has proliferated toward separate differentiation lineages. Carcinosarcomas are thought to result from epithelial–mesenchymal transition (EMT) characterized by epithelial plasticity with transdifferentiation toward a mesenchymal cell type. Most tumors are heterologous, and 80% occur in postmenopausal women. The signs and symptoms are similar to those of most ovarian malignancies. These tumors are biologically aggressive, and most patients have evidence of metastases at presentation. They are treated either with *CP* or *ifosfamide* and *cisplatin*, or anthracycline-based combination regimens, but in general have a poor prognosis.

Small Cell Carcinoma, Hypercalcemic Type

This rare tumor occurs at an average age of 24 years (range 2 to 46 years) (516). **The tumors are typically unilateral. Approximately two-thirds of the tumors are accompanied by paraendocrine hypercalcemia.** This tumor accounts for one-half of all of the cases of hypercalcemia associated with ovarian tumors. About 50% of the tumors have spread beyond the ovaries when they are diagnosed (516). Small cell carcinoma, hypercalcemic type is characterized by germline or somatic mutations in *SMARCA4*. Germline and somatic **SMARCA4** mutations characterize **small cell carcinoma** of the ovary, **hypercalcemic** type. Similar mutations have been described in rhabdoid tumors and it has been proposed that small cell ovarian cancers should be

considered to be ovarian rhabdoid tumors and treated as such (517,518).

Immunohistochemical stains are helpful to differentiate this tumor from a lymphoma, leukemia, or sarcoma.

The management of these malignancies consists of surgery followed by *platinum*-based chemotherapy, radiation therapy, or both. It has been suggested that these patients may benefit from aggressive combination chemotherapy regimens that have been used in rhabdoid tumors at other sites. In addition to the primary treatment of the disease, control of the hypercalcemia may require aggressive hydration, loop diuretics, and the use of bisphosphonates or *calcitonin.* The prognosis tends to be poor, with most patients dying within 2 years of diagnosis, in spite of treatment.

METASTATIC TUMORS

[14] About 5% to 6% of ovarian tumors are metastatic from other organs, most frequently from the female genital tract, the breast, or the gastrointestinal tract (519–533). The metastases may occur from direct extension of another pelvic neoplasm, by hematogenous or lymphatic spread, or by transcoelomic dissemination, with surface implantation of tumors that spread in the peritoneal cavity.

Gynecologic

Nonovarian cancers of the genital tract can spread by direct extension or metastasize to the ovaries. Tubal carcinoma involves the ovaries secondarily in 13% of cases, usually by direct extension (2,4). Under some circumstances, it is difficult to know whether the tumor originated in the tube or the ovary, when both are involved. Cervical cancer spreads to the ovary only in rare cases (<1%), and most of these are of an advanced clinical stage or are adenocarcinomas. Adenocarcinoma of the endometrium can spread and implant directly onto the surface of the ovaries in about 5% of cases, but two synchronous primary tumors probably occur with greater frequency (532). In these cases, an endometrioid carcinoma of the ovary is usually associated with the adenocarcinoma of the endometrium.

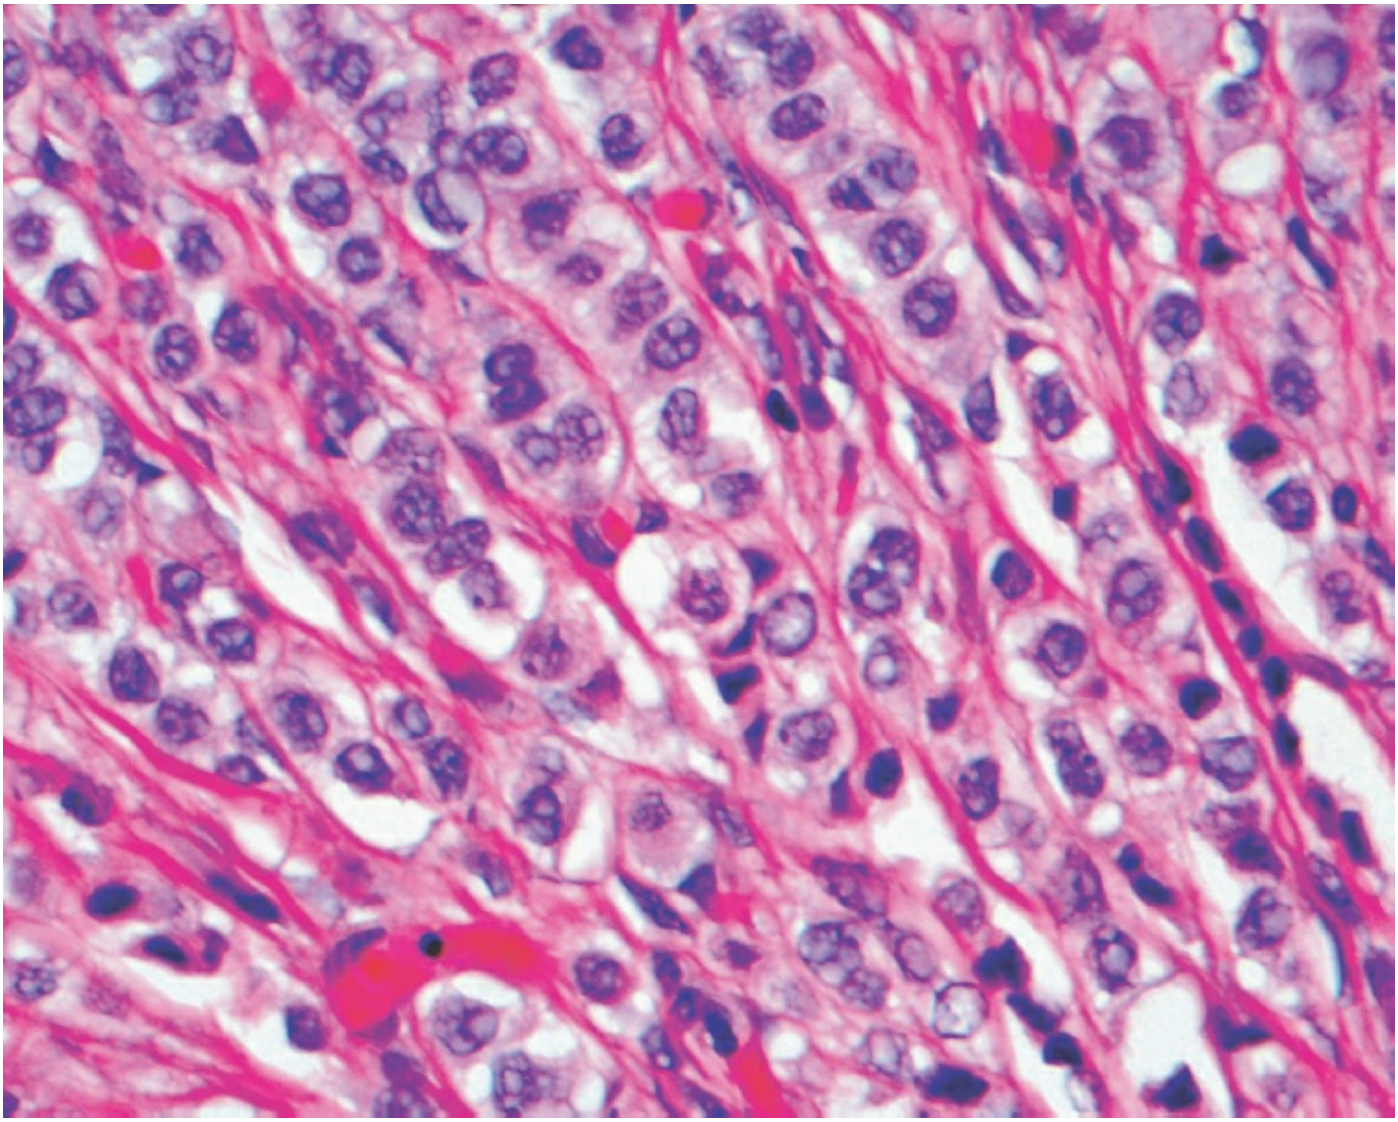

FIGURE 39-25 Metastatic carcinoma in the ovary. Note the linear, single-cell pattern found in this metastatic breast carcinoma.

Nongynecologic

The frequency of metastatic breast carcinoma to the ovaries varies according to the method of determination, but the phenomenon is common (Fig. 39-25). In the autopsy data of women who died of metastatic breast cancer, the ovaries were involved in 24% of cases, and 80% of the involvement was bilateral (519–524). Similarly, when ovaries are removed to palliate advanced breast cancer, about 20% to 30% of the cases reveal ovarian involvement, 60% of those bilaterally. The involvement of ovaries in early-stage breast cancer seems to be considerably lower, but precise figures are not available. In almost all cases, ovarian involvement is occult or a pelvic mass is discovered after other metastatic disease becomes apparent.

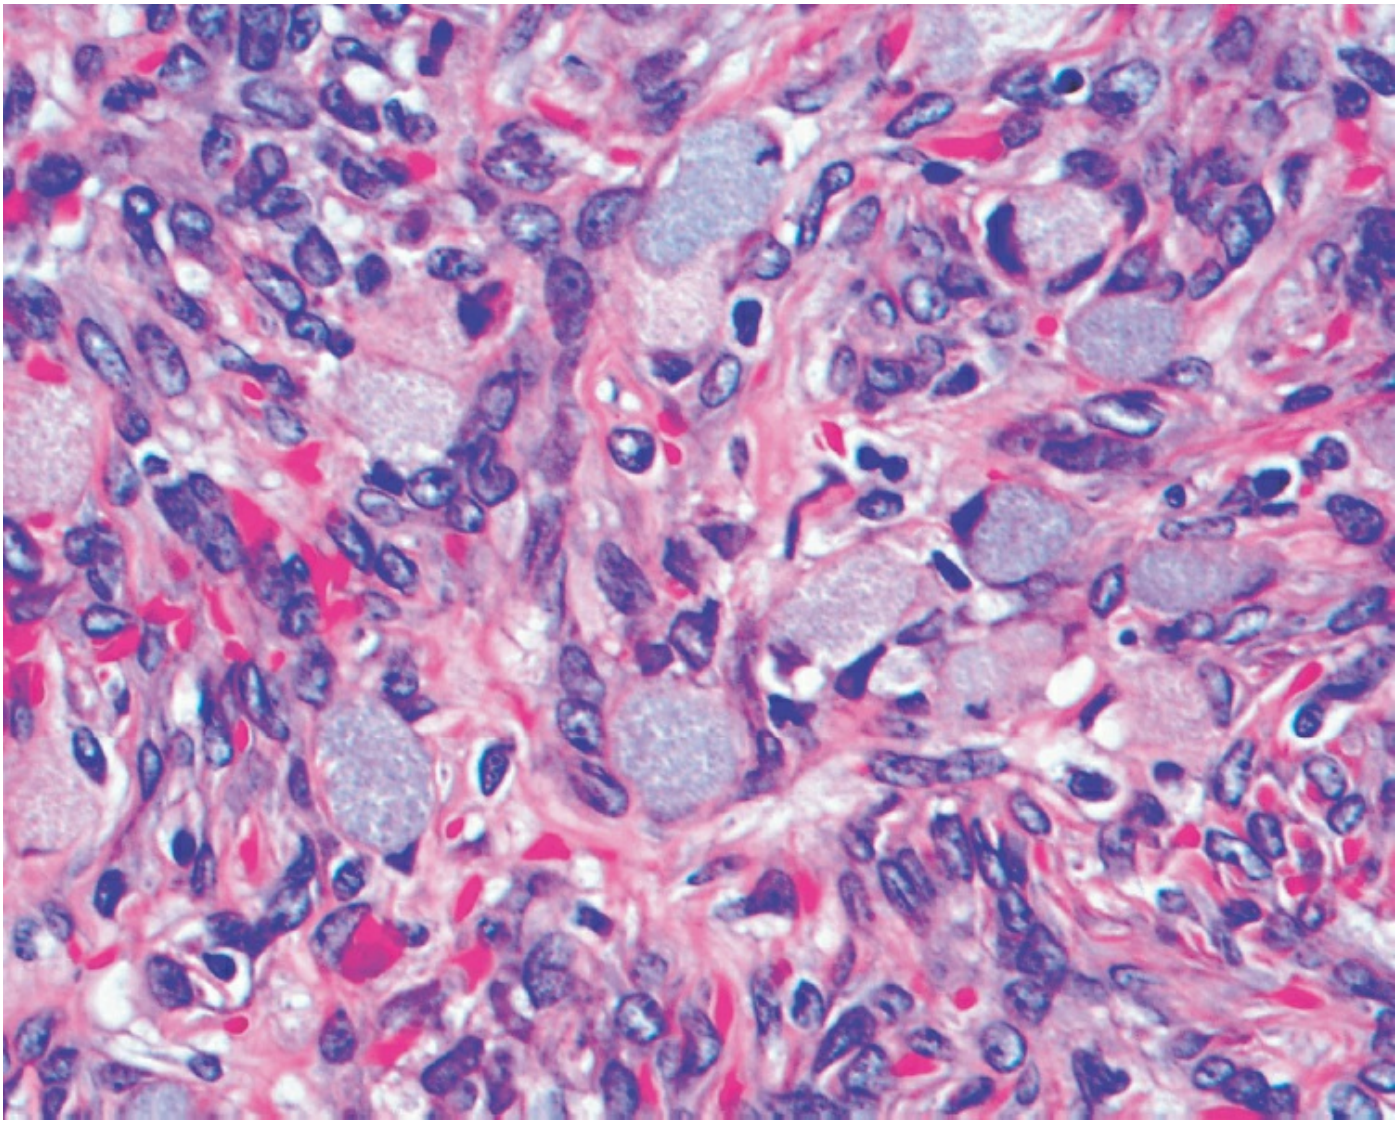

FIGURE 39-26 Krukenberg tumor of the ovary metastatic from a gastric carcinoma. Malignant cells have discrete vacuoles that push nuclei eccentrically, giving a signet-ring appearance. Mucicarmine stain demonstrates the cytoplasmic vacuoles to be mucin.

Krukenberg Tumor

Krukenberg tumors are characterized by mucin-filled signet ring cells and make up 30% to 40% of metastatic cancers to the ovaries (Fig. 39-26) (525,526,534). The primary tumor is frequently located in the stomach and less commonly in the colon, appendix (the so-called goblet cell carcinoid), breast, or biliary tract. Rarely, the cervix or the bladder may be the primary site. Krukenberg tumors can account for about 2% of ovarian cancers, and they are usually bilateral. They are associated with a very poor prognosis and most patients die of their disease within 1 year. In some cases, a primary tumor is never found.

Other Gastrointestinal Tumors

In other cases of metastasis from the gastrointestinal tract to the ovary, the tumor

does not have the classic histologic appearance of a Krukenberg tumor; most of these are from the colon and, less commonly, the pancreatobiliary tract, appendix, and small intestine (Fig. 39-27). As many as 1% to 2% of women with intestinal carcinomas will develop metastases to the ovaries during the course of their disease (521). Before exploration for an adnexal tumor in a woman older than 40 years, a barium enema or colonoscopy is recommended to exclude a primary gastrointestinal carcinoma with metastases to the ovaries, if there are any gastrointestinal symptoms. Metastatic colon cancer can mimic a mucinous cystadenocarcinoma of the ovary histologically, and the histologic distinction between the two can be difficult (520,521,526–530). Tumors that arise in the appendix may be associated with ovarian metastasis and can be confused with primary ovarian mucinous cancer. Pseudomyxoma peritonei almost always is associated with an appendiceal primary and the appendix should always be resected at surgery and carefully examined pathologically (526,530).

Melanoma

Rare cases of malignant melanoma metastatic to the ovaries have been reported (533). In these circumstances, the melanomas are usually widely disseminated. Removal would be warranted for palliation of abdominal or pelvic pain, bleeding, or torsion. Malignant melanoma can arise, rarely, in a mature cystic teratoma (535).

Carcinoid Tumors

Metastatic carcinoid tumors represent fewer than 2% of metastatic lesions to the ovaries (536). Only about 2% of patients with primary carcinoids have evidence of ovarian metastasis, and only 40% of them have the carcinoid syndrome at the discovery of the metastatic carcinoid. In perimenopausal and postmenopausal women explored for an intestinal carcinoid, it is reasonable to remove the ovaries to prevent subsequent ovarian metastasis. The discovery of an ovarian carcinoid should prompt a careful search for a primary intestinal lesion (537).

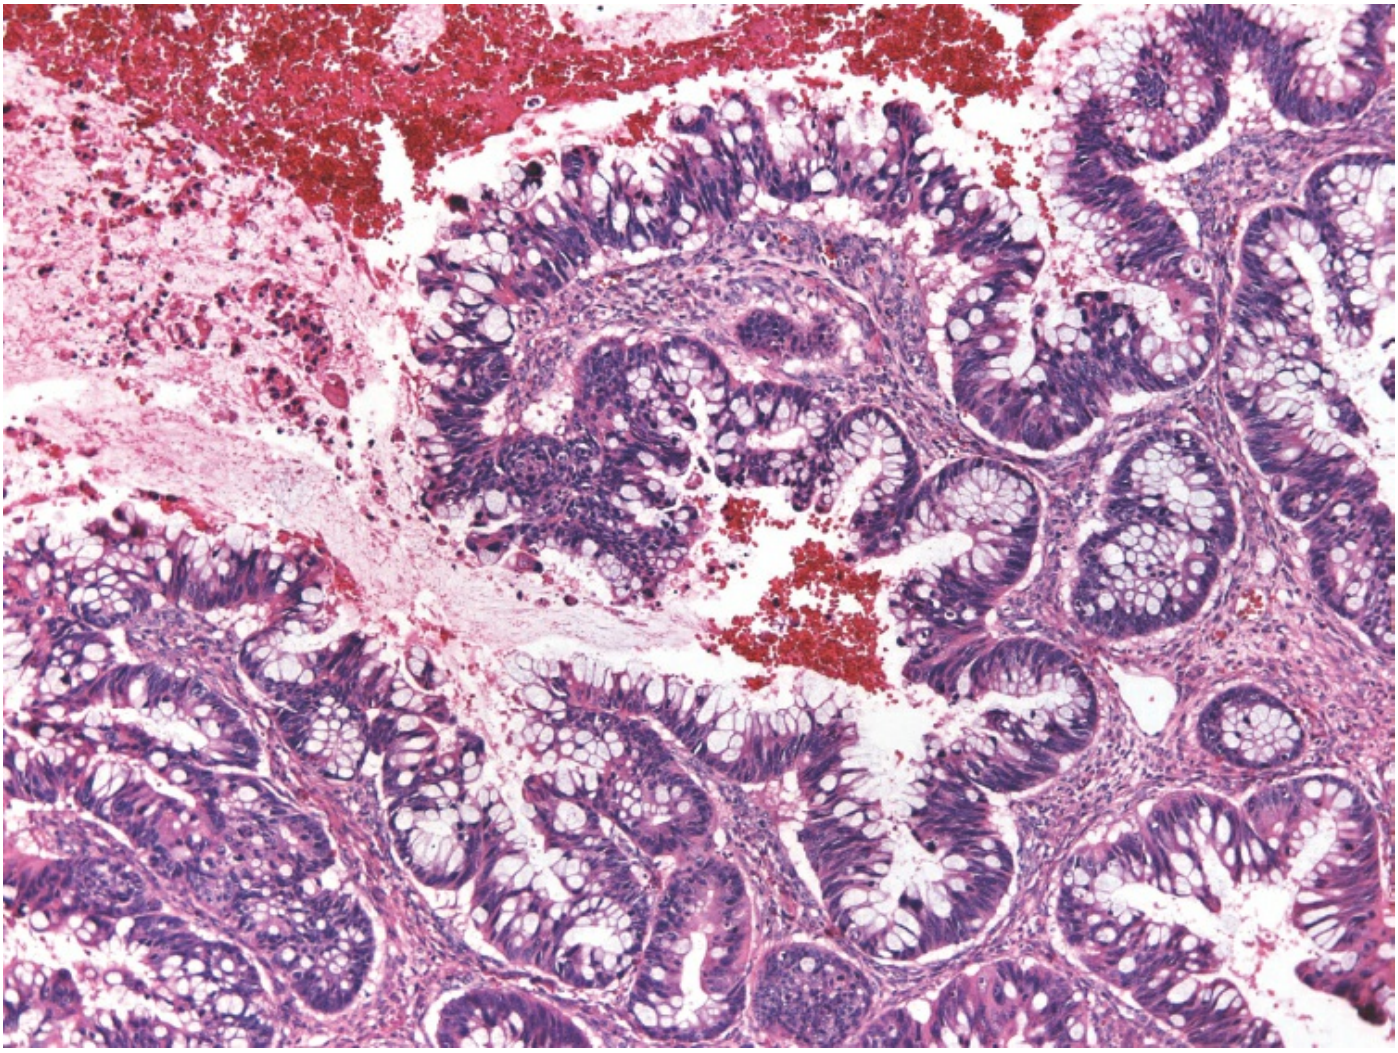

FIGURE 39-27 Metastatic colorectal carcinoma in the ovary often has areas of necrotic debris (so-called dirty necrosis) adjacent to partial gland structures showing a cribriform pattern.

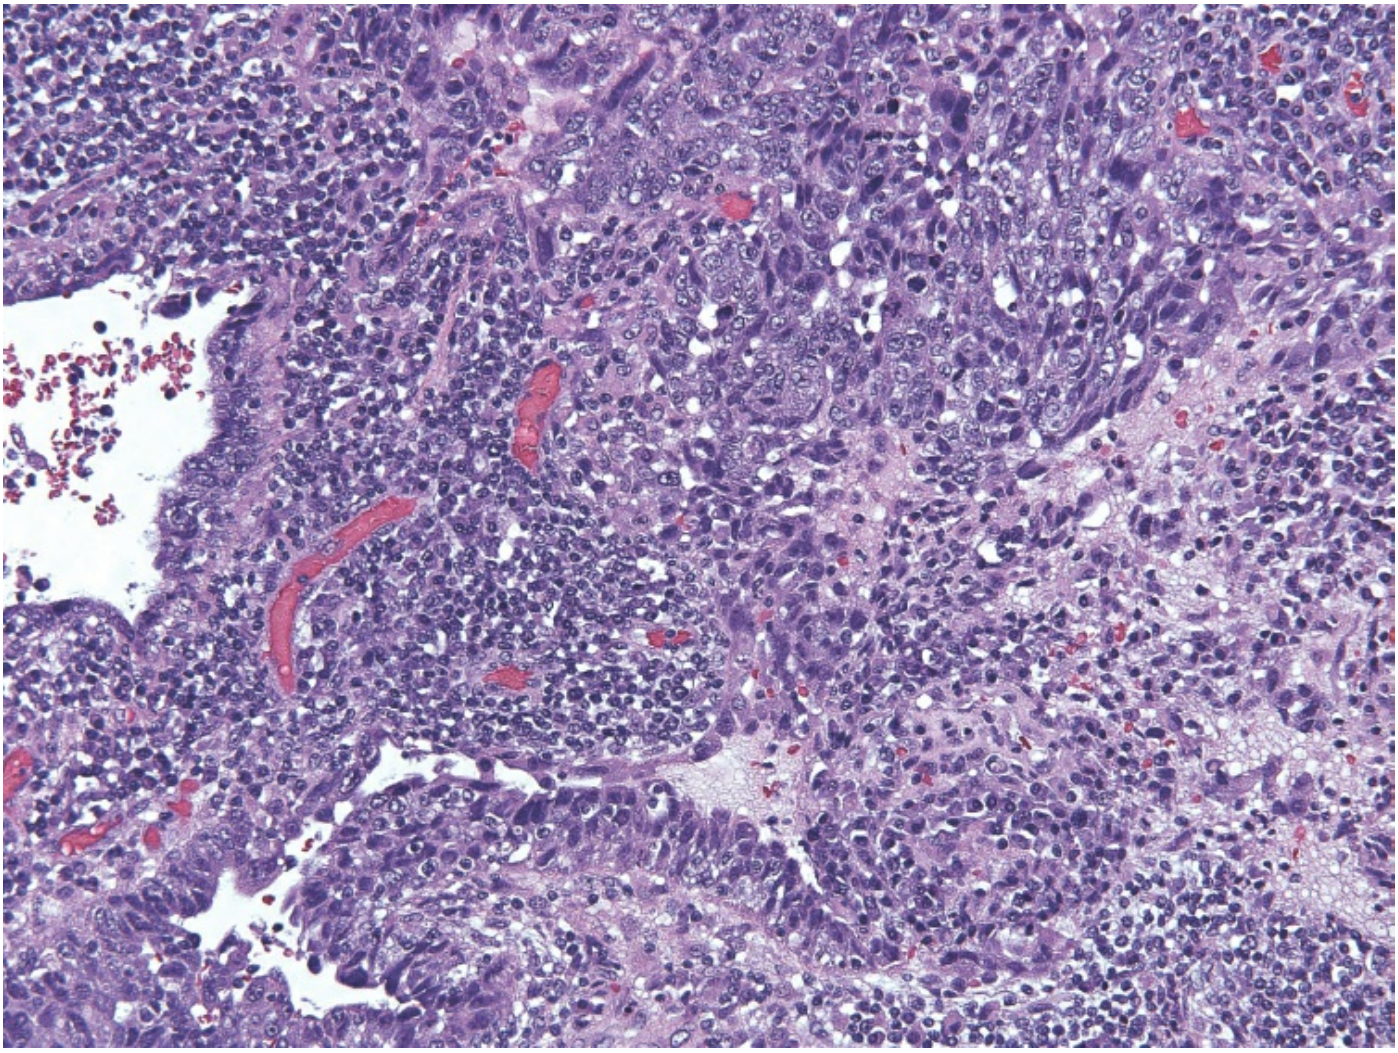

FIGURE 37-28 Carcinoma of the fallopian tube. This is a high-grade serous carcinoma that has invaded the lamina propria of the tubal mucosa. Most primary fallopian tube carcinomas arise in the distal (fimbria) portion of the fallopian tube.

Lymphoma and Leukemia

Lymphomas and leukemia can involve the ovary. When they do, the involvement is usually bilateral (538–540). About 5% of patients with Hodgkin lymphoma will have lymphomatous involvement of the ovaries, but this involvement typically occurs with advanced-stage disease. **With Burkitt lymphoma, ovarian involvement is very common. Other types of lymphoma involve the ovaries less frequently, and leukemic infiltration of the ovaries is uncommon** (540). Sometimes the ovaries can be the only apparent sites of involvement of the abdominal or pelvic viscera with a lymphoma; if this circumstance is found, a careful surgical exploration may be necessary. Intraoperatively, a hematologist–oncologist should be consulted to determine the need for these procedures if frozen section of a solid ovarian mass reveals a lymphoma. Most lymphomas no longer require extensive surgical staging; biopsy of enlarged lymph nodes should be performed. In some cases of Hodgkin lymphoma, a

more extensive evaluation may be necessary. Treatment involves that of the lymphoma or leukemia. Removal of a large ovarian mass may improve patient comfort and facilitate a response to subsequent radiation or chemotherapy.

Metastatic Tumors of the Vulva

KEY POINTS

1 Vulvar lesions require biopsy to avoid delay in diagnosis.
2 The modern approach to patients with vulvar cancer is multidisciplinary and individualized.
3 Management of the primary lesion and groin nodes is determined separately.
4 Most T_1 and early T_2 lesions can be managed with radical local excision.
5 Large T_2 and T_3 primary tumors are best treated with chemoradiation followed by limited surgical resection.
6 Unifocal tumors less than 4 cm in diameter with clinically negative nodes are suitable for sentinel lymph node dissection in experienced hands.
7 When groin dissection is indicated, it should be a thorough inguinofemoral lymphadenectomy.
8 The single most important prognostic factor is lymph node status: 5-year survival without groin node metastases is greater than 90%; with groin node metastases, 5-year survival is 50%.
9 Postoperative (chemo-) radiation decreases the risk of groin recurrence in patients with multiple positive inguinofemoral lymph nodes.
10 Recurrence in the groin is almost universally fatal.

With 6,020 new cases and 1,150 deaths annually in the United States, vulvar cancer is uncommon, resulting in age-adjusted incidence rates of 2.8 and 1.7 per 100,000 in white and black women, respectively. Vulvar cancer represents about 4% to 6% of malignancies of the female genital tract and 0.6% of all cancers in women (1,2). Vulvar cancer predominantly affects postmenopausal women, and it is the most common anogenital cancer in women more than 70 years of age (3). HPV infection is associated with a significant number of vulvar cancers. **[1]** **The incidence of in situ vulvar cancer has been increasing worldwide, primarily because of the increasing occurrence in young women, who account for 75% of the cases. The incidence of lichen sclerosus, which is associated with an increased risk of vulvar cancer, has doubled over the past two decades, predominantly in postmenopausal women** (4). **The overall rate of invasive vulvar carcinoma is increasing, but at a much lower rate** (5,6). Squamous cell carcinomas account for over 80% of all primary vulvar malignancies, whereas melanomas, adenocarcinomas, basal cell carcinomas, Paget disease, and sarcomas are less common. Most vulvar cancers are diagnosed at an early stage. In the United States, 5-year survival rates for vulvar cancer are 72%.

Following the initial reports of Taussig in the United States and Way in Great Britain, radical vulvectomy and en bloc groin dissection, with or without pelvic lymphadenectomy, was standard treatment for all patients with operable disease (7,8). Postoperative morbidity was high and prolonged hospitalization common. **Over the past 4 decades, significant advances in the management of vulvar cancer have been made, reflecting a paradigm shift toward a more conservative surgical approach without compromised survival and with markedly decreased physical and psychological morbidity:**

1. **[2] Individualization of treatment for all patients with invasive disease.**

2. **Vulvar conservation for patients with unifocal tumors and an otherwise normal vulva.**
3. **Omission of the groin dissection for patients with microinvasive tumors (T1a, Ä2 cm diameter and Ä1 mm of stromal invasion).**
4. **Elimination of routine pelvic lymphadenectomy.**
5. **Incorporation of the sentinel lymph node procedure to eliminate complete inguinofemoral lymphadenectomy in node-negative patients who may not derive benefits from the procedure.**
6. **The use of separate incisions for the groin dissection to improve wound healing.**
7. **Omission of the contralateral groin dissection in patients with lateral T_1 lesions and negative ipsilateral nodes.**
8. **The use of preoperative radiation therapy to obviate the need for exenteration in patients with advanced disease.**
9. **The use of postoperative (chemo-) radiation therapy to decrease the incidence of groin recurrence in patients with multiple positive groin nodes.**

ETIOLOGY

The etiology of vulvar cancer is multifactorial. Reported risk factors for vulvar cancer include human papillomavirus (HPV) infection, vulvar intraepithelial neoplasia (VIN), cervical intraepithelial neoplasia (CIN), lichen sclerosus, cigarette smoking, alcohol consumption, obesity, immunosuppression, a prior history of cervical cancer, and northern European ancestry (9,10). **Growing evidence has established two distinct etiologic entities of squamous cell carcinoma of the vulva:**

1. ***Basaloid or warty types*, which comprise about 40% of vulvar squamous cell carcinomas, tend to be multifocal, occur generally in younger patients, and are related to HPV infection, usual type VIN (uVIN), immunosuppression, and cigarette smoking.**
2. ***Keratinizing, differentiated, or simplex types*, which account for about 60% of cases, tend to be unifocal, occur predominantly in older patients, are not related to HPV, and often are found in areas adjacent to lichen sclerosus, chronic inflammatory dermatoses, and differentiated type VIN (dVIN).**

High-grade VIN was closely studied as a potential precancerous lesion. The direct progression of VIN to cancer is difficult to document, but a review of 3,322 published patients with high-grade VIN reports a 9% progression rate to cancer for untreated and 3.8% for treated cases (11). VIN is found adjacent to basaloid or warty vulvar squamous cell carcinomas in more than 80% of cases and 10% to 20% of vulvar

carcinoma in situ lesions harbor an occult invasive component (12,13). A meta-analysis comprising 5,015 vulvar cancers demonstrated a 40% prevalence of HPV in vulvar cancer with nearly 80% of warty or basaloid cancers testing positive for HPV, compared with only 13% of keratinizing carcinomas. The predominant high-risk HPV type was HPV16, followed by HPV33 and HPV18 (14). **Epidemiologic risk factors for the basaloid or warty-type squamous cell carcinoma of the vulva are similar to those for cervical cancer and include a history of multiple lower genital tract neoplasias, immunosuppression, and smoking**. Based on immunogenicity and efficacy studies, it is expected that HPV vaccination, particularly with the nine-valent HPV vaccine, has the potential to prevent up to 90% of HPV-associated vulvar cancers (15).

