Preface and Acknowledgments to the Thirteenth Edition

Andrews' remains as it was from the beginning: an authored text whose one volume is filled with clinical signs, symptoms, diagnostic tests, and therapeutic pearls. The authors are committed to keeping *Andrews'* as an excellent tool for anyone who needs help in diagnosing a patient with a clinical conundrum or treating a patient with a therapeutically challenging disease. This edition retains Drs. James, Elston and Neuhaus but we were saddened that Dr. Berger decided the 12th edition was his last. However, we are excited that two new experts have joined the team. Dr. Jim Treat is a superb pediatric dermatologist who was recruited to update many areas of the book. He is knowledgeable in investigations which have led to reclassification of diseases, insights into etiopathogenesis, and newer treatments. He also has updated the vascular anomalies portion of the text, reflecting the continuing improvements in our understanding of these important primarily pediatric conditions. Additionally, Dr. Misha Rosenbach agreed to add his expertise to *Andrews'*. He is a dually board certified internist and dermatologist who has prominent roles in the Medical Dermatology Society and Dermatology Hospitalist group. Dr. Rosenbach was able to update and revamp the adverse drug reaction section, as so many of the new chemotherapeutic agents and small molecular/targeted inhibitors are inducing novel eruptions. New diseases such as the interferonopathies and those along the JAK/STAT pathway, and updated therapeutics in such conditions as autoimmune blistering conditions are also described in his sections of the text.

Andrews' is primarily intended for the practicing dermatologist. It is meant to be used on the desktop of his or her clinic, giving consistent, concise advice on the whole spectrum of clinical situations faced in the course of a busy workday. While we have been true to our commitment to a single-volume work, we provide our text in a convenient online format as well. Because of its relative brevity but complete coverage of our field, many find the text ideal for learning dermatology the first time. It has been a mainstay of the resident yearly curriculum for many programs. We are hopeful that trainees will learn clinical dermatology by studying the clinical descriptions, disease classifications, and treatment insights that define Andrews'. We believe that students, interns, internists or other medical specialists, family practitioners, and other health professionals who desire a comprehensive dermatology textbook will find that ours meets their needs. Long-time dermatologists will hopefully discover Andrews' to be the needed update that satisfies their lifelong learning desires. On our collective trips around the world, we have been gratified to see our international colleagues studying *Andrews'*. Thousands of books have been purchased by Chinese and Brazilian dermatologists alone.

Many major changes have been made to this edition. The new authorship team has worked closely to continue to improve the quality of our text. The surgical chapters have been updated and expanded by Isaac Neuhaus. He has added more videos to complement those already online. He has as well information on new cosmetic procedures. We thank him for his continued work to improve this portion of our textbook. We have tried to ensure that each entity is only discussed once, in a complete yet concise manner. In order to do this we have had to make decisions regarding the placement of disease processes in only one site. Clearly, netrophilic eccrine hidradenitis, for example, could be presented under drug eruptions, netrophilic reactive conditions, infection or cancer-associated disease, or with eccrine disorders. The final decisions are a team effort and made in the interest of eliminating redundancy. This allows us to present our unified philosophy in treating patients in one dense volume.

Medical science continues to progress with break-neck speed. Our understanding of the etiology of certain conditions has now led us to recategorize well-recognized disease states and dictated the addition over many newly described entities. Molecular investigative techniques, technologic breakthroughs, and designer therapeutics lead the way in providing advances in our specialty. We cover the new understanding following from such discoveries as new tools in the diagnosis and treatment of lymphoma; new staging, diagnostic modalities and treatment for melanoma and non-melanoma skin cancers; new treatment paradigms for hair disorders; and new biologics for psoriasis and JAK inhibitors for alopecia area and vitilago. We have attempted to define therapeutics in a fashion that emphasizes those interventions with the highest level of evidence, but also present less critically investigated therapeutic options. To care for our patients we need a large array of options. Not all are fully supported by formal evidence, yet are helpful to individual patients.

Extensive revisions were necessary to add this wealth of new information. We selectively discarded older concepts. By eliminating older, not currently useful information we maintain the brief but complete one-volume presentation that we and all previous authors have emphasized. Additionally, older references have been updated. The classic early works are not cited; instead we have chosen to include only new citations and let the bibliographies of the current work provide the older references as you need them. A major effort in this edition was to reillustrate the text with hundreds of new color images. Many have been added to the printed text; you will also find a number only in the online version. Enjoy! We have looked to our own collections to accomplish this. Two years ago we published an Atlas to accompany this textbook. Many newer photos in our text are included in the Atlas. The Atlas has over 3000 images covering the depth and breadth of our specialty and is a superb companion to this textbook. We are able to present these photos due to many hours of personal effort, the generosity of our patients, and a large number of residents and faculty of the programs in which we currently work or have worked in the past. Additionally, friends and colleagues from all parts of the globe have allowed us to utilize their photographs. They have given their permission for use of these wonderful educational photos to enhance your understanding of dermatology and how these diseases affect our patients. We cannot thank them enough.

All of the authors recognize the importance of our mentors, teachers, colleagues, residents, and patients in forming our collective expertise in dermatology. Dirk and Bill were trained in military programs, and our indebtedness to this fellowship of clinicians in unbounded. Jim and Misha were trained and continue to teach, see patients and publish at the University of Pennsylvania. Isaac is a

product of our sister institution, The University of California, San Francisco. The other institutions we have called home, including Walter Reed, Geisinger Medical Center, Brooke in San Antonio, the Cleveland Clinic, and the Medical University of South Carolina, nurtured us and expanded our horizons. Our friendship goes well beyond the limits of our profession; it is wonderful to work with people you not only respect as colleagues, but also enjoy as closely as family. Jennifer Lu and Barbara Lang provided expert assistance throughout the revision process to Bill. He is indebted to them for their hard work. Finally, we are proud to be a part of the Elsevier team and have such professionals as Charlotta Kryhl, Louise Cook, and Andrew Riley supporting us every step of the way.

1 Skin: Basic Structure and Function

Bonus images for this chapter can be found online at expertconsult.inkling.com

Skin is composed of three layers: the epidermis, dermis, and subcutaneous fat (panniculus) (Fig. 1.1). The outermost layer, the epidermis, is composed of viable keratinocytes covered by a layer of keratin, the stratum corneum. The principal component of the dermis is the fibrillar structural protein collagen. The dermis lies on the panniculus, which is composed of lobules of lipocytes separated by collagenous septa that contain the neurovascular bundles.

There is considerable regional variation in the relative thickness of these layers. The epidermis is thickest on the palms and soles, measuring approximately 1.5 mm. It is very thin on the eyelid, where it measures less than 0.1 mm. The dermis is thickest on the back, where it is 30–40 times as thick as the overlying epidermis. The amount of subcutaneous fat is generous on the abdomen and buttocks compared with the nose and sternum, where it is meager.

EPIDERMIS AND ADNEXA

During the first weeks of life, the fetus is covered by a layer of nonkeratinizing cuboidal cells called the periderm (Fig. 1.2). Later, the periderm is replaced by a multilayered epidermis. Adnexal structures, particularly follicles and eccrine sweat units, originate during the third month of fetal life as downgrowths from the developing epidermis. Later, apocrine sweat units develop from the upper portion of the follicular epithelium and sebaceous glands from the midregion of the follicle. Adnexal structures appear first in the cephalic portion of the fetus and later in the caudal portions.

The adult epidermis is composed of three basic cell types: keratinocytes, melanocytes, and Langerhans cells. An additional cell, the Merkel cell, can be found in the basal layer of the palms and soles, oral and genital mucosa, nail bed, and follicular infundibula. Located directly above the basement membrane zone, Merkel cells contain intracytoplasmic dense-core neurosecretory-like granules and, through their association with neurites, act as slow-adapting touch receptors. They have direct connections with adjacent keratinocytes by desmosomes and contain a paranuclear whorl of intermediate keratin filaments. Both polyclonal keratin immunostains and monoclonal immunostaining for keratin 20 stain this whorl of keratin filaments in a characteristic paranuclear dot pattern. Merkel cells also label for neuroendocrine markers such as chromogranin and synaptophysin.

Keratinocytes

Keratinocytes are of ectodermal origin and have the specialized function of producing keratin, a complex filamentous protein that not only forms the surface coat (stratum corneum) of the epidermis but also is the structural protein of hair and nails. Multiple distinct keratin genes have been identified and consist of two subfamilies, acidic and basic. The product of one basic and one acidic keratin gene combines to form the multiple keratins that occur in many tissues. Mutations in the genes for keratins 5 and 14 are associated with epidermolysis bullosa simplex. Keratin 1 and 10 mutations are associated with epidermolytic hyperkeratosis. Mild forms of this disorder may represent localized or widespread expressions of mosaicism for these gene mutations.

The epidermis can be divided into the innermost basal layer (stratum germinativum), the malpighian or prickle layer (stratum spinosum), the granular layer (stratum granulosum), and the horny layer (stratum corneum). On the palms and soles, a pale clear to pink layer, the stratum lucidum, is noted just above the granular layer (Fig. 1.3). When the skin in other sites is scratched or rubbed, the malpighian and granular layers thicken, a stratum lucidum forms, and the stratum corneum becomes thick and compact. Histones appear to regulate epidermal differentiation, and histone deacetylation suppresses expression of profilaggrin. Slow-cycling stem cells provide a reservoir for regeneration of the epidermis. Sites rich in stem cells include the deepest portions of the rete, especially on palmoplantar skin, as well as the hair bulge. Stem cells divide infrequently in normal skin, but in cell culture they form active, growing colonies. They can be identified by their high expression of β1-integrins and lack of terminal differentiation markers. Stem cells can also be identified by their low levels of desmosomal proteins, such as desmoglein 3. The basal cells divide, and as their progeny move upward, they flatten and their nucleus disappears. Abnormal keratinization can manifest as parakeratosis (retained nuclei), as corps ronds (round, clear to pink, abnormally keratinized cells), or as grains (elongated, basophilic, abnormally keratinized cells).

During keratinization, the keratinocyte first passes through a synthetic and then a degradative phase on its way to becoming a horn cell. In the synthetic phase, within its cytoplasm the keratinocyte accumulates intermediate filaments composed of a fibrous protein, keratin, arranged in an α-helical coiled pattern. These tonofilaments are fashioned into bundles, which converge on and terminate at the plasma membrane, where they end in specialized attachment plates called desmosomes. The degradative phase of keratinization is characterized by the disappearance of cell organelles and the consolidation of all contents into a mixture of filaments and amorphous cell envelopes. This programmed process of maturation resulting in death of the cell is called terminal differentiation. Terminal differentiation is also seen in the involuting stage of keratoacanthomas, where the initial phase of proliferation gives way to terminal keratinization and involution. Degradation of the mitochondrial network within keratinocytes occurs with aging. Oxidation injury to keratinocytes occurs with environmental exposure and thermal burns, and can be partially prevented by vitamin C in the form of L-ascorbic acid.

Premature programmed cell death, or apoptosis, appears in hematoxylin and eosin (H&E)–stained sections as scattered bright-red cells, some of which may contain small, black pyknotic nuclei. These cells are present at various levels of the epidermis, because this form of cell death does not represent part of the normal process of maturation. Widespread apoptosis is noted in the verrucous phase of incontinentia pigmenti. It is also a prominent finding in catagen hairs, where apoptosis results in the involution of the inferior segment of the hair follicle.

In normal skin, the plasma membranes of adjacent cells are separated by an intercellular space. Electron microscopic histochemical studies have shown that this interspace contains glycoproteins and lipids. Lamellar granules (Odland bodies or membrane-coating granules) appear in this space, primarily at the interface between the granular and cornified cell layers. Lamellar granules contribute to skin cohesion and impermeability. Conditions such as lamellar ichthyosis and Flegel hyperkeratosis demonstrate abnormal lamellar granules. Glycolipids such as ceramides

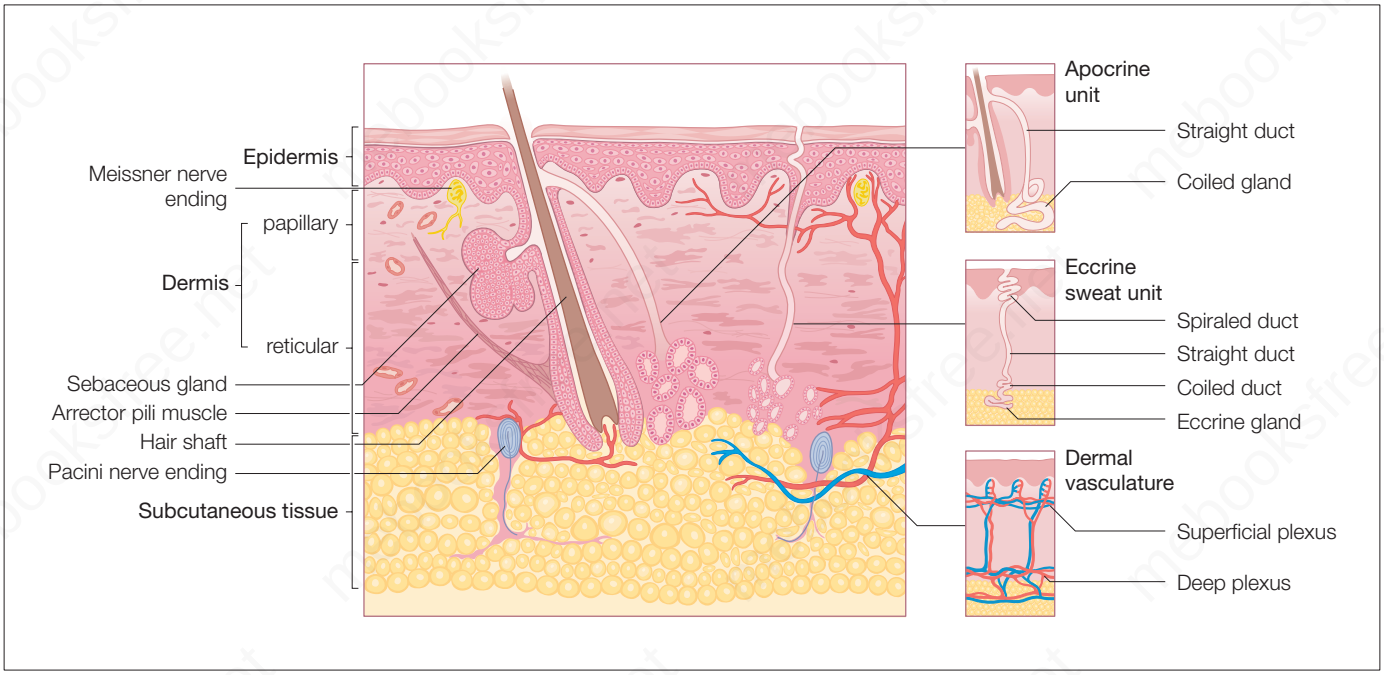

Fig. 1.1 Diagrammatic cross section of the skin and panniculus.

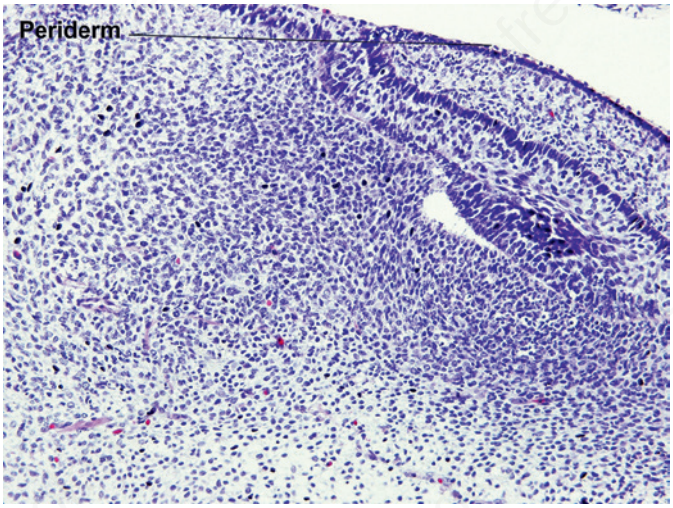

Fig. 1.2 In early fetal life, a cuboidal periderm is present, rather than an epidermis. Fetal skin, H&E × 40.

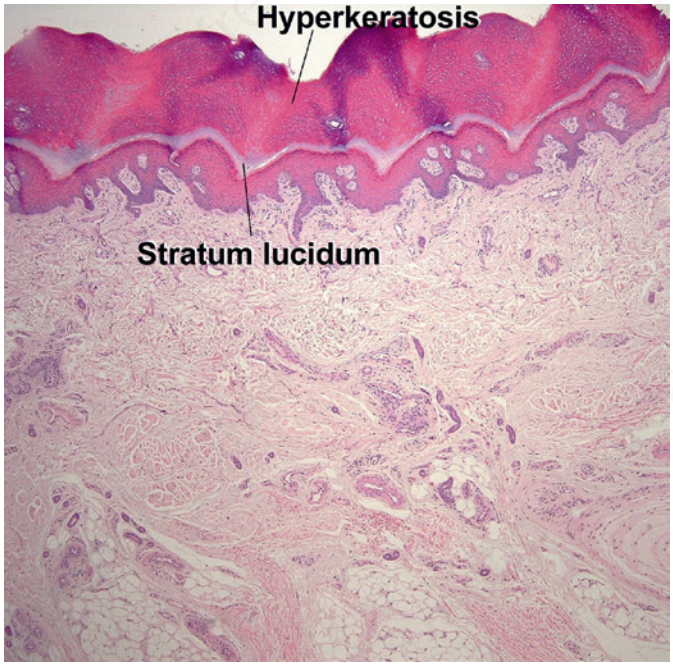

Fig. 1.3 Volar skin demonstrating a thick corneum and dermis, H&E × 100.

contribute a water-barrier function to skin and are typically found in topical products meant to restore the epidermal barrier. Lamellar bodies form abnormally in the absence of critical ceramides such as glucosylceramide, or there is disproportion of critical lipids. Desmosomal adhesion depends on cadherins, including the calcium-dependent desmogleins and desmocollins. Antibodies to these molecules result in immunobullous diseases, but desmogleins function not only in adhesion but also in differentiation. The binding of the desmoglein 1 cytoplasmic tail to the scaffolding-protein Erbin downregulates the Ras-Raf pathway to promote stratification and differentiation of keratinocytes in the epidermis.

Keratinocytes of the granular zone contain, in addition to the keratin filament system, keratohyaline granules, composed of amorphous particulate material of high sulfur-protein content. This material, profilaggrin, is a precursor to filaggrin, so named because it is thought to be responsible for keratin filament aggregation. Conversion to filaggrin takes place in the granular layer, and this forms the electron-dense interfilamentous protein matrix of mature epidermal keratin. Kallikrein-related peptidase 5, a serine protease secreted from lamellar granules, appears to function in profilaggrin cleavage.

Keratohyalin is hygroscopic, and repeated cycles of hydration and dehydration contribute to normal desquamation of the stratum corneum. Ichthyosis vulgaris is characterized by a diminished or absent granular layer, contributing to the retention hyperkeratosis

noted in this disorder. Keratohyalin results in the formation of soft, flexible keratin. Keratin that forms in the absence of keratohyaline granules is typically hard and rigid. Hair fibers and nails are composed of hard keratin.

Keratinocytes play an active role in the immune function of the skin. In conditions such as allergic contact dermatitis, these cells participate in the induction of the immune response, rather than acting as passive casualties. Keratinocytes secrete a wide array of cytokines and inflammatory mediators, including tumor necrosis factor–alpha (TNF-α). They also can express molecules on their surface, such as intercellular adhesion molecule 1 (ICAM-1) and major histocompatibility complex (MHC) class II molecules, suggesting that keratinocytes actively respond to immune effector signals.

During wound healing, epithelial cell migration occurs before dermal remodeling. Tight junction proteins claudin-1 and occludin are critical for effective migration. Downregulation of claudin-1 expression results in delayed migration and reduced epithelial proliferation. For occludin, downregulation impairs wound healing when cells are also subjected to mechanical stress. Wound healing occurs best in a moist environment but can be impaired by excessive maceration.

Melanocytes

Melanocytes are derived from the neural crest and by the eighth week of development can be found within the fetal epidermis. In normal, sun-protected trunk epidermis, melanocytes reside in the basal layer at a frequency of about 1 in every 10 basal keratinocytes. Areas such as the face, shins, and genitalia have a greater density of melanocytes, and in heavily sun-damaged facial skin, Mart-1 immunostaining can demonstrate ratios of melanocytes to basal keratinocytes that approach 1:1. Recognition of the variation in melanocyte/keratinocyte ratio is critical in the interpretation of biopsies of suspected lentigo maligna (malignant melanoma in situ) on sun-damaged skin.

Racial differences in skin color are not caused by differences in the number of melanocytes. It is the number, size, and distribution of the melanosomes or pigment granules within keratinocytes that determine differences in skin color. Pale skin has fewer melanosomes, and these are smaller and packaged within membrane-bound complexes. Dark skin has more melanosomes, and these tend to be larger and singly dispersed. Chronic sun exposure can stimulate melanocytes to produce larger melanosomes, thereby making the distribution of melanosomes within keratinocytes resemble the pattern seen in dark-skinned individuals.

In histologic sections of skin routinely stained by H&E, the melanocyte appears as a cell with ample amphophilic cytoplasm or as a clear cell in the basal layer of the epidermis. The apparent halo is an artifact formed during fixation of the specimen. This occurs because the melanocyte, lacking tonofilaments, cannot form desmosomal attachments with keratinocytes. Keratinocytes also frequently demonstrate clear spaces but can be differentiated from melanocytes because they demonstrate cell-cell junctions and a layer of cytoplasm peripheral to the clear space.