Frequently implied as an etiologic variable for the keratinizing carcinoma is the itch–scratch cycle associated with lichen sclerosus and chronic inflammatory dermatoses, with atypical changes occurring in the repaired epithelium. Differentiated VIN is a precursor to keratinizing squamous cell carcinoma and is strongly associated with lichen sclerosus. In keratinizing carcinoma, adjacent lichen sclerosus or dVIN is found in more than 80% of patients (4). **Women with vulvar lichen sclerosus are at increased risk of developing invasive squamous cell cancer of the vulva**. A population-based study found a 36-fold increased risk of vulvar cancer for women with lichen sclerosus (16). During the past 20 years, the incidence of lichen sclerosus has nearly doubled from 7.4 to 14.6 per 100,000 woman-years. In a cohort of more than 3,000 women with lichen sclerosus, the observed cumulative incidence of squamous cell carcinoma of the vulva was 6.7% with concurrent VIN and age ≥70 years being independent risk factors (4). Supportive evidence that some of these lesions are precancerous comes from molecular studies that demonstrate aneuploid DNA content, *p53* overexpression, high Ki67 expression, indicating high proliferation indices and monoclonal expansion of keratinocytes in lichen sclerosus and dVIN (17–19), though the exact molecular mechanism of non–HPV-associated vulvar cancer remains to be elucidated. An area of active research explores whether treatment of lichen sclerosus with superpotent topical steroids can impact the malignancy risk (20). A prospective longitudinal cohort study of 507 women with biopsy-proven vulvar lichen sclerosus demonstrated that patients who were compliant with active treatment, typically with superpotent topical steroids, had improved symptom control and a reduced incidence of vulvar carcinoma (21).

TYPES OF INVASIVE VULVAR CANCER

The histologic subtypes of invasive vulvar cancer are shown in Table 40-1.

Squamous Cell Carcinoma

Approximately 90% to 92% of all invasive vulvar cancers are of the squamous cell type. Squamous carcinomas of the vulva can be divided into distinct histologic subtypes designated as *basaloid carcinoma*, *warty carcinoma*, and *keratinizing squamous carcinoma*. Mitoses are noted in these malignancies, but atypical keratinization is the histologic hallmark of invasive vulvar cancer (23). Most vulvar squamous carcinomas reveal keratinization **(Fig. 40-1)**. Histologic features that correlate with the occurrence of inguinal lymph node metastasis are lymph–vascular space invasion, tumor thickness, depth of stromal invasion, grade of differentiation, histologic pattern of invasion (spray and stellate versus confluent, compact, broad, and pushing), and increased amount of keratin (24–27).

Table 40-1 Malignant Tumors of the Vulva Based on IARC/WHO Classification (22)

Type	Percent
Malignant Epithelial Tumors	
Squamous cell carcinoma (keratinizing, non-keratinizing, basaloid, warty, verrucous)	90–92%
Basal cell carcinoma	2–3%
Paget disease	<1%
Bartholin gland (adenocarcinoma, squamous cell, adenosquamous, adenoid cystic, transitional cell)	1%
Tumors arising from other specialized anogenital glands (adenocarcinoma of mammary gland type, adenocarcinoma of Skene gland or minor vestibular gland origin, malignant Phylloides tumor)	<1%
Adenocarcinomas of other types (sweat gland type, intestinal type)	<1%
Malignant Neuroectodermal Tumors	<1%
Ewing sarcoma	
Malignant Soft Tissue Tumors	<1%
Rhabdomyosarcoma	
Leiomyosarcoma	
Epithelioid sarcoma	
Alveolar soft part sarcoma	
Other sarcomas	
Malignant Melanocytic Tumors	

Malignant melanoma	2–5%
Malignant Germ Cell Tumors	<1%
Neuroendocrine tumors (small cell or large cell high-grade neuroendocrine carcinoma)	
Merkel cell tumor	
Yolk sac tumor	
Lymphoid and Myeloid Tumors	<1%
Lymphomas	
Myeloid neoplasms	
Secondary (metastatic) Tumors	1%

IARC, International Agency for Research on Cancer; WHO, World Health Organization.

[3] Microinvasive carcinoma of the vulva (T_{1a}) is defined as a lesion 2 cm or less in diameter with 1 mm or less stromal invasion (28). Depth of stromal invasion is measured vertically from the epithelial–stromal junction (basement membrane) of the adjacent most superficial dermal papilla to the deepest point of tumor invasion (Fig. 40-2). **When the tumor invades 1 mm or less, metastasis to the inguinal lymph nodes is extremely rare among reported series. When invasion is greater than 1 mm, there is a significant risk of inguinal lymph node metastasis.**

Clinical Features

[4] Squamous cell carcinoma of the vulva is predominantly a disease of postmenopausal women. The mean age at diagnosis is about 65 years and 15% of patients who develop vulvar cancer do so before age 40. There may be a longstanding history of an associated vulvar intraepithelial disorder, such as lichen sclerosus or VIN. As many as 27% of patients with vulvar cancer have a second primary malignancy (29–31). Based on data from the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) program, patients with invasive vulvar cancer have an increased risk of 1.3% for developing a subsequent cancer. **Most of the excess second cancers were smoking related** (e.g., cancers of the lung, buccal cavity and pharynx, esophagus, nasal cavity, and larynx) **or related to infection with HPV** (e.g., cervix, vulva, vagina, and anus) (32).

Most patients are asymptomatic at the time of diagnosis. If symptoms exist, vulvar pruritus, a lump, or a mass are the most common findings. Less frequent symptoms include a bleeding or ulcerative lesion, discharge, pain, or dysuria. Occasionally, a large metastatic mass in the groin is the initial symptom.

A careful inspection of the vulva should be part of every gynecologic

examination. On physical examination, vulvar carcinoma is usually raised and may be fleshy, ulcerated, plaquelike, or warty in appearance. It may be pigmented, red or white, and tender or painless. The lesion may be clinically indistinct, especially in the presence of VIN, lichen sclerosus, or other vulvar dermatoses (13). Any lesion of the vulva warrants a biopsy.

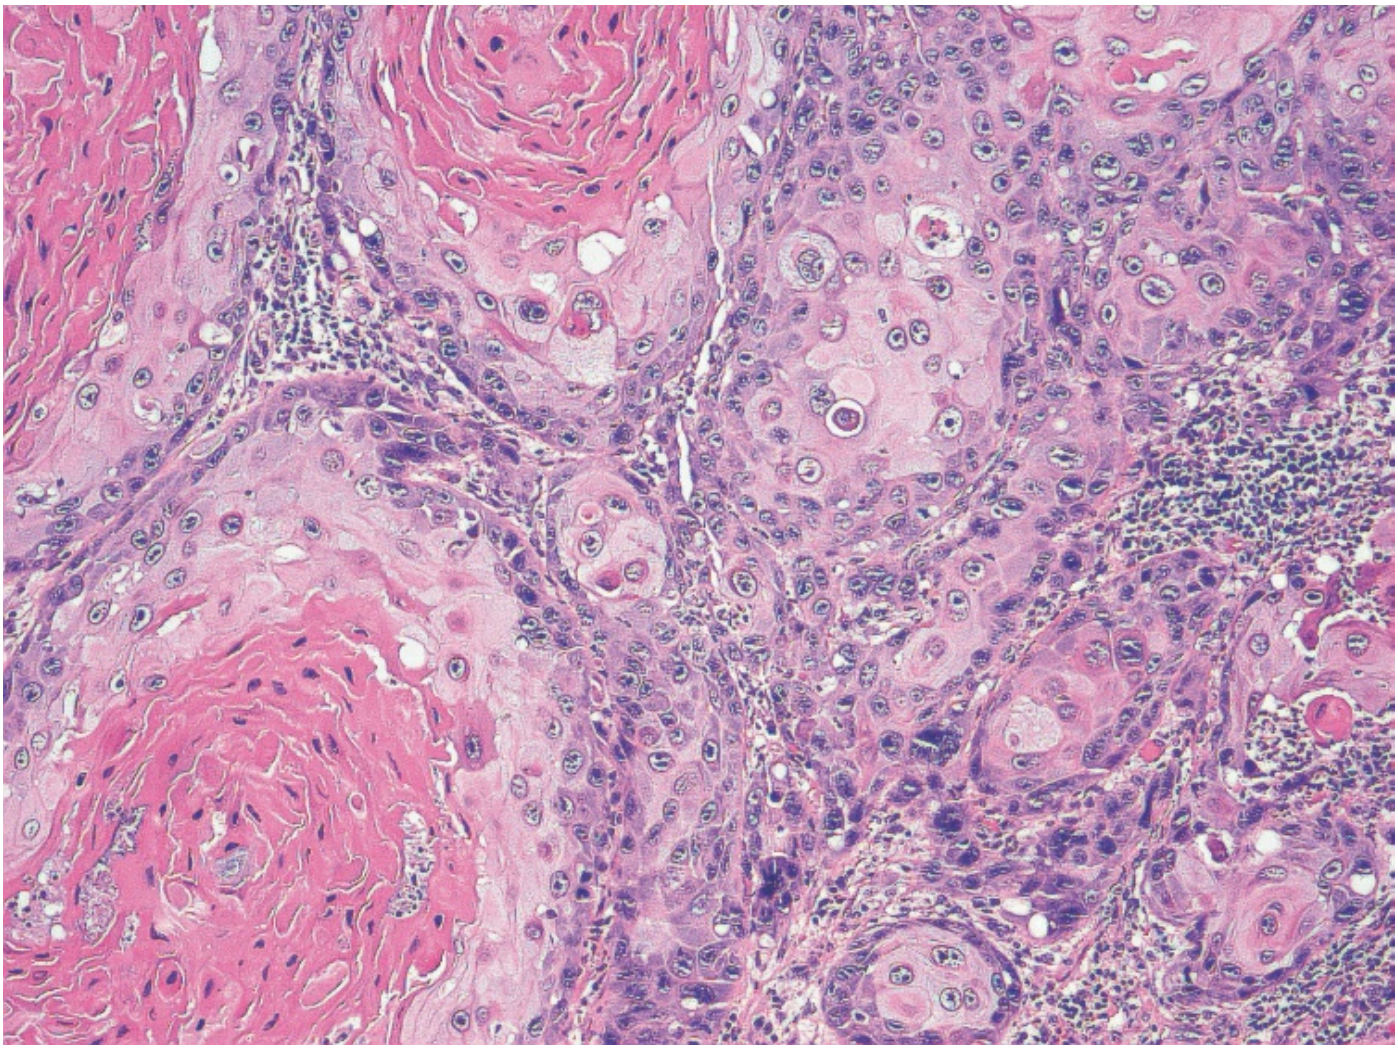

FIGURE 40-1 Squamous cell carcinoma of the vulva, keratinizing type. The multiple pearl formations consist of laminated keratin.

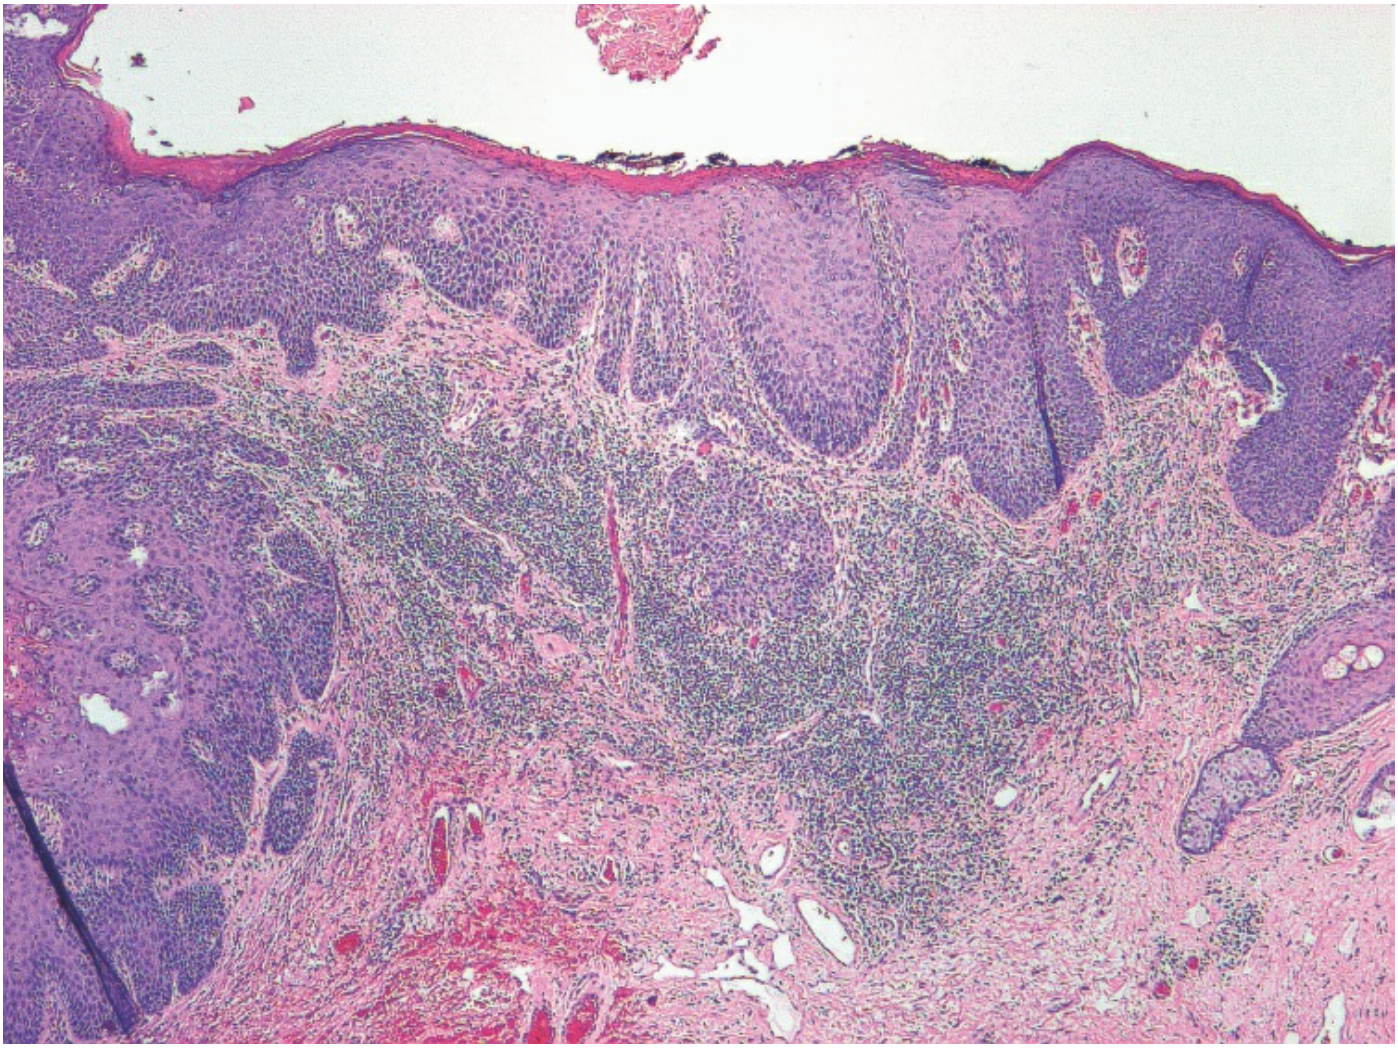

FIGURE 40-2 Early invasive carcinoma of vulva originating from vulvar intraepithelial neoplasia. An irregular nest of malignant cells extend from the base of rete pegs. Desmoplastic stromal reaction and chronic inflammation are useful diagnostic signs of stromal invasion. The depth of stromal invasion is measured from the base of the most superficial dermal papilla vertically to the deepest tumor cells.

Most squamous carcinomas of the vulva occur on the labia majora and minora (60%), but the clitoris (15%) and perineum (10%) may be primary sites. Approximately 10% of the cases are too extensive to determine a site of origin, and about 5% of the cases are multifocal.

As part of the clinical evaluation, a careful assessment of the extent of the lesion, including whether it is unifocal or multifocal, should be performed. The lesion diameter should be measured and its proximity to the midline and/or involvement of midline structures including urethra, vagina, clitoris, and anus should be assessed. The groin lymph nodes should be evaluated carefully, and a complete pelvic examination should be performed. A cytologic sample should be taken from the cervix, and **colposcopy of the vulva, cervix, and vagina should be performed because of the common association with other squamous intraepithelial or invasive neoplasms of the lower genital tract.**

Diagnosis

Diagnosis requires a Keys punch biopsy or wedge biopsy, which can be obtained in the office using local anesthesia. The biopsy must include sufficient underlying dermis to assess for microinvasion.

Physician delay is a common problem in the diagnosis of vulvar cancer, particularly if the lesion has a warty appearance. Any large or confluent warty lesion requires biopsy before medical or ablative therapy is initiated.

Routes of Spread

Vulvar cancer spreads by the following routes:

1. **Direct extension**, to involve adjacent structures such as the vagina, urethra, clitoris, and anus.
2. **Lymphatic embolization** to the regional inguinal and femoral lymph nodes.
3. **Hematogenous spread** to distant sites, including the lungs, liver, and bone.

[5] Lymphatic metastases may occur early in the disease. Twelve percent of tumors 2 cm in diameter or smaller have regional metastases (29,33). Initially, spread is usually to the inguinal lymph nodes, which are located between Camper's fascia and the fascia lata (34). From these superficial groin nodes, the disease spreads to the deep femoral nodes, which are located medial to the femoral vessels (Fig. 40-3). *Cloquet's* or *Rosenmüller's node*, situated beneath the inguinal ligament, is the most cephalad of the femoral node group. **Metastases to the femoral nodes without involvement of the inguinal nodes are reported** (35–38). A study from the M. D. Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer who had negative nodes on superficial inguinal lymphadenectomy at initial surgery, and intraoperative lymphatic mapping studies found the sentinel node deep to the cribriform fascia in 5% to 16% of these cases (39–41). This pattern of lymphatic spread needs to be taken into consideration when determining the extent of inguinofemoral lymphadenectomy and the radiotherapeutic techniques and target volumes.

From the inguinal–femoral nodes, the cancer spreads to the pelvic nodes, particularly the external iliac group. Although direct lymphatic pathways from the clitoris and Bartholin gland to the pelvic nodes were described, these channels seem to be of minimal clinical significance (42–44). The lymphatics from either side of the vulva form a rich network of anastomoses along the midline. Lymphatic drainage from the clitoris, anterior labia minora, and perineum is bilateral. Metastases to contralateral lymph nodes in the absence of ipsilateral nodal involvement is very rare (0% to 0.4%) for lateral vulvar tumors that are either 2 cm or less in diameter or with 5 mm or less invasion (33,45).

The overall incidence of inguinal–femoral lymph node metastases is reported to

be about 32% (38,40,43–53) (Table 40-2). **Metastases to pelvic nodes occur in about 12% of cases.** Pelvic nodal metastases are rare (0.6%) in the absence of groin node involvement, but they occur in about 16% of cases with positive groin nodes (Table 40-2). The risk increases to 33% in the presence of clinically suspicious groin nodes and to 40% to 50% if there are three or more pathologically positive inguinal–femoral nodes (30,45,54–57). The incidence of lymph node metastases correlates positively with depth of invasion, as shown in Table 40-3. Hematogenous spread usually occurs late in the course of vulvar cancer and is rare in the absence of lymph node metastases.

Staging

Initially, vulvar carcinoma was staged clinically based on tumor size and location, palpable regional lymph node status, and a limited search for distant metastases. The prognostic importance of the lymph node status is significant, but clinical assessment of the lymph nodes has limited accuracy. This led the Cancer Committee of FIGO to introduce a surgical staging system for vulvar cancer in 1988, which underwent several revisions, most recently in 2009, to provide better prognostic discrimination between stages and less heterogeneity within stages (28,58,59) (Table 40-4), by separating patients whose tumors involve adjacent perineal structures from those with positive lymph nodes and taking into account the number and morphology of the involved nodes.

The new FIGO staging system was validated in 269 patients, 42% of whom were restaged (61). The number of positive nodes negatively correlated with survival, as did the presence of extracapsular growth. This study confirmed Gynecologic Oncology Group (GOG) and SEER data indicating that in patients with negative nodes, tumor size was not predictive of survival (59). This study confirmed reports demonstrating that, when corrected for the number of positive nodes, bilaterality of nodal metastases was not predictive of survival (61–65).

Paralleling the changes to the FIGO staging, the American Joint Committee on Cancer (AJCC) significantly modified the vulvar cancer tumor-node-metastasis (TNM) classification with the release of the 2009 edition of the AJCC Cancer Staging Manual (Table 40-4) (60).

Table 40-3 Nodal Status in T_1 Squamous Cell Carcinoma of the Vulva Versus Depth of Stromal

Invasion

Depth of Invasion	No. of Patients	Positive Nodes	Nodes
1 mm	163	0	0
1.1–2 mm	145	11	7.7
2.1–3 mm	131	11	8.3
3.1–5 mm	101	27	26.7
>5	38	13	34.2

Table 40-4 The 2009 FIGO Staging and TNM Classification for Vulvar Cancer (28,61)

FIGO Stage	TNM Classification	Clinical/Pathologic Findings
Stage IA	$T_{1a}N_0M_0$	Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm,[a] no nodal metastasis
Stage IB	$T_{1b}N_0M_0$	Lesions >2 cm in size or with stromal invasion >1 mm, confined to the vulva or perineum, with negative nodes
Stage II	$T_2N_0M_0$	Tumor of any size with extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with negative nodes
Stage III		Tumor of any size with or without extension to adjacent perineal structures (1/3 lower urethra, 1/3 lower vagina, anus) with positive inguinofemoral lymph nodes
IIIA	$T_{1or2}\ N_{1b}\ M_0\ T_{1or2}\ N_{1a}\ M_0$	(i) with 1 lymph node metastasis (≥5 mm) or (ii) 1–2 lymph node metastasis(es) (<5 mm)
IIIB	$T_{1or2}\ N_{2b}\ M_0\ T_{1or2}\ N_{2a}\ M_0$	(i) with 2 or more lymph node metastasis (≥5 mm) or (ii) 3 or more lymph node metastases (<5 mm)
IIIC	$T_{1or2}\ N_{2c}\ M_0$	with positive nodes with extracapsular spread
Stage IV		Tumor invades other regional (2/3 upper

		urethra, 2/3 upper vagina), or distant structures
IVA	$T_3N_{any}M_0$ $T_{any}N_3$	Tumor invades any of the following:
(i) Upper urethral and/or vaginal mucosa, bladder mucosa, rectal mucosa, or fixed to pelvic bone		
(ii) Fixed or ulcerated inguino-femoral lymph nodes		
IVB	$T_{any}N_{any}M_1$	Any distant metastasis including pelvic lymph nodes
TNM Classification	T: Primary tumor	N: Regional lymph nodes (femoral and inguinal nodes)
	T_x: Primary tumor cannot be assessed	N_x: Regional lymph nodes cannot be assessed
	T_0: No evidence of primary tumor	N_0: No regional lymph node metastases
	T_{is}: Carcinoma in situ (preinvasive carcinoma)	N_1: One or two regional lymph node metastases with the following features:
	T_{1a}: Lesions ≤2 cm in size, confined to the vulva or perineum and with stromal invasion ≤1 mm	N_{1a}: One or two lymph node metastases each <5 mm
	T_{1b}: Lesions >2 cm in size or any size with stromal invasion >1 mm, confined to the vulva or perineum	N_{1b}: One lymph node metastasis ≥5 mm
	T_2: Tumor of any size with extension to adjacent perineal structures (lower 1/3 of urethra, lower of 1/3 vagina, anal involvement)	N_2: Regional lymph node metastases with the following features:
	T_3: Tumor of any size with extension to any of the following:	N_{2a}: ≥3 lymph node metastases, each <5 mm in diameter
	upper 2/3 of urethra, upper 2/3 of vagina, bladder mucosa, rectal mucosa, or fixed to pelvic	N_{2b}: ≥2 lymph node metastases ≥5 mm

	bone	
	M_1: Distant metastasis (including pelvic lymph node metastasis)	N_{2c}: Lymph node metastases with extracapsular spread
		N_3: Fixed or ulcerated regional lymph node metastasis
		M: Distant metastasis
		M_0: No distant metastasis

[a]The depth of stromal invasion is measured from the epithelial–stromal junction of the adjacent most superficial dermal papilla to the deepest point of invasion.

Prognosis and Survival

Survival of patients with vulvar cancer correlates with FIGO stage (66). The prognosis for patients with early-stage disease is generally good (Table 40-5). **The single most important prognostic factor is lymph node status** (51–53,56,67,68). A report from the Mayo Clinic on 330 patients with primary squamous cell carcinoma of the vulva demonstrated a significant correlation between lymph node status and risk of treatment failure, especially in the first 2 years following initial therapy: 44.2% overall recurrence rate with positive versus 17.5% with negative lymph nodes. **[6]** **More than one-third of relapses presented 5 years or more after initial therapy** (69). There is a strong negative correlation between the number of positive lymph nodes and survival (Table 40-6). **Patients with negative lymph nodes have a 5-year survival rate of over 80%; for patients with positive nodes, 5-year survival falls below 50%.** The number of positive nodes is of critical importance: **Patients with one microscopically positive lymph node have a prognosis similar to those with all negative lymph nodes, whereas patients with three or more positive nodes have a poor prognosis and a 2-**

year survival rate of 20% (70). The survival rate for patients with positive pelvic nodes is about 11% (71). In addition to the number of nodes involved, the morphology of the positive groin nodes is of prognostic significance. As demonstrated in several studies, significant negative predictors of survival are the size of the nodal metastasis, the proportion of the node replaced by tumor cells, and the presence of any extracapsular spread (59,67,72,73). Histologic grade, tumor thickness, depth of stromal invasion, and lymph–vascular space involvement contribute to the risk of lymph node involvement but are not independent predictors of survival (70).

Post-treatment surveillance as recommended by the Society of Gynecologic Oncology entails serial reviews of systems and careful physical examination with annual cervical/vaginal cytology and imaging reserved for patients where findings are concerning for recurrent disease (74). The frequency of surveillance visits depends on the stage and recurrence risk:

- Stage I, II disease every 6 months in years 1 and 2, and annually thereafter.
- Stage III/IV disease every 3 months for the first two years, every 6 months in years 3 to 5, and annually thereafter.

Table 40-6 Five-Year Survival for Patients With Vulvar Squamous Cell Carcinoma by Number of Lymph Node Metastases (28)

No. of Lymph Node Metastases	No. of Patients	5-Year Survival (%)
0	302 (61%)	81
1	66 (13%)	63
2	43 (9%)	30
3	24 (5%)	19
4 or more	62 (12%)	13

Treatment

[7] To individualize the patient's care and determine the appropriate therapy, it is necessary to independently manage the primary lesion and groin lymph nodes using a separate incision technique for resection of the vulvar lesion and for the node dissection. This is associated with lower morbidity and metastases rarely occur in the skin bridge between vulva and groin in patients without clinically suspicious inguinofemoral nodes (75,76). Before initiation of therapy, all patients should undergo a careful clinical examination, and colposcopy of the cervix, vagina, and vulva. Preinvasive (and rarely invasive) lesions may be present at other sites along the lower genital tract, and vulvar cancer is frequently multifocal. If disease is locally advanced, an examination under anesthesia may be required to determine its full extent. Imaging

with PET/CT or MRI is performed for all but T1a lesions to aid in assessment of the local disease and evaluate for metastases.

Management of the Primary Lesion

Microinvasive Vulvar Cancer (T_{1a})

[8] Tumors 2 cm or less in diameter with 1 mm or less invasion are appropriately treated with a wide local excision, which is as effective as radical surgery for the prevention of vulvar recurrences for these tumors (77). The excision should go sufficiently deep into the dermis that depth of invasion is fully assessed.

Early Vulvar Cancer (T_{1b})

[9] The modern approach to the management of patients with T_{1b} carcinoma of the vulva should be individualized. There is no standard approach applicable to every patient, and emphasis is on performing the most conservative operation that is consistent with cure of the disease through radical local excision and surgical lymph node assessment while minimizing anatomic alterations and disfigurement. An analysis of the literature indicates that the incidence of local invasive recurrence after radical local excision or radical hemivulvectomy is not higher than that after the historically performed radical vulvectomy (33,46,71,78–80). In the presence of an otherwise normal-appearing vulva, **radical local excision is a safe surgical option, regardless of the size of the tumor or the depth of invasion.** Based on cumulative data of 413 patients reported in four studies, an 8 mm or greater histopathologic resection margin results in a high rate of local disease control (78,81–83). Of the 252 patients whose tumors were resected with margins of 8 mm or greater, 2.4% experienced a local recurrence, compared with 30.3% of the 161 patients whose margins were less than 8 mm. Neither clinical tumor size nor the presence of coexisting benign vulvar pathology correlated with local recurrence. It is important to bear in mind that paraffin-embedded tissue shrinks by 20% to 25%. **At the time of radical local excision, at least a 1-cm grossly negative margin, without putting the skin under tension, should be obtained and extended down to the level of the inferior fascia of the urogenital diaphragm.**

When vulvar cancer arises in the presence of VIN, lichen sclerosus, or some nonneoplastic epithelial disorder, treatment is influenced by the patient's age, treatment history, and symptomatology. Elderly patients who often had many years of chronic itching may not be disturbed by the prospect of a vulvectomy. In younger women, it is desirable to conserve as much of the vulva as possible. Radical local excision should be performed for the invasive disease, and the associated intraepithelial disease should be treated in the manner most appropriate to the patient. For example, topical steroids may be required for lichen sclerosus, whereas VIN may require superficial local excision with primary closure, ablation, topical therapy, or a combination thereof.

FIGURE 40-4 Small (T1) vulvar carcinoma at the posterior fourchette. (From **Hacker NF, Eifel PJ.** Vulvar cancer. In: Berek JS, Hacker NF. *Berek & Hacker's Gynecologic Oncology*. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:574.)

Radical local excision is most appropriate for lesions on the lateral or posterior aspects of the vulva (Fig. 40-4). Midline lesions pose special challenges because of their proximity to clitoris, urethra, or anus. For anterior lesions, conservative clitoris-

sparing surgery allows for excellent local control as long as pathologic margins are at least 8 mm (84). For tumors that involve the clitoris or that are in close proximity to it, any type of surgical excision will have psychosexual consequences. In addition, marked edema of the posterior vulva may occur. For young patients with periclitoral lesions, the primary lesion can be treated with a small field of radiation therapy with concomitant sensitizing chemotherapy. Small vulvar lesions should respond very well to about 5,000 cGy external radiation, and biopsy can be performed after therapy to confirm the absence of any residual disease (58).

Early T_2 Vulvar Cancer

[10] The indications for vulvar conservation can be extended to selected patients with early T_2 tumors. The tumor-free margin should be the same, whether or not a radical vulvectomy or a radical local excision is performed. It seems feasible and desirable to extend the indications for vulvar conservation, particularly for younger patients. Tumors that are suitable for a conservative resection are those involving the posterior vulva and lower vagina, where preservation of the anus, clitoris, and urethra is feasible.

For patients with more advanced T_2 lesions, management consists of radical vulvectomy and/or chemoradiation therapy. When the disease involves the distal urethra or anus, partial resection of these organs would be required. Thus, it is often preferable to give preoperative radiation therapy with chemosensitization to allow for a less radical resection depending on location and response.