The melanocyte is a dendritic cell. Its dendrites extend for long distances within the epidermis, and any one melanocyte is therefore in contact with a great number of keratinocytes; together they form the so-called epidermal melanin unit. Keratinocytes actively ingest the tips of the melanocytic dendrites, thus imbibing the melanosomes.

Melanosomes are synthesized in the Golgi zone of the cell and pass through a series of stages in which the enzyme tyrosinase acts on melanin precursors to produce the densely pigmented granules. Melanocytes in red-haired individuals tend to be rounder and to produce more pheomelanin. The melanocortin 1 receptor (MC1R) is important in the regulation of melanin production. Loss-of-function mutations in the *MC1R* gene bring about a change from eumelanin to pheomelanin production, whereas activating gene mutations can enhance eumelanin synthesis. Most redheads are compound heterozygotes or homozygotes for a variety of loss-of-function mutations in this gene.

Antimicrobial peptides, including cathelicidin and β-defensins, are key components of the innate immune system. They protect against infection, are implicated in the pathogenesis of atopic dermatitis, and play a role in control of pigmentation. The β-defensins encompass a class of small, cationic proteins important to both the innate and the adaptive immune system. β-Defensin 3 also functions as a melanocortin receptor ligand.

Eumelanin production is optimal at pH 6.8, and changes in cellular pH also result in alterations of melanin production and the eumelanin/pheomelanin ratio. Within keratinocytes, melanin typically forms a cap over the nucleus, where it presumably functions principally in a photoprotective role. Evidence of keratinocyte photodamage in the form of pyrimidine dimer formation can be assessed using gas chromatography–mass spectrometry or enzyme-linked immunosorbent assays. Pigment within melanocytes also serves to protect the melanocytes themselves against photodamage, such as ultraviolet A (UVA)–induced membrane damage.

Areas of leukoderma, or whitening of skin, can be caused by very different phenomena. In vitiligo, the affected skin becomes white because of destruction of melanocytes. In albinism, the number of melanocytes is normal, but they are unable to synthesize fully pigmented melanosomes because of defects in the enzymatic formation of melanin. Local areas of increased pigmentation can result from a variety of causes. The typical freckle results from a localized increase in production of pigment by a near-normal number of melanocytes. Black "sunburn" or "ink spot" lentigines demonstrate basilar hyperpigmentation and prominent melanin within the stratum corneum. Nevi are benign proliferations of melanocytes. Melanomas are their malignant counterpart. Melanocytes and keratinocytes express neurotrophins (ectodermal nerve growth factors). Melanocytes release neurotrophin 4, but the release is downregulated by ultraviolet B (UVB) irradiation, suggesting neurotrophins as possible targets for therapy of disorders of pigmentation. Melanocytes express toll-like receptors (TLRs) and stimulation by bacterial lipopolysaccharides increases pigmentation. Melatonin and its metabolites protect melanocytes from UVB damage.

Langerhans Cells

Langerhans cells are normally found scattered among keratinocytes of the stratum spinosum. They constitute 3%–5% of the cells in this layer. As with melanocytes, Langerhans cells are not connected to adjacent keratinocytes by the desmosomes. The highest density of Langerhans cells in the oral mucosa occurs in the vestibular region, and the lowest density is in the sublingual region, suggesting the latter is a relatively immunologically "privileged" site.

At the light microscopic level, Langerhans cells are difficult to detect in routinely stained sections. However, they appear as dendritic cells in sections impregnated with gold chloride, a stain specific for Langerhans cells. They can also be stained with CD1α or S-100 immunostains. Ultrastructurally, they are characterized by a folded nucleus and distinct intracytoplasmic organelles called Birbeck granules. In their fully developed form, the organelles are rod shaped with a vacuole at one end, resembling a tennis racquet. The vacuole is an artifact of processing.

Functionally, Langerhans cells are of the monocyte-macrophage lineage and originate in bone marrow. They function primarily in the afferent limb of the immune response by providing for the recognition, uptake, processing, and presentation of antigens to sensitized T lymphocytes and are important in the induction of delayed-type sensitivity as well as humoral immunity. Once an antigen is presented, Langerhans cells migrate to the lymph nodes. Hyaluronan (hyaluronic acid) plays a critical role in Langerhans

cell maturation and migration. Langerhans cells express langerin, membrane adenosine triphosphatase (ATPase, CD39), and CCR6, whereas CD1α+ dermal dendritic cells express macrophage mannose receptor, CD36, factor XIIIa, and chemokine receptor 5, suggesting different functions for these two CD1α+ populations. If skin is depleted of Langerhans cells by exposure to UV radiation, it loses the ability to be sensitized until its population of Langerhans cell is replenished. Macrophages that present antigen in Langerhans cell–depleted skin can induce immune tolerance. In contrast to Langerhans cells, which make interleukin-12 (IL-12), the macrophages found in the epidermis 72 hours after UVB irradiation produce IL-10, resulting in downregulation of the immune response. At least in mice, viral immunity appears to require priming by CD8α+ dendritic cells, rather than Langerhans cells, suggesting a complex pattern of antigen presentation in cutaneous immunity.

Vaccine studies suggest the importance of various cutaneous dendritic cells. Microneedle delivery of vaccine into skin can provoke CD8+ T-cell expansion mediated by CD11c(+) CD11b(+) langerin-negative dendritic cells. Intradermal immunization is dependent on Langerhans cells to stimulate follicular T helper cells and germinal center formation.

DERMOEPIDERMAL JUNCTION

The junction of the epidermis and dermis is formed by the basement membrane zone (BMZ). Ultrastructurally, this zone is composed of four components: the plasma membranes of the basal cells with the specialized attachment plates (hemidesmosomes); an electron-lucent zone called the lamina lucida; the lamina densa (basal lamina); and the fibrous components associated with the basal lamina, including anchoring fibrils, dermal microfibrils, and collagen fibers. At the light microscopic level, the periodic acid–Schiff (PAS)–positive basement membrane is composed of the fibrous components. The basal lamina is synthesized by the basal cells of the epidermis. Type IV collagen is the major component of the basal lamina. Type VII collagen is the major component of anchoring fibrils. The two major hemidesmosomal proteins are BP230 (bullous pemphigoid antigen 1) and BP180 (bullous pemphigoid antigen 2, type XVII collagen).

In the upper permanent portion of the anagen follicle, plectin, BP230, BP180, α6β4-integrin, laminin 5, and type VII collagen show essentially the same expression as that found in the interfollicular epidermis. Laminin 5 (laminin-332) is a component of the lamina lucida/lamina densa interface, and collagen IV is the major component of the lamina densa. Staining in the lower, transient portion of the hair follicle, however, is different. All BMZ components diminish and may become discontinuous in the inferior segment of the follicle. Hemidesmosomes are also not apparent in the BMZ of the hair bulb. The lack of hemidesmosomes in the deep portions of the follicle may relate to the transient nature of the inferior segment, whereas abundant hemidesmosomes stabilize the upper portion of the follicle.

The BMZ is considered to be a porous semipermeable filter, which permits exchange of cells and fluid between the epidermis and dermis. It further serves as a structural support for the epidermis and holds the epidermis and dermis together. The BMZ also helps regulate growth, adhesion, and movement of keratinocytes and fibroblasts, as well as apoptosis. Much of this regulation takes place through activation of integrins and syndecans. Extracellular matrix protein 1 demonstrates loss-of-function mutations in lipoid proteinosis, resulting in reduplication of the basement membrane.

EPIDERMAL APPENDAGES (ADNEXA)

Eccrine and apocrine glands, ducts, and pilosebaceous units constitute the skin adnexa. Embryologically, they originate as downgrowths from the epidermis and are therefore ectodermal in origin. Hedgehog signaling by the transducer known as *smoothened* appears critical for hair development. Abnormalities in this pathway contribute to the formation of pilar tumors and basal cell carcinoma. In the absence of hedgehog signaling, embryonic hair germs may develop instead into modified sweat gland or mammary epithelium.

Although the various adnexal structures serve specific functions, all can function as reserve epidermis, in that reepithelialization occurs after injury to the surface epidermis, principally because of the migration of keratinocytes from the adnexal epithelium to the skin surface. It is not surprising, therefore, that skin sites such as the face or scalp, which contain pilosebaceous units in abundance, reepithelialize more rapidly than skin sites such as the back, where adnexa of all types are comparatively scarce. Once a wound has reepithelialized, granulation tissue is no longer produced. Deep, saucerized biopsies in an area with few adnexa will slowly fill with granulation tissue until they are flush with the surrounding skin. In contrast, areas rich in adnexa will quickly be covered with epithelium. No more granulation tissue will form, and the contour defect created by the saucerization will persist.

The pseudoepitheliomatous hyperplasia noted in infections and inflammatory conditions consists almost exclusively of adnexal epithelium. Areas of thin intervening epidermis are generally evident between areas of massively hypertrophic adnexal epithelium.

Eccrine Sweat Units

The intraepidermal spiral duct, which opens directly onto the skin surface, is called the *acrosyringium*. It is derived from dermal duct cells through mitosis and upward migration. The acrosyringium is composed of small polygonal cells with a central round nucleus surrounded by ample pink cytoplasm. In the stratum corneum overlying an actinic keratosis, the lamellar spiral acrosyringeal keratin often stands out prominently against the compact red parakeratotic keratin produced by the actinic keratosis.

The straight dermal portion of the duct is composed of a double layer of cuboidal epithelial cells and is lined by an eosinophilic cuticle on its luminal side. The coiled secretory acinar portion of the eccrine sweat gland may be found within the superficial panniculus. In areas of skin such as the back that possess a thick dermis, the eccrine coil is found in the deep dermis, surrounded by an extension of fat from the underlying panniculus. An inner layer of epithelial cells, the secretory portion of the gland, is surrounded by a layer of flattened myoepithelial cells. The secretory cells are of two types: large, pale, glycogen-rich cells and smaller, darker-staining cells. The pale glycogen-rich cells are thought to initiate the formation of sweat. The darker cells may function similar to cells of the dermal duct, which actively reabsorb sodium, thereby modifying sweat from a basically isotonic to a hypotonic solution by the time it reaches the skin surface. Sweat is similar in composition to plasma, containing the same electrolytes, but in a more dilute concentration. Physical conditioning in a hot environment results in production of larger amounts of extremely hypotonic sweat in response to a thermal stimulus. This adaptive response allows greater cooling with conservation of sodium.

In humans, eccrine sweat units are found at virtually all skin sites. In most other mammals, the apocrine gland is the major sweat gland.

Physiologic secretion of sweat occurs as a result of many factors and is mediated by cholinergic innervation. Heat is a prime stimulus to increased sweating, but other physiologic stimuli, including emotional stress, are important as well. During early development, there is a switch between adrenergic and cholinergic innervation of sweat glands. Some responsiveness to both cholinergic and adrenergic stimuli persists. Cholinergic sweating involves a biphasic response, with initial hyperpolarization and secondary depolarization mediated by the activation of calcium and chloride ion conductance. Adrenergic secretion involves monophasic depolarization and is dependent on cystic fibrosis transmembrane conductance regulator GCl. Cells from patients with cystic fibrosis demonstrate no adrenergic secretion. Vasoactive intestinal polypeptide may also play a role in stimulating eccrine secretion.

Apocrine Units

Apocrine units develop as outgrowths not of the surface epidermis, but of the infundibular or upper portion of the hair follicle. Although immature apocrine units are found covering the entire skin surface of the human fetus, these regress and are absent by the time the fetus reaches term. The straight excretory portion of the duct, which opens into the infundibular portion of the hair follicle, is composed of a double layer of cuboidal epithelial cells.

The coiled secretory gland is located at the junction of the dermis and subcutaneous fat (Fig. 1.4). It is lined by a single layer of cells, which vary in appearance from columnar to cuboidal. This layer of cells is surrounded by a layer of myoepithelial cells. Apocrine coils appear more widely dilated than eccrine coils, and apocrine sweat stains more deeply red in H&E sections, contrasting with the pale pink of eccrine sweat.

The apices of the columnar cells project into the lumen of the gland and in histologic cross section appear as if they are being extruded (decapitation secretion). Controversy surrounds the mode of secretion in apocrine secretory cells, whether merocrine, apocrine, holocrine, or all three. The composition of the product of secretion is only partially understood. Protein, carbohydrate, ammonia, lipid, and iron are all found in apocrine secretion. It appears milky white, although lipofuscin pigment may rarely produce dark shades of brown and gray-blue (apocrine chromhidrosis). Apocrine sweat is odorless until it reaches the skin surface, where it is altered by bacteria, which makes it odoriferous. Apocrine secretion is mediated by adrenergic innervation and by circulating catecholamines of adrenomedullary origin. Vasoactive intestinal polypeptide may also play a role in stimulating apocrine secretion.

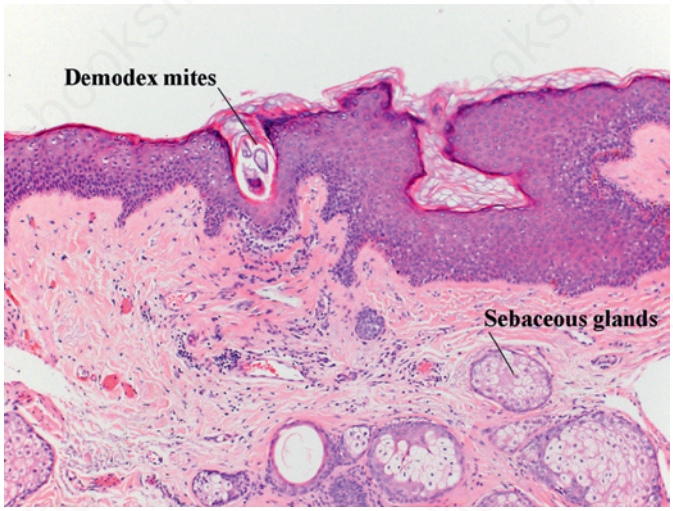

Fig. 1.4 Axillary skin is rugose and demonstrates large apocrine glands. Axillary skin, H&E × 40.

Apocrine excretion is episodic, although the actual secretion of the gland is continuous. Apocrine gland secretion in humans serves no known function. In other species, it has a protective as well as a sexual function, and in some species, it is important in thermoregulation as well.

Although occasionally found in an ectopic location, apocrine units of the human body are generally confined to the following sites: axillae, areolae, anogenital region, external auditory canal (ceruminous glands), and eyelids (glands of Moll). They are also generally prominent in stroma of the sebaceous nevus of Jadassohn. Apocrine glands do not begin to function until puberty.

Hair Follicles

During embryogenesis, mesenchymal cells in the fetal dermis collect immediately below the basal layer of the epidermis. Epidermal buds grow down into the dermis at these sites. The developing follicle forms at an angle to the skin surface and continues its downward growth. At this base, the column of cells widens, forming the bulb, and surrounds small collections of mesenchymal cells. These papillary mesenchymal bodies contain mesenchymal stem cells with broad functionality. At least in mice, they demonstrate extramedullary hematopoietic stem cell activity, representing a potential therapeutic source of hematopoietic stem cells and a possible source of extramedullary hematopoiesis in vivo.

Along one side of the fetal follicle, two buds are formed; an upper bud develops into the sebaceous gland, and a lower bud becomes the attachment for the arrector pili muscle. A third epithelial bud develops from the opposite side of the follicle above the level of the sebaceous gland anlage and gives rise to the apocrine gland. The uppermost portion of the follicle, which extends from its surface opening to the entrance of the sebaceous duct, is called the infundibular segment. It resembles the surface epidermis, and its keratinocytes may be of epidermal origin. The portion of the follicle between the sebaceous duct and the insertion of the arrector pili muscle is the isthmus. The inner root sheath fully keratinizes and sheds within this isthmic portion. The inferior portion includes the lowermost part of the follicle and the hair bulb. Throughout life, the inferior portion undergoes cycles of involution and regeneration.

Hair follicles develop sequentially in rows of three. Primary follicles are surrounded by the appearance of two secondary follicles; other secondary follicles subsequently develop around the principal

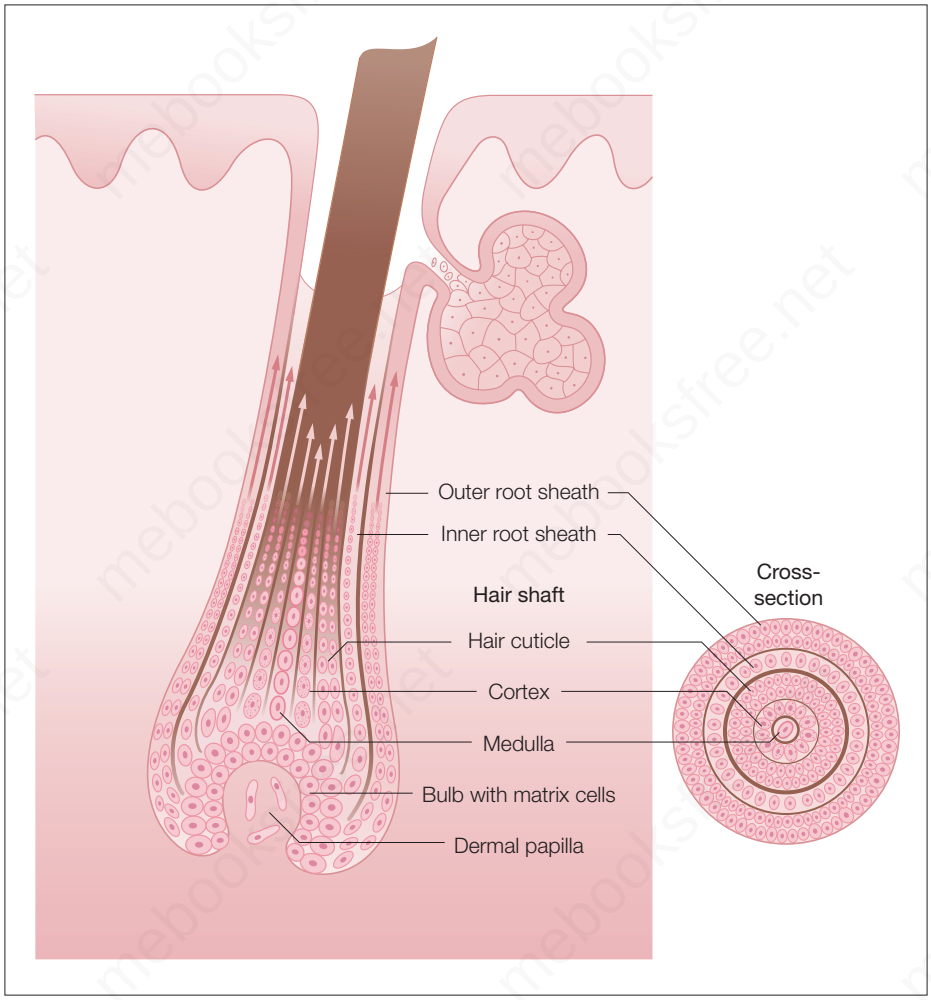

Fig. 1.5 Anatomy of the hair follicle. Additional eFigures are available.

units. The density of pilosebaceous units decreases throughout life, possibly because of dropout of the secondary follicles. In mouse models, signaling by molecules designated as ectodysplasin A and noggin is essential for the development of primary hair follicles and induction of secondary follicles. Arrector pili muscles contained within the follicular unit interconnect at the level of the isthmus.

The actual hair shaft, as well as an inner and an outer root sheath, is produced by the matrix portion of the hair bulb (Fig. 1.5). The sheaths and contained hair form concentric cylindrical layers. The hair shaft and inner root sheath move together as the hair grows upward until the fully keratinized, inner root sheath sheds at the level of the isthmus. The epidermis of the upper part of the follicular canal is contiguous with the outer root sheath. The upper two portions of the follicle (infundibulum and isthmus) are permanent; the inferior segment is completely replaced with each new cycle of hair growth. On the scalp, anagen, the active growth phase, lasts about 3–5 years. Normally, about 85%–90% of all scalp hairs are in the anagen phase, a figure that decreases with age and decreases faster in individuals with male-pattern baldness (as length of anagen decreases dramatically). Scalp anagen hairs grow at a rate of about 0.37 mm/day. Catagen, or involution, lasts about 2 weeks. Telogen, the resting phase, lasts about 3–5 months. Most sites on the body have a much shorter anagen and much longer telogen, resulting in short hairs that stay in place for long periods without growing longer. Prolongation of the anagen phase results in long eyelashes in patients with acquired immunodeficiency syndrome (AIDS).

Human hair growth is cyclic, but each follicle functions as an independent unit and regulatory T cells play a role in control of follicular stem cells and hair regeneration (Fig. 1.6). Humans do not shed hair synchronously, as most animals do. Each hair follicle undergoes intermittent stages of activity and quiescence. Synchronous termination of anagen or telogen results in telogen effluvium. Most commonly, telogen effluvium is the result of early release from anagen, such as that induced by a febrile illness, surgery, or weight loss.

Pregnancy is typically accompanied by retention of an increased number of scalp hairs in anagen, as well as a prolongation of telogen. Soon after delivery, telogen loss can be detected as abnormally prolonged telogen hairs are released. At the same time, abnormally prolonged anagen hairs are converted synchronously to telogen. Between 3 and 5 months later, a more profound effluvium is noted. Patients receiving chemotherapy often have hair loss because the drugs interfere with the mitotic activity of the hair matrix, leading to the formation of a tapered fracture. Only anagen hairs are affected, leaving a sparse coat of telogen hairs on the scalp. As the matrix recovers, anagen hairs resume growth without having to cycle through catagen and telogen.