Closure of Large Defects

After radical local excision, primary closure without tension can be accomplished for smaller defects. If an extensive dissection is required to treat a large primary lesion, a number of options are available to repair the defect based on the defect location, dimension, patient age, and comorbidities:

1. An area may be left open to granulate, which it will usually do over a period of 6 to 8 weeks (85); this may be hastened by the application of vacuum-assisted wound closure and negative pressure dressings (86).
2. Full-thickness rotational or advancement fasciocutaneous flaps may be devised, such as the rhomboid flap, the mons pubis pedicle flap, the pudendal thigh flap, or the V-Y-advancement flap (87–91). Fasciocutaneous flaps are reliable and can be transferred as pedicle or island flaps (92). For the lower and mid vulva, a V-Y gluteal fold flap may be preferred because of the good esthetic outcome and well-concealed donor scar (91,93).
3. A broad range of myocutaneous flaps have been used for vulvar reconstruction to cover large defects. These include unilateral or bilateral gracilis myocutaneous

grafts or a vertically oriented rectus abdominis muscle flap. Because the graft brings a new blood supply to the area, it is particularly applicable if the vulva is poorly vascularized from prior surgical resection or radiation (91,93,94). Disadvantages include complexity and duration of the procedure, the bulkiness of the flap, and donor-site sequelae.

Advanced Disease: Large T_2 and T_3 Primary Tumors

Treatment of locally advanced vulvar cancer remains challenging. To achieve primary surgical clearance for tumors involving the upper urethra, anus, rectum, or rectovaginal septum, pelvic exenteration is needed in addition to radical vulvectomy and inguinal–femoral lymphadenectomy, which carries an extremely high physical and psychological morbidity (95,96). Reported 5-year survival rates with this approach are about 50% (97–99), with survival being significantly determined by lymph node status. A series including 57 patients undergoing primary anovulvectomy reported a median survival of 69 months with 59% of patients experiencing one or more postoperative complications and 33% requiring adjuvant therapy (100). For many of these patients, a combined approach of chemoradiation therapy with or without subsequent surgery offers equal or improved survival with reduced morbidity and may be the preferred treatment approach. Numerous small prospective and retrospective series report on the use of external beam radiation with concomitant chemotherapy to shrink the primary tumor. Reported initial response rates to chemoradiation are 80% to 90%, and operability is achieved in 63% to 92% of cases (101–109). This chemoradiation is followed by a limited resection of the tumor bed on an individualized basis. Case series suggest that approximately one-half of the specimens will contain residual tumor, and local relapse rates are as high as 50% with external chemoradiation alone (110). The GOG phase II study using a combination of weekly cisplatin with radiation followed by surgical resection of gross residual disease, or biopsy if clinically no residual cancer, resulted in a complete clinical response in 64% of patients, with biopsy showing complete pathologic response in 50% of patients without the need for posttreatment surgery in this subset of patients (111).

As experience with this combination therapy evolved, it appeared that **external beam therapy is appropriate for most cases, with more selective use of brachytherapy. The extensiveness of the surgery is significantly modified. A limited vulvar resection is advocated, and bulky N2 and N3 nodes are resected without full groin lymphadenectomy to avoid the leg edema associated with groin lymphadenectomy and radiation. With this combined radiation–surgical approach, 5-year survival rates as high as 76% are reported**. With the experience accrued, preoperative radiation with concurrent chemotherapy is regarded as the first treatment of choice for patients with advanced vulvar cancer who would otherwise require some

type of pelvic exenteration or stoma. Neoadjuvant therapy is not justified in patients with tumors that can be adequately treated with primary radical vulvectomy and bilateral groin node dissection.

Management of the Lymph Nodes

Appropriate assessment for nodal involvement and groin dissection is the single most important factor in decreasing the mortality from early vulvar cancer. A careful examination of the groin is carried out as the presence of clinically palpable inguinofemoral lymph nodes is an important determinant of management.

When assessing a patient for groin dissection, the following facts should to be kept in mind:

1. The only patients with virtually no risk of lymph node metastases are those whose tumor is small (≤2 cm) and invades the stroma to 1 mm or less (T_{1a}).
2. Patients who develop recurrent disease in an undissected groin have a greater than 90% mortality (111).
3. Based on the laterality of the vulvar lesions and the status of the ipsilateral groin, an ipsilateral or bilateral lymphadenectomy becomes necessary.

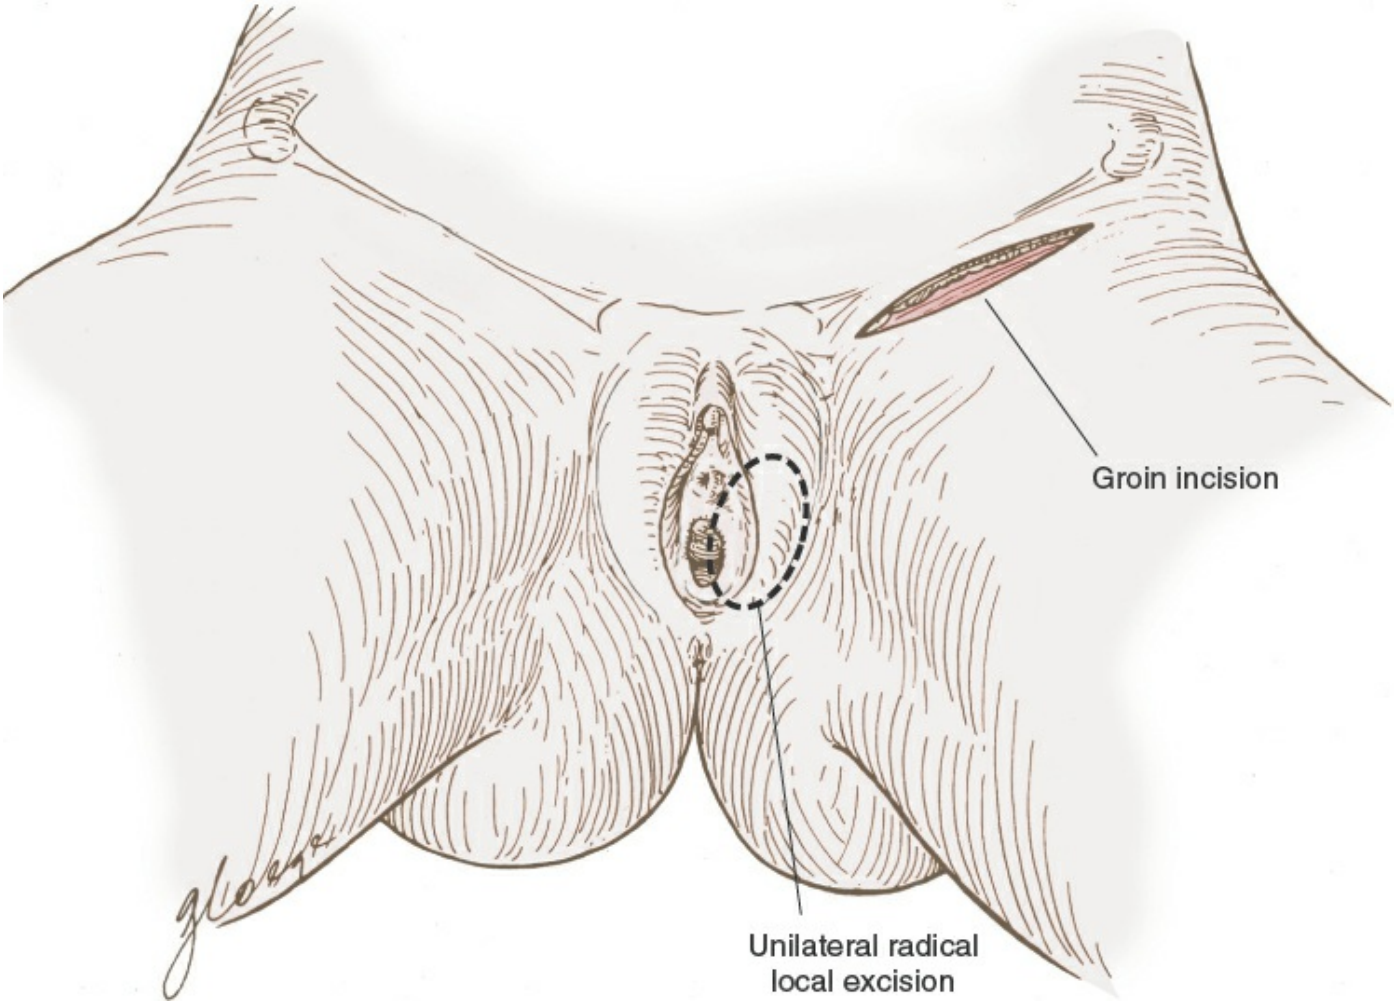

FIGURE 40-5 Skin incision for groin dissection through a separate incision. A line is drawn 1 cm above and parallel to the groin crease, and a narrow ellipse of skin is removed. (Revised with permission from **Berek JS, Hacker NF.** *Practical Gynecologic Oncology*. 2nd ed. Baltimore, MD: Williams & Wilkins; 1994:418.)

Groin dissection is associated with postoperative wound infection and breakdown. Although the incidence of wound breakdown is reduced significantly when separate incisions are used for the groin dissection and drains are left in situ until daily output is below 25 to 30 cc, lymphocyst formation and chronic leg edema remain a major problem **(Fig. 40-5)** (77).

All patients whose tumors demonstrate more than 1 mm of stromal invasion or whose tumors are larger than 2 cm (T_{1b} and above) require inguinal–femoral lymphadenectomy. If there is any question regarding the need for inguinofemoral lymphadenectomy, a Keys biopsy or wedge biopsy of the primary tumor should be obtained, and the depth of invasion should be determined. If it is smaller than 1 mm on the wedge biopsy specimen, the entire lesion should be locally excised and analyzed histologically to determine the depth of invasion. If the lesion is 2 cm in diameter or smaller and there is no invasive focus larger than 1 mm, groin dissection may be omitted, provided there is no lymph–vascular space invasion and there are no clinically

suspicious groin lymph nodes. An occasional patient with less than 1 mm of stromal invasion has documented groin node metastases, but the incidence is so low that it is of no practical significance (112,113).

Inguinal–Femoral Lymphadenectomy

If groin dissection is indicated in patients with vulvar cancer, it should be a thorough inguinal–femoral lymphadenectomy. The GOG reported six groin recurrences among 121 patients with tumors 2 cm or less after a superficial (inguinal) dissection, although the removed inguinal nodes were negative, and a study from the M. D. Anderson Cancer Center reported a 9% groin recurrence rate in 104 patients with vulvar cancer and negative nodes on superficial inguinal lymphadenectomy (38,39). Although it is unclear whether all of these recurrences were in the femoral nodes, both studies indicate that an incomplete groin dissection will increase the number of groin recurrences and mortality. GOG data indicate that radiation therapy cannot substitute for groin dissection followed by selective radiation as indicated, even in patients with clinically nonsuspicious lymph nodes (114). This GOG study was closed early because a significantly higher incidence of recurrences occurred in women who were receiving groin radiation therapy only (19% vs. 0%). The dose of radiation was 5,000 cGy given in daily 200-cGy fractions to a depth of 3 cm below the anterior skin surface. Although the radiation regimen prescribed was criticized extensively, other uncontrolled studies give no evidence for better groin control with radiotherapy (115,116). Surgery remains the treatment of choice for the groin for women with vulvar cancer. Vulvar cancer patients with T_2 or T_3 lesions scheduled for primary or neoadjuvant chemoradiation should undergo an inguinofemoral lymphadenectomy prior to initiation of chemoradiation, given the lower survival with primary groin radiation compared with groin dissection followed by radiation (115). Some patients with T_{1b} and T_2 tumors and no palpable groin lymph nodes on examination are candidates for sentinel lymph node assessment.

Unilateral Versus Bilateral Groin Dissection

It is not necessary to perform a bilateral groin dissection if the primary lesion is unilateral and the ipsilateral lymph nodes are negative. In a patient with a unilateral lesion and negative ipsilateral groin nodes, the risk of contralateral lymph node metastasis is very low (33,45). In a study from the Mayo Clinic, 8 of 163 patients with unilateral vulvar cancers (4.8%) had bilateral lymph node metastases and only 3 (1.8%) had isolated contralateral lymph node metastases. None of the patients with unilateral vulvar lesions that were either 2 cm or less or had 5 mm or less depth of invasion had bilateral groin node involvement at diagnosis (45). There is an increase in the risk of contralateral nodal involvement proportional to the number of positive ipsilateral inguinal nodes (45,57). **It is recommended that patients with any bulky or multiple**

microscopically positive ipsilateral groin lymph nodes undergo contralateral inguinal–femoral lymphadenectomy. Bilateral inguinal–femoral lymphadenectomy should be performed for midline lesions (clitoris, anterior labia minora, posterior fourchette) or those within 2 cm of the midline because of the more frequent contralateral lymph flow from these regions (117).

Management of Bulky Groin Nodes

All clinically or radiologically suspicious groin nodes should be resected if deemed resectable and the patient is a surgical candidate. If nodal metastasis is confirmed by preoperative biopsy or intraoperative frozen section, a full inguinofemoral lymphadenectomy may be omitted to decrease morbidity with subsequent radiation without compromising survival (118,119). If groin lymph nodes are palpably enlarged, but frozen section does not demonstrate metastatic disease, a complete inguinofemoral lymphadenectomy should be performed. Patients with fixed, unresectable groin nodes should be treated with primary chemoradiation. If there is no other evidence of metastatic disease following chemoradiation, GOG data suggest that it may be appropriate to resect the residual nodes (120).

Management of Pelvic Lymph Nodes

In the past, pelvic lymphadenectomy was part of the routine surgery for invasive vulvar cancer. The incidence of pelvic lymph node metastasis is rare in the absence of groin node involvement, and a more selective approach is preferred **(Table 40-2)**. Patients most prone to pelvic lymph node metastasis are those with three or more pathologically positive groin nodes (30,42,54,121). In addition to the number of nodes involved, the morphology of the positive groin nodes is of prognostic significance. As demonstrated in several studies, significant negative predictors of survival are the number of positive nodes, the size of the nodal metastasis, the proportion of the node replaced by tumor cells, and the presence of any extracapsular spread (63,67,72,73). In these patients, the pelvis requires treatment by radiation. **If a preoperative pelvic imaging study reveals bulky pelvic lymph nodes, resection of these nodes should be performed via an extraperitoneal approach prior to radiation because of the limited ability of external beam radiation therapy to sterilize bulky positive pelvic nodes.**

Sentinel Lymph Node Studies

Increasing evidence supports the use of intraoperative lymphatic mapping using lymphoscintigraphy with technetium-99m-labeled nanocolloid and isosulfan blue dye to identify a sentinel node that would predict the presence or absence of regional nodal metastases. The strong interest in the sentinel node concept lies in the desire to reduce the significant lifelong morbidity of lymphedema associated with a thorough inguinofemoral lymphadenectomy, as only 25% to 35% of patients with early-stage vulvar cancer will have lymph node metastases and thus benefit from the procedure.

Reliable identification of the sentinel node and forgoing full lymphadenectomy in patients with clinically nonsuspicious groin lymph nodes and a negative sentinel node significantly reduces the number of patients who undergo unnecessary, extensive lymphadenectomy in the absence of disease. This is contingent upon a negative sentinel lymph node reliably predicting the absence of any other nodal metastases given the greater than 90% mortality associated with a groin recurrence.

The sentinel lymph node procedure has led to a major decrease in morbidity compared with a complete inguinofemoral lymphadenectomy without negatively impacting prognosis in select patients (122–126). **In experienced hands, this procedure is reliable and suitable in early-stage disease with unifocal tumor lesions less than 4 cm in size and clinically negative lymph nodes on groin examination and imaging.** A Cochrane Database review of 34 studies evaluating 2,396 groins in 1,614 women reported for blue dye plus technetium combined a sentinel node detection rate of 98% with a pooled sensitivity estimate of 0.95 (95% CI 0.89 to 0.97), and a negative predictive value of greater than 95% (127). The combination of blue dye and radiocolloid is superior over blue dye alone for sentinel node identification. Ultrastaging techniques such as serial micro-sectioning and immunohistochemistry staining are used to detect micrometastases in the sentinel node if initial hematoxylin and eosin section is negative. This increases the detection rate of lymph node metastasis (123).

Recurrence in the groin is fatal in over 90% of patients. Thus, groin recurrence is ultimately a critical outcome measure for surgical groin assessment techniques. A meta-analysis of recurrence rate included 23 studies and demonstrated a significantly higher groin recurrence rate with superficial inguinal lymphadenectomy (6.6%; 95% CI 4.4–9.0) than with complete inguinofemoral lymphadenectomy (1.4%; 95% CI 0.4–2.9) with the recurrence rate for patients undergoing the sentinel node procedure being 3.4% (95% CI 1.8–5.4) (128). Long-term follow-up of the GROINSS-V study, one of the largest studies on the safety of the sentinel node procedure in vulvar cancer, reported for 377 patients with unifocal <4 cm T1 vulvar cancer a local recurrence rate of 27.2% at 5 years and 39.5% at 10 years. Isolated groin recurrences occurred in 2.5% of patients with negative sentinel nodes and 8% of patients with positive sentinel nodes. All groin recurrences occurred within 25 months of primary treatment (129). Some small series of sentinel nodes in vulvar cancer with inclusion criteria similar to those in GROINSS-V showed unexpectedly high false-negative rates of 8% to 27%, some of which may be attributable to patient selection and insufficient experience of low-volume providers. This highlights the prerequisites for high-quality sentinel node procedures, which include careful patient selection, trained personnel, and appropriate infrastructure. The technique might otherwise carry with it an unjustifiable rise in the frequency of groin recurrences.

Postoperative Management

Despite the age and general medical condition of many elderly patients with vulvar cancer, surgery is usually remarkably well tolerated. Patients should be able to commence eating a low-residue diet on the first postoperative day. In the past, bed rest was advised for 3 to 5 days postoperatively to allow for immobilization of the wounds and to foster healing. **Because radical local excisions are being performed with increasing frequency and groin lymphadenectomy is done through separate incisions, patients begin ambulation on postoperative day 1 or 2.** Pneumatic calf compression and subcutaneous *low molecular weight heparin* should be given to help prevent deep venous thrombosis, and active leg movements are to be encouraged. Frequent dressing changes are performed to keep the vulvar wound dry. Meticulous perineal hygiene is maintained. Suction drainage of each side of the groin is continued until output is minimal to help decrease the incidence of groin seromas. It is not uncommon for suction drainage to continue for 10 or more days. The Foley catheter is removed when the patient is ambulatory. If there is significant periurethral swelling, prolonged bladder drainage may be advisable. If there is breakdown of the vulvar wound, sitz bath or whirlpool therapy is helpful, followed by drying of the perineum with a hair dryer.

Early Postoperative Complications

The major immediate morbidity is related to groin wound infection, necrosis, and breakdown. This complication used to be reported in as many as 53% to 85% of patients having an en bloc operation (29,30). **With the separate-incision approach,** the incidence of wound breakdown has been reduced to approximately 44%; **major breakdown occurs in about 14% of patients** (31,75,130,131). With appropriate antibiotics, debridement, and wound dressings, the area will granulate and re-epithelialize over several weeks and may be managed with home nursing. Whirlpool therapy is effective for areas of extensive breakdown. The most common complication with the separate incision approach continues to be wound infection requiring antibiotic therapy and lymphocyst formation, reported in up to 40% of cases (131). The GROINSS-V study reported wound break down of the groin in 34% of patients undergoing complete inguinofemoral lymphadenectomy and 12% of patients undergoing the sentinel lymph node procedure with respective cellulitis rates of 21% and 5% (122). Symptomatic lymphocysts should be managed by periodic sterile aspiration.

Other early postoperative complications include urinary tract infection, seromas in the femoral triangle, deep venous thrombosis, pulmonary embolism, myocardial infarction, hemorrhage, and, rarely, osteitis pubis. Anesthesia of the anterior thigh resulting from femoral nerve injury is common and usually resolves slowly.

Late Complications

One major late complication is chronic lymphedema, which occurs in about 30% of patients (29–31,130–132). Recurrent lymphangitis or cellulitis of the leg develops in about 10% of patients and usually responds to oral antibiotics. The GROINSS-V study, prospectively following 403 patients and 623 groin evaluations, reports lymphedema in 25% of patients undergoing complete inguinofemoral lymphedema and 2% of patients undergoing the sentinel lymph node procedure with respective recurrent erysipela rates of 16% and 0.4% (122). Urinary stress incontinence, with or without genital prolapse, occurs in about 10% of patients after radical vulvectomy and may require corrective surgery. Introital stenosis can lead to dyspareunia and may require a vertical relaxing incision, which is sutured transversely. An uncommon late complication is femoral hernia, which can be prevented intraoperatively by closure of the femoral canal with a suture from the inguinal ligament to Cooper's ligament. Pubic osteomyelitis and rectovaginal or rectoperineal fistulas are rare late complications.

Other major long-term treatment complications associated with the extent of vulvar surgery include depression, altered body image, and sexual dysfunction (95,96). Modifications in the radical extent of the surgical approach and appropriate preoperative and postoperative counseling may help lessen some of the psychological trauma.

Role of Radiation Therapy

Radiation therapy traditionally had a limited role in the management of patients with vulvar cancer. In the orthovoltage era, local tissue tolerance was poor and vulvar necrosis was common, but with megavoltage therapy, tolerance improved significantly. Radiation therapy, frequently with concurrent chemotherapy, has an increasingly important role in the management of patients with vulvar cancer. It is important to remember that, with a rare exception, radiation therapy alone has little place in the primary management of vulvar cancer. It is primarily indicated in conjunction with surgery.

The indications for radiation therapy for patients with primary vulvar cancer are evolving. **Radiation is indicated in the following situations:**

1. Preoperative chemoradiation in patients with advanced disease who would otherwise require pelvic exenteration or suffer loss of anal or urethral sphincteric function.
2. Preoperative chemoradiation in patients with fixed, unresectable groin nodes.
3. Postoperatively, to treat the pelvic lymph nodes and groins of patients with multiple microscopically positive groin nodes, one or more macrometastasis (10 mm or larger), or any evidence of extracapsular spread.

Possible indications for radiation therapy to the vulva include the following:

1. Postoperatively, to help prevent local recurrences in patients with involved (or close) surgical margins. Radiation to the primary tumor bed following resection with involved margins may improve 5-year overall survival to 67%, which is comparable to that of patients with negative margins (133,134).
2. As primary therapy for patients with small primary tumors, particularly clitoral or periclitoral lesions in young and middle-aged women, for whom surgical resection would have significant psychological consequences (135).

The benefit to adjuvant radiation therapy in patients with a single groin micrometastasis is unclear. While the prognosis appears somewhat worse for this group of patients compared with node negative patients (126,136), there is little evidence of benefit to adjuvant radiation therapy (54,136,137). Thus, no additional treatment and careful observation is an option if one microscopically positive groin node (5 mm or less tumor deposit) is found in a fully dissected groin. For patients with a single groin node metastasis, a retrospective SEER database review suggests that adjuvant radiation may provide a therapeutic benefit, especially if the groin dissection was limited (138). However, size and characteristics of the nodal metastasis were not known. If unilateral groin dissection was performed for a lateral lesion, there seems to be no indication for dissection of the other side, because contralateral lymph node involvement is likely only if there are multiple microscopic or any gross ipsilateral inguinal node metastases (54,57). **If clinically evident groin metastases, any extracapsular spread, or two or more microscopically positive groin nodes are found, the patient is at increased risk of groin and pelvic recurrence and should receive postoperative groin and pelvic irradiation.** In 1977, the GOG initiated a prospective trial in which patients with positive groin nodes were randomized to either ipsilateral pelvic node dissection or bilateral pelvic plus groin irradiation (57). The survival rate for the radiation group (68% at 2 years) was significantly better than the survival rate for the pelvic lymphadenectomy group (54% at 2 years) ($p = 0.03$). The survival advantage was limited to patients with clinically evident groin nodes or more than one microscopically positive groin node. Groin recurrence occurred in 3 of 59 patients (5%) treated with radiation, compared with 13 of 55 (23.6%) patients treated with lymphadenectomy ($p = 0.02$). Four patients who received radiation had a pelvic recurrence, compared with one who had lymphadenectomy. These data highlight the value of groin irradiation in preventing groin recurrence in patients with multiple positive groin nodes. This concept of adjuvant radiation therapy including bilateral groins and pelvis for patients with two or more positive nodes is further supported by the contemporary AGO-CaRE-1 study demonstrating better outcomes with this adjuvant treatment approach (136).

Recurrent Vulvar Cancer

Recurrence of vulvar cancer correlates closely with the number of positive groin nodes (54). Patients with fewer than three positive nodes, particularly if the nodes are only microscopically involved, have a lower incidence of recurrence at any site, whereas patients with three or more positive nodes have a high incidence of local, regional, and systemic recurrences (54,57).

Most recurrences of vulvar cancer occur within the first 2 years from initial therapy, with groin recurrences occurring sooner (median time to recurrence 6 to 7 months) than vulvar recurrences (median time to recurrence 3 years) (69,139–141). **About one-third of vulvar cancer relapses present 5 or more years after initial therapy** (69). In a long-term follow-up study at the Mayo Clinic, nearly 1 in 10 patients with vulvar cancer had a late (longer than 5 years) reoccurrence of disease (69). More than 95% of those late relapses had local reoccurrences (same site recurrence or second primary vulvar site). Because of this propensity for late local reoccurrence, regular and long-term careful examinations of the vulva and groin constitute the cornerstone of posttreatment surveillance for these patients.

The published literature on the management and outcome of recurrent disease is limited. The timing and primary site of recurrence is critical to the prognosis postrecurrence. Although groin recurrences tend to occur early and are nearly always fatal, 5-year overall survival rates of 50% to 70% are reported for patients with surgically treated isolated vulvar recurrences and more than 60% of patients with local recurrence or reoccurrence were alive at 20 years in the Mayo Clinic long-term follow-up study (69,141,142). In contrast, a series of 502 patients demonstrate the poor prognosis for patients with groin, pelvic, or distant recurrences: 5-year survival rates of 27% with inguinal or pelvic recurrence, 15% with distant recurrence, and 14% with multiple sites of recurrence (143). Management of recurrent vulvar cancer depends on site of recurrence, prior treatments, and patient performance status.

Local Vulvar Recurrence

Margin status at the time of radical resection of the vulvar cancer is the most powerful predictor of local vulvar recurrence, with an almost 50% recurrence risk with margins closer than 0.8 cm (81). Margin status does not predict survival (68). Local vulvar recurrences are more likely in patients with primary lesions larger than 4 cm in diameter, especially if lymph–vascular space invasion is present, and in patients with deeply invasive tumors (133,144,145). When detected early, isolated local failure is usually treatable by additional surgical therapy, often with a myocutaneous graft to cover the defect (31,38,46,75,146). Radiation therapy, particularly a combination of external beam therapy plus interstitial needles, frequently combined with chemotherapy, is used to treat vulvar recurrences (147).

Three distinct patterns of local recurrence are described: remote vulvar recurrence (greater than 2 cm from the primary tumor site), primary tumor site recurrence (within 2

cm of the primary tumor site), and skin bridge recurrence (78,145). Although reported treatment outcomes are excellent for remote site recurrences with 3-year survival rates of 67% to 100%, the literature is controversial as to the prognostic significance of primary tumor site recurrences, with one study reporting a 3-year survival rate of only 15% and the other a 5-year survival of 93% (78,145). Patients with skin bridge recurrence have a very poor prognosis, similar to those with groin recurrence.

Regional Inguinal and Distant Recurrence

Regional and distant recurrences are difficult to manage and are associated with a poor prognosis (133,139,140). Radiation therapy may be used in conjunction with surgery for groin recurrence, and chemotherapeutic agents that have activity against squamous carcinomas may be offered for distant metastases. The literature on the use of chemotherapy for recurrent vulvar cancer consists mainly of small series. The most extensively studied regimens contain *bleomycin*, *methotrexate*, and *lomustine* (a nitrosourea); *bleomycin* and *mitomycin C;* or *cisplatin*, *vinorelbine*, and *paclitaxel*, but response rates are low and the duration of response is usually disappointing (148–152). Extrapolating from data for the management of recurrent cervical cancer, many experts recommend the administration of platinum/taxane-based chemotherapy with or without *bevacizumab*. There is a role for palliative radiation of select symptomatic recurrences. Long-term survival is very uncommon with regional or distant recurrence. Symptom control and quality of life are important treatment goals, and early involvement of a multidisciplinary palliative care team is generally indicated.

MELANOMA

Vulvar melanomas are rare, with an incidence of 0.1 to 0.19 per 100,000 women (153,154). **They account for approximately 10% of all cases and are the second most common form of vulvar malignancy.** Most melanomas arise de novo, but they may arise from a preexisting junctional nevus. Vulvar melanomas occur most frequently in postmenopausal white women, but are commonly seen in individuals with darker pigmented skin. Contrary to cutaneous melanoma, based on SEER data, there are low racial differences in vulvar melanomas, the development of which appears to be determined by factors other than ultraviolet radiation exposure and the photoprotective effects of melanin seen in cutaneous melanoma (155). The incidence of cutaneous melanomas worldwide is increasing significantly, but not that of vulvar melanoma (155). Vulvar melanomas appear to behave in a manner similar to that of other truncal cutaneous melanomas. From a molecular genetic perspective, vulvar melanoma more closely resembles acral lentiginous melanoma rather than cutaneous melanoma. KIT is the most commonly mutated gene detected in up to 35% of vulvar melanomas. More rarely NRAS and BRAF mutations have been described (156).

FIGURE 40-6 Melanoma of the vulva involving the right labium minus. (From **Hacker NF, Eifel PJ.** Vulvar cancer. In: Berek JS, Hacker NF. *Berek & Hacker's Gynecologic Oncology*. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015:595.)

Most patients with vulvar melanoma have no symptoms other than a pigmented lesion that may be enlarging. The lesion may present as macules, papules, or nodules of irregular configuration and coloration, typically greater than 7 mm in diameter. Some patients have pruritus or bleeding, a few have a groin mass, and some lesions are amelanotic. Vulvar melanomas occur most frequently on the labia majora, followed by the labia minora and the clitoris (157) **(Fig. 40-6)**; extension into the urethra or vagina at discovery is not uncommon. Any pigmented lesion on the vulva should be excised or, if the lesion is large, sampled for biopsy unless it is known to have been present and unchanged for some years. Most vulvar nevi are junctional and may be precursor lesions to melanoma; any nevus of the vulva should be removed. **Excisional biopsy, rather than a shave, wedge, or punch biopsy, is recommended to ensure evaluation of the entire lesion and facilitate microstaging and measurement of tumor thickness.**

Histopathology

There are three basic histologic types of vulvar melanoma (158; Fig. 40-7):

1. The *mucosal lentiginous melanoma* (25% to 57%) is a flat freckle that may become quite extensive but tends to remain superficial.
2. The *nodular melanoma* (22% to 28%), which is the most aggressive, is characterized by a raised lesion that penetrates deeply and may metastasize widely.
3. The *superficial spreading melanoma* (4% to 56%) tends to remain relatively superficial early in its development.

In one of the larger reported series, more than one-fourth of the cases of melanomas were macroscopically amelanotic (153). Vulvar melanoma tends to spread early, lymphatically and hematogenously.

Staging

The FIGO staging used for squamous lesions is not applicable to melanomas because the lesions are usually much smaller and the prognosis is related to tumor thickness rather than to the diameter of the lesion. The vulvar skin lacks a well-defined papillary dermis. Breslow measured the thickest portion of the melanoma from the surface of intact epithelium to the deepest point of invasion (159). It is important to recognize that tumor thickness and lymph node status are the primary determinants of survival. **The AJCC staging guidelines for cutaneous melanoma** (160) **should be used for vulvar melanoma.** Validation studies of staging systems for vulvar melanoma have confirmed that survival is best predicted by the AJCC staging system (161,162). The AJCC staging system for cutaneous melanoma is shown in Table 40-7.