The growing anagen hair is characterized by a pigmented bulb and an inner root sheath. Histologically, catagen hairs are best identified by the presence of many apoptotic cells in the outer root sheath. Telogen club hairs have a nonpigmented bulb with a shaggy lower border. The presence of bright-red trichilemmal keratin bordering the club hair results in a flamethrower-like

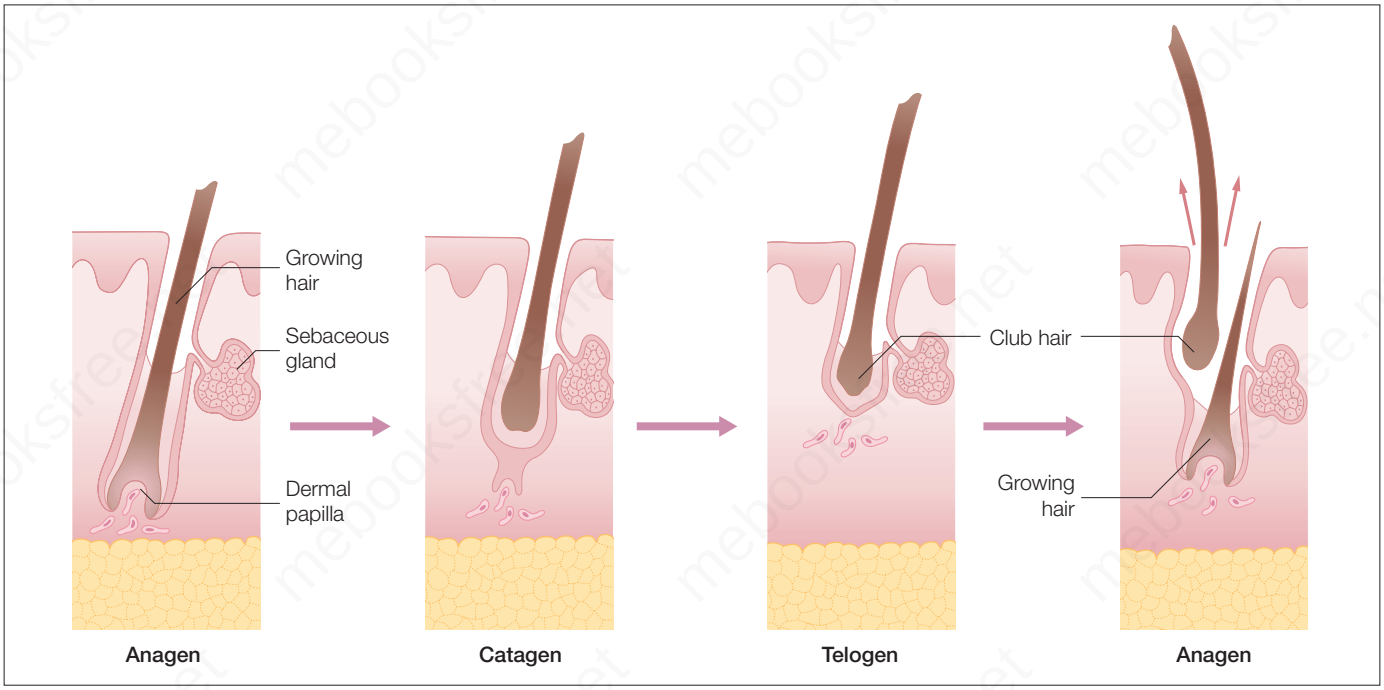

Fig. 1.6 Phases of the growth cycle of a hair.

appearance in vertical H&E sections. As the new anagen hair grows, the old telogen hair is shed.

The scalp hair of white people is round; pubic hair, beard hair, and eyelashes are oval. The scalp hair of black people is also oval, and this, along with curvature of the follicle just above the bulb, causes black hair to be curly. Uncombable hair is triangular with a central canal. Hair shape is at least partially controlled by the trichohyalin gene.

Hair color depends on the degree of melanization and distribution of melanosomes within the hair shaft. Melanocytes of the hair bulb synthesize melanosomes and transfer them to the keratinocytes of the bulb matrix. Larger melanosomes are found in the hair of black persons; smaller melanosomes, which are aggregated within membrane-bound complexes, are found in the hair of white persons. Red hair is characterized by spherical melanosomes. Graying of hair results from a decreased number of melanocytes, which produces fewer melanosomes. Repetitive oxidative stress causes apoptosis of hair follicle melanocytes, resulting in normal hair graying. Premature graying is related to exhaustion of the melanocyte stem cell pool.

Although the genetics of balding is complex, it is known that polymorphisms in the androgen receptor gene are carried on the X chromosome, inherited from the mother. The genetics of female pattern hair loss is less clear, because polymorphisms in the androgen receptor do not appear to be associated with female-pattern hair loss, and adrenal androgens may play a larger role.

Sebaceous Glands

Sebaceous glands are formed embryologically as an outgrowth from the upper portion of the hair follicle. They are composed of lobules of pale-staining cells with abundant lipid droplets in their cytoplasm. At the periphery of the lobules, basaloid germinative cells are noted. These cells give rise to the lipid-filled pale cells, which are continuously being extruded through the short sebaceous duct into the infundibular portion of the hair follicle. The sebaceous duct is lined by a red cuticle that undulates sharply in a pattern resembling a shark's teeth. This same undulating cuticle is seen in steatocystoma and some dermoid cysts.

Sebaceous glands are found in greatest abundance on the face and scalp, although they are distributed throughout all skin sites except the palms and soles. They are always associated with hair follicles, except at the following sites: tarsal plate of the eyelids (meibomian glands), buccal mucosa and vermilion border of the lip (Fordyce spots), prepuce and mucosa lateral to the penile frenulum (Tyson glands), labia minora, and female areola (Montgomery tubercles).

Most lipids produced by the sebaceous gland are also produced elsewhere in the body. Wax esters and squalene are unique secretory products of sebaceous glands. Sebocytes express histamine receptors, and antihistamines can reduce squalene levels, suggesting that antihistamines could play a role in modulating sebum production. Skin lipids contribute to the barrier function, and some have antimicrobial properties. Antimicrobial lipids include free sphingoid bases derived from epidermal ceramides and fatty acids (e.g., sapienic acid) derived from sebaceous triglycerides.

Nails

Nails act to assist in grasping small objects and in protecting the fingertip from trauma and serve a sensory function. Pacinian corpuscle-like structures are present in the nail bed of human fetuses, but are difficult to identify in adults. Fingernails grow an average of 0.1 mm/day, requiring about 4–6 months to replace a complete nail plate. The growth rate is much slower for toenails, with 12–18 months required to replace the great toenail.

The keratin types found in the nail are a mixture of epidermal and hair types, with the hair types predominating. Nail isthmus keratinization differs from that of the nail bed in that keratin 10 is only present in nail isthmus. Brittle nails demonstrate widening of the intercellular space between nail keratinocytes on electron microscopy.

Whereas most of the skin is characterized by rete pegs that resemble an egg crate, the nail bed has true parallel rete ridges. These ridges result in the formation of splinter hemorrhages when small quantities of extravasated red blood cells mark their path. The nail cuticle is formed by keratinocytes of the proximal nailfold, whereas the nail plate is formed by matrix keratinocytes. Endogenous pigments tend to follow the contour of the lunula (distal portion of matrix), whereas exogenous pigments tend to follow the contour of the cuticle. The dorsal nail plate is formed by the proximal matrix, and the ventral nail plate is formed by the distal matrix with some contribution from the nail bed. The location of a melanocytic lesion within the matrix can be assessed by the presence of pigment within the dorsal or ventral nail plate.

DERMIS

The constituents of the dermis are mesodermal in origin except for nerves, which, as with melanocytes, derive from the neural crest. Until the sixth week of fetal life, the dermis is merely a pool of scattered dendritic-shaped cells containing acid mucopolysaccharide, which are the precursors of fibroblasts. By the 12th week, fibroblasts are actively synthesizing reticulum fibers, elastic fibers, and collagen. A vascular network develops, and by the 24th week, fat cells have appeared beneath the dermis. During fetal development, Wnt/β-catenin signaling is critical for differentiation of ventral versus dorsal dermis, and the dermis then serves as a scaffold for the adnexal structures identified with ventral or dorsal sites.

Infant dermis is composed of small collagen bundles that stain deeply red. Many fibroblasts are present. In adult dermis, few fibroblasts persist; collagen bundles are thick and stain pale red. Two populations of dermal dendritic cells are noted in the adult dermis. Factor XIIIa–positive dermal dendrocytes appear to give rise to dermatofibromas, angiofibromas, acquired digital fibrokeratomas, pleomorphic fibromas, and fibrous papules. CD34+ dermal dendrocytes are accentuated around hair follicles but exist throughout the dermis. They disappear from the dermis early in the course of morphea. Their loss can be diagnostic in subtle cases. CD34+ dermal dendrocytes reappear in the dermis when morphea responds to UVA1 light treatment.

The principal component of the dermis is collagen, a family of fibrous proteins comprising at least 15 genetically distinct types in human skin. Collagen serves as the major structural protein for the entire body; it is found in tendons, ligaments, and the lining of bones, as well as in the dermis. Collagen represents 70% of the dry weight of skin. The fibroblast synthesizes the procollagen molecule, a helical arrangement of specific polypeptide chains that are subsequently secreted by the cell and assembled into collagen fibrils. Collagen is rich in the amino acids hydroxyproline, hydroxylysine, and glycine. The fibrillar collagens are the major group found in the skin.

Type I collagen is the major component of the dermis. The structure of type I collagen is uniform in width, and each fiber displays characteristic cross-striations with a periodicity of 68 nm. Collagen fibers are loosely arranged in the papillary and adventitial (periadnexal) dermis. Large collagen bundles are noted in the reticular dermis (dermis below level of postcapillary venule). Collagen I messenger ribonucleic acid (mRNA) and collagen III mRNA are both expressed in the reticular and papillary dermis and are downregulated by UV light, as is the collagen regulatory proteoglycan decorin. This downregulation may play a role in photoaging.

Type IV collagen is found in the BMZ. Type VII collagen is the major structural component of anchoring fibrils and is produced predominantly by keratinocytes. Abnormalities in type VII collagen are seen in dystrophic epidermolysis bullosa, and autoantibodies to this collagen type characterize acquired epidermolysis bullosa. Collagen fibers are continuously being degraded by proteolytic enzymes called "spare collagenases" and replaced by newly synthesized fibers. Additional information on collagen types and diseases can be found in Chapter 25.

The fibroblast also synthesizes elastic fibers and the ground substance of the dermis, which is composed of acid mucopolysaccharides and fibronectin. They can be stimulated to produce fibronectin by agents such as phytosphingosine-1-phosphate and epidermal growth factor.

Elastic fibers differ both structurally and chemically from collagen. They consist of aggregates of two components: protein filaments and elastin, an amorphous protein. The amino acids desmosine and isodesmosine are unique to elastic fibers. Elastic fibers in the papillary dermis are fine, whereas those in the reticular dermis are coarse. The extracellular matrix or ground substance of the dermis is composed of sulfated acid mucopolysaccharide, principally chondroitin sulfate and dermatan sulfate, neutral mucopolysaccharides, and electrolytes. Sulfated acid mucopolysaccharides stain with colloidal iron and with alcian blue at both pH 2.5 and pH 0.5. They stain metachromatically with toluidine blue at both pH 3.0 and pH 1.5. Hyaluronan (hyaluronic acid) is a minor component of normal dermis but is the major mucopolysaccharide that accumulates in pathologic states. It stains with colloidal iron, and with both alcian blue and toluidine blue (metachromatically), but only at the higher pH for each stain.

Collagen is the major stress-resistant material of the skin. Elastic fibers contribute little to resisting deformation and tearing of skin but have a role in maintaining elasticity. *Connective tissue disease* is a term generally used to refer to a clinically heterogeneous group of autoimmune diseases, including lupus erythematosus, scleroderma, and dermatomyositis. Scleroderma involves the most visible collagen abnormalities, as collagen bundles become hyalinized and the space between collagen bundles diminishes. Both lupus and dermatomyositis produce increased dermal mucin, mostly hyaluronic acid. Bullous lupus has autoantibodies directed against type VII collagen.

Defects in collagen synthesis have been described in a number of inheritable diseases, including Ehlers-Danlos syndrome, X-linked cutis laxa, and osteogenesis imperfecta. Defects in elastic tissue are seen in Marfan syndrome and pseudoxanthoma elasticum.

Vasculature

The dermal vasculature consists principally of two intercommunicating plexuses. The subpapillary plexus, or upper horizontal network, contains the postcapillary venules and courses at the junction of the papillary and reticular dermis (Fig. 1.7). This plexus furnishes a rich supply of capillaries, end arterioles, and venules to the dermal papillae. The deeper, lower horizontal plexus is found at the dermal-subcutaneous interface and is composed of larger blood vessels than those of the superficial plexus. Nodular lymphoid infiltrates surrounding this lower plexus are typical of early inflammatory morphea. The vasculature of the dermis is particularly well developed at sites of adnexal structures. Associated with the vascular plexus are dermal lymphatics and nerves.

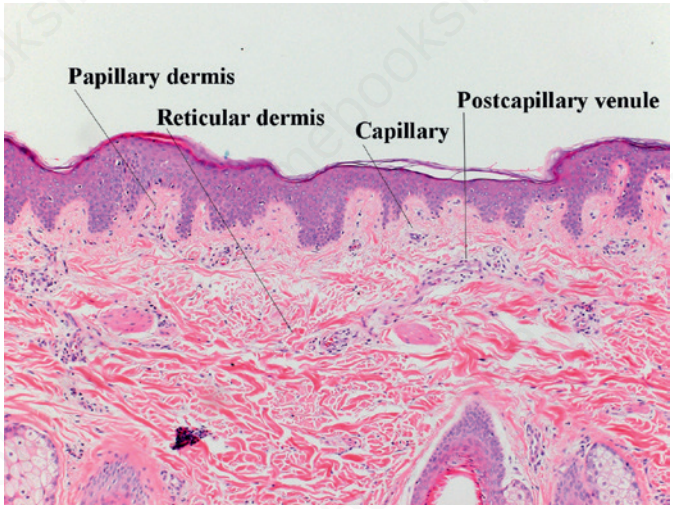

Fig. 1.7 Below the epidermis, the papillary dermis is composed of fine, nonbundled collagen. Capillaries are present within the papillary dermis, and the postcapillary venule sits at the junction of the papillary and reticular dermis. H&E × 40.

Muscles

Smooth muscle occurs in the skin as arrectores pilorum (erectors of the hairs), as the tunica dartos (or dartos) of the scrotum, and in the areolas around the nipples. The arrectores pilorum are attached to the hair follicles below the sebaceous glands and, in contracting, pull the hair follicle upward, producing gooseflesh. The presence of scattered smooth muscle throughout the dermis is typical of anogenital skin.

Smooth muscle also comprises the muscularis of dermal and subcutaneous blood vessels. The muscularis of veins is composed of small bundles of smooth muscle that crisscross at right angles. Arterial smooth muscle forms a concentric, wreathlike ring. Specialized aggregates of smooth muscle cells (glomus bodies) are found between arterioles and venules and are especially prominent on the digits and at the lateral margins of the palms and soles. Glomus bodies serve to shunt blood and regulate temperature. Most smooth muscle expresses desmin intermediate filaments, but vascular smooth muscle instead expresses vimentin. Smooth muscle actin is consistently expressed by all types of smooth muscle.

Striated (voluntary) muscle occurs in the skin of the neck as the platysma muscle and in the skin of the face as the muscles of expression. This complex network of striated muscle, fascia, and aponeuroses is known as the superficial muscular aponeurotic system (SMAS).

Nerves

In the dermis, nerve bundles are found together with arterioles and venules as part of the neurovascular bundle. In the deep dermis, nerves travel parallel to the surface, and the presence of long, sausage-like granulomas following this path is an important clue to the diagnosis of Hansen disease.

Touch and pressure are mediated by Meissner corpuscles found in the dermal papillae, particularly on the digits, palms, and soles, and by Vater-Pacini corpuscles located in the deeper portion of the dermis of weight-bearing surfaces and genitalia. Mucocutaneous end organs are found in the papillary dermis of modified hairless skin at the mucocutaneous junctions: the glans, prepuce, clitoris, labia minora, perianal region, and vermilion border of the lips. Temperature, pain, and itch sensation are transmitted by unmyelinated nerve fibers that terminate in the papillary dermis and around hair follicles. Impulses pass to the central nervous system by way of the dorsal root ganglia. Histamine-evoked itch is transmitted by slow-conducting unmyelinated C-polymodal neurons. Signal transduction differs for sensations of heat and cold and in peripheral nerve axons.

Postganglionic adrenergic fibers of the autonomic nervous system regulate vasoconstriction, apocrine gland secretions, and contraction of arrector pili muscles of hair follicles. Cholinergic fibers mediate eccrine sweat secretion.

Mast Cells

Mast cells play an important role in the normal immune response, as well as immediate-type sensitivity, contact allergy, and fibrosis. Measuring 6–12 microns in diameter, with ample amphophilic cytoplasm and a small round central nucleus, normal mast cells resemble fried eggs in histologic sections. In telangiectasia macularis eruptiva perstans (TMEP mastocytosis), they are spindle shaped and hyperchromatic, resembling large, dark fibroblasts. Mast cells are distinguished by containing up to 1000 granules, each measuring 0.6–0.7 micron in diameter. Coarse particulate granules, crystalline granules, and granules containing scrolls may be seen. On the cell's surface are 100,000–500,000 glycoprotein receptor sites for immunoglobulin E (IgE). There is heterogeneity to mast cells with type I, or connective tissue mast cells found in the dermis and submucosa, and type II, or mucosal mast cells found in the bowel and respiratory tract mucosa.

Mast cell granules stain metachromatically with toluidine blue and methylene blue (in Giemsa stain) because of their high content of heparin. They also contain histamine, neutrophil chemotactic factor, eosinophil chemotactic factor of anaphylaxis, tryptase, kininogenase, and β-glucosaminidase. Slow-reacting substance of anaphylaxis (leukotrienes C4 and D4), leukotriene B4, platelet-activating factor, and prostaglandin D2 are formed only after IgE-mediated release of granules. Mast cells stain reliably with the Leder ASD–chloracetase esterase stain. Because this stain does not rely on the presence of mast cell granules, it is particularly useful in situations when mast cells have degranulated. In forensic medicine, fluorescent labeling of mast cells with antibodies to the mast cell enzymes chymase and tryptase is useful in determining the timing of skin lesions in regard to death. Lesions sustained while living show an initial increase and then a decline in mast cells. Lesions sustained postmortem demonstrate few mast cells.

Cutaneous mast cells respond to environmental changes. Dry environments result in an increase in mast cell number and cutaneous histamine content. In mastocytosis, mast cells accumulate in skin because of abnormal proliferation, migration, and failure of apoptosis. The terminal deoxynucleotidyl transferase–mediated deoxyuridine triphosphate–biotin nick end labeling (TUNEL) method is used to assess apoptosis and demonstrates decreased staining in mastocytomas. Proliferation usually is only moderately enhanced.

SUBCUTANEOUS TISSUE (FAT)

Beneath the dermis lies the panniculus, with lobules of fat cells or lipocytes separated by fibrous septa composed of collagen and large blood vessels (Fig. 1.8). The collagen in the septa is continuous with the collagen in the dermis. Just as the epidermis and dermis vary in thickness according to skin site, so does the subcutaneous tissue. The panniculus provides buoyancy and functions as a repository of energy and an endocrine organ. It is an important site of hormone conversion, such as that of androstenedione into estrone by aromatase. Leptin, a hormone produced in lipocytes, regulates body weight through the hypothalamus and influences how we react to flavors in food. Various substances can affect lipid accumulation within lipocytes. Obestatin is a polypeptide that

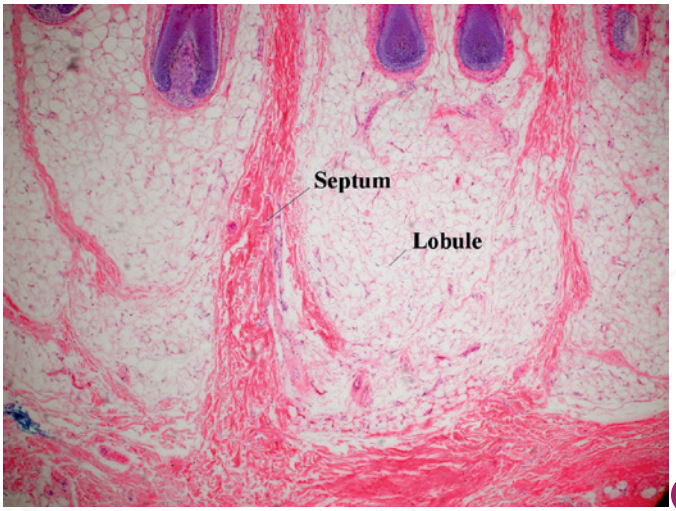

Fig. 1.8 The lobules of the subcutaneous fat are separated by fibrous septae. H&E × 40.

reduces feed intake and weight gain in rodents. (–)Ternatin, a highly *N*-methylated cyclic heptapeptide that inhibits fat accumulation, produced by the mushroom *Coriolus versicolor*; has similar effects in mice. Study of these molecules provides insight into the molecular basis of weight gain and obesity. Abnormal fat distribution and insulin resistance are seen in Cushing syndrome and as a result of antiretroviral therapy. In obese children and adolescents developing diabetes, severe peripheral insulin resistance is associated with intramyocellular and intraabdominal lipocyte lipid accumulation.

Certain inflammatory dermatoses, known as the panniculitides, principally affect this level of the skin, producing subcutaneous nodules. The pattern of the inflammation, specifically whether it primarily affects the septa or the fat lobules, serves to distinguish various conditions that may be clinically similar.

2 Cutaneous Signs and Diagnosis

Bonus images for this chapter can be found online at expertconsult.inkling.com

In some patients, the appearance of skin lesions may be so distinctive that the diagnosis is clear at a glance. In others, subjective symptoms and clinical signs alone are inadequate, and a complete history and laboratory examination, including a biopsy, are essential to arrive at a diagnosis.

The same disease may show variations under different conditions and in different individuals. The appearance of the lesions may have been modified by previous treatment or obscured by extraneous influences, such as scratching or secondary infection. Subjective symptoms may be the only evidence of a disease, as in pruritus, and the skin appearance may be generally unremarkable. Although history is important, the diagnosis in dermatology is most frequently made based on the objective physical characteristics and location or distribution of one or more lesions that can be seen or felt. Therefore careful physical examination of the skin is paramount in dermatologic diagnosis.

CUTANEOUS SIGNS

Typically, most skin diseases present with lesions that have distinct characteristics. They may be uniform or diverse in size, shape, and color or may be in different stages of evolution or involution. The original lesions are known as the primary lesions, and identification of such lesions is the most important aspect of the dermatologic physical examination. They may continue to full development or be modified by regression, trauma, or other extraneous factors, producing secondary lesions.

Primary Lesions

Primary lesions are of the following forms: macules (or patches), papules (or plaques), nodules, tumors, wheals, vesicles, bullae, and pustules.

Macules (Maculae, Spots)

Macules are variously sized, circumscribed changes in skin color, without elevation or depression (nonpalpable) (Fig. 2.1). They may be circular, oval, or irregular and may be distinct in outline or may fade into the surrounding skin. Macules may constitute the whole lesion or part of the eruption or may be merely an early phase. If the lesions become slightly raised, they are then designated papules or, in some cases, morbilliform eruptions.

Patches

A patch is a large macule, 1 cm or greater in diameter, as may be seen in nevus flammeus or vitiligo.

Papules

Papules are circumscribed, solid elevations with no visible fluid, varying in size from a pinhead to 1 cm (Fig. 2.2). They may be acuminate, rounded, conical, flat topped, or umbilicated and may appear white (as in milium), red (eczema), yellowish (xanthoma), or black (melanoma).

Papules are generally centered in the dermis and may be concentrated at the orifices of the sweat ducts or at the hair follicles. They may be of soft or firm consistency. The surface may be smooth or rough. If capped by scales, they are known as squamous papules, and the eruption is called papulosquamous.

Some papules are discrete and irregularly distributed, as in papular urticaria, whereas others are grouped, as in lichen nitidus. Some persist as papules, whereas those of the inflammatory type may progress to vesicles or to pustules, or they may erode before regression takes place.

The term "maculopapular" should not be used. There is no such thing as a "maculopapule," although there may be both macules and papules in an eruption. Typically, such eruptions are morbilliform.

Plaques

A plaque is a broad papule (or confluence of papules), 1 cm or more in diameter (Fig. 2.3). It is generally flat but may be centrally depressed.

Nodules

Nodules are morphologically similar to papules but are larger than 1 cm in diameter. Nodules most frequently are centered in the dermis or subcutaneous fat.

Tumors

Tumors are soft or firm, freely movable or fixed masses of various sizes and shapes, but usually are greater than 2 cm in diameter. General usage dictates that the word "tumor" means a neoplasm. They may be elevated or deep seated and in some cases are pedunculated (neurofibromas). Tumors have a tendency to be rounded. Their consistency depends on the constituents of the lesion. Some tumors remain stationary indefinitely, whereas others increase in size or break down.

Wheals (Hives)

Wheals are evanescent, edematous, plateaulike elevations of various sizes (Fig. 2.4). They are usually oval or of arcuate contours, pink to red, and surrounded by a "flare" of macular erythema. Wheals may be discrete or may coalesce. These lesions often develop quickly (minutes to hours). Because the wheal is the prototypic lesion of urticaria, diseases in which wheals are prominent are frequently described as "urticarial" (e.g., urticarial vasculitis). Dermatographism, or pressure-induced whealing, may be evident.

Vesicles (Blisters)

Vesicles are circumscribed, fluid-containing elevations 1–0 mm in size (Fig. 2.5). They may be clear from serous exudate or red from serum mixed with blood. The apex may be rounded, acuminate, or umbilicated, as in eczema herpeticum. Vesicles may be discrete, irregularly scattered, grouped (e.g., herpes zoster), or linear, as in allergic contact dermatitis from urushiol (poison ivy/oak). Vesicles may arise directly or from a macule or papule and generally lose their identity in a short time. They may break spontaneously or develop into bullae through coalescence or enlargement. The

Fig. 2.4 Acute urticaria.

Fig. 2.5 Piroxicam hypersensitivity (vesicles and bullae, some with hemorrhage).

inflammatory process may lead to pustule formation. When the contents are of a seropurulent character, the lesions are known as vesicopustules. Vesicles have either a single cavity (unilocular) or several compartments (multilocular).

Bullae

Bullae are rounded or irregularly shaped blisters containing serous or serosanguineous fluid. They differ from vesicles only in size, being larger than 1 cm (see Fig. 2.5). They are usually unilocular but may be multilocular. Bullae may be located superficially in the epidermis, so their walls are flaccid and thin and subject to rupture spontaneously or from slight injury. After rupture, remnants of the thin walls may persist and, together with the exudate, may dry to form a thin crust. Alternatively the broken bleb may leave a raw and moist base, which may be covered with seropurulent or purulent exudate. Less frequently, irregular vegetations may appear on the base (as in pemphigus vegetans). When subepidermal, the bullae are tense, do not rupture easily, and are often present when the patient is examined.

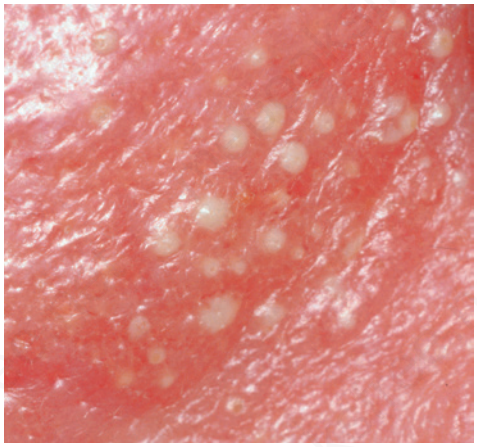

Fig. 2.6 Staphylococcal folliculitis (pustules).

Nikolsky sign refers to the diagnostic maneuver of putting lateral pressure on unblistered skin in a patient with a bullous eruption; a positive result occurs when the epithelium shears off. Asboe-Hansen sign refers to the extension of a blister to adjacent, unblistered skin when pressure is put on the top of the blister. Both these signs demonstrate the principle that in some diseases, the extent of microscopic vesiculation is more than what is evident by simple inspection. These findings are useful in evaluating the severity of pemphigus vulgaris and severe bullous drug reactions. Hemorrhagic bullae are common in pemphigus, herpes zoster, severe bullous drug reactions, and lichen sclerosus. The cellular contents of bullae may be useful in cytologically confirming the diagnosis of pemphigus, herpes zoster, and herpes simplex.

Pustules

Pustules are small elevations of the skin containing purulent material, usually necrotic inflammatory cells (Fig. 2.6). They are similar to vesicles in shape and usually have an inflammatory areola. Pustules are usually white or yellow centrally but have a red tinge if they also contain blood. They may originate as pustules or may develop from papules or vesicles, passing through transitory early stages, during which they are known as papulopustules or vesicopustules.

Secondary Lesions

Secondary lesions are of many types; the most important are scales, crusts, erosions, ulcers, fissures, and scars.

Scales (Exfoliation)

Scales are dry or greasy, laminated masses of keratin. The body ordinarily is constantly shedding imperceptible tiny, thin fragments of stratum corneum. When the formation of epidermal cells is rapid or the process of normal keratinization is disturbed, pathologic exfoliation results, producing scales. These scales vary in size; some are fine, delicate, and branny, as in tinea versicolor, whereas others are coarser, as in eczema and ichthyosis, and still others are stratified, as in psoriasis. Scales vary in color from white-gray to yellow or brown from the admixture of dirt or melanin. Occasionally, they have a silvery sheen from trapping of air between their layers; these are micaceous scales, characteristic of psoriasis. When scaling occurs, it usually suggests a pathologic process in the epidermis, and parakeratosis is often present histologically.

Crusts (Scabs)

Crusts are dried serum, pus, or blood, usually mixed with epithelial and sometimes bacterial debris. When crusts become detached, the base may be dry or red and moist.

Excoriations and Abrasions (Scratch Marks)

An excoriation is a punctate or linear abrasion produced by mechanical means, usually involving only the epidermis but sometimes reaching the papillary layer of the dermis. Excoriations are caused by scratching with the fingernails in an effort to relieve itching. If the skin damage is the result of mechanical trauma or constant friction, the term "abrasion" may be used. Frequently, there is an inflammatory areola around the excoriation or a covering of yellowish dried serum or red dried blood. Excoriations may provide access for pyogenic microorganisms and the formation of crusts, pustules, or cellulitis, occasionally associated with enlargement of the neighboring lymphatic glands. In general, the longer and deeper the excoriations, the more severe is the pruritus that provoked them. Lichen planus is an exception, however, in which pruritus is severe, but excoriations are rare.

Fissures (Cracks, Clefts)

A fissure is a linear cleft through the epidermis or into the dermis. These lesions may be single or multiple and vary from microscopic to several centimeters in length with sharply defined margins. Fissures may be dry or moist, red, straight, curved, irregular, or branching. They occur most often when the skin is thickened and inelastic from inflammation and dryness, especially in regions subjected to frequent movement. Such areas are the tips and flexural creases of the thumbs, fingers, and palms; the edges of the heels; the clefts between the fingers and toes; at the angles of the mouth; the lips; and around the nares, auricles, and anus. When the skin is dry, exposure to cold, wind, water, and cleaning products (soap, detergents) may produce a stinging, burning sensation, indicating microscopic fissuring is present. This may be referred to as chapping, as in "chapped lips." When fissuring is present, pain is often produced by movement of the parts, which opens or deepens the fissures or forms new ones.

Erosions

Loss of all or portions of the epidermis alone, as in impetigo, produces an erosion. It may or may not become crusted, but it heals without a scar.

Ulcers

Ulcers are rounded or irregularly shaped excavations that result from complete loss of the epidermis plus some portion of the dermis. They vary in diameter from a few millimeters to several centimeters (Fig. 2.7). Ulcers may be shallow, involving little beyond the epidermis, as in dystrophic epidermolysis bullosa, the base being formed by the papillary layer, or they may extend deeply into the dermis, subcutaneous tissues, or deeper, as with leg ulcers. Ulcers heal with scarring.

Scars

Scars are composed of new connective tissue that has replaced lost substance in the dermis or deeper parts resulting from injury or disease, as part of the normal reparative process. Their size and shape are determined by the form of the previous destruction. Scarring is characteristic of certain inflammatory processes and is therefore of diagnostic value. The pattern of scarring may be characteristic of a particular disease. Lichen planus and discoid

Fig. 2.7 Basal cell carcinoma (ulcer). (Courtesy Steven Binnick, MD.)

lupus erythematosus, for example, have inflammation that is in relatively the same area anatomically, yet discoid lupus characteristically causes scarring as it resolves, whereas lichen planus rarely results in scarring of the skin. Both processes, however, cause scarring of the hair follicles when occurring on the scalp. Scars may be thin and atrophic, or the fibrous elements may develop into neoplastic overgrowths, as in hypertrophic scars or keloids. Some individuals and some areas of the body, especially the anterior chest and upper back, are especially prone to hypertrophic scarring. Scars first tend to be pink or violaceous, later becoming white, glistening, and, rarely, hyperpigmented. Scars are persistent but usually become softer, less elevated, and less noticeable over years.

GENERAL DIAGNOSIS

Interpretation of the clinical picture may be difficult because identical clinical lesions may have many different causes. Moreover, the same skin disease may give rise to diverse eruptions. Thus for each specific type of primary morphologic lesion, there is a differential diagnosis of the conditions that could produce that lesion. Also, there is a parallel list of all the variations that a single skin disease can cause; for example, lichen planus may have hyperpigmented patches, violaceous plaques, hypertrophic papules, and, rarely, minute papules.

Being superficial, skin lesions can be easily observed and palpated. Magnification may be easily applied, enhancing visualization of the fine details of the lesions. Smears and cultures may be readily obtained for bacteria and fungi. Biopsy and histologic examination of skin lesions are usually minor procedures, making histopathology an important component of many dermatologic evaluations. The threshold for biopsy should be low. This is especially true of inflammatory dermatoses, potentially infectious conditions, and skin disorders in immunosuppressed and hospitalized patients in whom clinical morphology may be atypical. Once therapy is begun empirically, histologic features may be altered by the treatment, making pathologic diagnosis more difficult.

History

Knowledge of the patient's age, health, occupation, hobbies, diet, and living conditions is important, as well as the onset, duration, and course of the disease and the response to previous treatment. The family history of similar disorders and other related diseases may be useful.

A complete drug history is one of the most important aspects of a thorough history. This includes prescription and over-the-counter medications, supplements, herbal products, eyedrops, and suppositories. Drug reactions are frequent and may simulate many different skin diseases clinically and histologically. It is equally important to inquire about topical agents that have been applied to the skin and mucous membranes for medicinal or cosmetic purposes, because these agents may cause cutaneous or systemic reactions.

A complete medical history that includes other medical diagnoses of the patient is essential. Certain skin diseases are specific to or associated with other conditions, such as cutaneous Crohn disease and pyoderma gangrenosum in Crohn disease. Travel abroad, the patient's environment at home and at work, seasonal occurrences and recurrences of the disease, and the temperature, humidity, and weather exposure of the patient are all important factors in a dermatologic history. Habitation in certain parts of the world predisposes to distinctive diseases for that particular geographic locale, including San Joaquin Valley fever (coccidioidomycosis), Hansen disease, leishmaniasis, and histoplasmosis. Sexual orientation and practices may be relevant, as in genital ulcer diseases and human immunodeficiency virus (HIV) infection.

Examination

Examination should be conducted in a well-lit room. Natural sunlight is the ideal illumination. Abnormalities of melanin pigmentation (e.g., vitiligo, melasma) are more clearly visible under ultraviolet (UV) light. A Wood's light (365 nm) is most often used and is also valuable for the diagnosis of some types of tinea capitis, tinea versicolor, and erythrasma.

A magnifying lens is of inestimable value in examining small lesions. It may be necessary to palpate the lesion for firmness and fluctuation; rubbing will elucidate the nature of scales, and scraping will reveal the nature of the lesion's base. Pigmented lesions, especially in infants, should be rubbed in an attempt to elicit Darier sign (whealing), as seen in urticaria pigmentosa. Dermoscopy is an important part of the examination of neoplasms.

The entire eruption must be seen to evaluate distribution and configuration. This is optimally done by having the patient completely undress and viewing from a distance to take in the whole eruption at once. "Peek-a-boo" examination, by having the patient expose one anatomic area after another while remaining clothed, is not optimal because the examination of the skin will be incomplete, and the overall distribution is difficult to determine. After the patient is viewed at a distance, individual lesions are examined to identify primary lesions and to determine the evolution of the eruption and the presence of secondary lesions.

Diagnostic Details of Lesions

Distribution

Lesions may be few or numerous, and in arrangement they may be discrete or may coalesce to form patches of peculiar configuration. Lesions may appear over the entire body or may follow the lines of cleavage (pityriasis rosea), dermatomes (herpes zoster), or lines of Blaschko (epidermal nevi) (Fig. 2.8). Lesions may form groups, rings, crescents, or unusual linear patterns. A remarkable degree of bilateral symmetry is characteristic of certain diseases, such as dermatitis herpetiformis, vitiligo, and psoriasis.

Evolution

Some lesions appear fully evolved. Others develop from smaller lesions, then remain the same during their entire existence (e.g.,

Fig. 2.8 Linear epidermal nevus (blaschkoid).

warts). When lesions succeed one another in a series of crops, as in varicella and dermatitis herpetiformis, a polymorphous eruption results, with lesions in various stages of development or involution all present at the same time.

Involution

Certain lesions disappear completely, whereas others leave characteristic residual pigmentation or scarring. Residual dyspigmentation, although a significant cosmetic issue, is not considered a scar. The pattern in which lesions involute may be useful in diagnosis, as with the typical keratotic papule of pityriasis lichenoides varioliformis acuta.

Grouping

Grouping is a characteristic of dermatitis herpetiformis, herpes simplex, and herpes zoster. Small lesions arranged around a large one are said to be in a corymbose (corymbiform) arrangement. Concentric annular lesions are typical of borderline Hansen disease and erythema multiforme. These are sometimes said to be in a "cockade" pattern, referring to the tricolor cockade hats worn by French revolutionists. Flea and other arthropod bites are usually grouped and linear (breakfast-lunch-and-dinner sign). Grouped lesions of various sizes may be called agminated.

Configuration

Certain terms are used to describe the configuration that an eruption assumes either primarily or by enlargement or coalescence. Lesions in a line are called linear, and they may be confluent or discrete. Lesions may form a complete circle with normal-appearing skin centrally (annular) or a portion of a circle (arcuate or gyrate), or may be composed of several intersecting portions of circles (polycyclic). If the eruption is not straight but does not form parts of circles, it may be serpiginous (Fig. 2.9). Round lesions may be small, like drops, called guttate; or larger, like a coin, called nummular. Unusual configurations that do not correspond to these patterns or to normal anatomic or embryonic patterns should raise the possibility of an exogenous dermatosis or factitia.

Fig. 2.9 Cutaneous larva migrans (serpiginous).

Color

The color of the skin is determined by melanin, oxyhemoglobin, reduced hemoglobin, lipid, and carotene. Not only do the proportions of these components affect the color, but also their depth within the skin, the thickness of the epidermis, and hydration play a role. The Tyndall effect modifies the color of skin and of lesions by the selective scattering of light waves of different wavelengths. The blue nevus and mongolian spots are examples of this light dispersion effect, in which brown melanin in the dermis appears blue-gray.

The color of lesions may be valuable as a diagnostic factor. Dermatologists should be aware that there are many shades of pink, red, and purple, each of which tends to suggest a diagnosis or disease group. Interface reactions such as lichen planus or lupus erythematosus are described as violaceous. Lipid-containing lesions are yellow, as in xanthomas (Fig. 2.10) or steatocystoma multiplex. The orange-red (salmon) color of pityriasis rubra pilaris is characteristic. The constitutive color of the skin determines the quality of the color one observes with a specific disorder. In dark-skinned persons, erythema is difficult to perceive. Pruritic lesions in African Americans may evolve to be small, shiny, flat-topped papules with a violaceous hue, from the combination of erythema and pigment incontinence. These lichenified lesions would be suspected of being lichenoid by the untrained eye, but may be in fact eczematous.

Patches lighter in color than the normal skin may be completely depigmented or may have lost only part of their pigment (hypopigmented). This is an important distinction because certain conditions are or may be hypopigmented, such as tinea versicolor, Hansen disease, ash-leaf macules of tuberous sclerosis, hypomelanosis of Ito, seborrheic dermatitis, and idiopathic guttate hypomelanosis. True depigmentation should be distinguished from this; it suggests vitiligo, nevus depigmentosus, halo nevus, scleroderma, morphea, or lichen sclerosus.

Hyperpigmentation may result from epidermal or dermal causes. It may be related to either increased melanin or deposition of other substances. Epidermal hyperpigmentation occurs in nevi, melanoma, café au lait spots, melasma, and lentigines. These lesions are accentuated when examined with a Wood's light. Dermal pigmentation occurs subsequent to many inflammatory conditions (postinflammatory hyperpigmentation) or from deposition of metals, medications, medication-melanin complexes, or degenerated dermal material (ochronosis). These conditions are not enhanced when examined by a Wood's light. The hyperpigmentation following inflammation is most frequently the result of dermal melanin deposition, but in some conditions, such as lichen aureus, is caused

Fig. 2.10 Eruptive xanthoma. (A) Yellow color easily discerned on white skin. (B) Yellow color subtler in brown or black skin.

by iron. Dermal iron deposition appears more yellow-brown or golden than dermal melanin.

Texture/Consistency

Palpation is an essential part of the physical examination of lesions. Does the lesion blanch on pressure? If not, it may be purpuric. Is it fluctuant? If so, it may have free fluid in it. If there is a nodule or tumor, does it sink through a ring into the panniculus, like a neurofibroma? Is it hard enough for calcification to be suspected, or merely very firm, like a keloid or dermatofibroma?

Hyperesthesia/Anesthesia

Certain conditions may be associated with increased or decreased sensation. For example, the skin lesions of borderline and tuberculoid Hansen disease typically are anesthetic in their centers. In complex regional pain syndrome spontaneous pain and tenderness on palpation are characteristic. In other neuropathic conditions such as notalgia paresthetica, the patient may perceive both pruritus and hyperesthesia. Neurally mediated itch may be accompanied by other neural sensations, such as heat or burning. The combination of pruritus with other neural symptoms suggests the involvement of nerves in the pathologic process.

Hair, Nails, and Oral Mucosa

Involvement of hair-bearing areas by certain skin disorders causes characteristic lesions. Discoid lupus, for example, causes scarring alopecia with characteristic dyspigmentation (Fig. 2.11). On the skin, the lesions may be much less characteristic. Diffuse hair loss may be seen in certain conditions, such as acrodermatitis enteropathica, and may be a clue to the diagnosis. In addition, loss of hair within a skin lesion may suggest the diagnosis, such as the alopecia seen in the tumid plaques of follicular mucinosis.