The revised 2017 eighth edition of the AJCC staging for cutaneous melanoma reflects that tumor thickness remains the primary determinant of the T staging in addition to the presence of ulcerations (160). The mitotic rate is no longer a staging criterion for T1 tumors, but it remains an important prognostic factor and should be recorded for all patients with a T1 to T4 primary melanoma lesion. Specific immunohistochemistry criteria for the detection of micrometastases are included. Regional lymph node involvement is classified as either clinically occult (found microscopically, usually based upon a sentinel lymph node biopsy) or clinically detected (on physical examination or by imaging) without associated specific size criteria. Microsatellites, satellites, and in-transit cutaneous and/or subcutaneous metastases are included to stratify the lymph node staging. The site(s) of distant metastatic disease as stratified by serum lactate dehydrogenase levels remain part of the staging.

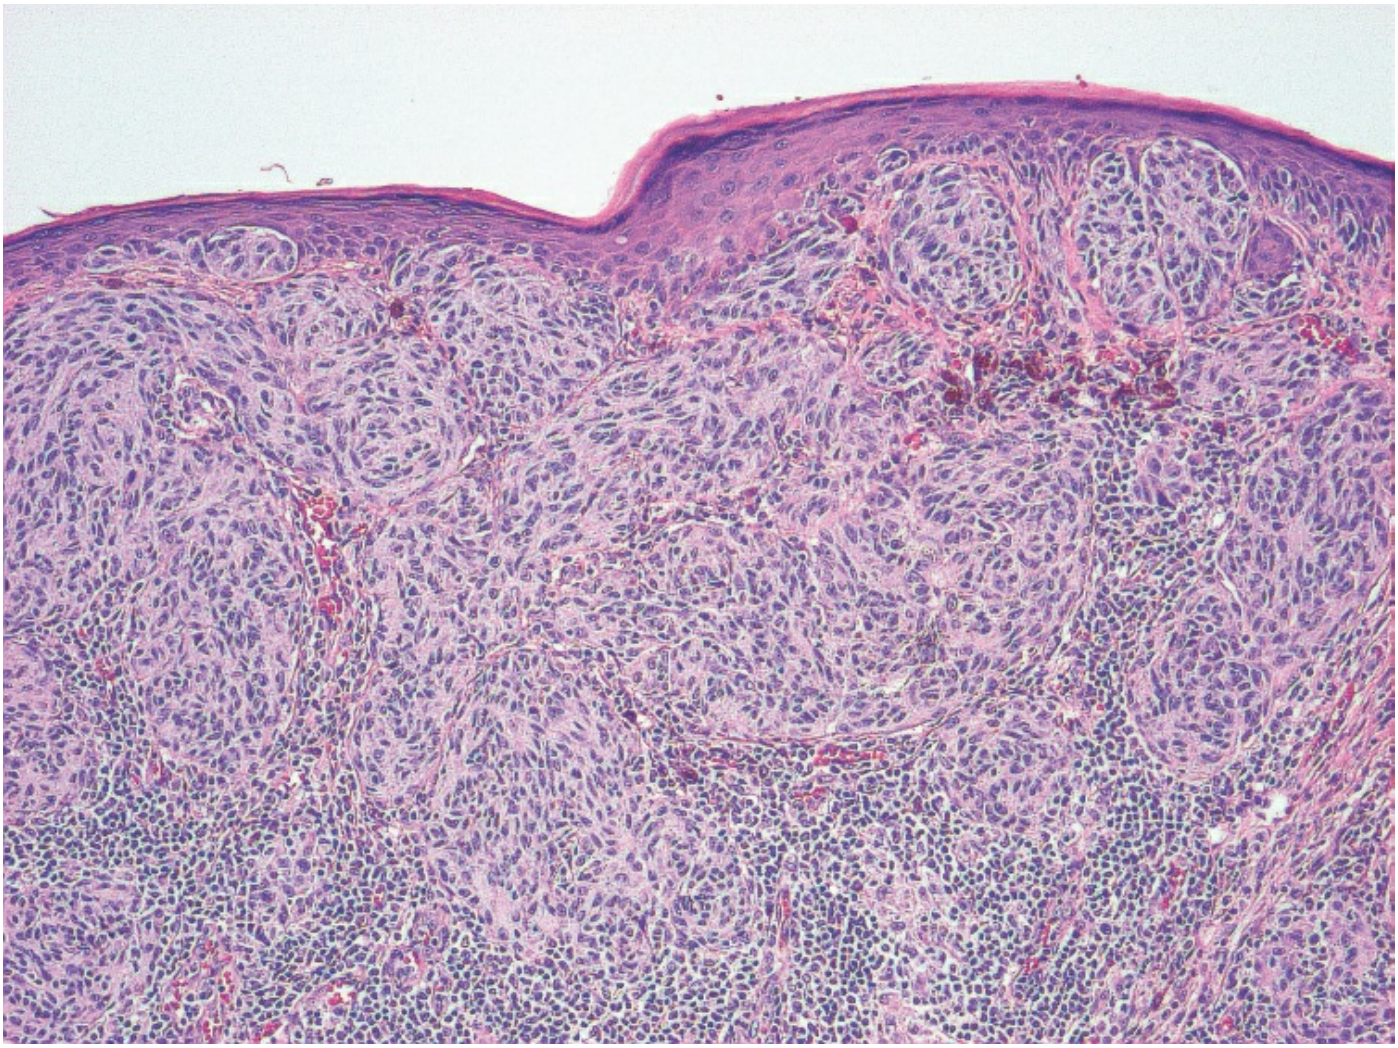

FIGURE 40-7 Vulvar melanoma. Spindle-shaped melanoma cells form interlacing bundles, and some contain melanin pigment (right upper corner). Epidermal invasion is evident in the form of Pagetoid migration (left upper corner).

Treatment

Vulvar melanomas are rare and there is minimal data specific to the treatment of vulvar melanoma. With better understanding of the prognostic significance of the microstage, some individualization of treatment developed. When feasible, the primary treatment modality for vulvar melanoma is excision. **It is accepted that lesions with less than 1 mm of invasion may be treated with radical local excision alone**. With more invasive lesions, radical vulvectomy with bilateral inguinofemoral lymphadenectomy has historically been the recommended treatment (163). Extrapolating from cutaneous melanoma and supported by smaller case series of the vulva, it has become apparent that most failures are distant and radical vulvectomy does not appear to enhance survival. Based on this recognition, the contemporary more conservative surgical approach evolved, where **surgery for vulvar melanoma entails a radical local excision with sentinel lymph node biopsy in clinically node negative patients,**

followed by complete inguinofemoral lymphadenectomy for those with involved sentinel lymph nodes. Skin margins for melanomas <1 mm thick should be 1 cm; if anatomically feasible, margins should be extended to 2 cm for melanomas with ≥1 mm thickness. At least a 1-cm tumor-free deep surgical margin down to the fascia is recommended, irrespective of tumor thickness. This conservative surgical approach is further supported by a SEER data analysis of 644 patients with vulvar melanoma which did not find a survival difference in patients with localized disease treated with more conservative versus radical surgery. Five-year disease-specific survival rates for patients undergoing conservative surgery for localized disease were 75% versus 79% for those undergoing radical surgery (164). Because melanomas commonly involve the clitoris and labia minora, the vaginourethral margin of resection is a common site of failure, and care should be taken to obtain an adequate "inner" resection margin (165). A 10-year survival rate of 61% was shown for lateral lesions, compared with 37% for medial lesions (p = 0.027) (144). In locally advanced cases, primary exenteration should not be routinely offered because of the high risk of distant failure. In these cases, radiation therapy with or without immunotherapy may be a preferred consideration.

Controversy exists as to which patients may benefit from inguinal–femoral lymphadenectomy. A prospective study by the GOG demonstrated that the risk of inguinal–femoral lymph node metastasis correlated with the Breslow microstage (166). As with cutaneous melanoma, it appears that for superficial lesions (tumor thickness <1 mm), the risk for nodal spread is so low that routine lymphadenectomy is not indicated as long as the nodes appear clinically free of disease. For intermediate-thickness (1 to 4 mm) cutaneous melanoma, a randomized controlled trial of elective lymph node dissection versus observation showed a 5-year survival advantage for patients who underwent elective lymph node dissection, who were younger than 60 years, and whose tumors were characterized by 1- to 2-mm thickness and no ulcerations (167). Patients with deeply invasive cutaneous melanomas (≥4 mm tumor thickness) have a high risk of regional and systemic metastases and were noted to be unlikely to benefit from regional lymphadenectomy (168). A randomized controlled trial evaluated 2,001 patients with intermediate thickness cutaneous melanoma and clinically negative nodes who underwent either nodal observation with lymphadenectomy for local relapse or sentinel node biopsy with immediate complete lymphadenectomy for those with positive sentinel nodes. Significantly improved melanoma-specific 10-year survival rates were observed in the sentinel node assessment group (169). Specific to patients with vulvar melanoma, there is a small body of literature to suggest that there may be a clinical benefit in elective groin lymphadenectomy and the resection of clinically positive nodes (170,171). Studies on the sentinel lymph node procedure specific to vulvar melanoma are limited. Although the sentinel node procedure appears appropriate for select patients with vulvar melanoma, the importance of an expert team familiar with the procedure and consisting of a gynecologic oncologist, a nuclear medicine specialist,

and a pathologist with expertise in microstaging cannot be overemphasized. The prognosis for patients with positive pelvic nodes is so poor that there seems to be no value in performing pelvic lymphadenectomy for this disease.

Table 40-7 Eighth (2017) Edition AJCC Melanoma TNM Definitions and Staging (161)

Primary Tumor	
Tx	Primary tumor thickness cannot be assessed
T0	No evidence of primary tumor
Tis	Melanoma in situ
T1	≤1 mm thickness
T1a	a: <0.8 mm and without ulceration
T1b	b: 0.8–1 mm or with ulceration
T2	>1 to 2 mm thickness
T2a	a: without ulceration
T2b	b: with ulceration
T3	>2 to 4 mm thickness
T3a	a: without ulceration
T3b	b: with ulceration
T4	>4 mm thickness
T4a	a: without ulceration
T4b	b: with ulceration
Regional Lymph Nodes	
NX	Regional nodes not assessed
N0	No regional metastases detected
N1	One tumor-involved node *or* in-transit, satellite, and/or microsatellite metastases with no tumor-involved nodes
N1a	a: one clinically occult (i.e., detected by SLN biopsy)
N1b	b: one clinically detected (on examination or imaging)
N1c	c: in-transit, satellite, and/or microsatellite metastases with no tumor-involved nodes
N2	Two or three tumor-involved nodes *or* in-transit, satellite, and/or microsatellite metastases with one tumor-involved node

N2a	a: two or three clinically occult (i.e., detected by SLN biopsy)
N2b	b: two or three positive, at least one clinically detected
N2c	c: in-transit, satellite, and/or microsatellite metastases with one tumor-involved node (occult or clinically detected)
N3	Four or more tumor-involved nodes *or* in-transit, satellite, and/or microsatellite metastases with two or more tumor-involved nodes, *or* any number of matted nodes without or with in-transit, satellite, and/or microsatellite metastases
N3a	a: four or more clinically occult (i.e., detected by SLN biopsy)
N3b	b: four or more, at least one clinically detected, or any number of matted nodes
N3c	c: in-transit, satellite, and/or microsatellite metastases with two or more tumor-involved nodes (occult or clinically detected) or any matted nodes
Distant Metastases	
M0	No evidence of distant metastasis
M1	Evidence of distant metastasis
M1a	a: Distant metastasis to skin, soft tissue including muscle, and/or nonregional lymph node
M1a(0)	a(0): LDH not elevated
M1a(1)	a(1): LDH elevated
M1b	b: Distant metastasis to lung with or without M1a sites of disease
M1b(0)	b(0): LDH not elevated
M1b(1)	b(1): LDH elevated
M1c	c: Distant metastasis to non-CNS visceral sites with or without M1a or M1b sites of disease
M1c(0)	c(0): LDH not elevated
M1c(1)	c(1): LDH elevated
M1d	d: Distant metastasis to CNS with or without M1a, M1b, or M1c sites of disease
M1d(0)	d(0): LDH not elevated
M1d(1)	d(1): LDH elevated
Stage	
0	Tis, N0, M0
IA	T1a, N0, M0
IB	T1b or T2a, N0, M0

IIA	T2b or T3a, N0, M0
IIB	T3b or T4a, N0, M0
IIC	T4b, N0, M0
III	Any T, ≥N1, Mo
IV	Any T, Any N, M1

SLN, sentinel lymph node.

Management of Patients With Nodal Metastases

The decision whether to recommend adjuvant therapy depends upon the stage at diagnosis, in the context of patient age, comorbidity, and patient preferences. The presence of lymph node involvement is associated with a significant increase in risk of recurrence. Adjuvant immunotherapy with *nivolumab*, a programmed cell death protein 1 (PD-1) inhibitor, is frequently recommended for patients with lymph node involvement. *Nivolumab* is more effective and less toxic than *ipilimumab*, which targets cytotoxic T-lymphocyte– associated protein 4 (CTLA-4) (172). In BRAF wild-type patients, *ipilimumab* is associated with improved disease-free and overall survival compared with *interferon alfa*, which had been the most promising adjuvant therapy prior to the development of checkpoint inhibitor immunotherapy. Among previously untreated patients with metastatic melanoma, *nivolumab* alone or combined with *ipilimumab* results in significantly longer progression-free survival than *ipilimumab* alone. In patients with PD-L1–negative tumors, the combination of PD-1 and CTLA-4 blockade appears more effective than either agent alone (173). The combined inhibition of T-cell checkpoint pathways by *nivolumab* and *ipilimumab* in previously untreated BRAF wild-type melanoma was associated with a 55% objective response rate compared with 11% with *nivolumab* monotherapy (174). For patients whose tumor contains a BRAF V600 mutation, adjuvant therapy targeting the mitogen-activated protein (MAP) kinase pathway with a combination of a BRAF inhibitor, such as *dabrafenib*, and a MEK inhibitor, such as *trametinib*, is an important treatment option (175).

Traditionally, melanomas were thought to be radiation resistant. However, radiation therapy can provide effective palliation in the setting of unresectable, locally recurrent, or symptomatic metastatic disease. Stereotactic radiosurgery and stereotactic body radiation therapy can be particularly useful in ablating oligometastatic disease.

Prognosis

The behavior of melanomas can be unpredictable, but the prognosis is poor. The reported 5-year overall survival rate for vulvar melanoma is in the range of 50% to 60% (153,154,164). A SEER database analysis showed disease-specific survival rates

for patients with localized, regional, and distant disease of 76%, 39%, and 22%, respectively (164). Localized disease, negative lymph nodes, and younger age were significant independent prognostic factors for improved survival. Because vulvar melanoma has a propensity for late recurrences, 5-year survival may not reflect cure. Prognosis is best predicted by microstaging. Patients with lesions invading to 1 mm or less have a good prognosis, but as depth of invasion increases, the prognosis worsens. For the primary tumor (T), increasing tumor thickness, an increased mitotic rate, and the presence of ulceration (i.e., the loss of the epidermal layer overlying the primary tumor) are associated with an increased risk of relapse. The AJCC stage correlates well with prognosis and takes into consideration tumor thickness, ulceration, lymph node status, in-transit, satellite, and/or microsatellite metastases, distant metastases, and serum Lactate dehydrogenase (LDH) level. Additional prognostic factors are the patient's age, central tumor location, histologic growth pattern, lymph–vascular space involvement, aneuploidy, and elevated serum S-100B protein (153,163,170,171,176–181).

BARTHOLIN GLAND CARCINOMA

Epidemiology

Primary carcinoma of the Bartholin gland is a rare form of vulvar cancer, which accounts for about 2% to 7% of vulvar malignancies (182). Because of its rarity, individual experience with the tumor is limited, and recommendations for management must be based on the review of small published series (43,182–184). Bartholin gland carcinoma is five times more common in postmenopausal than in premenopausal women (185).

Histopathology

The bilateral Bartholin glands are greater vestibular glands situated posterolaterally in the vulva. Their main duct is lined with stratified squamous epithelium, which changes to transitional epithelium as the terminal ducts are reached. Because tumors may arise from the gland or the duct, a variety of histologic types occur, including adenocarcinomas, squamous carcinomas, and, rarely, transitional cell, adenosquamous, and adenoid cystic carcinomas. A series from the MD Anderson Cancer Center reported squamous histology in 88% of the cases (184).

Classification of a vulvar tumor as a Bartholin gland carcinoma typically required that it fulfill Honan's criteria, which are as follows:

1. The tumor is in the correct anatomic position.
2. The tumor is located deep in the labium majus.
3. The overlying skin is intact.

4. There is some recognizable normal gland present.

Strict adherence to these criteria results in underdiagnosis of some cases. Large tumors may ulcerate through the overlying skin and obliterate the residual normal gland. Although transition between normal and malignant tissue is the best criterion, some cases will be diagnosed on the basis of their histologic characteristics and anatomic location.

Signs and Symptoms

The most common initial symptom of Bartholin gland carcinoma is a vulvar mass or perineal pain. About 10% of patients have a history of inflammation of the Bartholin gland, and malignancies may be mistaken for benign cysts or abscesses. Delay of diagnosis is common, particularly for premenopausal patients. A biopsy with histologic evaluation is indicated for all cases with a palpable or visible solid mass within a Bartholin cyst or abscess, and in all instances where a presumed Bartholin cyst or abscess does not respond to treatment.

Treatment

Traditionally, treatment was radical vulvectomy with bilateral groin and pelvic node dissection (186). There seems to be no indication for dissection of the pelvic nodes in the absence of positive groin nodes, and good results are reported with hemivulvectomy or radical local excision for the primary tumor (183,184). Because these lesions are deep in the vulva, extensive dissection is required in the ischiorectal fossa; surgical margins are often close. Patients with Bartholin gland carcinoma are more likely to require postoperative radiation therapy (184). Postoperative radiation to the vulva decreased the likelihood of local recurrence from 27% (6 of 22 patients) to 7% (1 of 14 patients) (183). If the ipsilateral groin nodes are positive, bilateral groin and pelvic irradiation may decrease regional recurrence. If the tumor is fixed to the inferior pubic ramus or involves adjacent structures, such as the anal sphincter or rectum, preoperative radiation and chemotherapy is preferable to avoid ultra-radical surgery. A report of 10 consecutive patients with primary Bartholin gland carcinoma suggests that treatment with radiation or chemoradiation using teletherapy combined with a boost to the primary site or regional nodes and/or interstitial brachytherapy may offer an effective alternative to surgery with 3- and 5-year survival rates of 72% and 66%, respectively (187).

Prognosis

Because of the deep location of the gland, disease tends to be more advanced than

squamous carcinomas at the time of diagnosis but, stage for stage, the prognosis is similar. A recent single-institution series from the MD Anderson Cancer Center reported on 429 patients with invasive vulvar carcinoma (184) and compared 33 patients with Bartholin gland carcinoma with 396 patients with non-Bartholin carcinoma. Patients with Bartholin gland carcinoma had a younger median age (57 vs. 63 years), higher rate of stage III/IV disease (61% vs. 36%), and were more likely to receive radiation therapy (79% vs. 44%). However, there was no significant difference in recurrence-free and overall survival. Five-year disease-free survival rates by stage are summarized in Table 40-8.

ADENOID CYSTIC CARCINOMA OF THE BARTHOLIN GLAND

The adenoid cystic variety accounts for 15% of Bartholin gland carcinomas. A review of 62 cases reported in the literature demonstrates that adenoid cystic carcinoma of the Bartholin gland is a slow-growing tumor characterized by perineural infiltration and a marked propensity for local relapse preceding distant recurrences by years. It is less likely to metastasize to lymph nodes and carries a somewhat better prognosis (Fig. 40-8) (188–190). The slowly progressive nature of these tumors and the tendency for late recurrences are reflected in the disparity between progression-free interval and overall survival (190).

OTHER ADENOCARCINOMAS

Adenocarcinomas of the vulva usually arise in a Bartholin gland or occur in association with Paget disease. They may arise rarely from the skin appendages, paraurethral glands, minor vestibular glands, aberrant breast tissue, endometriosis, or a misplaced cloacal remnant (191).

Adenosquamous Carcinoma

A particularly aggressive type of carcinoma is the adenosquamous carcinoma. This tumor has a number of synonyms, including cylindroma, pseudoglandular squamous cell carcinoma, adenoid squamous cell carcinoma, and adenoacanthoma of the sweat gland of Lever. The tumor has a propensity for perineural invasion, early lymph node metastasis, and local recurrence. One study noted a crude 5-year survival rate of 5.5% (1 of 18) for adenosquamous carcinoma of the vulva, compared with 62.3% (48 of 77) for patients with squamous cell carcinoma (192). Treatment should be radical surgical resection and groin dissection. Postoperative radiation therapy may be appropriate.

Table 40-8 Survival of Patients With Bartholin Gland Carcinoma

FIGO Stage	No. of Patients	No. of Patients With Recurrent Disease	No. of Patients NED at Last F/U[a]
I	15 (21%)	3 (20%)	14 (93%)
II	16 (23%)	2 (13%)	15 (94%)
III	30 (42%)	11 (37%)	22 (73%)
IV	10 (14%)	5 (50%)	5 (50%)
Total	71 (100%)	21 (30%)[b]	56 (79%)[b]

From references (43,185,186,188).

[a]Median follow-up in each study was at least 5 years.

[b]Total >100% because some patients with recurrence remained NED.

FIGO, International Federation of Gynecology and Obstetrics; NED, no evidence of disease; F/U, follow-up.

Basal Cell Carcinoma

Basal cell carcinomas represent about 2% of vulvar cancers. As with other basal cell carcinomas, vulvar lesions commonly appear as a "rodent ulcer" with rolled edges, although nodules and macules are other morphologic varieties that occur. Most lesions are smaller than 2 cm in diameter and are usually situated on the anterior labia majora. Giant lesions occasionally occur (193). Basal cell carcinoma usually affects postmenopausal white women and is locally aggressive. Symptoms are frequently present for a prolonged period and most often include pruritus, soreness, and irritation (194). It is diagnosed by biopsy, and **radical local excision is adequate treatment** (195). **Metastasis to regional lymph nodes is reported but is rare** (196–198). The local recurrence rate is about 10% to 20% (194,199). Basal cell carcinoma of the vulva is associated with a high incidence of antecedent or concomitant malignancies elsewhere (194). In a series of 28 women with vulvar basal cell carcinoma, 10 patients had other basal cell carcinomas, and 10 patients suffered from other primary malignancies (194).

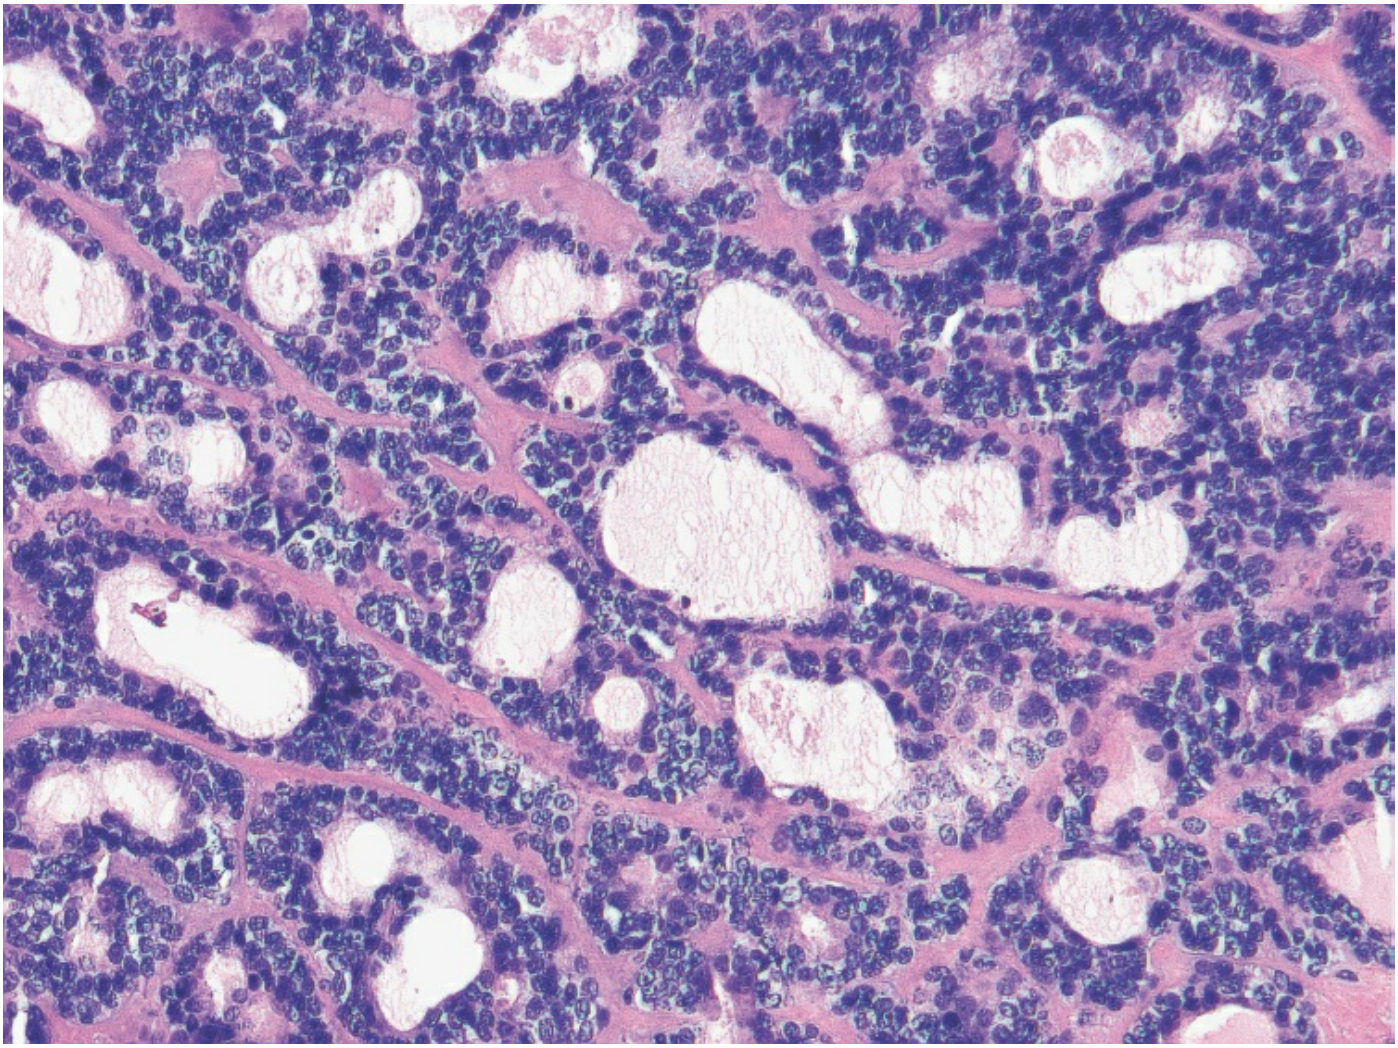

FIGURE 40-8 Adenoid cystic tumor of the Bartholin gland. Basaloid cells form cribriform, sieve-like spaces containing mucinous material. The hyaline stroma is another distinct feature of this tumor.

About 3% to 5% of basal cell carcinomas contain a malignant squamous component, the so-called *basosquamous carcinoma*. These lesions are more aggressive and should be treated as squamous carcinomas (198). Another subtype of basal cell carcinoma is the adenoid basal cell carcinoma, which must be differentiated from the more aggressive adenoid cystic carcinoma arising in a Bartholin gland or the skin (198).

Verrucous Carcinoma

Verrucous carcinoma is a variant of squamous cell carcinoma and has distinctive clinical and pathologic characteristics (200). Although most commonly found in the oral cavity, verrucous lesions may be found on any moist membrane composed of squamous epithelium (201). In the female genital tract, these lesions may develop on the cervix, vulva, and vagina. The cause of the lesion in the female genital tract is not fully understood, but associations with HPV-6 and HPV-11 were found in some studies,

whereas others found no association with HPV infection (202,203). Some studies found as many as one-third of the cases to have coexisting squamous carcinoma of the vulva, underscoring the importance of careful histopathologic assessment of these tumors (204).

Grossly, the tumors have a cauliflower-like appearance; microscopically, they contain multiple papillary fronds that lack the central connective tissue core that characterizes condylomata acuminata **(Fig. 40-9)**. The gross and microscopic features of a verrucous carcinoma are very similar to those of the **giant condyloma of Buschke-Loewenstein**, and they probably represent the same disease entity (191). Adequate biopsy from the base of the lesion is required to differentiate a verrucous carcinoma from a benign condyloma acuminatum or a squamous cell carcinoma with a verrucous growth pattern.

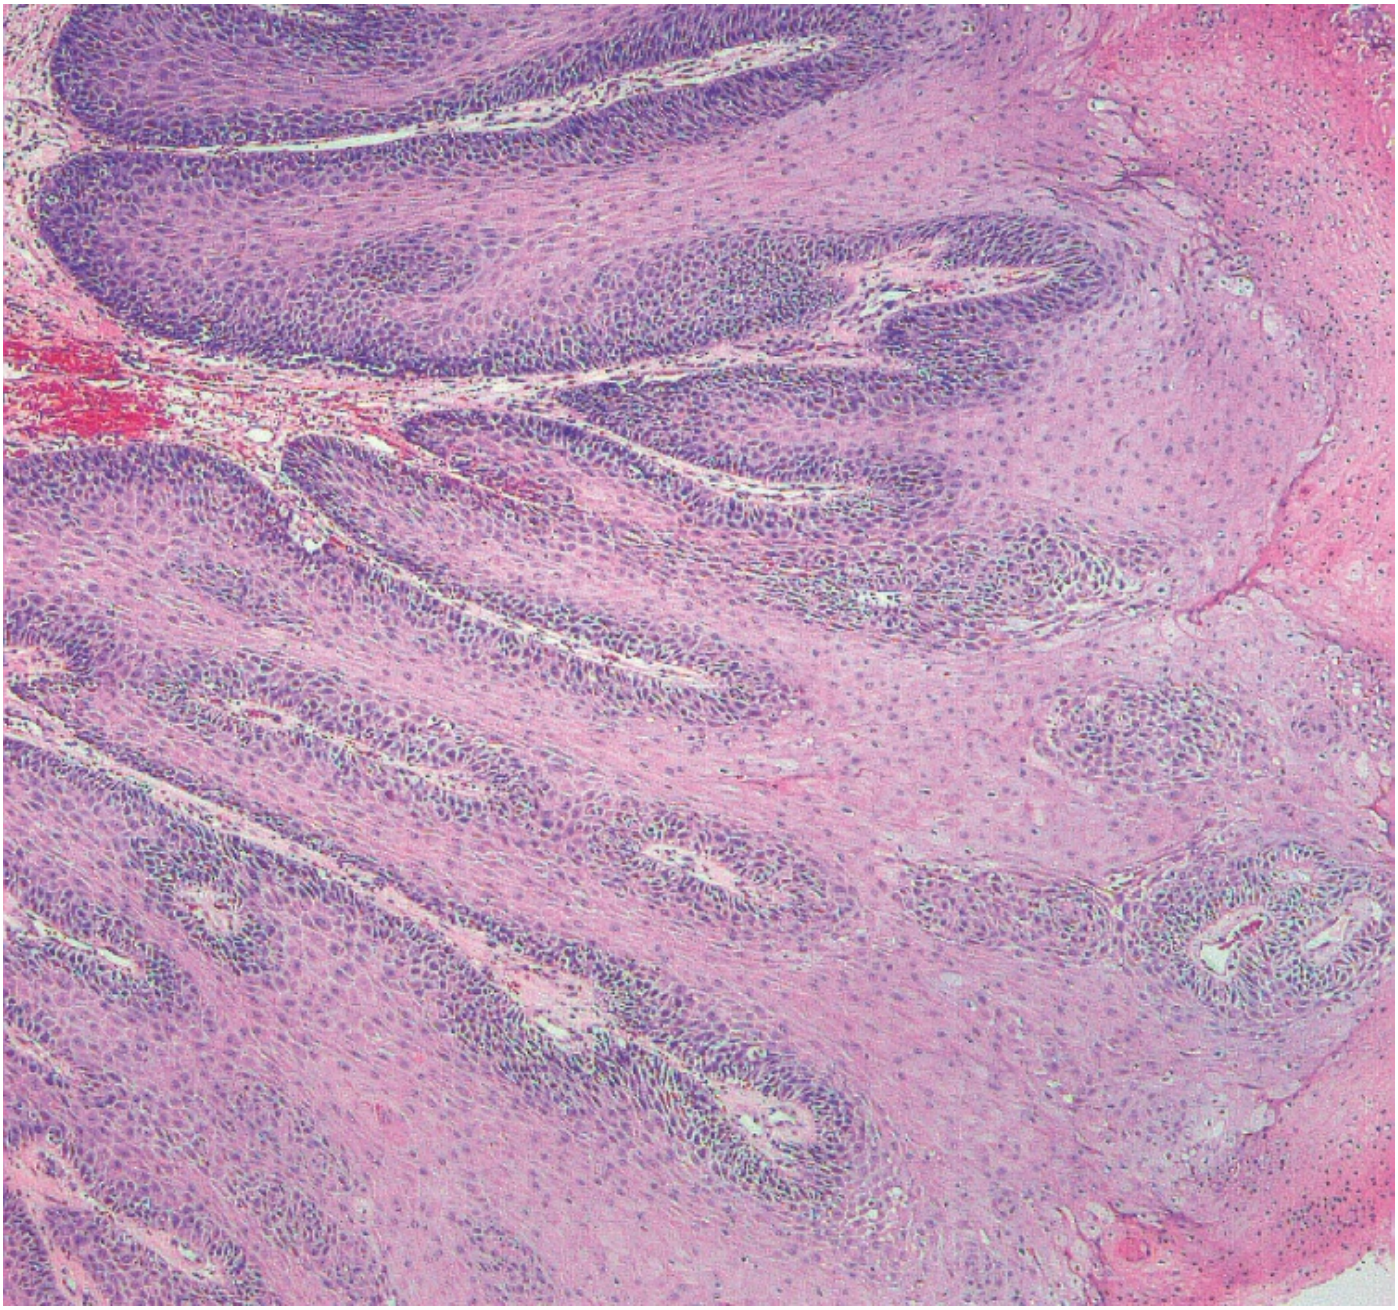

FIGURE 40-9 Verrucous carcinoma of the vulva. Note the exophytic hyperkeratotic papillary fronds and endophytic bulky rete pegs with smooth borders.

Verrucous carcinomas usually occur in postmenopausal women, and they are slow-growing but locally destructive lesions. Even bone may be invaded. Metastasis to regional lymph nodes is rare but was reported (205). Radical local excision is the basic treatment, although any palpably suspicious groin nodes should be evaluated with fine-needle aspiration cytology or excisional biopsy. Usually, enlarged nodes will be caused by inflammatory hypertrophy (206). If the nodes contain metastases, radical vulvectomy and bilateral inguinal–femoral lymphadenectomy are indicated.

Several small studies failed to document any therapeutic advantage with radiation therapy (206). There is concern that radiation may induce anaplastic transformation with

subsequent regional and distant metastasis (207). One study reported a corrected 5-year survival rate of 94% for 17 patients treated with surgery alone, compared with 42% for 7 patients treated with surgery and radiation (206). The latter patients had more advanced disease. If there is a recurrence, further surgical excision is the treatment of choice, which occasionally may necessitate some type of exenteration.

VULVAR SARCOMA

Sarcomas represent 1.5% of vulvar malignancies and constitute a heterogeneous group of tumors (208). Leiomyosarcomas are the most common, and other histologic types include fibrosarcomas, neurofibrosarcomas, liposarcomas, rhabdomyosarcomas, angiosarcomas, epithelioid sarcomas, and malignant schwannomas.

***Leiomyosarcomas* usually appear as enlarging, often painful masses, in the labium majus.** Smooth muscle tumors of the vulva that show at least three of the following four criteria should be regarded as sarcomas: (i) diameter greater than 5 cm, (ii) infiltrating margins, (iii) 5 or more mitotic figures per 10 high-power fields, (iv) moderate-to-severe cytologic atypia (209). The absence of one, or even all, of these features does not guarantee against recurrence (210). Lymphatic metastases are uncommon, and radical local excision is the usual treatment.

***Epithelioid sarcomas* characteristically develop in the soft tissues of the extremities of young adults but rarely may occur on the vulva.** A description of two cases and review of three other reports concluded that these tumors might mimic a Bartholin cyst, leading to inadequate initial treatment (211). The study indicated that vulvar epithelioid sarcomas behave more aggressively than their extragenital counterparts, with four of the five patients dying of metastatic disease, and suggested that early recognition and wide excision should improve the prognosis.

***Rhabdomyosarcomas* are the most common soft tissue sarcomas in childhood, and 20% involve the pelvis or genitourinary tract** (212). Dramatic gains were made in the treatment of these tumors during the past 20 years. Previously, radical pelvic surgery was the standard approach, but results were poor. A multimodal approach evolved, and survival rates improved significantly, with a corresponding decrease in morbidity. In a report of the experience of the Intergroup Rhabdomyosarcoma Study I and II (1972 to 1984) with primary tumors of the female genital tract, nine patients aged 1 to 19 years had primary vulvar tumors, and these tumors were often regarded as a form of Bartholin gland infection before biopsy (213). They were all managed with chemotherapy (*vincristine*, or *actinomycin D* and *cyclophosphamide* and *doxorubicin*), with or without radiotherapy. Wide local excision of the tumor, with or without inguinal–femoral lymphadenectomy, was carried out before or after the chemotherapy. Seven of the nine patients were free of disease 4 or more years from diagnosis, one patient was free of disease when lost to follow-up at 5 years, and one patient was alive

with disease.

RARE VULVAR MALIGNANCIES

In addition to the previously mentioned tumors, a number of malignancies more commonly seen in other areas of the body may rarely occur as isolated vulvar tumors.

Lymphomas

The genital tract may be involved primarily by malignant lymphomas but, more commonly, involvement is a manifestation of systemic disease. In the lower genital tract, the cervix is most often involved, followed by the vulva and the vagina (214). Most patients are in their third to sixth decades of life, and about three-fourths of the cases involve diffuse large cell or histiocytic non-Hodgkin lymphomas. The remainder are nodular or Burkitt lymphomas. Treatment is by surgical excision followed by chemotherapy and radiation or both, and the overall 5-year survival rate is approximately 70% (214).

Endodermal Sinus Tumor

There were four case reports of endodermal sinus tumor of the vulva, and three of the four patients died of distant metastases (215). All patients were in their third decade of life, but none was treated with modern chemotherapy.

Merkel Cell Carcinoma

Merkel cell carcinomas are primary small cell carcinomas of the skin that resemble oat cell carcinomas of the lung. They metastasize widely and have a very poor prognosis (216–218). They should be locally excised and treated with *cisplatin*-based chemotherapy.

Dermatofibrosarcoma Protuberans

This rare, low-grade cutaneous malignancy occasionally involves the vulva. It has a marked tendency for local recurrence but a low risk of systemic spread (219). Radical local excision should be sufficient treatment.

METASTATIC TUMORS OF THE VULVA

Metastatic tumors to the vulvas are rare. The most common primary site is the cervix, followed by the endometrium, kidney, and urethra. Most patients in whom vulvar metastases develop have advanced primary tumors when diagnosed, and in

approximately one-fourth of the patients, the primary lesion and the vulvar metastasis are diagnosed simultaneously (220).

KEY POINTS

1 Gestational trophoblastic disease (GTD) is a group of interrelated tumors which include complete and partial moles, invasive moles, choriocarcinoma, placental-site trophoblastic tumor (PSTT), and epithelioid trophoblastic tumor (ETT).

2 Complete and partial moles differ in terms of chromosomal origin, histopathology, clinical presentation, and risk of gestational trophoblastic neoplasia (gestational trophoblastic neoplasia [GTN]-persistent tumor).

3 Human chorionic gonadotropin (hCG) is a critical marker for GTD to diagnose the development of GTN, monitor response to chemotherapy, and occurrence of relapse.

4 Metastases can occur after any type of GTD but is more common after nonmolar pregnancies and most commonly occur in the lung and the vagina.

5 Single-agent chemotherapy achieves a high remission rate in nonmetastatic and low-risk metastatic GTN.

6 High-risk GTN requires primary combination chemotherapy, surgery to control complications of disease and drug-resistant sites and infrequently radiation therapy.

7 After achieving remission with chemotherapy, patients can anticipate normal future reproduction.

Gestational trophoblastic disease (GTD) is the term used to describe the heterogeneous group of interrelated lesions that arise from abnormal proliferation of placental trophoblasts. GTD lesions are histologically distinct and can be benign or malignant. Benign lesions consist of hydatidiform moles, complete and partial, whereas malignant lesions consist of invasive moles, placental-site trophoblastic tumors (PSTT), epithelioid trophoblastic tumors (ETT), and choriocarcinoma. [1] This subset of malignant lesions that have varying propensities for local invasion

and metastasis is referred to as gestational trophoblastic neoplasia (GTN). GTNs are among the rare human tumors that can be cured even in the presence of widespread dissemination (1,2). Although GTNs commonly follow a molar pregnancy, they can occur after any gestational event, including induced or spontaneous abortion, ectopic pregnancy, or term pregnancy.

HYDATIDIFORM MOLES

Epidemiology

[1] The incidence of molar pregnancy in Japan (2:1,000 pregnancies) is reported to be about threefold higher than the incidence in Europe or North America (about 0.6 to 1.1 per 1,000 pregnancies) (3). In Taiwan, 1 in 125 pregnancies are molar, while in the United States the incidence is 1 in 1,500 live births. The incidences of complete and partial hydatidiform moles in Ireland were investigated by reviewing all products of conception from first- and second-trimester abortions (4). **[1] Based on a thorough pathologic review, the incidence of complete and partial hydatidiform moles was 1:1,945 and 1:695 pregnancies, respectively.**

Table 41-1 Features of Complete and Partial Hydatidiform Moles

Features	Complete Mole	Partial Mole
Fetal or embryonic tissue	Absent	Present
Hydatidiform swelling of chorionic villi	Diffuse	Focal
Trophoblastic hyperplasia	Diffuse	Focal
Scalloping of chorionic villi	Absent	Present
Trophoblastic stromal inclusions	Absent	Present
Karyotype	46,XX (90%); 46,XY	Triploid

While variations in the worldwide incidence of molar pregnancy may result in part from reporting population-based versus hospital-based data, a number of studies suggest that the high incidence in some populations can be attributed to socioeconomic and nutritional factors. The decreasing incidence of molar pregnancy in South Korea is attributed to a more Western diet and improved standard of living (5). Case-control studies from Italy and the United States show that the rate of complete mole increases with decreasing consumption of dietary carotene (vitamin A precursor) and animal fat (6,7). **Maternal age and reproductive history influence the rate of molar pregnancy. Women older than 40 years have a 2- to 10-fold greater risk of having a complete mole,** while one in three pregnancies in women older than 50 years results in a molar

gestation (8,9). Similarly, **adolescents have a sevenfold increased risk of developing a complete mole** (8). **[1] These findings suggest that ova from adolescent and older women may be more susceptible to abnormal fertilization, resulting in a complete hydatidiform mole.**

Limited information is available concerning risk factors for partial molar pregnancy. The epidemiologic characteristics of complete and partial moles appear to differ significantly (8–11). The risk for partial moles is associated with the use of oral contraceptives and a history of irregular menstruation, but not with dietary factors (10). Nor does there appear to be a strong association between maternal age and the risk for partial moles (8,9).

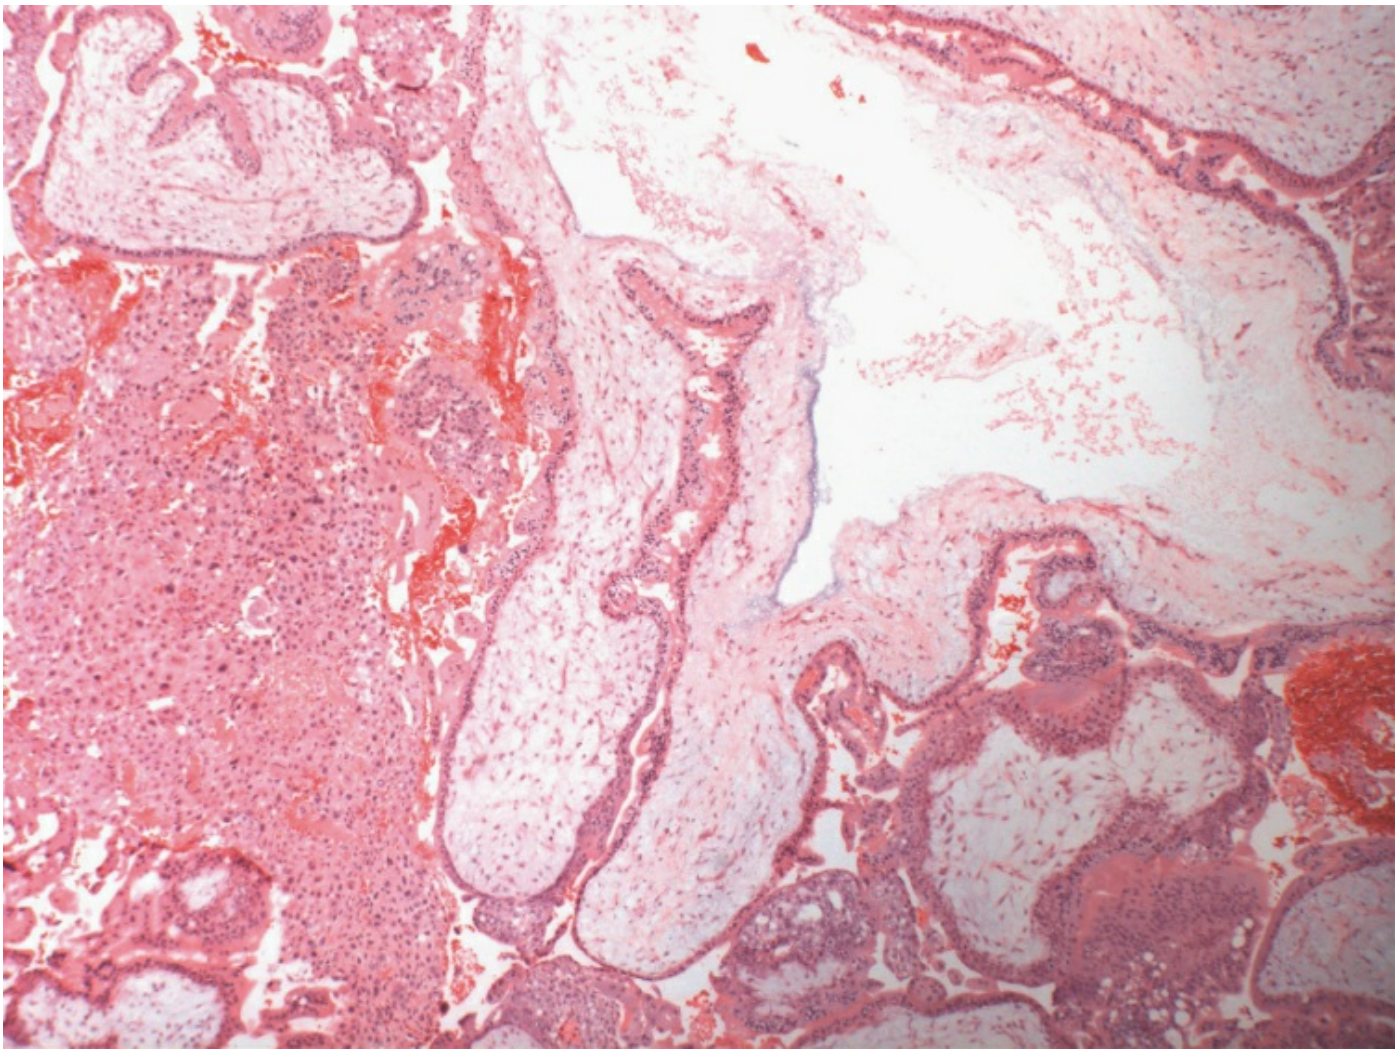

FIGURE 41-1 Photomicrograph of a complete mole demonstrating enlarged villous with central cavitation and surrounding trophoblastic hyperplasia.

Pathology and Cytogenetics

Hydatidiform moles may be categorized as either complete or partial moles on the

basis of gross morphology, histopathology, and karyotype (Table 41-1).

Complete Hydatidiform Mole

Complete hydatidiform moles exhibit characteristic swelling and trophoblastic hyperplasia (Fig. 41-1). They usually have a 46,XX karyotype, but about 10% have a 46,XY karyotype (12,13). **[2] The molar chromosomes are entirely of paternal origin,** with mitochondrial DNA of maternal origin **(Fig. 41-2)** (14). Complete moles usually arise from an ovum fertilized by a haploid sperm, which duplicates its own chromosomes. The ovum nucleus may be absent or inactivated (15).

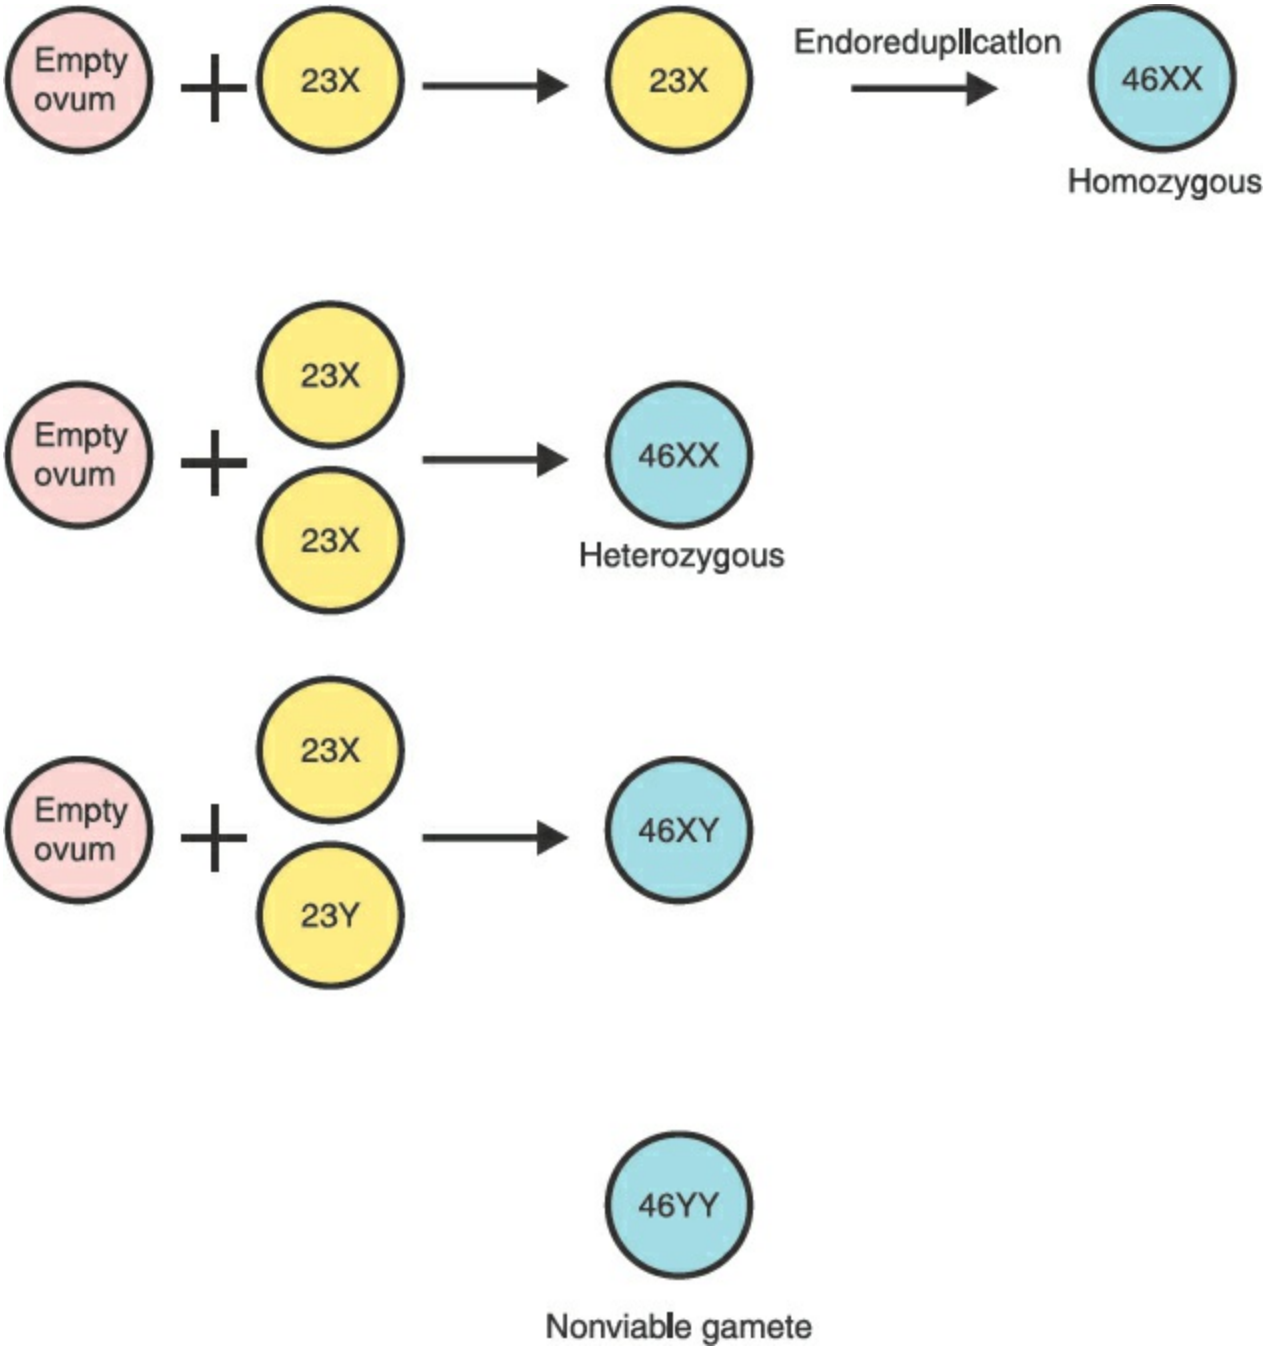

FIGURE 41-2 The karyotype of complete hydatidiform mole.

Partial Hydatidiform Mole

Partial hydatidiform moles are characterized by the following pathologic features (Fig. 41-3) (16):

1. Chorionic villi of varying size with focal hydatidiform swelling, cavitation, and trophoblastic hyperplasia
2. Marked villous scalloping
3. Prominent stromal trophoblastic inclusions
4. Identifiable embryonic or fetal tissues

[2] Partial moles have a triploid karyotype (69 chromosomes); the extra haploid set of chromosomes is derived from the father (Fig. 41-4) (17). It is possible that nontriploid partial moles do not exist (18). When a fetus is present in conjunction with a partial mole, it generally exhibits the stigmata of triploidy, including growth retardation and multiple congenital malformations such as syndactyly and hydrocephaly **(Fig. 41-5)**.

Advances in Pathologic Diagnosis

When molar pregnancy is diagnosed early in the first trimester, the pathologist can have difficulty distinguishing complete hydatidiform moles from partial hydatidiform moles or hydropic abortions because of smaller villi, less trophoblastic hyperplasia, more primitive villous stroma, and less global necrosis (19,20). Accurate diagnosis can be facilitated using flow cytometry to determine ploidy (i.e., diploid versus triploid moles) (21) and through assessment of biomarkers of paternally imprinted and maternally expressed gene products (22). Biomarkers that take advantage of imprinted genes to distinguish between complete moles and hydropic abortions from other gestations are identified. Because complete moles generally have no maternal chromosomes, paternally imprinted gene products, normally expressed only by maternal chromosomes, should be absent. In complete moles, the nuclei of the villous stroma and cytotrophoblastic cells do not express p57, whereas all other gestations, including partial moles, are characterized by nuclear immunostaining in these cells. Thus, a complete mole is diploid and negative for p57, a hydropic abortion is diploid (sometimes triploid) and positive for p57, and a partial mole is triploid and positive for p57.

Familial Recurrent Molar Pregnancy

Evaluation of families with recurrent molar pregnancy suggests that dysregulation of normal parental imprinting of genes, with loss of maternally transcribed genes, is likely

to contribute to the pathogenesis of molar pregnancy. Familial recurrent hydatidiform moles, is a rare occurrence, characterized by recurrent complete hydatidiform mole of biparental origin, rather than the more usual androgenetic origin (23). Genetic mapping shows that in most families the gene responsible, NLRP7, is located in a 1.1 Mb region on chromosome 19q13.4. Mutations in the gene result in dysregulation of imprinting in the female germline with abnormal development of embryonic and extraembryonic tissue.

Clinical Features

Patients with complete molar pregnancy are diagnosed increasingly earlier in pregnancy and treated before they develop the classic clinical signs and symptoms. **[2]** This is the result of many changes in clinical practice, such as the frequent use of human chorionic gonadotropin (hCG) measurement and transvaginal ultrasonography in early pregnancy for women with vaginal staining and for determining the gestational dates in

asymptomatic women. The following is a description of the classic and current clinical features of complete molar pregnancy (24,25).

Complete Hydatidiform Mole

Vaginal Bleeding

[2] Vaginal bleeding is the most common symptom causing patients to seek treatment for complete molar pregnancy. It is reported to occur in 46% of patients, rather than the previous reports of 97% of cases. Molar tissues may separate from the decidua and disrupt maternal vessels, and large volumes of retained blood may distend the endometrial cavity. Because vaginal bleeding may be considerable and prolonged, in the past one-half of these patients had anemia (hemoglobin <10 g/100 mL). Anemia is typically present in only 5% of patients.

Excessive Uterine Size

[2] Excessive uterine enlargement relative to the gestational age is one of the classic signs of a complete mole, although it was present in only about half of patients. Excessive uterine size occurs in only 28% of patients. The endometrial cavity may be expanded by chorionic tissue and retained blood. Excessive uterine size is generally associated with markedly elevated levels of hCG, because uterine enlargement results in part from trophoblastic overgrowth.

FIGURE 41-5 Photomicrograph of a fetal hand demonstrating syndactyly. The fetus had a triploid karyotype, and the chorionic tissues were a partial mole.

Preeclampsia

[2] Preeclampsia was observed in 27% of patients with a complete hydatidiform mole. Preeclampsia is reported in only 1 of 74 patients with complete mole at the initial visit. Although preeclampsia is associated with hypertension, proteinuria, and hyperreflexia, eclamptic convulsions rarely occur. Preeclampsia develops almost exclusively in patients with excessive uterine size and markedly elevated hCG levels. Hydatidiform moles should be considered whenever preeclampsia develops early in pregnancy.

Hyperemesis Gravidarum

[2] Hyperemesis requiring antiemetic or intravenous (IV) replacement therapy historically occurred in one-fourth of women with a complete mole, particularly those with excessive uterine size and markedly elevated hCG levels. Severe electrolyte disturbances may develop and require treatment with parenteral fluids. Typically 8% of patients have hyperemesis.

Hyperthyroidism

[2] Clinically evident hyperthyroidism was observed in 7% of patients with a complete molar gestation. These women may have tachycardia, warm skin, and tremor, and the diagnosis can be confirmed by detection of elevated serum levels of free thyroxine (T_4) and triiodothyronine (T_3). Clinical evidence of hyperthyroidism with complete mole is rare.

Anesthesia or surgery may precipitate thyroid storm. Thus, if hyperthyroidism is suspected before the induction of anesthesia for molar evacuation, a-adrenergic blocking agents should be administered. Thyroid storm may be manifested by hyperthermia, delirium, convulsions, tachycardia, high-output heart failure, or cardiovascular collapse. Administration of β-adrenergic blocking agents prevents or rapidly reverses many of the metabolic and cardiovascular complications of thyroid storm. After molar evacuation, thyroid function test results rapidly return to normal.

[2] Hyperthyroidism develops almost exclusively in patients with very high hCG levels. Some investigators suggest that hCG is the thyroid stimulator in women with molar pregnancy because positive correlations between serum hCG levels and total T_4 or T_3 concentrations were observed. However, in one study in which thyroid function was measured in 47 patients with a complete mole, no significant correlation was found between serum hCG levels and serum values of free T_4 index or free T_3 index (26). Although some investigators speculated about a separate chorionic thyrotropin, this substance is not yet isolated.

Trophoblastic Embolization

Respiratory distress rarely occurs in patients with a complete mole. It is usually diagnosed in patients with excessive uterine size and markedly elevated hCG levels.

These patients may have chest pain, dyspnea, tachypnea, and tachycardia and may experience severe respiratory distress during and after molar evacuation. Auscultation of the chest usually reveals diffuse rales, and chest radiographic evaluation may show bilateral pulmonary infiltrates. Respiratory distress usually resolves within 72 hours with cardiopulmonary support. In some circumstances, patients may require mechanical ventilation. Respiratory insufficiency may result from trophoblastic embolization and the cardiopulmonary complications of thyroid storm, preeclampsia, and massive fluid replacement.

Theca Lutein Ovarian Cysts

[2] **Prominent theca lutein ovarian cysts (6 cm in diameter) develop in about one-half of patients with a complete mole** (27). Theca lutein ovarian cysts result from high serum hCG levels, which cause ovarian hyperstimulation (28). Because the uterus may be excessively enlarged, theca lutein cysts can be difficult to palpate during physical examination; however, ultrasonography can accurately document their presence and size. **After molar evacuation, theca lutein cysts normally regress spontaneously within 2 to 4 months.**

Prominent theca lutein cysts may cause symptoms of marked pelvic pressure, and they can be decompressed by laparoscopically or ultrasonographically directed aspiration. If acute pelvic pain develops, laparoscopy should be performed to assess possible cystic torsion or rupture.

Partial Hydatidiform Mole

[2] Patients with partial hydatidiform mole usually do not have the dramatic clinical features characteristic of complete molar pregnancy. **These patients have the signs and symptoms of incomplete or missed abortion, and a partial mole is diagnosed after histologic review of the tissue obtained by curettage** (29).

In a survey of 81 patients with a partial mole, the main initial sign was vaginal bleeding, which occurred in 59 patients (72.8%) (30). Excessive uterine enlargement and preeclampsia were present in 3 patients (3.7%) and 2 patients (2.5%), respectively. No patient had theca lutein ovarian cysts, hyperemesis, or hyperthyroidism. The initial clinical diagnosis was an incomplete or missed abortion in 74 patients (91.3%) and hydatidiform mole in 5 patients (6.2%). Pre-evacuation hCG levels were measured in 30 patients and were higher than 100,000 mIU/mL in 2 patients (6.6%).

Natural History

Complete Hydatidiform Mole

[2] Complete moles have a potential for local invasion and dissemination. **After molar evacuation, local uterine invasion occurs in 15% of patients, and metastasis occurs**

in 4% (27).

A review of 858 patients with complete hydatidiform mole at the New England Trophoblastic Disease Center (NETDC) revealed that two-fifths of the patients had the following signs of marked trophoblastic proliferation at the time they sought treatment:

1. **[2] hCG level greater than 100,000 mIU/mL**
2. **Excessive uterine enlargement**
3. **Theca lutein cysts 6 cm in diameter or larger**

In this review, patients with any one of these signs were considered at high risk for developing postmolar tumor. [2] After molar evacuation, local uterine invasion occurred in 31%, and metastases developed in 8.8% of the 352 high-risk patients. For the 506 low-risk patients, local invasion was found in only 3.4%, and metastases developed in 0.6%.