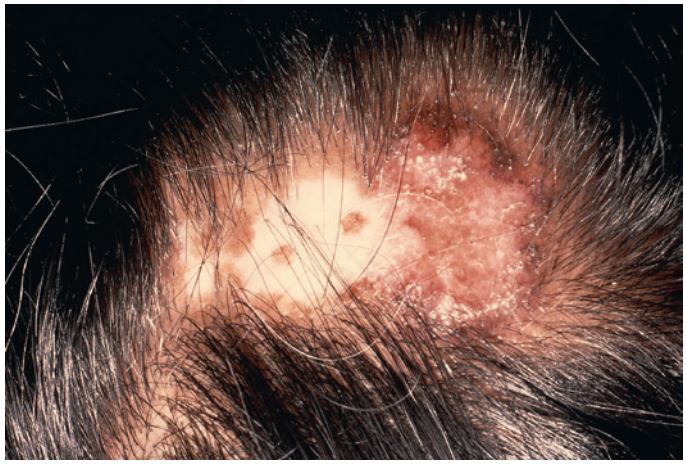

Fig. 2.11 Scalp plaque with scarring alopecia hyperpigmentation and depigmentation, discoid lupus erythematosus.

Fig. 2.12 Oral Kaposi sarcoma.

Some skin disorders cause characteristic changes of the nails, even when the periungual tissue is not involved. The pitting seen in psoriasis and alopecia areata may be useful in confirming these diagnoses when other findings are not characteristic. In addition, the nails and adjacent structures may be the sole site of pathology, as in candidal paronychia.

The complete skin examination includes examination of the oral mucosa. Oral lesions are characteristically found in viral syndromes (exanthems), lichen planus, HIV-associated Kaposi sarcoma (Fig. 2.12), and autoimmune bullous diseases (pemphigus vulgaris).

Self-Examination

Patients at risk for the development of skin cancer should be taught the correct method of skin self-examination, specifically, the ABCDEs of melanoma detection and the types of lesions that might represent basal cell carcinoma or squamous cell carcinoma.

3 Dermatoses Resulting From Physical Factors

Bonus images for this chapter can be found online at **expertconsult.inkling.com**

The body requires a certain amount of heat, but beyond definite limits, insufficient or excessive amounts are injurious. The local action of excessive heat causes burns or scalds; undue cold causes chilblains, frostbite, and congelation. Thresholds of tolerance exist in all body structures sensitive to electromagnetic wave radiation of varying frequencies, such as x-rays and ultraviolet (UV) rays. The skin, which is exposed to so many external physical forces, is more subject to injuries caused by this radiation than any other organ.

HEAT INJURIES

Thermal Burns

Injury of varying intensity may be caused by the action of excessive heat on the skin (Fig. 3.1). If this heat is extreme, the skin and underlying tissue may be destroyed. The changes in the skin resulting from dry heat or scalding are classified in four degrees, as follows:

- *First-degree burns* of the skin result merely in an active congestion of the superficial blood vessels, causing erythema that may be followed by epidermal desquamation (peeling). Ordinary sunburn is the most common example of a first-degree burn. The pain and increased surface heat may be severe, and some constitutional reaction can occur if the involved area is large.
- *Second-degree burns* are subdivided into superficial and deep forms.
  - In the superficial second-degree burn, there is a transudation of serum from the capillaries, which causes edema of the superficial tissues. Vesicles and bullae are formed by the serum gathering beneath the outer layers of the epidermis. Complete recovery without scarring is usual in patients with superficial burns.
  - The deep second-degree burn is pale and anesthetic. Injury to the reticular dermis compromises blood flow and destroys appendages, so healing takes more than 1 month and results in scarring.
- *Third-degree burns* involve loss of the full thickness of the dermis and often some of the subcutaneous tissues. Because the skin appendages are destroyed, there is no epithelium available for regeneration of the skin. An ulcerating wound is produced, which on healing leaves a scar.
- *Fourth-degree burns* involve the destruction of the entire skin, including the subcutaneous fat, and any underlying tendons.

Both third-degree and fourth-degree burns require grafting for closure. All third- and fourth-degree burns are followed by constitutional symptoms of varying severity, depending on the size of the involved surface, the depth of the burn, and particularly the location of the burned surface. The more vascular the involved area, the more severe are the symptoms.

The prognosis is poor for any patient in whom a large area of skin surface is involved, particularly if more than two thirds of the body surface has been burned. Women, infants, and toddlers all have a greater risk of death from burns than men. Excessive scarring, with either keloid-like scars or flat scars with contractures, may produce deformities and dysfunction of the joints, as well as chronic ulcerations from impairment of local circulation. Delayed postburn blistering may occur in partial-thickness wounds and skin graft donor sites. It is most common on the lower extremities and is self-limited. Although burn scars may be the site of development of carcinoma, evidence supports only the possibility of a modest excess of squamous cell carcinomas in burn scars. With modern reconstructive surgery, this unfortunate end result can be minimized.

Treatment

Immediate first aid for minor thermal burns consists of prompt cold applications (ice water, or cold tap water if no ice is available), which are continued until pain does not return on stopping them.

The vesicles and bullae of second-degree burns should not be opened but should be protected from injury because they form a natural barrier against contamination by microorganisms. If they become tense and unduly painful, the fluid may be evacuated under strictly aseptic conditions by puncturing it with a sterile needle, allowing collapse onto the underlying wound. Excision of full-thickness and deep dermal wounds that will not reepithelialize within 3 weeks (as soon as hemodynamic stability is achieved, normally 2–3 days) reduces wound infections, shortens hospital stays, and improves survival. Additionally, contractures and functional impairment may be mitigated by such intervention. Skin grafting, or coverage with biologic dressings such as allograft or xenograft skin, cultured epidermal autografts, or skin substitutes also assist in healing. The role of early ablative laser treatments to prevent disabling scars and its use in improving fully formed scars is an area of active investigation. The most superficial wounds may be dressed with greasy gauze, whereas silver-containing dressings are used for their antibiotic properties in intermediate wounds.

Fluid resuscitation, treatment of inhalation injury and hypercatabolism, monitoring and early intervention of sepsis, pain control, environmental control, and nutritional support are key components of the critical care of burns. Intensive care management in a burn center is recommended for patients with partial-thickness wounds covering more than 10% of the body surface, if involving the face, hands, feet, genitalia, perineum, or joints; if secondary to electrical, chemical, or inhalation injury; in patients with special needs; and for any full-thickness burn.

Electrical Burns

Electrical burns may occur from contact or as a flash exposure. A contact burn is small but deep, causing some necrosis of the underlying tissues. Low-voltage injuries usually occur in the home, are treated conservatively, and generally heal well. Oral commissure burns may require reconstructive procedures (Fig. 3.2). High-voltage burns are often occupational; internal damage may be masked by minimal surface skin change and may be complicated by subtle and slowly developing sequelae. Early surgical intervention to improve circulation and repair vital tissues is helpful in limiting loss of the extremity.

Flash burns usually cover a large area and, being similar to any surface burn, are treated as such. Lightning may cause burns after a direct strike, where an entrance and an exit wound are visible. This is the most lethal type of strike, and cardiac arrest

Fig. 3.1 Hot water burn. (Courtesy Steven Binnick, MD.)

Fig. 3.3 Miliaria crystallina.

Fig. 3.2 Electrical burn from biting electrical cord. (Courtesy Paul Hong, MD.)

or other internal injuries may occur. Other types of lightning strike are indirect and result in the following burns:

- Linear burns in areas on which sweat was present
- Burns in a feathery or arborescent pattern, which is believed to be pathognomonic
- Punctate burns with multiple, deep, circular lesions
- Thermal burns from ignited clothing or heated metal, which may occur if the patient was speaking on a cell phone or listening to an iPod or similar device when struck

Hot Tar Burns

Polyoxyethylene sorbitan in bacitracin zinc–neomycin–polymyxin B (e.g., Neosporin) ointment, vitamin E ointment, and sunflower oil are excellent dispersing agents that facilitate the removal of hot tar from burns.

Miliaria

Miliaria, the retention of sweat as a result of occlusion of eccrine sweat ducts, produces an eruption that is common in hot, humid climates, such as in the tropics and during the hot summer months in temperate climates. *Staphylococcus epidermidis*, which produces an extracellular polysaccharide substance, induces miliaria in an experimental setting. This polysaccharide substance may obstruct the delivery of sweat to the skin surface. The occlusion prevents normal secretion from the sweat glands, and eventually pressure causes rupture of the sweat gland or duct at different levels. The escape of sweat into the adjacent tissue produces miliaria. Depending on the level of the injury to the sweat gland or duct, several different forms are recognized.

Miliaria Crystallina

Miliaria crystallina is characterized by small, clear, superficial vesicles with no inflammatory reaction (Fig. 3.3). It appears in bedridden patients whose fever produces increased perspiration or when clothing prevents dissipation of heat and moisture, as in bundled children. Hypernatremia without fever may induce it.

Fig. 3.4 Miliaria rubra.

The lesions are generally asymptomatic, and their duration is short-lived because they tend to rupture at the slightest trauma. Drugs such as isotretinoin, adrenergic/cholinergic drugs, and doxorubicin may induce it. The lesions are self-limited; no treatment is required.

Miliaria Rubra (Prickly Heat)

The lesions of miliaria rubra appear as discrete, extremely pruritic, erythematous papulovesicles (Fig. 3.4) accompanied by a sensation of prickling, burning, or tingling. They later may become confluent on a bed of erythema. The sites most frequently affected are the antecubital and popliteal fossae, trunk, inframammary areas (especially under pendulous breasts), abdomen (especially at the waistline), and inguinal regions; these sites frequently become macerated because evaporation of moisture has been impeded. Exercise-induced itching or that of atopic dermatitis may also be caused by miliaria rubra. The site of injury and sweat escape is in the prickle cell layer, where spongiosis is produced.

Miliaria Pustulosa

Miliaria pustulosa is preceded by another dermatitis that has produced injury, destruction, or blocking of the sweat duct. The pustules are distinct, superficial, and independent of the hair follicle. The pruritic pustules occur most frequently on the intertriginous areas, flexural surfaces of the extremities, scrotum, and back of bedridden patients. Contact dermatitis, lichen simplex chronicus, and intertrigo are some of the associated diseases, although pustular miliaria may occur several weeks after these diseases have subsided. Recurrent episodes may be a sign of type I pseudohypoaldosteronism, because salt-losing crises may precipitate miliaria pustulosa or rubra, with resolution after stabilization.

Miliaria Profunda

Nonpruritic, flesh-colored, deep-seated, whitish papules characterize miliaria profunda. It is asymptomatic, usually lasts only 1 hour after overheating has ended, and is concentrated on the trunk and extremities. Except for the face, axillae, hands, and feet, where there may be compensatory hyperhidrosis, all the sweat glands are nonfunctional. The occlusion is in the upper dermis. Miliaria profunda is observed only in the tropics and usually follows a severe bout of miliaria rubra.

Postmiliarial Hypohidrosis

Postmiliarial hypohidrosis results from occlusion of sweat ducts and pores, and it may be severe enough to impair an individual's ability to perform sustained work in a hot environment. Affected persons may show decreasing efficiency, irritability, anorexia, drowsiness, vertigo, and headache; they may wander in a daze.

It has been shown that hypohidrosis invariably follows miliaria, and that the duration and severity of the hypohidrosis are related to the severity of the miliaria. Sweating may be depressed to half the normal amount for as long as 3 weeks.

Tropical Anhidrotic Asthenia

Tropical anhidrotic asthenia is a rare form of miliaria with long-lasting poral occlusion, which produces anhidrosis and heat retention.

Treatment

The most effective treatment for miliaria is to place the patient in a cool environment. Even a single night in an air-conditioned room helps to alleviate the discomfort. Circulating air fans can also be used to cool the skin. Anhydrous lanolin resolves the occlusion of pores and may help to restore normal sweat secretions. Hydrophilic ointment also helps to dissolve keratinous plugs and facilitates the normal flow of sweat. Soothing, cooling baths containing colloidal oatmeal or cornstarch are beneficial if used in moderation. Patients with mild cases may respond to dusting powders, such as cornstarch or baby talcum powder.

Erythema Ab Igne

Erythema ab igne is a persistent erythema—or the coarsely reticulated residual pigmentation resulting from it—that is usually produced by long exposure to excessive heat without the production of a burn (Fig. 3.5). It begins as a mottling caused by local hemostasis and becomes a reticulated erythema, leaving pigmentation. Multiple colors are simultaneously present in an active patch, varying from pale pink to old rose or dark purplish brown. After the cause is removed, the affection tends to disappear gradually, but sometimes the pigmentation is permanent.

Histologically, an increased amount of elastic tissue in the dermis is noted. The changes in erythema ab igne are similar to those of actinic elastosis. Interface dermatitis and epithelial atypia may be noted.

Erythema ab igne on the legs results from habitually warming them in front of open fireplaces, space heaters, or car heaters. Similar changes may be produced on the lower back or at other sites of an electric heating pad application, on the upper thighs with laptop computers, or on the posterior thighs from heated car seats. The reason for chronically exposing the skin to heat may be pain from an underlying cancer, or from a condition which predisposes to a feeling of cold, such as anorexia nervosa. The condition occurs also in cooks, silversmiths, and others exposed over long periods to direct moderate heat.

Epithelial atypia, which may lead to Bowen disease and squamous cell carcinoma, has rarely been reported to occur overlying erythema

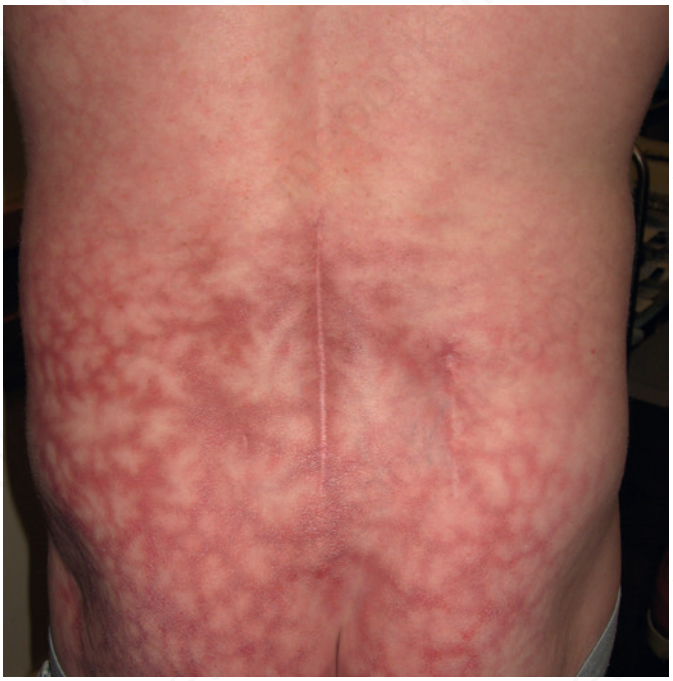

Fig. 3.5 Erythema ab igne.

ab igne. In remote areas of Kashmir, Kangri fire pots can induce erythema ab igne and cancer within the affected area. Treatment with 5-fluorouracil (5-FU), imiquimod, or photodynamic therapy may be effective in reversing this epidermal alteration.

The use of emollients containing α-hydroxy acids or a cream containing fluocinolone acetonide 0.01%, hydroquinone 4%, and tretinoin 0.05% may help reduce the unsightly pigmentation, as may treatment with the Q-switched neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser.

COLD INJURIES

Exposure to cold damages the skin by at least three mechanisms:

- Reduced temperature directly damages the tissue, as in frostbite and cold immersion foot.
- Vasospasm of vessels perfusing the skin prevents adequate perfusion of the tissue and causes vascular injury and consequent tissue injury (pernio, acrocyanosis, and frostbite).
- In unusual circumstances, adipose tissue is predisposed to damage by cold temperatures because of fat composition or location (cold panniculitis; see Chapter 23).

Outdoor workers and recreationalists, military service members, alcoholic persons, and homeless people are particularly likely to sustain cold injuries. Maneuvers to treat orthopedic injuries or heatstroke and cooling devices for other therapeutic use may result in cold injuries ranging from acrocyanosis to frostbite. Holding ice coated with salt (salt and ice challenge) will induce cold-induced blistering.

Fig. 3.6 Acrocyanosis.

Roussel LO, et al: Tweens feel the burn. Int J Adolesc Med Health 2016; 28: 217.

Acrocyanosis

Acrocyanosis is a persistent blue discoloration of the entire hand or foot worsened by cold exposure. The hands and feet may be hyperhidrotic (Fig. 3.6). It occurs chiefly in young women. Cyanosis increases as the temperature decreases and changes to erythema with elevation of the dependent part. The cause is unknown. Smoking should be avoided. Acrocyanosis is distinguished from Raynaud syndrome by its persistent (rather than episodic) nature and lack of tissue damage (ulceration, distal fingertip resorption).

Acrocyanosis with swelling of the nose, ears, and dorsal hands may occur after inhalation of butyl nitrite. Interferon alpha-2a and beta may induce it. Repeated injection of the dorsal hand with narcotic drugs may produce lymphedema and an appearance similar to the edematous phase of scleroderma. This so-called puffy hand syndrome may include erythema or a bluish discoloration of the digits. Patients with anorexia nervosa frequently manifest acrocyanosis as well as perniosis, livedo reticularis, and acral coldness. It may improve with weight gain. Approximately one third of patients with skin findings of POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, M component, skin changes) have acrocyanosis. Also, in patients with a homozygous mutation in *SAMDH1* and cerebrovascular occlusive disease, acrocyanosis was frequent.

Acral vascular syndromes, such as gangrene, Raynaud phenomenon, and acrocyanosis, may be a sign of malignancy. In 47% of 68 reported cases, the diagnosis of cancer coincided with the onset of the acral disease. If such changes appear or worsen in an elderly patient, especially a man, without exposure to vasoconstrictive drugs or prior autoimmune or vascular disorders, a paraneoplastic origin should be suspected.

Pernio (Chilblains, Perniosis)

Pernio constitutes a localized erythema and swelling caused by exposure to cold. Blistering and ulcerations may develop in severe cases. In people predisposed by poor peripheral circulation, even moderate exposure to cold may produce chilblains. Cryoglobulins, cryofibrinogens, antiphospholipid antibodies, or cold agglutinins may be present and pathogenic. Chilblain-like lesions may occur in discoid and systemic lupus erythematosus (SLE; chilblain lupus), particularly the TREX1-associated familial type, as a presenting sign of leukemia cutis, or if occurring in infancy may herald the Nakajo-Nishimura syndrome or the Aicardi-Goutières and Singleton-Merten syndrome. The chronic use of crack cocaine and its attendant peripheral vasoconstriction will lead to perniosis with cold, numb hands and atrophy of the digital fat pads, especially of the thumbs and index fingers, as well as nail curvature.

Pernio occur chiefly on the feet, hands, ears, and face, chiefly in women; onset is enhanced by dampness (Fig. 3.7). In surgery technicians, the hands are affected if an orthopedic cold therapy system is used; the skin under the device develops the lesions. The lateral thighs are involved in women equestrians who ride on cold, damp days and the hips in those wearing tight-fitting jeans with a low waistband. Wading across cold streams may produce similar lesions. Nondigital lesions of cold injury can be nodular.

Fig. 3.7 Chilblains (pernio) in adult (A) and child (B).

Patients with chilblains are often unaware of the cold injury when it is occurring, but later burning, itching, and redness call it to their attention. The affected areas are bluish red, with the color partially or totally disappearing on pressure, and are cool to the touch. Sometimes the extremities are clammy because of excessive sweating. As long as the dampness and cold exposure continues, new lesions will continue to appear. Investigation into an underlying cause should be undertaken in patients with pernio that is recurrent, chronic, extending into warm seasons, or poorly responsive to treatment.

Pernio histologically demonstrates a lymphocytic vasculitis. There is dermal edema, and a superficial and deep perivascular, tightly cuffed, lymphocytic infiltrate. The infiltrate involves the vessel walls and is accompanied by characteristic "fluffy" edema of the vessel walls.

Treatment

The affected parts should be protected against further exposure to cold or dampness. If the feet are involved, woolen socks should be worn at all times during the cold months. Because patients are often not conscious of the cold exposure that triggers the lesions, appropriate dress must be stressed, even if patients say they do not sense being cold. Because central cooling triggers peripheral vasoconstriction, keeping the whole body (not just the affected extremity) warm is critical. Heating pads may be used judiciously to warm the parts. Smoking is strongly discouraged.

Nifedipine, 20 mg three times a day, has been effective. Vasodilators such as nicotinamide, 500 mg three times a day, or dipyridamole, 25 mg three times a day, or the phosphodiesterase inhibitor sildenafil, 50 mg twice daily, may be used to improve circulation. Pentoxifylline and hydroxychloroquine may be effective. Spontaneous resolution occurs without treatment in 1–3 weeks. Systemic corticoid therapy is useful in chilblain lupus.

Frostbite

When soft tissue is frozen and locally deprived of blood supply, the damage is called frostbite. The ears, nose, cheeks, fingers, and

Fig. 3.8 Frostbite.

toes are most often affected. The frozen part painlessly becomes pale and waxy. Various degrees of tissue destruction similar to that caused by burns are encountered. These are erythema and edema, vesicles and bullae, superficial gangrene, deep gangrene, and injury to muscles, tendons, periosteum, and nerves (Fig. 3.8). The degree of injury is directly related to the temperature and duration of freezing. African Americans are at increased risk of frostbite. Arthritis of the small joints of the hands and feet may appear months to years later.