Older patients are at increased risk of developing postmolar GTN. One study reported that persistent tumor developed after a complete molar pregnancy in 37% of women older than 40 years (27), whereas in another study this finding occurred in 60% of women older than 50 years (31).

Partial Hydatidiform Mole

[2] Persistent tumor, usually nonmetastatic, develops in approximately 1% to 4% of patients with a partial mole, and chemotherapy is required to achieve remission (32). **Patients who develop persistent disease have no distinguishing clinical or pathologic characteristics** (33).

Diagnosis

[2] Ultrasonography is a reliable and sensitive technique for the diagnosis of complete molar pregnancy. Because the chorionic villi exhibit diffuse hydropic swelling, complete moles produce a characteristic vesicular ultrasonographic pattern as early as the first trimester (Fig. 41-6).

[2] Ultrasonography may contribute to the diagnosis of partial molar pregnancy by demonstrating focal cystic spaces in the placental tissues and an increase in the transverse diameter of the gestational sac (34). **When these criteria are present, the positive predictive value for a partial mole is 90%.**

Treatment

When molar pregnancy is diagnosed, the patient should be evaluated for the presence of associated medical complications, including preeclampsia, hyperthyroidism, electrolyte imbalance, and anemia. After the patient's condition is stabilized, a decision must be

made concerning the most appropriate method of evacuation.

Suction Curettage

[2] Suction curettage is the preferred method of evacuation, regardless of uterine size, for patients who desire to preserve fertility (32). It involves the following steps:

1. **Oxytocin infusion**—This procedure is begun before the induction of anesthesia.
2. **Cervical dilation**—As the cervix is being dilated, uterine bleeding often increases. Retained blood in the endometrial cavity may be expelled during cervical dilation. Active uterine bleeding should not deter the prompt completion of cervical dilation.
3. **Suction curettage**—Within a few minutes of commencing suction curettage, the uterine size may decrease dramatically, and the bleeding will be well controlled. The use of a 12-mm cannula is strongly advised to facilitate evacuation. If the uterus is larger than 14 weeks of gestation, one hand should be placed on top of the fundus, and the uterus should be massaged to stimulate uterine contraction and reduce the risk of perforation.
4. **Sharp curettage**—When suction evacuation is believed to be complete, gentle sharp curettage is performed to remove any residual molar tissue.

FIGURE 41-6 Ultrasonogram of a uterus showing a typical pattern of a complete hydatidiform mole. Note the characteristic vesicular ultrasonographic pattern.

Because trophoblast cells express the RhD factor, patients who are Rh negative should receive Rh immune globulin at the time of evacuation.

Hysterectomy

[2] If the patient desires surgical sterilization, a hysterectomy may be performed with the mole in situ. The ovaries may be preserved at the time of surgery, even in the presence of prominent theca lutein cysts. Large ovarian cysts may be decompressed by aspiration. Hysterectomy does not prevent metastasis; patients

still require follow-up with assessment of hCG levels.

Prophylactic Chemotherapy

The use of prophylactic chemotherapy at the time of molar evacuation is controversial. The debate concerns the wisdom of exposing all patients to potentially toxic treatment when only about 20% are at risk of developing persistent tumor.

In a study of 247 patients with complete molar pregnancy who prophylactically received a single course of *actinomycin D* (*ActD*) at the time of evacuation, local uterine invasion developed in 10 patients (4%), and no patients experienced metastasis (35). All 10 patients with local invasion achieved remission after one additional course of chemotherapy. **Prophylactic chemotherapy, prevented metastasis and reduced the incidence and morbidity of local uterine invasion.**

In two prospective randomized studies of prophylactic chemotherapy in patients with a complete mole, a significant decrease in persistent tumor was detected in patients with high-risk moles who received prophylactic chemotherapy (47% and 50% vs. 14%) (36,37). **[2] Prophylaxis may be particularly useful in the management of high-risk complete molar pregnancy, especially when hCG assessments for follow-up are unavailable or unreliable (38).**

Follow-Up

Human Chorionic Gonadotropin

[2] After molar evacuation, patients should be monitored with weekly determinations of a-subunit hCG levels until these levels are normal for 3 consecutive weeks, followed by monthly determinations until the levels are normal for 6 consecutive months (39). **The average time to achieve the first normal hCG level after evacuation is about 9 weeks** (40). **After achieving nondetectable serum hCG levels, the risk of developing GTN approaches zero** (41–43). If these findings are confirmed, it is possible that postmolar hCG surveillance could be safely abbreviated.

Contraception

Patients are encouraged to use effective contraception during the entire interval of hCG follow-up. Because of the potential risk of uterine perforation, bleeding, and infection, intrauterine devices should not be inserted until the patient achieves a normal hCG level. If the patient does not desire surgical sterilization, either oral contraceptives or barrier methods should be used.

Increased incidence of postmolar persistent tumor was reported among patients who used oral contraceptives before gonadotropin remission (44). However, data from a prospective trial and other centers indicate that oral contraceptive use does not increase

the risk of postmolar trophoblastic disease (45–47). **It appears that oral contraceptives may be used safely after molar evacuation during the entire interval of hormonal follow-up.**

GESTATIONAL TROPHOBLASTIC NEOPLASIA

Nonmetastatic Disease

[2] Locally invasive GTN develops in about 15% of patients after evacuation of a complete mole and infrequently after other gestations (1). These patients usually present with the following symptoms:

1. Irregular vaginal bleeding
2. Theca lutein cysts
3. Uterine subinvolution or asymmetric enlargement
4. Persistently elevated serum hCG levels.

The trophoblastic tumor may perforate the myometrium, causing intraperitoneal bleeding, or erode into uterine vessels, causing vaginal hemorrhage. Bulky, necrotic tumor may involve the uterine wall and serve as a nidus for infection. Patients with uterine sepsis may have a purulent vaginal discharge and acute pelvic pain.

[1] After molar evacuation, persistent GTN may exhibit the histologic features of either hydatidiform moles or choriocarcinoma. After a nonmolar pregnancy, persistent GTN always has the histologic pattern of choriocarcinoma. Histologic characterization of choriocarcinoma depends on sheets of anaplastic syncytiotrophoblast and cytotrophoblast without chorionic villi.

Placental-Site Trophoblastic Tumor and Epithelioid Trophoblastic Tumor

PSTT and ETT are uncommon but important variants of GTN that consist predominantly of intermediate trophoblast (48). Relative to their mass, these tumors produce small amounts of hCG and human placental lactogen (hPL), and they tend to remain confined to the uterus, metastasizing late in their course. **[1] In contrast to other trophoblastic tumors, they are relatively insensitive to chemotherapy.**

Metastatic Disease

[4] Metastatic GTN occurs in about 4% of patients after evacuation of a complete mole, but it is seen more often when GTN develops after nonmolar pregnancies (1). GTN usually metastasizes as choriocarcinoma because of its tendency for early vascular invasion with widespread dissemination. Trophoblastic tumors often are perfused by fragile vessels and are frequently hemorrhagic. Symptoms of metastases may result from

spontaneous bleeding at metastatic foci. [3] The most common sites of metastases are the lungs (80%), vagina (30%), pelvis (20%), liver (10%), and brain (10%).

Pulmonary

At the time of diagnosis, lung involvement is visible by chest radiography in 80% of patients with metastatic GTN. [4] Patients with pulmonary metastasis may have chest pain, cough, hemoptysis, dyspnea, or an asymptomatic lesion visible by chest radiography. Respiratory symptoms may be acute or chronic, persisting over many months.

GTN may produce four principal pulmonary patterns:

1. An alveolar or "snowstorm" pattern
2. Discrete rounded densities
3. Pleural effusion
4. An embolic pattern caused by pulmonary arterial occlusion.

Because respiratory symptoms and radiographic findings may be dramatic, the patient may be thought to have a primary pulmonary disease. Some patients with extensive pulmonary involvement have minimal, if any, gynecologic symptoms because the reproductive organs may be free of trophoblastic tumor. The diagnosis of GTN may be confirmed only after thoracotomy is performed, particularly in patients with a nonmolar antecedent pregnancy.

Pulmonary hypertension may develop in patients with GTN secondary to pulmonary arterial occlusion by trophoblastic emboli. The development of early respiratory failure requiring intubation is associated with a poor clinical outcome (49).

Vaginal

[4] **Vaginal metastases occur in 30% of the patients with metastatic tumor. These lesions are highly vascular and may bleed vigorously when biopsied.** Metastases to the vagina may occur in the fornices or suburethrally and may produce irregular bleeding or a purulent discharge.

Hepatic

Liver metastases occur in 10% of patients with disseminated trophoblastic tumor. Hepatic involvement is encountered when there is a protracted delay in diagnosis and the patient has an extensive tumor burden. Epigastric or right upper quadrant pain may develop if metastases stretch the hepatic capsule. Hepatic lesions may be hemorrhagic, causing hepatic rupture and exsanguinating intraperitoneal bleeding.

Central Nervous System

[4] **Metastatic trophoblastic disease involves the brain in 10% of patients.** Cerebral

involvement is seen in patients with advanced disease; virtually all patients with brain metastasis have concurrent pulmonary or vaginal involvement or both. Because cerebral lesions frequently hemorrhage spontaneously, most patients develop acute focal neurologic deficits (50,51).

Staging and Prognostic Score

Staging

[5] **An anatomic staging system for GTN was adopted by the International** [6] **Federation of Gynecology and Obstetrics (FIGO)** (Table 41-2). It is hoped that this staging system will encourage the objective comparison of data from various centers (52).

Stage I: Patients have persistently elevated hCG levels and tumor confined to the uterine corpus.

Stage II: Patients have metastases to the genital tract (i.e., adnexa, broad ligament, vagina).

Stage III: Patients have pulmonary metastases with or without uterine, vaginal, or pelvic involvement. The diagnosis is based on a rising hCG level in the presence of pulmonary lesions viewed by plain chest radiography and not chest computed tomography scans (CT scan).

Stage IV: Patients have advanced disease and involvement of the brain, liver, kidneys, or gastrointestinal tract. These patients are in the highest risk category because they are most likely to be resistant to chemotherapy. Choriocarcinoma is usually present, and the disease commonly follows a nonmolar pregnancy.

Table 41-2 Staging of Gestational Trophoblastic Tumors

Stage I	Disease confined to uterus
Stage II	GTN extending outside uterus but limited to genital structures (adnexa, vagina, broad ligament)
Stage III	GTN extending to lungs with or without known genital tract involvement
Stage IV	All other metastatic sites

Prognostic Scoring System

In addition to anatomic staging, it is important to consider other variables to predict the likelihood of drug resistance and to assist in selecting the appropriate chemotherapy (53). [5] **A prognostic scoring system proposed by the World Health** [6] **Organization reliably predicts the potential for resistance to chemotherapy** (Table

41-3).

When the prognostic score is higher than 6, the patient is categorized as high risk and requires multimodal therapy, which includes intensive combination chemotherapy, and may include surgery and radiation to achieve remission. Patients with stage-I disease usually have a low-risk score, and those with stage-IV disease have a high-risk score. The distinction between low and high risk applies mainly to patients with stage-II or III disease.

Table 41-3 Scoring System Based on Prognostic Factors[a]

	0	1	2	4
Age (years)	≤39	>39		
Antecedent pregnancy	Hydatidiform mole	Abortion	Term	
Interval between end of antecedent pregnancy and start of chemotherapy (months)	<4	4–6	7–12	>12
Human chorionic gonadotropin (IU/L) at the time of GTN diagnosis	$<10^3$	10^3–10^4	10^4–10^5	$>10^5$
ABO groups		O or A	B or AB	
Largest tumor, including uterine (cm)	<3	3–5	>5	
Site of metastases		Spleen, kidney	GI tract	Brain, liver
Number of metastases		1–3	4–8	>8
Prior chemotherapy			1 drug	≥2 drugs

[a]The total score for a patient is obtained by adding the individual scores for each prognostic factor. Total score: <7, low risk; ≥7, high risk.

Diagnostic Evaluation

[4] Optimal management of persistent GTN requires a thorough assessment [5] of the extent of the disease before the initiation of treatment. [6] **All patients with persistent GTN should undergo a careful pretreatment evaluation, including the following:**

1. Complete history and physical examination
2. Measurement of the serum hCG level
3. Hepatic, thyroid, and renal function tests
4. Determination of baseline peripheral white blood cell and platelet counts

The metastatic workup should include the following:

1. Chest radiograph or CT scan (see below regarding micrometastases)
2. Ultrasonography or CT scan of the abdomen and pelvis

3. CT or magnetic resonance imaging (MRI) scan of the head as indicated

When the pelvic examination and chest radiographic findings are negative, metastatic involvement of other sites is uncommon.

Liver ultrasonography and CT or MRI scanning will disclose most hepatic metastases in patients with abnormal liver function tests. CT or MRI scan of the head facilitates the early diagnosis of asymptomatic cerebral lesions. Chest CT scans may detect micrometastases not visible on chest radiography. Chest CT will demonstrate pulmonary micrometastases in about 40% of patients with presumed nonmetastatic disease (54). The presence of pulmonary micrometastases has not been shown to substantially change the clinical outcome.

In patients with choriocarcinoma or metastatic disease, hCG levels may be measured in the cerebrospinal fluid (CSF) to exclude cerebral involvement if the results of CT or MRI scanning of the brain are normal. The ratio of plasma-to-CSF hCG tends to be lower than 60 in the presence of cerebral metastases (55). A single plasma-to-CSF hCG ratio may be misleading, because rapid changes in plasma hCG levels may not be reflected promptly in the CSF (56).

Pelvic ultrasonography appears to be useful in detecting extensive trophoblastic uterine involvement and may aid in identifying sites of resistant uterine tumor (57). Because ultrasonography can accurately and noninvasively detect extensive uterine tumor, it may help identify patients who would benefit from hysterectomy.

Management of GTN

A protocol for the management of GTN is presented in Table 41-4.

Low-Risk Disease

Low-risk GTN includes patients with both nonmetastatic (stage I) and metastatic GTN whose prognostic score is less than 7. In patients with stage-I disease, the selection of treatment is based primarily on whether the patient desires to retain fertility.

Hysterectomy Plus Chemotherapy

[5] If the patient does not wish to preserve fertility, hysterectomy with adjuvant single-agent chemotherapy may be performed as primary treatment. Adjuvant chemotherapy is administered for three reasons:

1. To reduce the likelihood of disseminating viable tumor cells at surgery.
2. To maintain a cytotoxic level of chemotherapy in the bloodstream and tissues in case viable tumor cells are disseminated at surgery.
3. To treat any occult metastases that may be present at the time of surgery.

Chemotherapy can be administered safely at the time of hysterectomy without increasing the risk of bleeding or sepsis. In a series of 31 patients treated with primary hysterectomy and a single course of adjuvant chemotherapy, all achieved complete remission with no additional therapy (58).

Hysterectomy is performed in all patients with stage-I PSTT and ETT. Because PSTT and ETT are relatively resistant to chemotherapy, hysterectomy for presumed nonmetastatic disease is the most certain curative treatment. Patients with metastatic PSTT may still achieve remission, but their tumors are less responsive to chemotherapy (59).

Table 41-4 Protocol for Treatment of GTN

Stage I	
Initial	Single-agent chemotherapy or hysterectomy with adjunctive chemotherapy
Resistant	Combination chemotherapy
	Hysterectomy with adjunctive chemotherapy
	Local resection
	Pelvic infusion
Stages II and III	
Low risk[a]	
Initial	Single-agent chemotherapy
Resistant	Combination chemotherapy
High risk[a]	
Initial	Combination chemotherapy
Resistant	Second-line combination chemotherapy
Stage IV	
Initial	Combination chemotherapy
Brain	Whole-head radiation (3,000 cGy)
	Craniotomy to manage complications
Liver	Resection or embolization to manage complications
Resistant[a]	Second-line combination chemotherapy
	Hepatic arterial infusion

[a]Local resection optional.

Chemotherapy Alone

[5] Single-agent chemotherapy is the preferred treatment in patients with stage-I disease who desire to retain fertility (60). At the NETDC from July 1965 through December 2016, primary single-agent chemotherapy was administered to 592 patients with stage-I GTN and 487 patients (82.3%) attained complete remission. The remaining 105 patients with resistant disease subsequently achieved remission after combination chemotherapy or surgical intervention.

[6] When a patient's disease is resistant to single-agent chemotherapy and she desires to preserve fertility, combination chemotherapy should be administered. If the patient's disease is resistant to single-agent and combination chemotherapy and she wants to retain fertility, local uterine resection may be considered. When local resection is planned, a preoperative ultrasonography, MRI, positron emission tomography (PET) scan, or arteriography may help to define the site of the resistant tumor.

Low-Risk Metastatic GTN (Stages II and III)

Vaginal and Pelvic Metastasis

[5] Low-risk disease treated with primary single-agent chemotherapy has a high (approximately 80%) rate of remission in contrast to high-risk disease that usually does not achieve remission with single-agent treatment and requires treatment with primary intensive combination chemotherapy.

Vaginal metastases may bleed profusely because they are highly vascular and friable. When bleeding is substantial, it may be controlled by packing the vagina or by wide local excision. Infrequently, arteriographic embolization of the hypogastric arteries may be required to control hemorrhage from vaginal metastases (61).

Pulmonary Metastasis

At the NETDC from July 1965 through December 2016, of the 168 patients with low-risk stages II or III disease, 130 (77.3%%) attained complete remission with single-agent chemotherapy. The remaining 38 (22.6%) patients who had disease resistant to single-agent treatment subsequently achieved remission with combination chemotherapy.

Thoracotomy

[6] Thoracotomy has a limited but important role in the management of pulmonary metastases. **If a patient has a persistent viable pulmonary metastasis following intensive chemotherapy, thoracotomy may be indicated to excise the resistant focus.** A thorough metastatic workup should be performed before surgery is undertaken to exclude other sites of persistent disease. It is important to realize that fibrotic pulmonary nodules may persist indefinitely on chest radiography, even after complete gonadotropin remission is attained. In patients undergoing thoracotomy for resistant

disease, chemotherapy should be administered postoperatively to treat potential occult sites of micrometastases.

Hysterectomy

[6] Hysterectomy may be required in patients with metastatic disease to control uterine hemorrhage or sepsis. **[6]** In patients with extensive uterine tumor, hysterectomy may substantially reduce the trophoblastic tumor burden and limit the need for multiple courses of chemotherapy (62).

Follow-Up

[3] All patients with GTN should undergo follow-up with:

1. **Weekly measurement of hCG levels until they are normal for three consecutive weeks.**
2. **Monthly measurement of hCG values until levels are normal for twelve consecutive months.**
3. **Effective contraception during the entire interval of hormonal follow-up.**

High-Risk Metastatic GTN (Stages II to IV)

[6] All patients with high-risk GTN (stages II to IV) should be treated with primary intensive combination chemotherapy and the selective use of radiation therapy and surgery. Between July 1965 and December 2016, of the 144 patients with high-risk GTN stages II to IV treated at the NETDC, 121 (84%) achieved complete remission. Before 1975, when single-agent therapy was used primarily to treat patients with stage-IV GTN, only 6 of 20 patients (30%) attained complete remission. Since 1975, 25 of 33 patients (75.7%) achieved remission. This improvement in survival resulted from the use of multimodal therapy, including primary combination chemotherapy in conjunction with radiation and surgical treatment. Patients with stage-IV disease are at the greatest risk of developing rapidly progressive and unresponsive tumors despite intensive multimodal therapy. They should be referred to centers with special expertise in the management of trophoblastic disease.

Hepatic Metastasis

The management of resistant hepatic metastasis is particularly difficult (63). If a patient becomes resistant to systemic chemotherapy, hepatic arterial infusion of chemotherapy may induce complete remission in selected cases. Hepatic resection may be required to control acute bleeding or to excise a focus of resistant tumor. New techniques of arterial embolization may reduce the need for surgical intervention.

Cerebral Metastasis

At the NETDC, cerebral metastases are treated with either whole-brain radiation (3,000

cGy in 10 fractions) or stereotactic radiosurgery in conjunction with combination chemotherapy. **[6] Because irradiation may be hemostatic and tumoricidal, the risk of spontaneous cerebral hemorrhage may be lessened by the concurrent use of combination chemotherapy and brain irradiation.** Excellent remission rates (86%) were reported in patients with cranial metastases treated with intensive IV combination chemotherapy and intrathecal *methotrexate* (*MTX*) (64).

Craniotomy

[6] Craniotomy may be required to provide acute decompression or to control bleeding. It should be performed to manage life-threatening complications so that the patient ultimately will be cured with chemotherapy. In a study of six patients (65), the use of craniotomy to control bleeding resulted in complete remission in three patients. Infrequently, cerebral metastases that are resistant to chemotherapy may be amenable to local resection (66). Patients with cerebral metastases who achieve sustained remission generally have no residual neurologic deficits.

Follow-Up

An algorithm for the management of persistent GTN is presented in **Figure 41-7**.

CHEMOTHERAPY

Single-Agent Treatment

[5] Single-agent chemotherapy with either *ActD* or *MTX* achieved comparable and excellent remission rates in both nonmetastatic and low-risk metastatic GTN (67). Several protocols using these agents are available. *ActD* can be given every other week as a 5-day regimen or in a pulsatile fashion; similarly, *MTX* can be given either in a 5-day or 8-day regimen or pulsatile weekly (68,69). No study to date has compared these various protocols with regard to success. An optimal regimen should maximize the response rate while minimizing morbidity and cost.

An important phase III randomized trial examining *MTX* and *ActD* in the treatment of low-risk GTN was published by the Gynecologic Oncology Group (GOG) (70). Two hundred sixteen patients were randomized to receive either biweekly *ActD* 1.25 mg/m^2 IV bolus or weekly *MTX* 30 mg/m^2 intramuscular (IM). The remission rate was 58% in the *MTX* arm and 73% in the *ActD* arm. These results suggest that *ActD* is superior to the weekly *MTX* regimen in treating low-risk GTN. Before recommending pulse *ActD* as the primary modality in the treatment of patients with low-risk GTN, it is important to be aware of the potential for significant toxicity of this regimen compared to those receiving *MTX*. All patients with low-risk disease in this study ultimately achieved remission, regardless of their initial response. Regarding the true comparative effectiveness of these agents, it would be prudent to compare the biweekly *ActD*

regimen to the more commonly used 5-day or 8-day *MTX* regimens, which offer a high initial remission rate with minimal toxicity. The GOG attempted to repeat a randomized trial using these regimens but the trial was closed early as a result of lack of accrual. A 2016 meta-analysis of seven randomized controlled trials indicated that substantial heterogeneity made it difficult to be confident which was the preferred single agent (67).

The administration of *methotrexate* with folinic acid (*MTX*-FA) in GTN to limit systemic toxicity was first reported in 1964 (71). It has been confirmed that *MTX*-FA is effective and safe in the management of GTN.

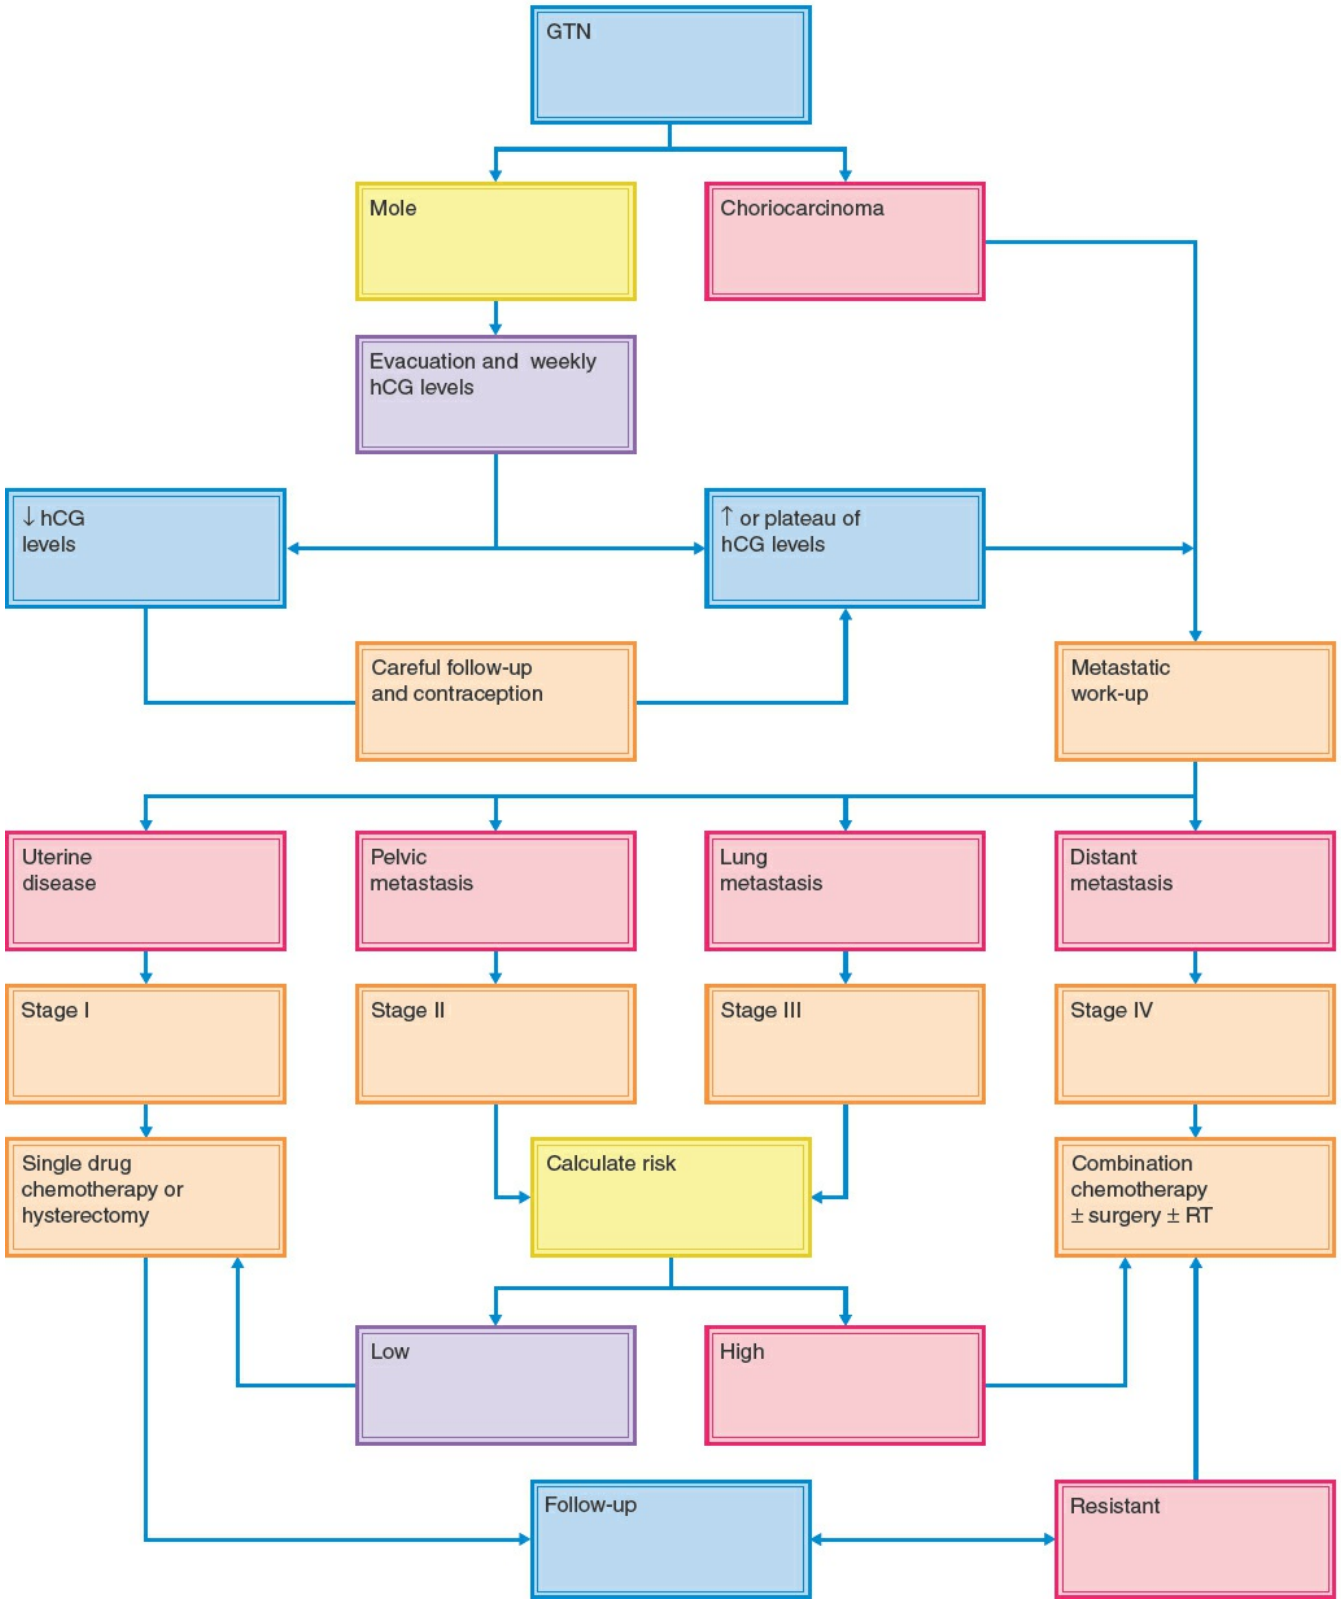

FIGURE 41-7 Management of gestational trophoblastic tumor. GTN, gestational trophoblastic neoplasia; hCG, human chorionic gonadotropin; RT, radiotherapy. (From **Berkowitz RS, Goldstein DP.** Gestational trophoblastic disease. In: Berek JS, Hacker NF. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia, PA: Wolters Kluwer; 2015;642.)

An evaluation of 185 patients treated with 8-day *MTX*-FA revealed that complete remission was achieved in 162 patients (87.6%); of these patients, 132 (81.5%) required only one course of *MTX*-FA to attain remission (72). *MTX*-FA induced remission in 147 of 163 patients (90.2%) with stage-I GTN and in 15 of 22 patients (68.2%) with low-risk stages II and III GTN. **[5] Resistance to therapy was more common in patients with choriocarcinoma, metastasis, and pretreatment serum hCG levels higher than 50,000 mIU/mL.** After treatment with MTX-FA, thrombocytopenia, granulocytopenia, and hepatotoxicity developed in 3 (1.6%), 11 (5.9%), and 26 (14.1%) patients, respectively. **[5] Thus, MTX-FA achieved an excellent therapeutic outcome with minimal toxicity and attained this goal with limited exposure to chemotherapy.**

Technique of Single-Agent Treatment

[5] Administration of single-agent chemotherapy (generally 8-day [6] MTX-FA) every 2 weeks until hCG is undetected and then three consolidation courses to reduce the risk of relapse is recommended (73,74). **Resistance to chemotherapy is diagnosed if the hCG level plateaus +/- 10% over the course of 2 weeks or re-elevates in at least one measurement of hCG level. If the patient is diagnosed as having resistance to the primary chemotherapy, treatment is promptly changed to the alternative single-agent regimen (generally ActD).**

Combination Chemotherapy

Triple Therapy

Prior to the introduction of *etoposide* in combination with *MTX, ActD, cyclophosphamide,* and *vincristine* (*EMA-CO*), triple therapy with *MTX, ActD,* and *cyclophosphamide* was the treatment of choice as initial therapy for patients with low-risk disease resistant to single-agent therapy and as primary therapy for high-risk patients. **Triple therapy is no longer indicated in patients with high-risk disease. It may be useful in selected patients with low-risk scores resistant to single agents.**

EMA-CO

Etoposide induces complete remission in 56 (95%) of 60 patients with nonmetastatic and low-risk metastatic GTN (75). **The use of *EMA-CO* induced an 83% remission rate in patients with metastasis and a high-risk score** (76). Another study confirmed that primary *EMA-CO* induced complete remission in 76% of the patients with metastatic GTN and a high-risk score (77). Another study reported that *EMA-CO* induced complete sustained remission in 87 (90.6%) of 96 patients with high-risk (score >6) GTN (78). Remission occurred with *EMA-CO* in 30 (86%) of 35 patients with brain metastasis (64).