Treatment

Early treatment of frostbite before swelling develops should consist of covering the part with clothing or with a warm hand or other body surface to maintain a slightly warm temperature so that adequate blood circulation can be maintained. Rapid rewarming in a water bath between 37°C and 43°C (100°F and 110°F) is the treatment of choice for all forms of frostbite. Rewarming should be delayed until the patient has been removed to an area where there is no risk of refreezing. Slow thawing results in more extensive tissue damage. Analgesics should be administered because of the considerable pain experienced with rapid thawing. When the skin flushes and is pliable, thawing is complete. The use of tissue plasminogen activator to lyse thrombi decreases the need for amputation if given within 24 hours of injury. Infusion of the vasodilator iloprost may be used if available. Supportive measures such as bed rest, a high-protein/high-calorie diet, wound care, and avoidance of trauma are imperative. Any rubbing of the affected part should be avoided, but gentle massage of proximal portions of the extremity that are not numb may be helpful.

The use of anticoagulants to prevent thrombosis and gangrene during the recovery period has been advocated. Pentoxifylline, ibuprofen, and aspirin may be useful adjuncts. Antibiotics should be given as a prophylactic measure against infection, and tetanus immunization should be updated. Recovery may take many months. Injuries that affect the proximal phalanx or the carpal or tarsal area, especially when accompanied by a lack of radiotracer uptake on bone scan, have a high likelihood of requiring amputation. Whereas prior cold injury is a major risk factor for recurrent disease, sympathectomy may be preventive against repeated episodes. Arthritis may be a late complication.

Immersion Foot Syndromes

Trench Foot

Trench foot results from prolonged exposure to cold, wet conditions without immersion or actual freezing. The term is derived from trench warfare in World War I, when soldiers stood, sometimes for hours, in trenches with a few inches of cold water in them. Fishermen, sailors, and shipwreck survivors may be seen with this condition. The lack of circulation produces edema, paresthesias, and damage to the blood vessels. Similar findings may complicate the overuse of ice, cold water, and fans by patients trying to relieve the pain associated with erythromelalgia. Gangrene may occur in severe cases. Treatment consists of removal from the causal environment, bed rest, and restoration of the circulation. Other measures, such as those used in the treatment of frostbite, should be employed.

Warm Water Immersion Foot

Exposure of the feet to warm, wet conditions for 48 hours or more may produce a syndrome characterized by maceration, blanching, and wrinkling of the soles and sides of the feet (Fig. 3.9). Itching and burning with swelling may persist for a few days after removal of the cause, but disability is temporary. This condition was often seen in military service members in Vietnam but has also been seen in persons wearing insulated boots.

Warm water immersion foot should be differentiated from tropical immersion foot, seen after continuous immersion of the feet in water or mud at temperatures above 22°C (71.6°F) for 2–10 days. This was known as "paddy foot" in Vietnam. It involves erythema, edema, and pain of the dorsal feet, as well as fever and adenopathy (Fig. 3.10). Resolution occurs 3–7 days after the feet have been dried.

Warm water immersion foot can be prevented by allowing the feet to dry for a few hours in every 24 or by greasing the soles with a silicone grease once a day. Recovery is usually rapid if the feet are thoroughly dry for a few hours.

ACTINIC INJURY

Sunburn and Solar Erythema

The solar spectrum has been divided into different regions by wavelength. The parts of the solar spectrum important in photomedicine include UV radiation (below 400 nm), visible light (400–760 nm), and infrared radiation (beyond 760 nm). Visible light has limited biologic activity, except for stimulating the retina. Infrared radiation is experienced as radiant heat. Below 400 nm is the UV spectrum, divided into three bands: UVA, 320–400 nm; UVB, 280–320 nm; and UVC, 200–280 nm. UVA is divided into two subcategories: UVA I (340–400 nm) and UVA II (320–340 nm). Virtually no UVC reaches the Earth's surface because it is absorbed by the ozone layer above the Earth.

The minimal amount of a particular wavelength of light capable of inducing erythema on an individual's skin is called the minimal erythema dose (MED). Although the amount of UVA radiation is 100 times greater than UVB radiation during midday hours, UVB is up to 1000 times more erythemogenic than UVA, and so essentially all solar erythema is caused by UVB. The most biologically effective wavelength of radiation from the sun for sunburn is 308 nm. Although it does not play a significant role in solar erythema, UVA is of major importance in patients with drug-induced photosensitivity and also play a role in photoaging and cutaneous immunosuppression.

The amount of UV exposure increases at higher altitudes, is substantially larger in temperate climates in the summer months, and is greater in tropical regions. UVA may be reflected somewhat more than UVB from sand, snow, and ice. Whereas sand and snow reflect as much as 85% of the UVB, water allows 80% of the UV to penetrate up to 3 feet. Cloud cover, although blocking substantial amounts of visible light, is a poor UV absorber. During the middle 4–6 hours of the day, the intensity of UVB is 2–4 times greater than in the early morning and late afternoon.

Fig. 3.11 Acute sunburn. (Courtesy Dr. L. Lieblich.)

Clinical Signs and Symptoms

Sunburn is the normal cutaneous reaction to sunlight in excess of an erythema dose. UVB erythema becomes evident at around 6 hours after exposure and peaks at 12–24 hours, but the onset is sooner and the severity greater with increased exposure. The erythema is followed by tenderness and in severe cases, blistering, which may become confluent (Fig. 3.11). Discomfort may be severe; edema typically occurs in the extremities and face; chills, fever, nausea, tachycardia, and hypotension may be present. In severe cases, such symptoms may last for as long as a week. Desquamation is common about 1 week after sunburn, even in areas that have not blistered.

After UV exposure, skin pigment undergoes two changes: immediate pigment darkening (IPD, Meirowsky phenomenon) and delayed melanogenesis. IPD is maximal within hours after sun exposure and results from metabolic changes and redistribution of the melanin already in the skin. It occurs after exposure to long-wave UVB, UVA, and visible light. With large doses of UVA, the initial darkening is prolonged and may blend into the delayed melanogenesis. IPD is not photoprotective. Delayed tanning is induced by the same wavelengths of UVB that induce erythema, begins 2–3 days after exposure, and lasts 10–14 days. Delayed melanogenesis by UVB is mediated through the production of DNA damage and the formation of cyclobutane pyrimidine dimers (CPD). Therefore, although UVB-induced delayed tanning does provide some protection from further solar injury, it is at the expense of damage to the epidermis and dermis. Tanning is not recommended for sun protection. Commercial tanning bed–induced tanning, while increasing skin pigment, does not increase UVB MED and is therefore not protective for UVB damage. Such tanning devices have been shown to cause melanoma, and their use for tanning purposes should be banned. An individual's inherent baseline pigmentation, ability to tan, and susceptibility to burns are described as the person's "skin type." Skin type is used to determine starting doses of phototherapy and sunscreen recommendations and reflects the risk of development of skin cancer and photoaging (Table 3.1).

Exposure to UVB and UVA causes an increase in the thickness of the epidermis, especially the stratum corneum. This increased epidermal thickness leads to increased tolerance to further solar radiation. Patients with vitiligo may increase their UV exposure without burning by this mechanism.

Treatment

Once redness and other symptoms are present, treatment of sunburn has limited efficacy. The damage is done, and the inflammatory

TABLE 3.1 Skin Types (Phototypes)

Skin Type	Baseline Skin Color	Sunburn and Tanning History
I	White	Always burns, never tans
II	White	Always burns, tans minimally
III	White	Burns moderately, tans gradually
IV	Olive	Minimal burning, tans well
V	Brown	Rarely burns, tans darkly
VI	Dark brown	Never burns, tans darkly black

cascades are triggered. Prostaglandins, especially of the E series, are important mediators. Aspirin (acetylsalicylic acid [ASA]) and nonsteroidal antiinflammatory drugs (NSAIDs), including indomethacin, have been studied, as well as topical and systemic steroids. Medium-potency (class II) topical steroids applied 6 hours after the exposure (when erythema first appears) provide a small reduction in signs and symptoms. Oral NSAIDs and systemic steroids have been tested primarily before or immediately after sun exposure, so there is insufficient evidence to recommend their routine use, except immediately after solar overexposure. Therefore treatment of sunburn should be supportive, with pain management (using acetaminophen, ASA, or NSAIDs), plus soothing topical emollients or corticosteroid lotions. In general, a sunburn victim experiences at least 1 or 2 days of discomfort and even pain before much relief occurs.

Prophylaxis

Sunburn is best prevented. Use of the UV index facilitates taking adequate precautions to prevent solar injury. Numerous educational programs have been developed to make the public aware of the hazards of sun exposure. Despite this, sunburn and excessive sun exposure continue to occur in the United States and Western Europe, especially in white persons under age 30, more than 50% of whom report at least one sunburn per year. Sun protection programs have the following four main messages:

- Avoid midday sun.
- Seek shade.
- Wear sun-protective clothing.
- Apply a sunscreen.

The period of highest UVB intensity, between 9 AM and 3–4 PM, accounts for the vast majority of potentially hazardous UV exposure. This is the time when the angle of the sun is less than 45 degrees, or when a person's shadow is shorter than his or her height. In temperate latitudes, it is almost impossible to burn if these hours of sun exposure are avoided. Trees and artificial shade provide substantial protection from UVB. Foliage in trees provides the equivalent of sun protection factor (SPF) 4–50, depending on the density of the greenery. Clothing can be rated by its ability to block UVB radiation. The scale of measure is the UV protection factor (UPF), analogous to SPF in sunscreens. Although it is an in vitro measurement, UPF correlates well with the actual protection the product provides in vivo. In general, denser weaves, washed older clothing, and loose-fitting clothes screen UVB more effectively. Wetting a fabric may substantially reduce its UPF. Laundering a fabric in a Tinosorb-containing material (SunGuard) will add substantially to the UPF of the fabric. Hats with at least a 4-inch brim all around are recommended.

A sunscreen's efficacy in blocking the UVB (sunburn-inducing) radiation is expressed as an SPF. This is the ratio of the number of MEDs of radiation required to induce erythema through a film of sunscreen (2 mg/cm^2) compared with unprotected skin. Most persons apply sunscreens in too thin a film, so the actual "applied SPF" is about half that on the label. Sunscreen agents include UV-absorbing chemicals (chemical sunscreens) and UV-scattering or blocking agents (physical sunscreens). Available sunscreens, especially those of high SPFs (>30), usually contain both chemical sunscreens (e.g., *p*-aminobenzoic acid [PABA], PABA esters, cinnamates, salicylates, anthranilates, benzophenones, benzylidene camphors such as ecamsule [Mexoryl], dibenzoylmethanes [Parsol 1789, in some products present as multicompound technology Helioplex], and Tinosorb [S/M]) and physical agents (zinc oxide or titanium dioxide). Sunscreens are available in numerous formulations, including sprays, gels, emollient creams, and wax sticks. Sunscreens may be water resistant, with some maintaining their SPF after 40 minutes of water immersion and others maintaining their SPF after 80 minutes of water immersion.

For skin types I to III (see Table 3.1), daily application of a broad-spectrum sunscreen with an SPF of 30 in a facial moisturizer, foundation, or aftershave is recommended. For outdoor exposure, a sunscreen of SPF 30 or higher is recommended for regular use. In persons with severe photosensitivity and at times of high sun exposure, high-intensity sunscreens of SPF 30+ with inorganic blocking agents may be required. Application of the sunscreen at least 20 minutes before and 30 minutes after sun exposure has begun is recommended. This dual-application approach will reduce the amount of skin exposure by twofold to threefold over a single application. Sunscreen should be reapplied after swimming or vigorous activity or toweling. Sunscreen failure occurs mostly in men, from failure to apply it to all the sun-exposed skin or failure to reapply sunscreen after swimming. Sunscreens may be applied to babies (under 6 months) on limited areas. Vitamin D supplementation is recommended with the most stringent sun protection practices. The dose is 600 IU daily for those 70 and younger and 800 IU for older patients.

Photoaging and cutaneous immunosuppression are mediated by UVA as well as UVB. For this reason, sunscreens with improved UVA coverage have been developed. Those containing excellent protection for both UVB and UVA are identified on the label by the words "broad spectrum," and these sunscreens should be sought by patients.

Ephelis (Freckle) and Lentigo

Freckles are small (<0.5 cm) brown macules that occur in profusion on the sun-exposed skin of the face, neck, shoulders, and backs of the hands. They become prominent during the summer when exposed to sunlight and subside, sometimes completely, during the winter when there is no exposure. Blonds and redheads with blue eyes and of Celtic origin (skin types I or II) are especially susceptible. Ephelides may be genetically determined and may

Fig. 3.12 Solar lentigines.

Fig. 3.13 Dermatoheliosis.

recur in successive generations in similar locations and patterns. They usually appear at about age 5 years.

Ephelis must be differentiated from lentigo simplex. The lentigo is a benign, discrete hyperpigmented macule appearing at any age and on any part of the body, including the mucosa. The intensity of the color is not dependent on sun exposure. The solar lentigo appears at a later age, mostly in persons with long-term sun exposure. The backs of the hands and face (especially the forehead) are favored sites (Fig. 3.12).

Histologically, the ephelis shows increased production of melanin pigment by a normal number of melanocytes. Otherwise, the epidermis is normal, whereas the lentigo has elongated rete ridges that appear to be club shaped.

Freckles and solar lentigines are best prevented by appropriate sun protection. Cryotherapy, topical retinoids, hydroquinone, intense pulse light, undecylenoyl phenylalanine, and lasers are effective in the treatment of solar lentigines.

Photoaging (Dermatoheliosis)

The characteristic changes induced by chronic sun exposure are called photoaging or dermatoheliosis. An individual's risk for developing these changes correlates with the person's skin type (see Table 3.1). Risk for melanoma and nonmelanoma skin cancer is also related to skin type. The persons most susceptible to the deleterious effects of sunlight are those of skin type I: blue-eyed, fair-complexioned persons who do not tan. They are frequently of Irish or other Celtic or Anglo-Saxon descent. Individuals who develop photoaging have the genetic susceptibility and have had sufficient actinic damage to develop skin cancer, and they therefore require more frequent and careful cutaneous examinations.

Chronic sun exposure and chronologic aging are additive. Cigarette smoking is also important in the development of wrinkles, resulting in the inability of observers to distinguish solar-induced from smoking-induced skin aging accurately. The areas primarily affected by photoaging are those regularly exposed to the sun: the V area of the neck and chest, back and sides of the neck, face, backs of the hands and extensor arms, and in women the skin between the knees and ankles. The skin becomes atrophic, scaly, wrinkled, inelastic, or leathery with a yellow hue (milian citrine skin). In some persons of Celtic ancestry, dermatoheliosis produces profound epidermal atrophy without wrinkling, resulting in an almost translucent appearance of the skin through which hyperplastic sebaceous glands and prominent telangiectasias are seen (Fig. 3.13). These persons are at high risk for nonmelanoma skin cancer. Pigmentation is uneven, with a mixture of poorly demarcated, hyperpigmented and white atrophic macules observed. The photodamaged skin appears generally darker because of these irregularities of pigmentation; in addition, dermal hemosiderosis occurs from actinic purpura. Solar lentigines occur on the face and dorsa of the hands.

Many of the textural and tinctorial changes in sun-damaged skin are caused by alterations in the upper dermal elastic tissue and collagen. This process is called solar (actinic) elastosis, which imparts a yellow color to the skin. Many clinical variants of solar elastosis have been described, and an affected individual may simultaneously have many of these changes. Small yellowish papules and plaques may develop along the sides of the neck. They have been variably named "striated beaded lines" (the result of sebaceous hyperplasia) or "fibroelastolytic papulosis" of the neck, which is caused by solar elastosis. At times, usually on the face or chest, this elastosis may form a macroscopic, translucent papule with a pearly color that may closely resemble a basal cell carcinoma (actinic elastotic plaque). Similar plaques may occur on the helix or antihelix of the ear (elastotic nodules of the ear). Poikiloderma of Civatte refers to reticulate hyperpigmentation with telangiectasia, and slight atrophy of the sides of the neck, lower anterior neck, and V of the chest. The submental area, shaded by the chin, is spared (Fig. 3.14). Poikiloderma of Civatte frequently presents in fair-skinned men and women in their mid to late thirties or early forties. Cutis rhomboidalis nuchae (sailor's or farmer's neck) is characteristic of long-term, chronic sun exposure (Fig. 3.15). The skin on the back of the neck becomes thickened, tough, and leathery, and the normal skin markings are exaggerated. Nodular elastoidosis with cysts and comedones occurs on the inferior periorbital and malar skin (Favre-Racouchot syndrome) (Fig. 3.16) on the forearms (actinic comedonal plaque) or helix of the ear. These lesions appear as thickened yellow plaques studded with comedones and keratinous cysts. The ears may exhibit one or more firm nodules on the helix, known as weathering nodules. Biopsy reveals fibrosis and cartilage metaplasia.

Telangiectasias over the cheeks, ears, and sides of the neck may develop. Because of the damage to the connective tissue of the dermis, skin fragility is prominent, and patients note skin tearing from trivial injuries. This is known as dermatoporosis. Most

Fig. 3.15 Cutis rhomboidalis nuchae.

frequently, patients complain that even minimal trauma to their extensor arms leads to an ecchymosis, a phenomenon called actinic purpura. As the ecchymoses resolve, dusky brown macules remain for months, increasing the mottled appearance of the skin. Deep dissecting hematomas may result as well, causing large areas of necrosis. Again, minor trauma may lead to a painful deep bruise or simply erythema, without fever. This severe complication of dermatoporosis occurs primarily on the legs of elderly women, many of whom are taking anticoagulants or systemic steroids. Slowly growing erythematous plaques called acquired elastotic hemangiomas, which show horizontal proliferation of capillary blood vessels in the upper dermis, may also appear on the sun-damaged skin of the arms and neck. White stellate pseudoscars on the forearms are a frequent complication of this enhanced skin fragility. In some patients, soft, flesh-colored to yellow papules and nodules coalesce on the forearms to form a cordlike band extending from the dorsal to the flexural surfaces (solar elastotic bands).

Both UVB and UVA radiation induce reactive oxygen species (ROS) and hydrogen peroxide. Acting through activator protein 1 (AP-1), transcription of various matrix-degrading enzymes is upregulated, specifically matrix metalloproteinase 1 (MMP-1; collagenase), MMP-3 (stromelysin 1), and MMP-9 (gelatinase). In darkly pigmented persons, UV exposure does not activate MMP-1, in part explaining the protective effect of skin pigmentation against photoaging. In chronologically aged skin, MMP-1 levels are also increased through AP-1. Thus chronologic aging and photoaging may be mediated through an identical biochemical mechanism.

Histologically, chronically sun-exposed skin demonstrates homogenization and a faint blue color of the connective tissue of the upper reticular dermis, so-called solar elastosis. This "elastotic" material is derived largely from elastic fibers, stains with histochemical stains for elastic fibers, and demonstrates marked increased deposition of fibulin 2 and its breakdown products. Types I and III collagen are decreased. Characteristically, there is a zone of normal connective tissue immediately below the epidermis and above the elastotic material.

Colloid Milium

There are two forms of colloid milium: adult and juvenile. In both the adult and the juvenile form of colloid milium, the primary skin lesion is a translucent, flesh colored or slightly yellow, 1–5 mm papule. Minimal trauma may lead to purpura from vascular fragility. Histologically, the colloid consists of intradermal, amorphous fissured eosinophilic material. In adult colloid milium, lesions appear in the sun-exposed areas of the hands, face, neck, forearms, and ears in middle-age and older adults, usually men. Lesions often coalesce into plaques and may rarely be verrucous. Petrochemical exposures have been associated with adult colloid milium. Pigmented forms of colloid milium are associated with hydroquinone use. Lesions have been induced by tanning bed exposure, and they can be unilateral, usually in commercial drivers. Adult colloid milium may be considered a papular variant of solar elastosis. The colloid material is derived from elastic fibers, and solar elastosis is found adjacent to the areas of colloid degeneration histologically.

Juvenile colloid milium is much rarer. It develops before puberty, and there may be a family history. The lesions are similar to the adult form but appear initially on the face, later extending to the neck and hands. Sun exposure also appears to be important in inducing lesions of juvenile colloid milium. Juvenile colloid milium, ligneous conjunctivitis, and ligneous periodontitis may appear in the same patient and are probably of similar pathogenesis. Histologically, juvenile colloid milium can be distinguished from adult colloid milium by the finding of keratinocyte apoptosis in the overlying epidermis. The colloid material in juvenile colloid milium is derived from the apoptotic keratinocytes and stains for cytokeratin.

Treatment with fractional photothermolysis or MAL-photodynamic therapy may be effective for colloid milium.

Prevention and Treatment

Because both UVB and UVA are capable of inducing the tissue-destructive biochemical pathways implicated in photoaging, sun protection against both portions of the UV spectrum is the primary prevention required against photoaging. Because photoaging, as with other forms of radiation damage, appears to be cumulative, reducing the total lifetime UV exposure is the goal. The guidelines previously outlined for sunburn prophylaxis should be followed.

The regular use of emollients or moisturizing creams on the areas of sun damage will reduce scaling and may improve fragility by making the skin more pliable. α-Hydroxy acids may improve skin texture when used in lower, nonirritating concentrations. Topical tretinoin, adapalene, and tazarotene can improve the changes of photoaging. Changes are slow and irritation may occur. Chemical peels, resurfacing techniques, laser and other light technologies (for vascular alterations, pigmented lesions, and dermal alterations), botulinum toxins, and soft tissue augmentation are all used to treat the consequences of photoaging. The surgical and laser treatments of photoaging are discussed in Chapter 38.