[6] The *EMA-CO* regimen is well tolerated, and treatment seldom is suspended because of toxicity. The *EMA-CO* regimen is the preferred primary treatment in patients with metastasis and a high-risk prognostic score >6.

EMA-EP

[6] Patients resistant to *EMA-CO* can be treated successfully by substituting *etoposide* and *cisplatin* on day 8 (*EMA-EP*). *EMA-EP* induced remission alone or with surgery in 16 (76%) of 21 patients who were resistant to *EMA-CO* (79). The optimal combination drug protocol will most likely include *etoposide, MTX,* and *ActD* and perhaps other agents administered in the most dose-intensive manner.

Management of Refractory GTN

Efforts continue to identify new agents and regimens effective in treating patients who prove resistant to all standard chemotherapy regimens. A combination of *cisplatin, vinblastine,* and *bleomycin* (*PVB*) was used effectively in patients with drug-resistant tumor (80). Although *ifosfamide* and *paclitaxel* were used successfully, further studies are needed to define their potential role in either primary or second-line therapy (81,82). Wang et al. reported that a novel three-drug doublet regimen consisting of paclitaxel, etoposide, and cisplatin (TE/TP) induced response in seven patients (three complete, four partial) who were resistant to EMA-CO (83). Wan et al. demonstrated that *floxuridine* (*FUDR*)-containing regimens induced complete remission in all of 21 patients with drug-resistant GTN (84). Matsui et al. found that 5-*fluorouracil* (5-*FU*) in combination with *ActD* induced remission in 9 of 11 (82%) patients with drug resistance (85). **[6]** The potential role for autologous bone marrow transplantation or stem cell rescue in conjunction with ultra–high-dose chemotherapy has yet to be defined, although complete remissions were reported in patients with refractory GTN (86,87).

Duration of Therapy

[6] Patients who require combination chemotherapy must be treated intensively to attain remission. Combination chemotherapy should be given as often as toxicity permits until the patient achieves three consecutive normal hCG levels. After normal hCG levels are attained, at least three additional courses of chemotherapy are administered to reduce the risk of relapse.

False-Positive hCG Tests

The concept of false-positive hCG tests caused by heterophile antibodies is critical to remember when following patients with molar gestation or GTN. Some assay systems

used by commercial laboratories are particularly vulnerable to false-positive tests resulting from the presence of heterophilic antibodies in the test kits they were using (88). For the most part this problem was corrected by adding blocking antibodies to the test systems. Since the hCG molecules in GTN are significantly more degraded or heterogeneous than in normal pregnancy, with higher proportions of free β-hCG, nicked hCG, and β-core fragments, it is important to use an assay that detects intact hCG and its metabolites and fragments in order to accurately assess the tumor burden (89–91). Cross-reactivity with luteinizing hormone (LH) can cause confusion when dealing with women in the perimenopausal age group whose hCG level may plateau above assay, even when there is no longer active tumor. The pituitary normally produces low hCG levels which may increase into the measurable range when chemotherapy induces ovarian failure. The use of hormone suppression will suppress LH and pituitary hCG and prevent unnecessary treatment. False-positive hCG tests caused by heterophile agglutinins or LH release may cause confusion in the diagnosis of early pregnancy, ectopic pregnancy, and the so-called phantom choriocarcinoma. When there is concern about the possibility of a false-positive serum hCG test, a urine sample should be tested, because patients with phantom hCG generally have no measurable hCG in a parallel urine sample.

Persistent Low-Level "Real" hCG

Some patients with molar pregnancy and GTN have persistent (weeks to months) very low levels of real hCG (usually <500 mIU/mL). In these women, extensive radiologic and clinical evaluations fail to reveal any lesions, and chemotherapy is usually not effective. This condition of "real" low-level hCG, where hCG is not hyperglycosylated, is called "quiescent GTN." These patients should be managed with careful follow-up, because 6% to 10% ultimately will relapse into active disease and rising hCG levels. The risk of relapse to active disease is correlated with the amount of hyperglycosylated hCG. If relapse does occur, chemotherapy usually proves effective (92).

Subsequent Pregnancies

Pregnancies After Uncomplicated Hydatidiform Mole

[7] Patients with hydatidiform moles can anticipate normal reproduction in the future (93). At the NETDC from 1965 until 2014, patients with uncomplicated complete mole had 1,388 subsequent pregnancies that resulted in 949 term live births (68.4%), 103 premature deliveries (7.4%), 11 ectopic pregnancies (0.8%), 7 stillbirths (0.5%), and 20 repeat molar pregnancies (1.4%). First- and second-trimester spontaneous abortions occurred in 256 (18.4%) pregnancies. Major and minor congenital malformations were detected in 40 infants (3.8%).

Although data regarding pregnancies after a partial mole are limited (357 subsequent pregnancies), the information is reassuring (93). [7] **Patients with complete or partial moles should be reassured that they are generally at no increased risk of complications in later gestations.**

[7] **When a patient has had a molar pregnancy, either partial or complete, she should be informed of the increased risk of having a molar gestation in subsequent conceptions. After one molar pregnancy, the risk of having molar disease in a future gestation is about 1% to 1.5%.** Of 37 patients with at least two documented molar pregnancies, every possible combination of repeat molar pregnancy was observed. After two molar gestations, these 37 patients had 40 later conceptions resulting in 25 (62.5%) term deliveries, 7 (17.5%) moles (6 complete, 1 partial), 3 spontaneous abortions, 3 therapeutic abortions, 1 intrauterine fetal death, and 1 ectopic pregnancy. In 6 patients, the medical records indicated that the patient had a different partner at the time of different molar pregnancies (93).

[7] **For any subsequent pregnancy, it seems prudent to undertake the following approach:**

1. **Perform pelvic ultrasonographic examination during the first trimester to confirm normal gestational development.**
2. **Obtain an hCG measurement 6 weeks after completion of the pregnancy to exclude occult trophoblastic neoplasia.**

Pregnancies After GTN

[7] **Patients with GTN who are treated successfully with chemotherapy can expect normal reproduction in the future.** Patients who were treated with chemotherapy at the NETDC from 1965 to 2014 had 667 subsequent pregnancies that resulted in 446 term live births (66.9%), 44 preterm deliveries (6.6%), 7 ectopic pregnancies (1.0%), 10 stillbirths (1.5%), and 9 repeat molar pregnancies (1.3%) (93). First- and second-trimester spontaneous abortions occurred in 123 (18.4%) pregnancies. Major and minor congenital malformations were detected in 12 infants (2.4%). The frequency of congenital anomalies is not increased, although chemotherapeutic agents have teratogenic and mutagenic potential.

KEY POINTS

1 Breast cancer accounts for 30% of cancers in women. The risk of breast cancer increases with age, a personal or family history of breast cancer, hormone exposure, and breast density.

2 Breast cancer screening modalities include clinical breast examination and imaging.

3 Breast cancer may be either *in situ* or invasive. *In situ* and invasive cancers should be assessed for estrogen and progesterone receptor expression, and invasive cancers should be assessed for the overexpression of human epidermal growth factor 2 receptors (HER2).

4 The combination of segmental mastectomy, axillary staging, and postoperative radiation therapy has the same overall survival compared to mastectomy with axillary staging for stage I and II breast cancer.

5 Sentinel lymph node dissection alone can replace axillary lymph node dissection if the patient is having breast-conserving therapy with adjuvant radiation and the sentinel lymph node is found to be tumor free or there are only one or two lymph nodes positive for malignancy without extracapsular extension.

6 Axillary lymph node status, tumor markers, and tumor genomic analysis are the most important prognostic factors for breast cancer.

7 Cytotoxic chemotherapy, hormone therapy, and targeted agents are used for the adjuvant and neoadjuvant treatment of breast cancer. These treatments decrease locoregional recurrence and improve survival.

[1] Breast cancer accounts for approximately 30% of all new cancers in women and is second only to lung cancer as the leading cause of cancer deaths among women. Breast cancer has the highest incidence of all cancers. According to statistics from the American Cancer Society, over 252,000 new cases of breast cancer will be diagnosed in women in 2017, with more than 40,000 women succumbing to the disease during the same period (1). During the past 50 years, the incidence of breast cancer in the United States increased significantly and then leveled off in the last decade. Some, but not all, of this increase is felt to be related to the diagnosis of indolent cancers that may have remained asymptomatic and undetected for the duration of a woman's life in the pre-screening era. The minor increase in breast cancer incidence during the last 10 years can be attributed almost entirely to cancers diagnosed in non-white women. The breast cancer mortality rate has declined since 1990.

CARCINOGENESIS

The doubling time of breast cancer ranges from several weeks for rapidly growing tumors to months or years for slowly growing lesions. If the doubling time of a breast tumor was constant and a tumor originated from one cell, a doubling time of 100 days would result in a 1-cm tumor in about 8 years **(Fig. 42-1)** (2). During the preclinical phase, tumor cells may be circulating throughout the body. **Because of the long preclinical tumor growth phase and the tendency of infiltrating lesions to metastasize early, many clinicians view breast cancer as a systemic disease at the time of diagnosis.** Although cancer cells may be released from the tumor before diagnosis, variations in the tumor's ability to colonize distant tissues and the host's immune response may inhibit dissemination of the disease. A tumor's ability to metastasize to the regional lymph nodes may not be indicative of the tumor's ability to metastasize to distant sites, and patients may be curable even in the presence of palpable axillary disease. A pessimistic attitude that a breast cancer that has spread to the regional lymph nodes is incurable is unwarranted.

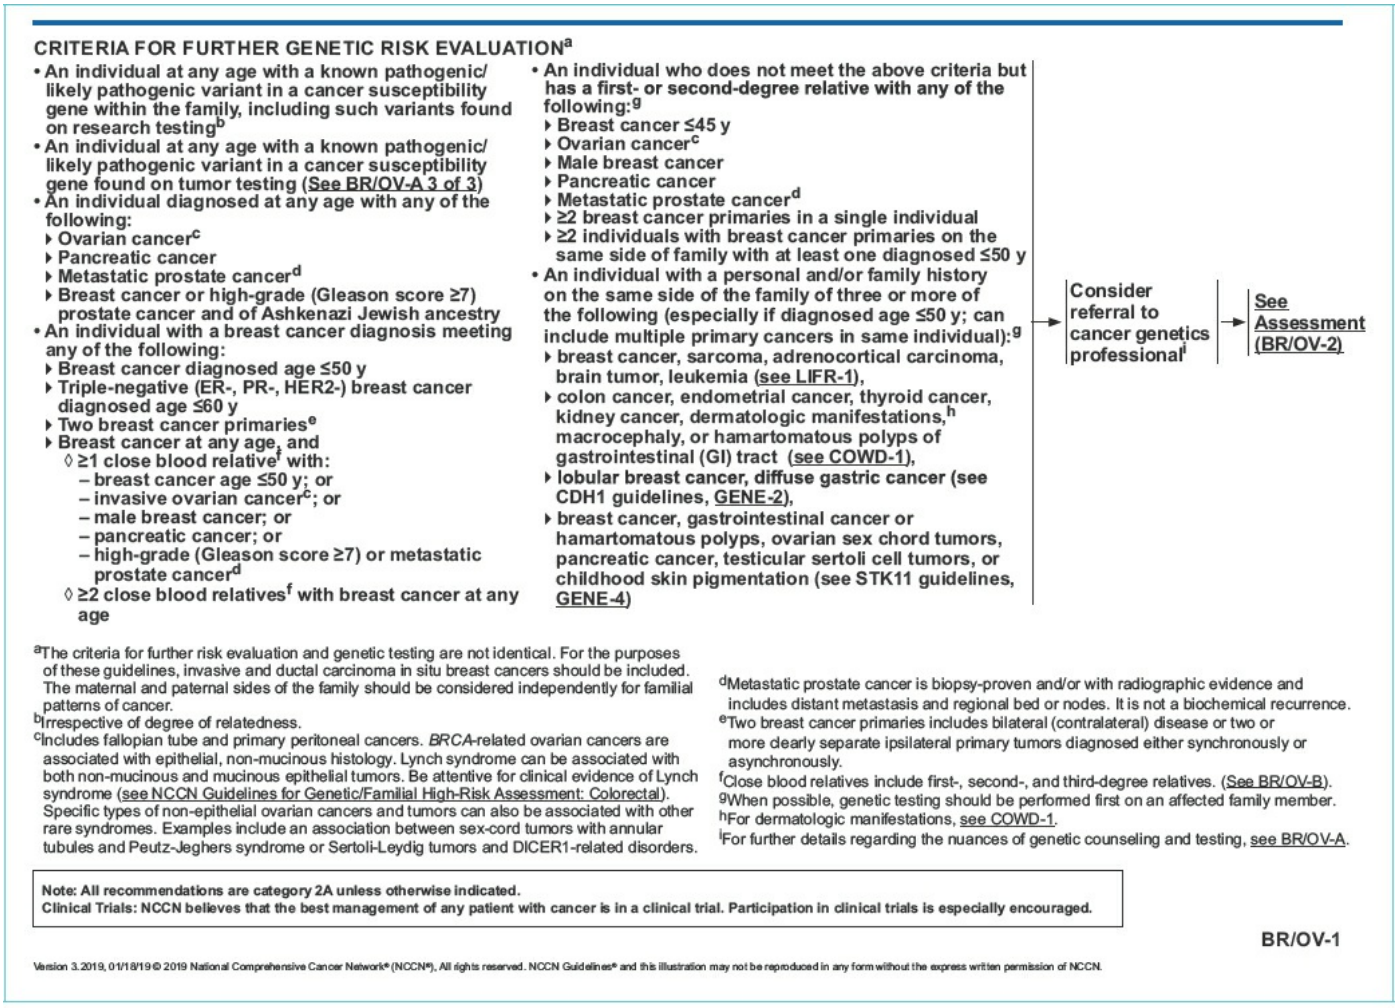
BREAST CANCER RISK FACTORS

Age

[1] The risk of developing breast cancer increases as a woman's age increases. The risk of developing breast cancer is less than 2% in women younger than 50 and increases steadily to almost 7% in women older than 70. The lifetime risk of developing breast cancer for women in the United States is 12.4%, or one in eight women (1).

Family History

[1] A family history of breast cancer is a well-established risk factor for the development of the disease. Although any family history of breast cancer increases a woman's overall relative risk, women with a first-degree relative who has been affected by the disease are at approximately a twofold increased risk of developing breast cancer compared to the general population (3). An individual's risk is not significantly increased if the affected relative was diagnosed postmenopausally (4). **[1] Other familial risk factors include multiple affected family members, early onset of disease in those family members, bilateral breast cancer, and male breast cancer.**



[1] Approximately 5% to 10% of breast cancers have a known inherited basis associated with mutations in high- and low-penetrance genes. The most well-studied mutations are the *BRCA1* (chromosome 17q21) and *BRCA2* (chromosome 13q12-13) gene deletions. Carriers of these germline mutations have a cumulative risk of breast cancer by age 70 of 57% and 49% for *BRCA1* and *BRCA2*, respectively. The *BRCA1* mutation is associated with an increased risk of ovarian and prostate cancer, whereas the *BRCA2* mutation is associated with an increased risk of ovarian, male breast, prostate, pancreatic, gastric and colon cancers, and melanoma. Both mutations are rare in the general population (0.1%) and are more commonly identified in those of Ashkenazi Jewish descent (1% to 2.3%) (5).

Genetic testing is available and should be considered if there is a high likelihood that the results will be positive and used to influence decisions regarding the clinical management of the care of the patient and her family. The National Comprehensive Cancer Network (NCCN) Clinical Practice Guidelines In Oncology (NCCN Guidelines®) regarding who should be referred for a breast and/or ovarian genetic assessment are listed in Table 42-1. If a patient meets the criteria for genetic testing, she should be referred to a cancer genetics specialist for consultation.

Genetic testing has become increasingly important given the evidence that prophylactic mastectomy and oophorectomy prevent new cancers from occurring and may prolong survival. A prospective multicenter cohort study of 2,482 women with *BRCA1* and *BRCA2* mutations between 1974 and 2008 showed prophylactic mastectomy was associated with a decreased risk of breast cancer. Risk-reducing salpingo-

oophorectomy was associated with decreased risk of ovarian cancer, first diagnosis of breast cancer, all-cause mortality, breast cancer–specific mortality, and ovarian cancer–specific mortality (6).

The NCCN Guidelines are a work in progress that may be refined as often as new significant data becomes available.

Reproductive and Hormonal Factors

[1] The risk of breast cancer increases with the length of a woman's reproductive phase (7). Although early menarche was reported among breast cancer patients, early menopause appears to protect against the development of the disease, with artificial menopause from oophorectomy lowering the risk more than early natural menopause (8). There is no clear association between the risk of breast cancer and menstrual irregularity or the duration of menses. Lactation seems to only affect the incidence of breast cancer in a subset of patients (those lactating for greater than 12 cumulative months) and a subset of cancers (premenopausal). Women who were never pregnant

have a higher risk of breast cancer than those who are multiparous. Women who give birth to their first child later in life have a higher incidence of breast cancer than do younger primigravida women (9).

[1] **Hormonal contraceptive use is associated with a small but statistically significant increased risk of developing breast cancer.** Historic data, from a well-controlled study by the Centers for Disease Control and Prevention, suggested that oral contraceptive use did not increase the risk of breast cancer, regardless of duration of use, family history, or coexistence of benign breast disease (10). Yet a contemporary prospective cohort study that included almost 1.8 million women concludes that women using hormonal contraception for longer than a year are at a 20% increased risk of developing breast cancer (11).

The relationship between the use of postmenopausal hormone replacement therapy and the development of breast cancer has been studied extensively. [1] **Randomized controlled trials have confirmed the finding that the use of combination estrogen plus progesterone hormone replacement increases a woman's risk of breast cancer, but the use of unopposed estrogen does not appear to carry the same risk** (12,13). Longer durations of use (>15 years plus current use) of estrogen alone have been shown to be associated with increased risk (14).

Personal History of Cancer

[1] **In women with a history of breast cancer, the absolute risk of developing a contralateral breast cancer exceeds that of the general population and was approximately 0.6% per year in historical series** (15). In the era of modern systemic adjuvant therapies, this risk is lower (16). Invasive lobular carcinoma (ILC) has a higher incidence of bilaterality than does ductal carcinoma. A history of endometrial, ovarian, or colon cancer is associated with an increased risk of subsequent breast cancer, as is a history of radiation therapy for Hodgkin lymphoma, even if the patient is *BRCA1* and *BRCA2* negative.

DIAGNOSIS

Breast Cancer Screening

[2] **The breast cancer screening modalities of clinical breast examination and breast imaging are complementary. Approximately 10% to 50% of cancers detected mammographically are not palpable, whereas physical examination detects 10% to 20% of cancers not seen radiographically** (17). The purpose of screening is to detect tumors early in an attempt to avoid breast cancer–related morbidity and mortality. Although many randomized controlled trials and systemic reviews comparing mammography screening to no screening have shown a protective

effect among women aged 40 to 69, a long-term follow-up study has raised questions regarding overdiagnosis and the possibility of mammography having less beneficial impact as systemic therapies improve (18). The benefit of breast cancer screening in women aged 40 to 49 is controversial, which has resulted in differing recommendations from medical societies for this age group. However, **[2] most expert groups recommend shared decision making regarding screening in the 40 to 49 age group, annual or biannual screening of women aged 50 to 74, and annual or biannual screening of women over 75 if their life expectancy is at least 10 years.**

Monthly breast self-examination (BSE) is no longer recommended because there is little evidence to show that BSE is superior to heightened breast awareness such that any new symptoms related to the breast in daily activities would be reported promptly when noticed. BSE has not been shown to improve survival. Women should be informed about the benefits and limitations of monthly BSE, including the risk of a false-positive result. Multiple other screening modalities have been suggested, including ultrasonography, computed tomography, sestamibi scan, positron emission tomography (PET), and serum tumor markers, but these have ultimately been found to be ineffective.

[2] The ACS recommends annual screening mammography and annual breast magnetic resonance imaging (MRI) starting at age 30 for women with known *BRCA* or other high-risk genetic mutations, women who are untested with a first-degree relative with the *BRCA* mutation, women with an approximately 20% to 25% or greater lifetime risk of breast cancer, and women who have been treated with radiation for Hodgkin lymphoma (18). Although breast MRI may prove to be advantageous for other women with an elevated risk of breast cancer, there is insufficient evidence to recommend MRI screening for women with less than 20% lifetime risk (19). Some studies have reported the presence of residual gadolinium in the brains of adult and pediatric patients who have undergone multiple gadolinium-based contrast-enhanced MRIs. The clinical significance of this finding is unclear and is under active investigation (20).

Physical Examination

[2] Masses are easier to palpate in older women with fatty breasts than in younger women with dense, nodular breasts. An area of thickening amid normal nodularity may be the only clue to an underlying malignancy. Skin dimpling, nipple retraction or skin erosion, while obvious, are later-stage disease signs. Breast cancer commonly arises in the upper outer quadrant, where there is proportionally more breast tissue. Metastatic breast cancer is found as an axillary mass without an obvious breast primary in less than 1% of cases.

[2] When a breast mass or abnormality is identified, the presence of a carcinoma must be considered, and biopsy should be performed to establish a tissue diagnosis.

About 30% to 40% of lesions clinically believed to be malignant will be benign on histologic examination (21). Conversely, 25% of clinically benign-appearing lesions will be malignant when biopsied (22). Algorithms for the evaluation of breast masses in pre- and postmenopausal women are presented in Chapter 19.

PATHOLOGY

Breast cancer may arise in the intermediate-size ducts, terminal ducts, or lobules. The diagnosis of ductal or lobular carcinoma is based on histologic appearance rather than the site of origin. The cancer may be either *in situ* or invasive.

Ductal Carcinoma *In Situ*

[3] By definition, *in situ* disease does not invade beyond the basement membrane and, therefore, lacks the ability to spread.

[3] The incidence of diagnosis of ductal carcinoma *in situ* (DCIS) has increased dramatically since the introduction of screening mammography. **The entity accounts for approximately 20% of breast cancers diagnosed in the United States** (1). The risk of DCIS increases with age, and although it may rarely manifest as a palpable mass, it is usually detected mammographically as a cluster of suspicious calcifications.

The goal of the treatment of DCIS is to prevent the development of invasive cancer. Thirty percent to 50% of patients with DCIS will develop an IDC within the same breast if treated by biopsy alone (23). **The standard treatment of DCIS includes resection to negative margins via segmental mastectomy followed by radiation or mastectomy. Endocrine therapy should be considered.**

It is being increasingly recognized that DCIS encompasses a spectrum of diseases that spans from indolent lesions, which will never progress to invasive cancer, to aggressive lesions that will progress quickly, and many experts believe that treating low-risk DCIS with surgery and radiation constitutes overtreatment. This notion is supported by evidence that while adjuvant radiation therapy decreases the risk of a patient experiencing an ipsilateral invasive recurrence, it is not associated with improved breast cancer–specific mortality (24). This notion is the basis of the COMET (Comparison of Operative to Monitoring and Endocrine Therapy for low-risk DCIS) study, which is a randomized clinical trial that will compare standard treatment to active surveillance for low-risk DCIS.

[3] Axillary metastases occur in fewer than 5% of patients diagnosed with DCIS on core needle biopsy, making routine axillary staging unnecessary. American Society of Clinical Oncology (ASCO) guidelines regarding the use of sentinel lymph node biopsy (SLNB) for DCIS recommend consideration of SLNB in patients undergoing a mastectomy, in patients undergoing breast-conserving surgery (BCS) for a

tumor in a location that may preclude future node sampling, in cases of DCIS diagnosed as a mass on imaging or clinical exam, or in cases of large-volume DCIS where the risk of finding invasive cancer at pathologic analysis is higher (25).

Invasive Carcinoma

[3] **Invasive ductal carcinoma (IDC) accounts for roughly 80% of all invasive tumors, with the final 20% split between ILC and special variants of infiltrating ductal carcinoma** (26). Mammographically, invasive ductal cancers (IDCs) are characterized by a stellate density or microcalcifications. Macroscopically, invasion of the surrounding stroma and fat with a fibrotic, desmoplastic reaction surrounding the invasive carcinoma generally is present. Microscopically, IDC is characterized by cords and nests of cells with varying amounts of gland formation.

ILC accounts for 5% to 10% of invasive carcinomas. [3] **ILCs more frequently arise in older women, are bilateral or multicentric, and have more favorable clinical features (lower grade, ER-positivity)** (27). Some ILCs have a macroscopic appearance similar to that of IDC, but more commonly no mass is present. Microscopically, ILC is characterized by small cells that insidiously infiltrate the breast and adipose tissue in a single-file pattern. This pattern of infiltration often results in a microscopic size that is greater than anticipated. It has been proposed that ILCs have a more favorable prognosis than IDCs and tend to metastasize later than IDC (28). If ILCs do metastasize, they often spread to unusual locations, such as the peritoneum, meninges, and gastrointestinal tract (29).

[3] **Special types of infiltrating ductal carcinoma are uncommon and typically account for approximately 10% of all invasive cancers. Medullary carcinoma,** which accounts for 5% to 8% of breast carcinomas, arises from larger ducts within the breast and has a dense lymphocytic infiltrate. The tumor **appears to be slower growing and less aggressive than other forms of carcinoma.** Even when axillary disease is present, the prognosis for patients with medullary carcinoma is better than that of other variants of invasive ductal carcinoma. Mucinous (colloid) carcinoma accounts for 5% of all breast cancers. Grossly, areas of the tumor may appear mucinous or gelatinous, whereas microscopically they are relatively acellular. Infiltrating comedocarcinoma accounts for less than 1% of all breast malignancies and is an invasive cancer characterized by foci of necrosis that exude a comedonecrosis-like substance when biopsied. Usually, comedocarcinomas are *in situ* malignancies. Papillary carcinoma is predominantly a noninvasive ductal carcinoma; when invasive components are present, it should be specified as invasive papillary carcinoma. [3] **Tubular carcinoma, a well-differentiated breast cancer that accounts for 1% to 2% of all malignant breast neoplasms, rarely metastasizes to axillary lymph nodes and tends to have a better prognosis than infiltrating ductal carcinoma.** Adenoid cystic carcinomas are

extremely rare breast tumors that histologically are similar to those seen in the salivary glands. They are well-differentiated cancers that are slow to metastasize.

Receptor Testing

[3] All breast cancer tumors should be evaluated for the expression of estrogen and progesterone receptors and for the overexpression of human epidermal growth factor 2 receptors (HER2) as this information guides clinical decision making and facilitates prognostication. Hormone receptor positivity is determined via immunohistochemical testing and is defined by the presence of estrogen or progesterone receptors on at least 1% of tumor cells. HER2 positivity is characterized by immunohistochemical staining of 3+ of the tumor cells or by a HER2/chromosome enumeration probe 17 (CEP17) fluorescent in situ hybridization (FISH) amplification ratio of ≥2.

[3] Breast cancer can be clinically divided into subtypes based on these receptors. Approximately 80% of tumors are hormone receptor positive, 23% overexpress HER2, and 13% are triple negative (estrogen receptor, progesterone receptor, and HER2 negative) (30).

Staging

The eighth edition of the *American Joint Committee on Cancer (AJCC) Staging Manual* was published in 2017 and effective since January of 2018. **[3] In addition to the primary tumor, lymph node, and metastasis (TNM) classification, the eighth edition of the staging manual incorporates biologic factors, such as tumor grade, hormone receptor status, HER2 status, and gene expression profiles into the staging system for breast cancer** (31).

Tumor stage and nodal status continue to be important predictors of outcomes. In a SEER analysis that included over 302,000 patients, survival was 100% in patients with tumors 0.1 to 0.9 cm; 91.8% for tumors 1.0 to 1.9 cm; 75.7% for tumors 2.0 to 2.9 cm; 61.3% for tumors 3.0 to 3.9 cm; 54.2% for tumors 4.0 to 4.9 cm; and 45.7% for tumors 5.0 to 9.9 cm (32). Even small tumors have a significantly worse prognosis if they are associated with positive lymph nodes. In a large series, 5-year survival worsened as number of positive lymph nodes increased (33). The number of positive lymph nodes involved and the presence of extracapsular invasion are important indicators of poor prognosis.

Histologic grade appears to predict overall survival. Patients with well-differentiated tumors tend to have more favorable outcomes than those with poorly differentiated ones. In a British study of 1,168 women, histologic grade, along with tumor size and lymph node status, was an independent predictor of overall survival at

10 years (34).

Hormone receptor status is an important predictor of long-term prognosis and response to endocrine therapy. Several studies have demonstrated that patients with positive estrogen and progesterone receptor (ER and PR) status have improved overall survival (35,36). Receptor status should be known when determining the need for and choice of adjuvant therapy. Additionally, **[3] an assay for HER2 overexpression and/or amplification should be routinely performed. The presence of HER2 amplification predicts sensitivity to several classes of chemotherapy and survival benefit from targeted agents, such as *trastuzumab* and *pertuzumab*** (37–39).

Several multigene assays have been developed and validated and are becoming increasingly important tools for prognosticating and predicting response to therapy. The 21-gene assay (Oncotype DX) and 70-gene signature (MammaPrint) are two of the more commonly used gene expression assays.

Oncotype DX (Genomic Health) evaluates the expression of 21 genes and is primarily validated in hormone receptor– positive, HER2-negative, node-negative breast cancers. Test results are reported as a Recurrence Score (RS). The test categorizes a patient's risk of breast cancer recurrence into low (RS 0 to 18), intermediate (RS 19 to 31), or high (RS 32 to 100) and also predicts benefit from chemotherapy. In the Trial Assigning IndividuaLized Options for Treatment (Rx) (TAILORx), the Oncotype DX test was used in an attempt to better define which patients with early-stage, ER+ breast cancer benefit from chemotherapy and which patients could be spared chemotherapy. The study included over 10,200 women. In TAILORx, women with Recurrence Scores of 0 to 10 were assigned to treatment with endocrine therapy alone and women with scores greater than 25 were assigned to treatment with endocrine therapy plus chemotherapy. Women with midrange scores of 11 to 25 were randomly assigned to receive either endocrine therapy plus chemotherapy or endocrine therapy alone. In 2015, preliminary prospective evidence from TAILORx demonstrated that women with a low risk of recurrence (RS 0 to 10) did well with endocrine therapy alone and could be spared chemotherapy (40). Then in 2018, final results from the TAILORx study revealed that endocrine therapy was not inferior to endocrine therapy plus chemotherapy for women with midrange scores of 11 to 25, although a degree of benefit of chemotherapy was found in some women 50 years of age or younger. Together, these results suggest that chemotherapy can be safely avoided in about 70% of the women with hormone receptor–positive, HER2-negative, node-negative breast cancers who would have received chemotherapy based on traditional criteria (41).

MammaPrint (Agendia) is a 70-gene signature assay that classifies patients into good and poor prognostic groups. This test may be used for patients with hormone receptor–negative or hormone receptor–positive breast cancer and patients with 0 to 3 positive lymph nodes (42). The Breast Cancer Index is another commonly used prognostic assay

that has been validated as an accurate predictor of endocrine therapy responsiveness in patients with estrogen receptor–positive breast cancer.

MANAGEMENT OF BREAST CANCER

Breast cancer should be viewed as a two-component disease involving the breast and the body as a whole. Although the primary breast tumor and issues of local control must be managed, the possibility of systemic metastases with life-threatening consequences should not be overlooked.

Staging Workup

Further preoperative workup for systemic disease should be obtained for patients with signs or symptoms concerning for metastatic disease or patients with locally advanced breast cancer. For patients with symptoms concerning for systemic spread of disease, the appropriate imaging should be obtained (i.e., a bone scan for a patient complaining of localized bone pain concerning for a skeletal metastasis). Only patients who are stage IIIA or higher should undergo a whole-body PET-CT or a bone scan and a CT scan of the chest, abdomen, and pelvis. These recommendations follow the NCCN guidelines (43), and are based on studies that have shown that in the majority of patients with newly diagnosed breast cancer, an extensive preoperative workup is unnecessary (44).

Radical Mastectomy

[4] **Traditionally, the treatment of breast cancer has been surgical and the type of procedure was a controversial and psychologically complex issue.** The selection of surgical treatment remains an emotionally charged, and highly politicized, issue for many patients. During the 19th century, surgical treatment of breast cancer was haphazard, varying from local excision alone to total mastectomy. The radical mastectomy was based on the principle that breast carcinoma was a locally infiltrative process that spread in a radial fashion, spiraling out from breast, to nodes, to distant sites (45). **Radical mastectomy removes the entire breast, the underlying pectoral muscles, and the contiguous axillary lymph nodes in continuity (Fig. 42-2A)** (46). A report of 51 years of experience with radical mastectomy, which included 1,036 patients with a follow-up of 47 years, is unequaled in evaluating any other single method of treating breast cancer (47).

During the 20th century, extensions and modifications of the radical mastectomy were devised that involved removal of more local and regional tissue. At one time, supraclavicular, mediastinal, and internal mammary lymph node dissections were routinely performed (48).

A

B

FIGURE 42-2 Appearance of breast after radical mastectomy (**A**) versus modified mastectomy (**B**). (From **Giuliano AE, Dang CM**. Breast disease. In: Berek JS, Hacker NF, eds. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2014:674.)

An en bloc internal mammary lymph node dissection was added to the standard radical mastectomy in the 1960s. This technique became popular and is the operation commonly referred to as the *extended radical mastectomy* (49). Extended radical mastectomy did not enhance overall survival rates, because only 3% to 5% of patients with negative axillary nodes will have involvement of internal mammary nodes (50). Locally destructive surgery is not justified, based on an understanding of the biologic behavior of breast cancer, and a radical mastectomy is no longer an indicated procedure, except in the most unusual circumstances with extensive pectoralis involvement by the breast tumor.

Modified Radical Mastectomy

[4] In contrast to radical mastectomy, modified radical mastectomy preserves the pectoralis major muscle (Fig. 42-2B) (51,52). The breast is removed in a manner similar to that of radical mastectomy, but neither the axillary lymph node dissection nor the skin excision is as extensive. Consequently, there is no need for skin grafting. There are no differences in survival rates between radical and modified radical mastectomy, but the latter procedure has a better functional outcome and a superior cosmetic result (53). Modified radical mastectomy has replaced radical mastectomy in the United States and is an alternative to BCS for some patients.

Total Mastectomy

The movement away from radical surgery for every patient with breast cancer began after dissemination of the results of the National Surgical Adjuvant Breast and Bowel Project (NSABP) B-04 trial, which randomized women to radical mastectomy, total mastectomy with node field irradiation, or total mastectomy with no axillary surgery and delayed axillary dissection if clinically indicated. **After 25 years of follow-up, there are no survival differences between the three arms** (54).

[4] Total mastectomy involves removal of the entire breast, nipple, and areolar complex without resection of the underlying muscles or intentional excision of axillary lymph nodes. Low-lying lymph nodes in the upper outer portion of the breast and low axilla often are excised. Previously, regional recurrence would occur in at least 15% to 20% of patients treated with total mastectomy alone. With the addition of SLNB, which selects patients who are lymph node negative, local recurrence rates should be low in patients who undergo total mastectomy and have node-negative disease compared to those patients with unknown axillary status.

Skin-Sparing Mastectomy

[4] Patients who wish to have immediate reconstruction may wish to undergo a mastectomy that preserves the skin envelope of the breast. A skin-sparing mastectomy (SSM) removes the breast tissue and the nipple–areolar complex and is followed by immediate breast reconstruction. Initially, there were concerns that immediate reconstruction might complicate surveillance for local recurrence, but this has not been shown to be the case (55).

Nipple-Sparing Mastectomy

[4] Removal of all breast parenchyma with preservation of the entire skin envelope, including the nipple–areolar complex, has become increasingly popular because of the improved cosmetic results. However, patient selection is key as involvement of the nipple–areolar complex is seen in 11.5% of cases (56). Despite this finding, many studies have now shown that nipple-sparing mastectomy (NSM) is an oncologically safe procedure in carefully selected patients. In a meta-analysis that included 5,594 women, there were no significant differences in overall survival, disease-free survival, or locoregional recurrence between NSM and SSM groups (57). Patients who have undergone NSM have been reported to have a better postreconstruction quality of life, specifically in the Satisfaction with Breasts and Satisfaction with Outcome domains of the BREAST-Q when compared to non–nipple-sparing mastectomies (58). For these reasons, NSM with immediate implant–based or autologous reconstruction is becoming a common procedure for women who need or desire a mastectomy.

Contralateral Prophylactic Mastectomy

Women may wish to undergo a contralateral prophylactic mastectomy (CPM) in order to reduce their risk of getting a contralateral breast cancer, to eliminate the need for breast cancer screening, or to achieve symmetry of reconstruction. **[4]** Although CPM significantly reduces the risk of cancer developing in the contralateral breast, there has been no demonstrated survival benefit associated with CPM in women who are not at particularly high risk of developing a second breast cancer (59,60).

Postmastectomy Radiation Therapy

Some patients treated with mastectomy benefit from adjuvant radiation therapy. McWhirter developed the concept of total mastectomy followed by radiation (61). Historical trials, both prospective randomized and historical control studies, have shown that **[7]** adjuvant radiation therapy improves local control but not overall survival (62–64). In a prospective randomized trial performed by NSABP, the roles of

postoperative radiation therapy and axillary treatment were examined further. Patients were randomly assigned to either total mastectomy, radical mastectomy, or total mastectomy with radiation therapy. Findings from this trial supported the notion that radiation therapy and axillary treatment improve local and regional control but have no effect on survival, and the 25-year follow-up confirmed these findings (65).

During the 1990s, randomized controlled studies showed that postmastectomy radiation therapy (PMRT) reduced the risk of local–regional failure by 20% and produced an absolute survival benefit of 10% at 10 years among women with stage II to III breast cancer, regardless of menopausal status (66,67). Subsequently, additional trials challenged the need for PMRT among women with only one to three involved axillary nodes and T_1 or T_2 primary tumors. These studies showed adequate local–regional control rates with mastectomy and chemotherapy alone (68–70). In a large meta-analysis performed by the Early Breast Cancer Trialists' Collaborative Group (EBCTCG) that included 1,300 women with one to three involved lymph nodes, PMRT was shown to reduce recurrence and breast cancer mortality in women with one to three positive nodes (71).

Breast Conservation Therapy With or Without Radiation Therapy

[4] Throughout the last quarter of the 20th century, a paradigm shift occurred in the surgical management of breast cancer. NSABP B-04 trial established the equivalency of radical versus total mastectomy with regard to overall survival. **Shortly after initiation of the B-04 trial, a number of studies were designed to evaluate the efficacy of breast conservation among women with early-stage breast cancers.** The Milan trial, a major prospective randomized trial that began accruing patients in 1973, compared treatment with either radical mastectomy or a combination of quadrantectomy, axillary lymph node dissection, and postoperative radiation therapy. In total, 701 clinically node-negative patients with non-centrally located, small tumors (<2 cm) ($T_1N_0M_0$) were enrolled. After 20 years of follow-up, there continues to be no statistically significant difference between the two groups in either local control or overall survival rates (72).

FIGURE 42-3 Appearance of breast after lumpectomy, axillary dissection, and radiation therapy. (From **Giuliano AE, Dang CM**. Breast disease. In: Berek JS, Hacker NF, eds. Berek & Hacker's Gynecologic Oncology. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2014:675.)

At nearly the same time, in the NSABP B-06 trial, patients with early breast cancer (stage I or stage II, T_1 or T_2, and N_0 or N_1) were randomized to modified radical mastectomy, segmental mastectomy (lumpectomy) and axillary lymph node dissection, or segmental mastectomy, axillary lymph node dissection, and postoperative radiation therapy. Unlike the quadrantectomy performed in the Milan study, segmental mastectomy consists of removing only the tumor and a small rim of normal surrounding tissue, yielding cosmetically superior results **(Fig. 42-3)**. A total of 1,843 women were enrolled, with the lowest local recurrence rate seen among patients treated with segmental mastectomy and postoperative radiation therapy. The addition of radiation improved the local control rate, but no significant differences in overall survival or disease-free survival rates were detected among the three treatment arms; there was a trend, however, in favor of patients who had received radiation. **This NSABP study, now [4] with a 20-year follow-up, established that the combination of segmental mastectomy (with negative surgical margins), axillary lymph node dissection, and**

postoperative radiation therapy is as effective as modified radical mastectomy for the management of patients with stage I and II breast cancer (73).

There has been considerable debate regarding the definition of a negative margin for BCS. [3] A multidisciplinary panel convened by the Society of Surgical Oncology and the American Society for Radiation Oncology recommended using "no ink on tumor" as the standard margin for patients with stage I and II invasive breast cancer treated with BCS followed by whole-breast irradiation (74). The recommendation was based on a meta-analysis of 33 studies, including 28,162 patients, that reported that a positive margin, defined as ink on tumor, was associated with a greater than twofold increase in ipsilateral breast tumor recurrence and that margins wider than "no ink on tumor" were not associated with a lower incidence of ipsilateral breast tumor recurrence (75). **A similar panel was convened and a meta-analysis was performed that resulted in the recommendation that the standard margin for DCIS should be 2 mm** (76,77).

[4] Many randomized studies have shown that the addition of whole-breast irradiation to BCS for early-stage breast cancer reduces the rate of local recurrence (78–80). **More important than local recurrence, it appears that the use of radiation therapy after BCS reduces the risk of death from breast cancer.** A meta-analysis from the EBCTCG of all of the randomized prospective trials comparing BCS or mastectomy with or without radiation reported a 4:1 ratio between avoiding local recurrence at 5 years and improving overall survival at 15 years. In 2011, an update to this meta-analysis was performed that included only women who had undergone BCS. The updated meta-analysis included 17 randomized trials and 10,801 women, and demonstrated that **[7] radiation therapy reduced the annual rate of failure (local or systemic) by about half and the annual rate of breast cancer death by one-sixth** (81).

Axillary Staging

[6] Although markers of tumor biology are becoming increasingly important in determining the optimal treatment and prognosis of breast cancer, the status of the axillary lymph nodes remains one of the most important prognostic indicators. Axillary lymphadenectomy traditionally was used to detect and quantify the extent of nodal metastasis. Before the introduction of sentinel lymph node dissection in the 1990s, axillary lymph node dissection was performed routinely on all patients with early breast cancer. **[5] Although axillary dissection is associated with a very low risk of regional recurrence (1% to 3%), the rate of acute complications is as high as 30%** (82). **Similarly, the risk of chronic lymphedema ranges from 6% to as high 30%** (83). Because only one-third of patients with a clinically negative axilla will have nodal

metastasis, one can infer that two-thirds of patients will be exposed to the morbidity of axillary lymph node dissection without proven benefit when performed routinely in the presence of invasive breast cancer (84).

In 1991, intraoperative lymphatic mapping and sentinel lymph node dissection were introduced to address these problems (85). [5] **The sentinel node is the lymph node that has the greatest potential to harbor metastasis if axillary disease is present. Numerous investigations have demonstrated that examination of the sentinel lymph nodes can accurately predict the status of the entire nodal basin with identification rates ranging from 90% to 99% and false-negative rates of less than 5% in most large studies.** In one study of 107 patients with T_1 and T_2 breast cancer who underwent sentinel lymph node dissection followed by axillary lymph node dissection, the sentinel node was successfully identified in 100 patients (93.5%). There were no false-negative results, and the sentinel node accurately predicted axillary status in all 100 patients (86).

[5] **Sentinel lymph node dissection is accurate at staging the axilla and has comparable long-term outcomes and less morbidity when compared to axillary lymph node dissection, as supported by numerous randomized controlled trials, including NSABP B-32, ALMANAC, and SNAC** (87–90). **In light of these findings, SLNB has become the preferred procedure for staging the axilla in clinically node-negative early breast cancer.** The standard of care for patients found to have a positive sentinel lymph node was complete axillary lymph node dissection until the Z0011 trial demonstrated that in patients with one or two positive sentinel lymph nodes, without extranodal extension of the metastasis, there was no statistically significant difference in overall survival between those randomized to complete axillary lymph node dissection and those randomized to SLNB alone (91). The 10-year results of the trial confirm this finding (92).

[5] **The use of SLNB after neoadjuvant chemotherapy (NAC) is controversial.** In women with a clinically negative axilla prior to NAC, SLNB performed at the time of breast tumor excision is believed to be safe. A meta-analysis that included 72 prospective and retrospective studies reported a sentinel node identification rate of almost 90% and a false-negative rate of 14.2% in this population (93). In women with a clinically positive axilla prior to NAC who convert to a clinically negative axilla during NAC, the ACOSOG Z1071 and SENTINA trials conclude that SLNB after NAC is not an adequate staging method for patients with positive lymph nodes prior to NAC (94,95). However, the studies suggest that the use of SLNB at the time of breast tumor excision under certain conditions (the use of blue dye and radioactive colloid tracer, obtaining ≥3 sentinel nodes) may yield acceptable false-negative rates.

SYSTEMIC THERAPY

Adjuvant Systemic Therapy

For many patients, local and regional control of breast cancer is achieved with a combination of surgery and radiation therapy. About 90% of patients will never experience an in-breast recurrence, but these [7] patients may develop metastatic disease. **The goal of adjuvant systemic therapy is to eliminate occult metastases and thus reduce the risk of local and distant recurrence.**

Adjuvant systemic therapy prolongs survival in selected breast cancer patients. In patients with favorable biology and a low risk of recurrence and subsequent death, such as those with small, node-negative cancers that have a favorable biomarker and genomic profiles, the benefit of chemotherapy is small and may not justify the risks (43). Cytotoxic chemotherapy and hormonal therapy have inherent risks that must be considered when treatment decisions are made. There are many known acute side effects with standard regimens, and there is growing evidence that patients who undergo chemotherapy report more frequent chronic neurocognitive deficits than do untreated controls (96). The impact of these deficits remains undefined. Systemic therapy with *tamoxifen* is associated with an increased incidence of uterine cancer, vaginal dryness, and hot flashes, whereas aromatase inhibitors (AIs) are linked to osteoporosis and musculoskeletal symptoms. Choosing those patients who should receive adjuvant therapy can be a difficult decision that often entails analyzing a variety of prognostic and predictive factors, identifying patients at risk for recurrence, and quantifying that risk. [7] **Comorbidities, stage, biomarker profile, and results of genomic analysis, such as Oncotype DX and MammaPrint, are often taken into consideration when deciding whether or not a patient needs systemic therapy. Genomic assays examine gene expression in the primary tumor and can indicate a higher or lower than expected risk of recurrence. Patients with low risk of recurrence have been shown not to benefit from the use of adjuvant systemic chemotherapy** (40,41,97,98).

Choice of Regimen

Based on the results of more than 100 prospective, randomized trials examining the role of adjuvant chemotherapy in breast cancer, [7] a variety of systemic regimens emerged. **Systemic therapy includes cytotoxic agents, targeted agents, and hormonal agents, used alone or in combination.**

Initially, trials involved a single perioperative course of chemotherapy aimed at eradicating circulating tumor cells. The Nissen-Meyer study from Norway showed that a single course of *cyclophosphamide* improved overall survival rates (99). Subsequently, numerous trials demonstrated the benefit of adjuvant chemotherapy for certain subgroups of patients (100). In the initial NSABP adjuvant trial, a 2-year course of *melphalan* was superior to no treatment, and further trials demonstrated enhanced beneficial effect with the use of multiple drugs and the combination of hormonal

manipulation with chemotherapy (101,102).

[7] Historically, the most frequently used adjuvant combination chemotherapy was *CMF: cyclophosphamide* (*C*), *methotrexate* (*M*), and *5-fluorouracil* (*5-FU*). In the original study by Bonadonna et al., patients with positive axillary lymph nodes were randomized to receive either 12 monthly cycles of *CMF* or no therapy after radical mastectomy (103). A statistically significant benefit was found with *CMF* treatment for premenopausal patients, especially those with one to three positive nodes. A subsequent study showed six cycles of *CMF* to be as effective as 12 cycles (104). After 20 years of follow-up, this trial demonstrated a persistent survival advantage for premenopausal women receiving *CMF* adjuvant therapy (105). In a later study involving node-negative, estrogen receptor– negative breast cancer patients, after 12 years of follow-up, 71% of patients treated with adjuvant *CMF* remained disease free compared with 48% in the control group, regardless of menopausal status (106).

***Anthracyclines* (*A*) were more commonly used in the adjuvant and metastatic treatment of breast cancer than any other agents.** A large randomized NSABP study compared *CMF* with *AC* regimens in node-positive patients and found similar treatment outcomes among both groups. The *AC* regimen was preferred because of its shorter duration (four cycles for 3 months versus six cycles for 6 months) (107).

[7] Several landmark trials showed that taxanes such as *paclitaxel* and *docetaxel* in combination with *anthracyclines* have significant efficacy and are commonly used as adjuvant therapy for breast cancer. The Cancer and Leukemia Group B was the first to show a 17% improvement in the rate of recurrence and 18% reduction in the rate of death with the addition of *paclitaxel* to *cyclophosphamide* (108). Given concerns over the cardiotoxicity of anthracyclines and the 0.21% risk of leukemia after the *AC* regimen at 5 years, a US oncology trial randomized stage I, II, and III patients to *AC* or *docetaxel* and *cyclophosphamide* (TC) every 3 weeks for four cycles and found that after 7 years' follow-up disease-free survival and overall survival statistically favored the *TC* group (109). This was the first trial to compare a *taxane*-based regimen to an *anthracycline*-based regimen. Concerns remain because multiple trials demonstrate that the duration of therapy is significant and the *TC* regimen used was a short-duration treatment of four cycles (110). In 2017, the Joint Analysis of the Anthracyclines in Early Breast Cancer (ABC) trials compared *TC* chemotherapy to an *anthracyclines-, cyclophosphamide-,* and *taxane*-based regimen in over 4,000 women with HER2-negative disease and found that **[7] *anthracycline*-based chemotherapy does not significantly improve outcomes in low-risk, hormone receptor–positive breast cancer. However, in higher-risk hormone receptor–positive and triple-negative disease, there appears to be a benefit to administering an *anthracycline*-based regimen** (111).

Neoadjuvant Systemic Therapy

Neoadjuvant therapy refers to the use of systemic treatments prior to definitive surgical treatment. NAC regimens are often the same as those that are used for adjuvant treatment.

[7] **Traditionally, the goal of preoperative systemic therapy was to convert inoperable patients into operable patients and to convert mastectomy candidates into candidates for breast conservation on the basis of pathologic and clinical responses** (112). Reports indicate that breast conservation therapy is possible and that low rates of in-breast or local–regional recurrences occur when NAC results in clinical and pathologic tumor downstaging (113). [7] **NAC permits the observation of an in vivo response of the tumor to chemotherapy, and a pathologic complete response is a strong prognostic indicator, especially in triple negative and HER2 positive breast cancer** (114). Randomized trials demonstrate similar long-term outcomes when patients are given the same treatment preoperatively compared with postoperatively (115). **Giving the systemic treatment before surgery permits tailoring the adjuvant regimen, which may affect outcomes.** In the CREATE-X trial, women with residual HER2-negative disease after NAC were randomly assigned to adjuvant treatment with capecitabine versus no further chemotherapy. The women who received adjuvant capecitabine experienced longer disease-free and overall survival (116). This was most significant for patients with triple-negative breast cancer.

Hormonal Therapy

[7] **Hormonal manipulation with *tamoxifen* or an AI, used alone or in combination with a cytotoxic regimen, is beneficial for women with hormone receptor–positive breast cancer. *Tamoxifen*, a selective estrogen receptor modulator, offers substantial benefits in pre- and postmenopausal women.** Taken at a dose of 20 mg per day for 5 or 10 years, ***tamoxifen*** **results in a significant and sustained reduction in the risk of breast cancer recurrence and mortality at 15 years** (117).

AIs suppress plasma estrogen levels by inhibiting or inactivating the enzyme responsible for the peripheral conversion of androgens to estrogens. These drugs should be used only in postmenopausal patients or premenopausal women who have undergone chemical ovarian suppression or oophorectomy. [7] **AIs have consistently been shown to improve outcomes for postmenopausal women with hormone receptor–positive breast cancer compared with *tamoxifen*** (118). The AIs, such as anastrozole, letrozole, and exemestane, have similar efficacy. Although AIs cause fewer episodes of thrombotic events, hot flashes, and endometrial cancers, musculoskeletal symptoms and osteoporosis are more commonly encountered among AI users than those taking *tamoxifen*.

Endocrine therapy is recommended for a minimum of 5 years. The risk of hormone receptor–positive disease recurrence persists for 20 years and extended hormone therapy has been studied. [7] Data supports the use of 10 years of hormone therapy, especially for women at high risk of recurrence (119). Data from the MA.17, ATLAS and aTTom trials suggest that extended endocrine therapy improves disease-free survival and possibly overall survival (120,121).

Ovarian ablation plays a role in the treatment of premenopausal, hormone receptor–positive breast cancer. Ovarian ablation can be achieved surgically via oophorectomy or medically with the administration of gonadotropin-releasing hormone (GnRH) agonists, such as Lupron. According to the Suppression of Ovarian Function Trial (SOFT) and the Tamoxifen and Exemestane Trial (TEXT), the addition of ovarian suppression to tamoxifen or aromatase inhibition does not provide a significant benefit for the average-risk patient, but the addition of ovarian suppression to exemestane rather than tamoxifen improves outcomes for high-risk patients (122,123).

[7] Bisphosphonates can be used to prevent or treat cancer therapy–induced bone loss in pre- and postmenopausal women. In addition to improving bone density, bisphosphonates may impact long-term outcomes. A meta-analysis investigating the impact of zoledronic acid on outcomes reported improved overall survival and lower fracture rates with the use of adjuvant zoledronic acid, but there were no improvements in the risks of locoregional recurrence, bone metastases, or disease-free survival (124). *Denosumab*, another bone-stabilizing drug, is being investigated for its impact on breast cancer–related outcomes. Side effects of bisphosphonate therapy include bone pain, fever, and rarely osteonecrosis of the jaw, esophagitis, ulcers or renal failure.

HER2-Targeted Therapy

[6] It is essential that all breast cancers be assessed for HER2 overexpression because HER2-directed therapies, such as *trastuzumab* and *pertuzumab*, are a cornerstone of the treatment of HER2-positive breast cancer (38,125). HER2-amplified breast cancer had been associated with worse prognosis prior to the use of targeted agents. **[7] *Trastuzumab* should be given with chemotherapy and should be given alone or with hormonal therapy to complete 1-year duration. *Pertuzumab* can be added to the neoadjuvant regimen for women with ≥T2 or ≥N1 HER2-positive tumors** (126). *Pertuzumab* was granted accelerated approval by the FDA in 2013 as a result of its beneficial effects on progression-free survival for patients with metastatic disease and on pathologic complete response rates when given neoadjuvantly. The addition of *pertuzumab* to *trastuzumab* and chemotherapy resulted in less remarkable effects as an adjuvant therapy (39). This has led to some controversy regarding the use of pathologic response after neoadjuvant therapy as an indicator of efficacy and basis for accelerated drug approval.

Trastuzumab has been associated with an increased risk for cardiac toxicity, and for that reason, patients receiving *trastuzumab* therapy should have their cardiac function monitored during and after treatment (127).

[7] Summary of recommendations regarding systemic therapy for early breast cancer:

1. Factors to consider when deciding if a patient should receive systemic chemotherapy include age, stage, biomarker profile, and results of genomic assays, such as Oncotype DX or MammaPrint.
2. Combination *anthracycline* and *taxane*-based regimens are the most commonly used in the United States and can be administered before (neoadjuvant) or after (adjuvant) surgery. Neoadjuvant administration may allow for less extensive surgical and radiation treatments and for the tailoring of adjuvant chemotherapy regimens.
3. Hormone receptor–positive breast cancer should be treated with adjuvant AI in postmenopausal patients. In premenopausal patients, *tamoxifen* should be administered or ovarian suppression should be given in conjunction with AI for high-risk patients.
4. HER2-positive breast cancer should be treated with HER2-targeted therapies, such as *trastuzumab* and *pertuzumab*. *Pertuzumab* is approved for use only as neoadjuvant treatment for tumors >2 cm or node-positive patients.

Systemic Therapy for Metastatic Breast Cancer

Up to 5% of women with breast cancer have metastatic disease at the time of presentation and up to 30% will develop metastatic disease over the course of their illness. Breast cancer can metastasize to any organ, and involvement of bone, lungs, or liver occurs in up to 85% of women who develop distant disease (128,129). In addition to these sites, ILC is known to disseminate to the abdominal viscera, uterus, ovaries, and peritoneal surfaces. Patients with visceral metastases and/or a short disease-free interval generally have an aggressive phenotype, while patients with bone metastases have a more indolent phenotype. **The goals of the treatment of metastatic breast cancer are to prolong survival and maintain or improve quality of life.** Treatment strategies are inherently different than those used with curative intent in patients without signs of metastasis.

Systemic disease may be controlled by hormonal, targeted, or cytotoxic therapy. For metastatic hormone receptor–positive disease it is preferable to attempt endocrine manipulation first because the quality of life during an endocrine-induced remission is usually superior to one during treatment with cytotoxic chemotherapy. **First-line treatment for postmenopausal women with metastatic hormone receptor–positive breast cancer includes a combination of an AI and a cyclin-dependent kinase (CDK) 4/6 inhibitor, such as *palbociclib* or *ribociclib*.** *Fulvestrant* appears superior

to *anastrozole* as first-line therapy. *Palbociclib* and *ribociclib* are well tolerated except for nonfebrile neutropenia (130). In phase III studies, the addition of CDK4/6 inhibitors results in improved progression-free survival, but may not substantially improve overall survival (131,132). **For premenopausal patients, ovarian suppression should be administered in addition to endocrine therapy with or without a CDK4/6 inhibitor.**

If organ involvement is potentially life threatening (brain, lung, or liver), hormonal treatment is unsuccessful, or the disease has progressed after an initial response to endocrine manipulation, cytotoxic chemotherapy should be considered. The most useful single chemotherapeutic agent is an *anthracycline* such as *doxorubicin,* which has an estimated response rate of 40% to 50%. Combination therapy using multiple agents has response rates as high as 60% to 80% (133). Metastatic HER2-positive breast cancers should receive HER2-targeted therapy as first-line treatment of their disease. Poly adenosine diphosphate ribose polymerase (PARP) inhibitors are effective agents to treat metastatic breast cancer in patients with *BRCA* mutations (134).

SPECIAL BREAST CANCERS

Paget Disease

In the 1870s, Sir James Paget described a nipple lesion similar to eczema and recognized that this nipple change was associated with an underlying breast malignancy (135). The erosion results from invasion of the nipple and surrounding areola by characteristic large cells with irregular nuclei, now called Paget cells. Although the origin of these cells is debated, they are probably extensions of an underlying carcinoma into the major ducts of the nipple–areolar complex. There may be no visible changes associated with the initial invasion of the nipple. Often, the patient's presenting symptom will be nipple discharge, which is actually a combination of serum and blood from the involved ducts. The patient may have a delay in the diagnosis because the presenting symptoms are often overlooked. The diagnosis is established by incisional or punch biopsy of the area of the nipple changes.

The overall prognosis for patients with this rare form of breast cancer depends on the stage of the underlying malignancy. When an intraductal carcinoma alone is identified, the prognosis remains favorable, whereas patients with infiltrating ductal carcinoma metastatic to the regional lymph nodes have worse outcomes. Traditional treatment was total mastectomy and lymph node dissection, although breast conservation therapy with resection of the tumor and nipple– areolar complex, followed by whole-breast radiation, is being performed in appropriately identified patients (136). In patients without a palpable mass or imaging abnormality, radiation treatment alone has been reported with local recurrence rates ranging from 0% to 17% (137,138).

Inflammatory Breast Cancer

Inflammatory breast cancer (IBC) is characterized by diffuse erythema and edema involving the skin of the breast. The diagnosis of IBC can be made when the erythema and edema have been present for no more than 6 months, occupy at least one-third of the breast, and when a biopsy confirms invasive carcinoma. Mammographically, the breast shows skin thickening with an infiltrative process and may or may not show a mass or calcifications.

IBC is an aggressive form of locally advanced breast cancer. A metastatic workup should be performed. In women without evidence of metastatic disease, standard treatment begins with chemotherapy. Women who experience a good clinical response to chemotherapy may go on to modified radical mastectomy and postmastectomy radiation. Limited data suggest that BCS with an SLNB is not appropriate for these patients (139,140).

Breast Cancer in Pregnancy

Gestational breast cancer is defined as breast cancer that is diagnosed during pregnancy, in the first postpartum year or any time during lactation. Breast cancer complicates 1 in 3,000 pregnancies (141). It is the second most common malignancy seen in association with pregnancy, surpassed only by cervical cancer. **When pregnant patients are matched stage for stage with nonpregnant patients, outcomes are equivalent** (142).

Patients typically present with a painless mass. Up to 60% will have concurrent lymph node involvement. The evaluation includes imaging with ultrasonography and mammography, which exposes the fetus to less than 0.02 cGy of radiation when used with proper abdominal shielding (143). If biopsy is warranted, the procedure can be performed safely and should not be delayed until after delivery.

The treatment of breast cancer in pregnant women must be highly individualized. Considerations include the patient's age, desire to continue the pregnancy, and overall prognosis. It is believed that the duration of pregnancy does not alter the prognosis for patients with potentially curable breast cancer. Following are generalized recommendations for treatment of pregnant women with breast cancer:

1. **Breast conservation and mastectomy are feasible options for the surgical management of the pregnant patient. The choice between them is guided by clinicopathologic characteristics, patient preferences, and the gestational age of the fetus. SLNB can be performed during pregnancy.** The use of blue dye is contraindicated as it is classified as a pregnancy category C drug. The risk to the fetus is felt to be minimal with the use of radiocolloid, although there is no clear randomized data to confirm this (144).

2. **Adjuvant radiation therapy should be administered after delivery in patients for whom it is indicated.** In a patient diagnosed before the third trimester, waiting until after delivery to administer radiation may result in an unacceptable delay in the initiation of therapy and should not be encouraged.
3. **Adjuvant chemotherapy can be given after the first trimester.** The data suggest that it is safe for the mother and the baby to administer many of the chemotherapeutic agents used for the treatment of breast cancer during pregnancy when initiated after the first trimester (145,146).
4. ***Trastuzumab* during pregnancy is associated with oligo- and anhydramnios, pulmonary hypoplasia, fetal developmental abnormalities, and fetal death and should not be used.**
5. ***Tamoxifen* is a class D drug and should not be given to pregnant or lactating patients with breast cancer.**
6. **If breast cancer is diagnosed during lactation, lactation should be suppressed and the cancer should be treated definitively.**
7. **Advanced, incurable cancer should be treated with palliative therapy.** Decisions regarding continuation of the pregnancy should be based on the therapy necessary and the desires of the patient.

Counseling regarding future childbearing is important for women who have had carcinoma of the breast. It was assumed that subsequent pregnancies would be detrimental because of the high levels of circulating estrogens, but **there is no clear difference in survival for women who become pregnant after the diagnosis of breast cancer.** A meta-analysis that included 1,244 women who became pregnant after being treated for breast cancer found that pregnancy did not impact survival and may even have a protective effect (147).