PHOTOSENSITIVITY

Photosensitivity disorders include cutaneous reactions that are chemically induced (from an exogenous source), metabolic (inborn errors such as the porphyrias, resulting in production of endogenous photosensitizers), idiopathic, and light exacerbated (genetic and acquired). Phototoxicity and the idiopathic disorders are discussed here; the other conditions are covered in later chapters.

Chemically Induced Photosensitivity

A number of substances known as photosensitizers may induce an abnormal reaction in skin exposed to sunlight or its equivalent. The result may be a greatly increased sunburn response without allergic sensitization called phototoxicity. Phototoxicity may occur from both externally applied (phytophotodermatitis and berloque dermatitis) and internally administered chemicals (phototoxic drug reaction). In contrast, photoallergic reactions are true allergic sensitizations triggered by sunlight, produced either by internal administration (photoallergic drug reaction) or by external contact (photoallergic contact dermatitis). Chemicals capable of inducing phototoxic reactions may also produce photoallergic reactions.

In the case of external contactants, the distinction between phototoxicity and photoallergy is usually straightforward. Phototoxicity occurs on initial exposure, has an onset of less than 48 hours, occurs in the vast majority of persons exposed to the phototoxic substance and sunlight, and shows a histologic pattern similar to sunburn. By contrast, photoallergy occurs only in sensitized persons, may have a delayed onset (up to 14 days, the period of initial sensitization), and shows histologic features of allergic contact dermatitis.

Action Spectrum

Chemicals known to cause photosensitivity (photosensitizers) are usually resonating compounds with a molecular weight of less than 500 daltons. Absorption of radiant energy (sunlight) by the photosensitizer produces an excited state; returning to a lower-energy state gives off energy through fluorescence, phosphorescence, charge transfer, heat, or formation of free radicals. Each photosensitizing substance absorbs only specific wavelengths of light, called its absorption spectrum. The specific wavelengths of light that evoke a photosensitive reaction are called the action spectrum. The action spectrum is included in the absorption spectrum of the photosensitizing chemical. The action spectrum that produces phototoxicity is mostly in the long ultraviolet (UVA) region and may extend into the visible light region (320–425 nm).

Photosensitivity reactions occur only when there is sufficient concentration of the photosensitizer in the skin, and when the skin is exposed to a sufficient intensity and duration of light in the action spectrum of that photosensitizer. The intensity of the photosensitivity reaction is generally dose dependent and is worse with a greater dose of photosensitizer and greater light exposure.

Phototoxic Reactions

A phototoxic reaction is a nonimmunologic reaction that develops after exposure to a specific wavelength and intensity of light in the presence of a photosensitizing substance. It is a sunburn-type reaction, with erythema, tenderness, and even blistering occurring only on the sun-exposed parts. This type of reaction can be elicited in many persons who have no previous history of exposure or sensitivity to that particular substance, but individual susceptibility

Fig. 3.17 Photo-onycholysis from minocycline.

Fig. 3.18 Two friends who made limeade in the sun to sell in the summer.

varies widely. In general, to elicit a phototoxic reaction, a considerably greater amount of the photosensitizing substance is necessary than that needed to induce a photoallergic reaction. The erythema begins, as with any sunburn, within 2–6 hours but worsens for 48–96 hours before beginning to subside. Exposure of the nail bed may lead to onycholysis, called photo-onycholysis (Fig. 3.17). Phototoxic reactions, especially from topically applied photosensitizers, may cause marked hyperpigmentation, even without significant preceding erythema.

Phototoxic Tar Dermatitis. Coal tar, creosote, crude coal tar, or pitch, in conjunction with sunlight exposure, may induce a sunburn reaction associated with a severe burning sensation. These volatile hydrocarbons may be airborne, so the patient may give no history of touching tar products. The burning and erythema may continue for 1–3 days. Although up to 70% of white persons exposed to such a combination develop this reaction, persons with type V or VI skin are protected by their constitutive skin pigmentation. After the acute reaction, hyperpigmentation occurs, which may persist for years. Coal tar or its derivatives may be found in cosmetics, drugs, dyes, insecticides, and disinfectants.

Phytophotodermatitis. Furocoumarins in many plants may cause a phototoxic reaction when they come in contact with skin that is exposed to UVA light. This is called phytophotodermatitis. Several hours after exposure, a burning erythema occurs, followed by edema and the development of vesicles or bullae. An intense residual hyperpigmentation results that may persist for weeks or months. The intensity of the initial phototoxic reaction may be mild and may not be recalled by the patient despite significant hyperpigmentation. Fragrance products containing bergapten, a component of oil of bergamot, will produce this reaction. If a fragrance containing this 5-methoxypsoralen or other furocoumarin is applied to the skin before exposure to the sun or tanning lights, berloque dermatitis may result. This hyperpigmentation, which may be preceded by redness and edema, occurs primarily on the neck and face. Artificial bergapten-free bergamot oil and laws limiting the use of furocoumarins in Europe and the United States have made this a rare condition. However, "Florida Water" and "Kananga Water" colognes, formerly popular in the Hispanic, African American, and Caribbean communities, contain this potent photosensitizer and can still be ordered online, as can other aromatherapy products containing furocoumarins.

Most phototoxic plants are in the Umbelliferae, Rutaceae (rue), Compositae, and Moraceae families. Incriminated plants include

Fig. 3.19 Severe phytophototoxicity.

agrimony, angelica, atrillal, bavachi, buttercup, common rice, cowslip, dill, fennel, fig, garden and wild carrot, garden and wild parsnip, gas plant, goose foot, zabon, lime and Persian lime (Fig. 3.18), lime bergamot, masterwort, mustard, parsley, St. John's wort, and yarrow. In Hawaii, the anise-scented mokihana berry *(Pelea anisata)* was known to natives for its phototoxic properties (mokihana burn). It is a member of the rue family. Exposure through limes used to flavor gin and tonics and Mexican beer may result in phototoxic reactions in outdoor bartenders and their customers. Home tanning solutions containing fig leaves can produce phytophotodermatitis. These conditions may be widespread and severe enough to require burn unit management (Fig. 3.19).

Occupational disability from exposure to the pink rot fungus *(Sclerotinia sclerotiorum)*, present on celery roots, occurs in celery farmers. In addition, disease-resistant celery contains furocoumarins and may produce phytophotodermatitis in grocery workers. Usually, insufficient sensitizing furocoumarin is absorbed from dietary exposure; however, ingested herbal remedies may cause systemic phototoxicity.

Fig. 3.20 Phytophotodermatitis; the patient had rinsed her hair with lime juice on the beach in Mexico.

Dermatitis bullosa striata pratensis (grass or meadow dermatitis) is a phytophotodermatitis caused by contact not with grass, but with yellow-flowered meadow parsnip or a wild, yellow-flowered herb of the rose family. The eruption consists of streaks and bizarre configurations with vesicles and bullae that heal with residual hyperpigmentation. The usual cause is sunbathing in fields containing the phototoxic plants. Similarly, tourists in the tropics may rinse their hair with lime juice outdoors, and streaky hyperpigmentation of the arms and back will result where the lime juice runs down (Fig. 3.20).

Blistering phytophotodermatitis must be differentiated from rhus dermatitis. The vesicles and bullae of rhus are not necessarily limited to the sun-exposed areas, and itching is the most prominent symptom. Lesions continue to occur in rhus dermatitis for a week or more. In phytophotodermatitis, the reaction is limited to sun-exposed sites, a burning pain appears within 48 hours, and marked hyperpigmentation results. The asymmetry, atypical shapes, and streaking of the lesions are helpful in establishing the diagnosis. These features may lead to a misdiagnosis of child abuse.

Treatment of a severe, acute reaction is similar to the management of a sunburn, with cool compresses, mild analgesics if required, and topical emollients. Use of topical steroids and strict sun avoidance immediately after the injury may protect against the hyperpigmentation. The hyperpigmentation is best managed by "tincture of time."

Idiopathic Photosensitivity Disorders

This idiopathic group includes the photosensitivity diseases for which no cause is known. These disorders are not associated with external photosensitizers (except for some cases of chronic actinic dermatitis) or inborn errors of metabolism.

Polymorphous Light Eruption

Polymorphous light eruption (PLE, PMLE) is the most common form of photosensitivity. In various studies of Northern European white persons, a history of PLE can be elicited in between 5% and 20% of the adult population. It represents about one quarter of all photosensitive patients in referral centers. All races and skin types can be affected. The onset is typically in the first four decades of life, and females outnumber males by 2 : 1 or 3 : 1. The pathogenesis is unknown, but a family history may be elicited in 10%–50% of patients. Some investigators report that 10%– 20% of patients with PLE may have positive antinuclear antigens (ANAs) and a family history of lupus erythematosus. Photosensitive SLE patients may give a history of PLE-like eruptions for years before the diagnosis of SLE is made. PLE patients should be followed for the development of symptoms of SLE.

Clinically, the eruption may have several different morphologies, although in the individual patient, the morphology is usually constant. The papular (or erythematopapular) variant is the most common, but papulovesicular, eczematous, erythematous, and plaquelike lesions also occur (Fig. 3.21). Plaquelike lesions are more common in elderly patients and may closely simulate lupus erythematosus, with indurated, erythematous, fixed lesions. In African Americans, a pinpoint papular variant has been observed, closely simulating lichen nitidus but showing spongiotic dermatitis histologically (Fig. 3.22). Scarring and atrophy do not occur; in darkly pigmented races, however, marked postinflammatory hyperpigmentation or hypopigmentation may be present. In some patients, pruritus only, without an eruption, may be reported (PLE sine eruptione). Some of these patients will develop typical PLE later in life.

Fig. 3.22 Polymorphous light eruption, micropapular variant resembling lichen nitidus.

Fig. 3.23 Juvenile spring eruption of the ears.

The lesions of PLE appear most often 1–4 days after exposure to sunlight, although patients may report itching and erythema during sun exposure and development of lesions within the first 24 hours. A change in the amount of sun exposure appears to be more critical than the absolute amount of radiation. Patients living in tropical climates may be free of eruption, only to develop disease when they move to temperate zones, where there is more marked seasonal variation in UV intensity. Areas of involvement include the face, the V area of the chest, neck, and arms. In general, for each individual, certain areas are predisposed. Typically, however, areas protected during the winter, such as the extensor forearms, are particularly affected, whereas areas exposed all year (face and dorsa of hands) may be relatively spared. The eruption appears most frequently in the spring. The eruption often improves with continued sun exposure (hardening), so patients may be clear of the condition in the summer or autumn.

An unusual variant of PLE is juvenile spring eruption of the ears (Fig. 3.23). This occurs most frequently in boys age 5–12 years but may also be found in young adult males. It presents in the spring, often after sun exposure on cold but sunny days. The typical lesions are grouped small papules or papulovesicles on the helices. Lesions may form visible vesicles and crusting. Juvenile spring eruption of the ears is self-limited and does not scar. UVA is the inducing spectrum, and some patients also have lesions of PLE elsewhere. The histologic picture is identical to that of PLE. Another localized variant of PLE is spring and summer eruption of the elbows, but this occurs in adults, equally in men and women.

Histologically, a perivascular, predominantly T-cell infiltrate is present in the upper and middle dermis. There is often edema and endothelial swelling, with occasional neutrophils. Epidermal changes are variable, with spongiosis and exocytosis most often observed. Occasionally, a virtual absence of findings microscopically may paradoxically be reported and has been referred to as pauci-inflammatory photodermatitis.

The reported action spectrum of PLE varies, possibly depending on the different ethnic backgrounds of reported populations. UVA is most often responsible; however, UVB and both wavelengths in combination are also frequently necessary. Patients often report eruptions following sun exposure through window glass. Although rare, visible light sensitivity can also occur. Typically, women are more sensitive than men to UVA only, and men are more sensitive to visible light. Men, although the minority of PLE patients, tend to have more severe PLE and broader wavelengths of sensitivity. Most patients react more in affected sites, and in some, lesions can only be induced in affected areas. Phototesting produces variable results. One protocol produced positive results in 83% of tested patients using four exposures of UVB, UVA, or a combination in previously affected sites. However, the light sources are not readily available, and reported protocols vary widely. In clinical practice, the diagnosis is usually made clinically.

The differential diagnosis of PLE includes lupus erythematosus, photosensitive drug eruption, prurigo nodularis, and photoallergic contact dermatitis. Histopathologic examination, ANA testing, and direct immunofluorescence (DIF) are helpful in distinguishing these diseases. Serologic testing alone may not distinguish PLE from SLE because of the possibility of positive ANA tests in PLE patients. Lupus erythematosus may present initially with photosensitivity before other features of lupus occur. Sebaceous neutrophilic adenitis, is characterized by erythematous circinate plaques on the head, neck, and upper chest and has been reported in the first to second month of spring. Histologically, neutrophilic infiltration of the sebaceous glands occurs, sometimes forming microabscesses. Although it may be photoinduced, it may also be idiopathic as in the cases reported in the genital area. Acute pustular folliculitis is a recurrent eruption of the head and neck that may be photoinduced, viral associated, or idiopathic. It resolves in most cases spontaneously in several days. The presence of follicular pustules distinguishes the photoinduced cases from PLE.

Therapeutically, most patients with mild PLE can be managed by avoiding the sun and using barrier protection and high-SPF, broad-spectrum sunscreens. It is critical that the sunblocks contain specific absorbers or blockers (ecamsule, avobenzone, titanium dioxide, zinc oxide) of long-wave UVA because this is the most common triggering wavelength. Sunblocks containing more than one of these agents are more effective. DermaGard film can be applied to windows at home and in the car to block the transmission of almost all UVB and UVA rays while allowing visible light to be transmitted. Degradation does occur, so the film should be replaced every 5 years. These measures of photoprotection are critical for all patients, because they are free of toxicity and reduce the amount and duration of other therapies required. Patient education is important in the management of PLE. Phototesting may be required to convince patients that they are UV sensitive and will also determine the action spectrum.

The use of topical tacrolimus ointment at night or twice daily, combined with the previous measures for sun avoidance and the use of sunscreens, controls PLE in many patients. At times, topical steroids, frequently of super or high potency and in several daily

to weekly pulses, are necessary to control the pruritus and clear the eruption. Antihistamines may be used for pruritus. Systemic corticosteroids in short courses may be necessary, especially in the spring. In patients whose condition is not controlled by these measures, hardening in the spring with UVB, narrow-band (NB) UVB, or psoralen plus UVA (PUVA) can dramatically decrease the sun sensitivity of patients with PLE, and up to 80% can be controlled with phototherapy. In the most sensitive patients, systemic steroids may be needed at the inception of the phototherapy. Systemic hydroxychloroquine sulfate, 200–400 mg/day, may be used. It has a delayed onset and is best instituted in the late winter to prevent spring outbreaks. Chloroquine or quinacrine may be effective if hydroxychloroquine is not, but in general, antimalarials are inferior to phototherapy. In the most severe cases, management with azathioprine, cyclosporine, thalidomide, or mycophenolate mofetil may be considered. If these agents are used in a patient considered to have PLE, an evaluation for chronic actinic dermatitis should be performed because patients with PLE rarely require these agents.

Actinic Prurigo

Actinic prurigo probably represents a variant of PLE; it is most often seen in Native Americans of North and Central America and Colombia. The incidence in Mexico has been reported at between 1.5% and 3.5%. It has been reported in Europe, Australia, and Japan as well. The female/male ratio is between 2:1 and 6:1. Actinic prurigo in Native Americans in the United States begins before age 10 in 45% of cases and before age 20 in 72%. Up to 75% of patients have a positive family history (hereditary PLE of Native Americans). In Europe, 80% of cases occur before age 10. In the Inuit Canadian population, onset is later and frequently in adulthood.

In childhood, lesions begin as small papules or papulovesicles that crust and become impetiginized. They are intensely pruritic and frequently excoriated. In children, the cheeks, distal nose, ears, and lower lip are typically involved. Cheilitis may be the initial and only feature for years. Conjunctivitis is seen in 10%–20% of patients (limbal-type vernal catarrh). Lesions of the arms and legs are also common and usually exhibit a prurigo nodule–like configuration (Fig. 3.24). The eruption may extend to involve sun-protected areas, especially the buttocks, but lesions in these areas are always less severe. In adults, chronic, dry papules and plaques are most typical, and cheilitis and crusting occur less frequently. Skin lesions tend to persist throughout the year in the tropics but are clearly worse during periods of increased sun exposure. In temperate and high-latitude regions, lesions occur from March through the summer and substantially remit in the winter. Hardening, as seen with PLE, does not occur. In up to 60% of patients with actinic prurigo that present before age 20, the condition improves or resolves within 5 years, whereas adults usually have the disease throughout life.

Initial therapy is identical to that for PLE. Thalidomide has been used effectively and safely over many years for this condition. In patients refractory to or intolerant of thalidomide, cyclosporine can be effective. Topical cyclosporine 2% may be effective in controlling limbal lesions of actinic prurigo–associated conjunctivitis.

Brachioradial Pruritus

PLE may present initially and only on the brachioradial area. This type of brachioradial eruption was the initial pattern of brachioradial pruritus described and was termed solar pruritus (Fig. 3.25). The majority of cases of brachioradial pruritus, especially those characterized by severe, refractory, intractable pruritus and secondary severe lichenification, are now thought to represent a form of neuropathic pruritus, sometimes related to cervical spine disease (see Chapter 4). Sunlight may be an eliciting factor and cervical spine disease a predisposing factor in patients with brachioradial pruritus. To identify those patients in whom photosensitivity plays a prominent role, a high-SPF (UVA/UVB)

Fig. 3.25 Polymorphous light eruption, brachioradial distribution.

sunscreen should be applied to one arm only for several weeks. In patients with PLE, this usually leads to improvement of that one arm compared with the contralateral unprotected arm. In patients with primarily neuropathic disease, sunscreen application leads to minimal improvement. The capsaicin patch provides both itch relief and a physical barrier but is expensive.

Solar Urticaria

Solar urticaria is most common in women age 20–40. Within seconds to minutes after light exposure, typical urticarial lesions appear and resolve in 1–2 hours, rarely lasting more than 24 hours (Fig. 3.26). Delayed reactions rarely occur. Chronically exposed sites may have some reduced sensitivity. In severe attacks, syncope, bronchospasm, and anaphylaxis may occur.

Patients with solar urticaria may be sensitive to wavelengths over a broad spectrum. The wavelengths of sensitivity and the minimal urticarial doses (MUDs) may vary with anatomical site and over time within the same patient. UVA sensitivity is the most common, but visible light sensitivity is also frequently reported. The photosensitivity can be passively transferred, and irradiation of the patient's serum with the activating wavelength followed by reinjection will create a wheal in the patient, but not in an unaffected patient. This suggests the presence of a circulating photoinducible allergen to which the individual patient with solar urticaria is sensitive. In some patients, an inhibition spectrum may be identified that inhibits the binding of the endogenous photoallergen to mast cells.

Solar urticaria is virtually always idiopathic. Rarely, medications such as tetracycline (but not minocycline), chlorpromazine, progestational agents, and repirinast have been reported to induce solar urticaria. Erythropoietic protoporphyria and more rarely porphyria cutanea tarda may present with lesions simulating solar

Fig. 3.26 Solar urticaria.

urticaria. There are rare reports of solar urticaria in patients with lupus erythematosus.

The diagnosis of solar urticaria is usually straightforward from the history. Phototesting is useful to determine the wavelengths of sensitivity and to ascertain the MUD if UVA desensitization is being considered.

Because many patients have sensitivity in the UVA or even visible range, broad-spectrum sunscreens should be instituted. Antihistamines, especially the nonsedating H1 agents loratadine, cetirizine HCl, and fexofenadine, may increase the MUD 10-fold or more. Higher doses, twice or more the standard recommendation, may be required. These drugs, plus sun avoidance and broad-spectrum sunscreens, are the first-line therapy. The leukotriene receptor antagonist motelukast may provide additive efficacy when used in combination with the above regimen. PUVA or increasing UVA exposures are effective in more difficult cases, with PUVA having greater efficacy. Rush hardening may induce UVA tolerance, allowing patients to begin PUVA therapy. PUVA is effective, even if the patient is not sensitive to UVA. Cyclosporine (4.5 mg/kg/day) and intravenous immune globulin at various doses and time frames have been anecdotally reported as effective. For the most difficult cases, plasmapheresis may be used to remove the circulating photoallergen, allowing PUVA to be given and leading to remission. Multiple reports attest to positive responses in some patients with the use of omalizumab.

Hydroa Vacciniforme

Hydroa vacciniforme is a rare, chronic photodermatosis with onset in childhood. Boys and girls are equally represented, but boys present earlier and on average have longer-lasting disease. There is a bimodal onset, between ages 1 and 7 and between 12 and 16. The natural history of the typical disorder is spontaneous remission before age 20, but rare cases in young adults do occur. Within 6 hours of exposure, stinging begins. At 24 hours or sooner, erythema and edema appear, followed by the characteristic 2–4 mm vesicles. Over the next few days, these lesions rupture, become centrally necrotic, and heal with a smallpox-like scar. Lesions tend to appear in crops with disease-free intervals. The ears, nose, cheeks, and extensor arms and hands are affected. Subungual hemorrhage, ocular involvement, or oral ulcerations may occur.

Histologically, early lesions show intraepidermal vesiculation and dermal edema that evolve into a subepidermal blister. Necrotic lesions show reticular degeneration of keratinocytes, with epidermal necrosis flanked by spongiosis with a dense perivascular infiltrate of neutrophils and lymphocytes. Dermal vessels may be thrombosed, simulating vasculitis. Lesions may be reproduced by repetitive UVA, with the action spectrum in the 330–360 nm range.

The differential diagnosis includes PLE, actinic prurigo, and erythropoietic protoporphyria. Porphyrin levels are normal in hydroa vacciniforme. In erythropoietic protoporphyria, the burning typically begins within minutes of sun exposure, and over time patients develop diffuse, thickened, waxlike scarring, rather than the smallpox-like scars of hydroa vacciniforme. Histologic evaluation, DIF and porphyrin studies are useful in distinguishing these two conditions. Treatment is principally to avoid sunlight exposure and to use broad-spectrum sunscreens that block in the UVA range. Prophylactic NB UVB phototherapy in the early spring may be effective. Choloroquine and systemic corticosteroids have provided relief in some cases.

A subset of children and less often adults with photosensitive hydroa vacciniforme–like skin lesions manifest facial swelling, indurated nodules or progressive ulcers, fever, and liver damage. Oral, esophageal, or colonic ulcerations may occur. Hypersensitivity to mosquito bites may also be seen. These patients may develop Epstein-Barr virus (EBV)–associated natural killer (NK) cell/T-cell lymphomas and die of this or a hemophagocytic syndrome. The hydroa vacciniforme–like skin lesions may precede the diagnosis of the lymphoma by up to a decade. Initially the patient may appear to have typical hydroa vacciniforme of the self-limited type; older age is more concerning for a complex course. This is therefore a disease spectrum, with both typical and severe hydroa vacciniforme being EBV associated. Treatment of the lymphoma may lead to clearing of these lesions.

Chronic Actinic Dermatitis

Chronic actinic dermatitis represents the end stage of progressive photosensitivity in some patients. It has replaced the terms persistent light reactivity, actinic reticuloid, photosensitive eczema, and chronic photosensitivity dermatitis. The basic components of this disease are as follows:

- Persistent, chronic, eczematous eruption in the absence of exposure to known photosensitizers
- Usually, broad-spectrum photosensitivity with decreased MED to UVA and/or UVB and at times visible light
- Histology consistent with a chronic dermatitis, with or without features of lymphoma

Clinically, chronic actinic dermatitis predominantly affects middle-age or elderly men. In the United States patients with skin types V and VI may be disproportionately affected (Fig. 3.27). Skin lesions consist of edematous, scaling, thickened patches and plaques that tend to be confluent. Lesions occur primarily or most severely on the exposed skin and may spare the upper eyelids, behind the ears, and the bottom of wrinkles. Involvement of unexposed sites often occurs, progressing to erythroderma in the most severe cases. Marked depigmentation resembling vitiligo

Fig. 3.27 Chronic actinic dermatitis.

may result. Patients may not realize their condition is exacerbated by exposure to light. It may persist in all seasons.

The pathogenesis of this syndrome is unknown. In some patients, a preceding topical or oral photosensitizer may be implicated, but chronic actinic dermatitis fails to improve with discontinuation of the inciting agent. In about one third of patients, photopatch testing yields a positive response to previously applied agents, especially musk ambrette, sunscreen ingredients, *p*-phenylenediamine, and hexachlorophene. Patch testing to standard agents may have a positive result in about 30% of patients, but no particular relevance is found. However, in approximately 65% of European patients, sesquiterpene lactone contact sensitivity from Compositae has been identified. In addition, more than 75% of men over age 60 with sesquiterpene lactone sensitivity have abnormal phototesting results. CD8 (suppressor/cytotoxic) T cells are disproportionately represented in the cutaneous infiltrates in the majority of patients and less frequently in the peripheral blood. IgE levels may be elevated.

In this clinical setting, diagnosis of chronic actinic dermatitis is established by histologic evaluation and phototesting. Phototesting often reproduces the lesions. About 65% of patients are sensitive to UVA, UVB, and visible light; 22% to UVA and UVB; and 5% to UVB or UVA only. The finding of photosensitivity to UVA and UVB helps to differentiate chronic actinic dermatitis from drug-induced photosensitivity, in which patients usually exhibit only UVA photosensitivity. PLE, photoallergic contact dermatitis, airborne contact dermatitis, and mycosis fungoides or Sézary syndrome must be excluded. PLE is excluded by the broad-spectrum–reduced MED in chronic actinic dermatitis, although some patients may begin with a PLE-like disease that later meets the criteria for chronic actinic dermatitis. Contact dermatitis is excluded by patch and photopatch testing. Mycosis fungoides may be difficult to differentiate from chronic actinic dermatitis in cases with atypical histology. Phototesting is critical in these patients. Mycosis fungoides will manifest a T-cell receptor rearrangement in lesional skin or peripheral blood and usually shows a CD4 (helper) T-cell predominance.

Therapy for chronic actinic dermatitis includes identifying possible topical photosensitizers by photopatch testing and scrupulously avoiding them. Maximum sun avoidance and broad-spectrum sunscreens are essential. Topical tacrolimus is useful in many patients. Topical and systemic steroids are effective in some patients, but chronic toxicity of systemic steroids limits chronic use. Azathioprine, 50–200 mg/day, is the most reproducibly effective treatment and may be required annually during periods of increased sun intensity. Low-dose PUVA or NB UVB can be effective when used with topical and systemic steroids, but patients may also be intolerant of this approach. Hydroxyurea, 500 mg twice daily, cyclosporine, thalidomide, and mycophenolate mofetil may also be used. Immunosuppressive agents may allow patients to tolerate PUVA therapy. With careful management, about 2 in 10 patients will lose their photosensitivity within 5 years, 1 in 4 by 10 years, and 1 in 3 of patients by 15 years. Most of the remaining will improve over this time with only one of 20 worsening in a study by Wolverton et al.

Photosensitivity and HIV Infection

Photosensitivity resembling PLE, actinic prurigo, or chronic actinic dermatitis is seen in about 5% of patients with human immunodeficiency virus (HIV) infection. In general, photosensitivity is seen when the CD4 count is below 200 (often <50), except in persons with a genetic predisposition (Native Americans). Photosensitivity may be the initial manifestation of HIV disease. African American patients are disproportionately represented among patients with HIV photosensitivity. Photosensitivity may be associated with ingestion of a photosensitizing medication, especially NSAIDs, efavirenz (an antiretroviral) or trimethoprim-sulfamethoxazole, but the skin eruption often does not improve even when the medication is discontinued. Histologically, the lesions may show subacute or chronic dermatitis, often with a dense dermal infiltrate with many eosinophils. Histology identical to PLE, lichen planus, or lichen nitidus may also occur. When the CD4 count is below 50, especially in black patients, chronic actinic dermatitis with features of actinic prurigo is typical. Widespread vitiliginous lesions may develop. Therapy is difficult, but thalidomide may be beneficial.

RADIODERMATITIS

The major target within the cell by which radiation damage occurs is the DNA. The effects of ionizing radiation on the cells depend on the amount of radiation, its intensity (exposure rate), and the characteristics of the individual cell. Rapidly dividing cells and anaplastic cells in general have increased radiosensitivity compared with normal tissue. When radiation therapy is delivered, it is frequently fractionated (i.e., divided into small doses). This allows the normal cells to recover between doses.

When the dose is large, cell death results. In small amounts, the effect is insidious and cumulative. Mitosis is arrested temporarily, with consequent retardation of growth. The exposure rate affects the number of chromosome breaks. The more rapid the delivery of a certain amount of radiation, the greater is the number of chromosome breaks.

Acute Radiodermatitis

When an "erythema dose" of ionizing radiation is given to the skin, there is a latent period of up to 24 hours before visible erythema appears. This initial erythema lasts 2–3 days but may be followed by a second phase beginning up to 1 week after the exposure and lasting up to 1 month. When the skin is exposed to a large amount of ionizing radiation, an acute reaction develops, the extent of which will depend on the amount, quality, genetic susceptibility, and duration of exposure. Such radiation reaction occurs in the treatment of malignancy and in accidental overexposure. The reaction is manifested by initial erythema, followed by a second phase of erythema at 3–6 days (Fig. 3.28). Vesiculation, edema, and

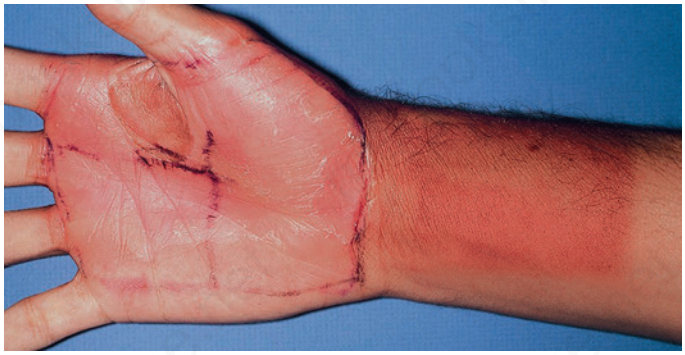

Fig. 3.28 Acute radiation burn during treatment of epithelioid sarcoma.

erosion or ulceration may occur, accompanied by pain. The skin develops a dark color that may be mistaken for hyperpigmentation but that desquamates. This type of radiation injury may subside in several weeks to several months, again depending on the amount of radiation exposure. Skin that receives a large amount of radiation will never return to normal. It will lack adnexal structures, will be dry, atrophic, and smooth, and will be hypopigmented or depigmented. Cutaneous necrosis may complicate yttrium-90 synovectomy, a treatment given for chronic synovitis.

Eosinophilic, Polymorphic, and Pruritic Eruption Associated With Radiotherapy

The polymorphic, pruritic eruption arising several days to several months after radiotherapy for cancer tends to favor the extremities. Acral excoriations, erythematous papules, vesicles, and bullae occur. It is not necessarily limited to the areas of radiation treatment. Histologically, a superficial and deep perivascular lymphohistiocytic infiltrate with eosinophils is present. Topical steroids, antihistamines, and UVB are all effective, and spontaneous resolution also occurs.

Chronic Radiodermatitis

Chronic exposure to "suberythema" doses of ionizing radiation over a prolonged period will produce varying degrees of damage to the skin and its underlying parts after a variable latent period ranging from several months to several decades. Radiodermatitis may also occur on the back or flank after fluoroscopy and roentgenography for diagnostic or therapeutic purposes (Fig. 3.29).

Telangiectasia, atrophy, and hypopigmentation with residual focal increased pigment (freckling) may appear (Fig. 3.30). The skin becomes dry, thin, smooth, and shiny. The nails may become striated, brittle, and fragmented. The capacity to repair injury is substantially reduced, resulting in ulceration from minor trauma. The hair becomes brittle and sparse. In more severe cases, these chronic changes may be followed by radiation keratoses and carcinoma. Additionally, subcutaneous fibrosis, thickening, and binding of the surface layers to deep tissues may present as tender, erythematous plaques 6–12 months after radiation therapy (Fig. 3.31). It may resemble erysipelas or inflammatory metastases.

Radiation Cancer

After a latent period averaging 20–40 years, various malignancies may develop, most frequently basal cell carcinoma (BCC), followed by squamous cell carcinoma (SCC). These may appear in sites of prior radiation, even if there is no evidence of chronic radiation damage. Sun damage may be additive to radiation therapy, increasing the appearance of nonmelanoma skin cancers. SCCs arising in sites of radiation therapy metastasize more frequently than

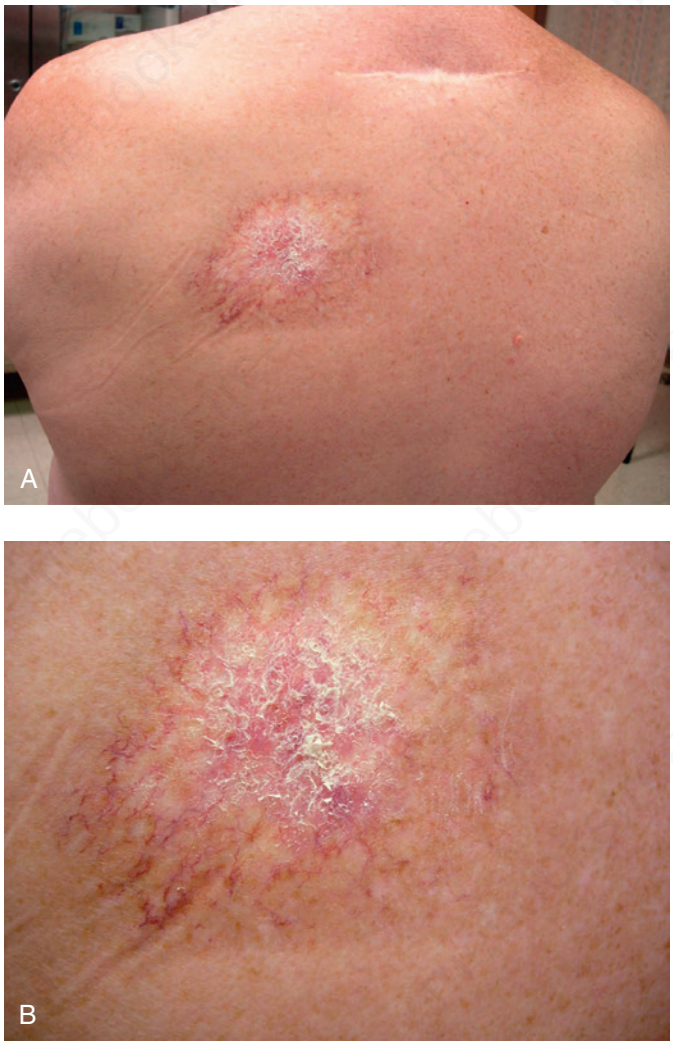

Fig. 3.29 (A) Fluoroscopy-induced radiodermatitis. (B) Close-up of Fig. 3.29A.

Fig. 3.30 Chronic radiodermatitis.

purely sun-induced SCCs. In some patients, either type of tumor may predominate. Location plays some role; SCCs are more common on the arms and hands, whereas BCCs are seen on the head and neck and lumbosacral area (Fig. 3.32). Other radiation-induced cancers include angiosarcoma, Kaposi sarcoma, malignant

Fig. 3.31 Delayed radiation reaction 8 months after therapy.

Fig. 3.32 Chronic radiodermatitis with basal cell cancer as a complication. (Courtesy Steven Binnick, MD.)

fibrous histiocytoma, sarcomas, and thyroid carcinoma. The incidence of malignant neoplasms increases with the passage of time.

Treatment

Acute radiodermatitis may be reduced with a topical corticosteroid ointment combined with an emollient cream applied twice a day and instituted at the onset of therapeutic radiotherapy. However the skin should be gently cleansed and dried shortly before radiation treatment. Chronic radiodermatitis without carcinoma requires little or no attention except protection from sunlight and the extremes of heat and cold. Careful cleansing with mild soap and water, the use of emollients, and occasionally hydrocortisone ointment are the only requirements for good care.

The early removal of precancerous keratoses and ulcerations is helpful in preventing the development of cancers. For radiation keratoses treatment with cryosurgery, 5-FU, imiquimod cream, ingenol, or topical 5-aminolevulinic acid (ALA)–photodynamic therapy may be sufficient. If the keratosis feels infiltrated, a biopsy is indicated. Radiation ulcerations should be studied by excisional or incisional biopsy if they have been present for 3 months or longer. Complete removal by excision is frequently required to obtain healing and exclude focal carcinoma in the ulceration. Radiation-induced nonmelanoma skin cancers are managed by standard methods. The higher risk of metastasis from radiation-induced SCCs mandates careful follow-up and regular regional lymph node evaluation.

MECHANICAL INJURIES

Mechanical factors may induce distinctive skin changes. Pressure, friction, and the introduction of foreign substances (as by injection) are some of the means by which skin injuries may occur.

Callus

Callus is a nonpenetrating, circumscribed hyperkeratosis produced by pressure. It occurs on parts of the body subject to intermittent pressure, particularly the palms and soles, and especially the bony prominences of the joints. Those engaged in various sports, certain occupations, or other repetitive activity develop callosities of distinctive size and location as stigmata. Examples are surfer's nodules, boxer's knuckle pads, jogger's toe, rower's rump, playstation thumb, milker's callus, tennis toe (Fig. 3.33), jogger's nipple, prayer callus, the yoga sign, neck callosities of violinists, pillar knocker's knuckles, bowler's hand, and Russell sign. The latter are calluses, small lacerations, or abrasions on the dorsum of the hand overlying the metacarpophalangeal and interphalangeal joints and are seen as a clue to the diagnosis of bulimia nervosa.

The callus differs from the clavus in that it has no penetrating central core and is a more diffuse thickening. Callus tends to disappear spontaneously when the pressure is removed. Most problems are encountered with calluses on the soles. Poorly fitting shoes, orthopedic problems of the foot caused by aging or a deformity of the foot exerting abnormal pressure, and high activity level are some of the etiologic factors to be considered in painful callosities of the feet.

Padding to relieve the pressure, paring of the thickened callus, and use of keratolytics such as 40% salicylic acid plasters are

Fig. 3.33 Tennis toe.

effective means of relieving painful callosities. Use of 12% ammonium lactate lotion or a urea-containing cream is often helpful.

Clavus (Corns)

Corns are circumscribed, horny, conical thickenings with the base on the surface and the apex pointing inward and pressing on subjacent structures. There are two varieties: the hard corns, which occur on the dorsa of the toes, or subungually on the soles, and the soft corns, which occur between the toes and are softened by the macerating action of sweat. In a hard corn, the surface is shiny and polished, and when the upper layers are shaved off, a core is noted in the densest part of the lesion. It is this core that causes a dull/boring or sharp/lancinating pain by pressing on the underlying sensory nerves. Corns arise at sites of friction or pressure, and when these causative factors are removed, they spontaneously disappear. Frequently, a bony spur or exostosis is present beneath both hard and soft corns of long duration, and unless this exostosis is removed, cure is unlikely. The soft interdigital corn usually occurs in the fourth interdigital space of the foot. Frequently, there is an exostosis at the metatarsophalangeal joint that causes pressure on the adjacent toe. These are soft, soggy, and macerated so that they appear white. Treatment by simple excision may be effective.

Plantar corns must be differentiated from plantar warts. Squeezing the lesion laterally will induce pain in a wart, while pressing perpendicularly will produce pain in a corn. Paring off the surface keratin until either the pathognomonic elongated dermal papillae of the wart with its blood vessels or the clear horny core of the corn can be clearly seen is another option. Porokeratosis plantaris discreta is a sharply marginated, cone-shaped, rubbery lesion that commonly occurs beneath the metatarsal heads. Multiple lesions may occur. It has a 3:1 female predominance, is painful, and is frequently confused with a plantar wart or corn. Keratosis punctata of the creases may be seen in the creases of the toes, where it may be mistaken for a corn.

The relief of pressure or friction by corrective footwear or the application of a ring of soft felt wadding around the region of the corn will often bring a good result. Soaking the feet in hot water and paring the surface by means of a scalpel blade or pumice stone leads to symptomatic improvement. Salicylic acid is successful when carefully and diligently used. After careful paring of the corn with emphasis on removing the center core, 40% salicylic acid plaster is applied. Soaking the foot for ½ hour before reapplying the medication enhances the effect. After 48 hours, the plaster is removed, the white macerated skin is rubbed off, and a new plaster is reapplied. This is continued until the corn is gone. Punch excisions of small lesions and the Er:YAG laser ablation are other options. It should be stressed that removal of any underlying bony abnormality, if present, is often necessary to effect a cure.

Fig. 3.34 Fire coral cuts. (Courtesy Steven Binnick, MD.)

Pseudoverrucous Papules and Nodules

These striking 2–8 mm, shiny, smooth, red, moist, flat-topped round lesions in the perianal area of children are considered to be a result of encopresis or urinary incontinence. There is a similarity to lesions affecting urostomy or elderly incontinent patients. Protection of the skin will help eliminate them. Similar lesions have been described in women who repeatedly apply an antifungal (Vagisil) to the groin area.

Coral Cuts

A severe type of skin injury may occur from the cuts of coral skeletons (Fig. 3.34). The abrasions and cuts are painful, and local therapy may provide little or no relief. Healing may take months. As a rule, if secondary infection is guarded against, such cuts heal as well as any others. The possibility of *Mycobacterium marinum* infection must be considered in persistent lesions.

Pressure Ulcers (Decubitus)

The bedsore, or decubitus, is a pressure ulcer produced anywhere on the body by prolonged pressure. The pressure sore is caused by ischemia of the underlying structures of the skin, fat, and muscles as a result of sustained and constant pressure. Usually, it occurs in chronically debilitated persons who are unable to change position in bed. The bony prominences of the body are the most frequently affected sites. About 95% of all pressure ulcers develop on the lower body, with 65% in the pelvic area and 30% on the legs. The ulcer usually begins with erythema at the pressure point; in a short time a "punched-out" ulcer develops. Necrosis with a grayish pseudomembrane is seen, especially in the untreated ulcer. Potential complications of pressure ulcers include sepsis, local infection, osteomyelitis, fistulas, and SCC.

More than 100 risk factors have been identified, with diabetes mellitus, peripheral vascular disease, cerebrovascular disease, sepsis, and hypotension being prominent. Pressure ulcers are graded

according to a four-stage system, with the earliest being recognized by changes in skin temperature, tissue consistency, and sensation. The lesion first appears as an area of persistent redness. Stage II is a superficial ulcer involving the epidermis and/or dermis. The deeper stage III ulcers damage the subcutaneous fat and stage IV, the muscle, bone, tendon, or joint capsule.

Prevention relies on redistributing pressure at a minimum interval of 2 hours. Treatment consists of relief of the pressure on the affected parts by frequent change of position, meticulous nursing care, and use of air-filled products, liquid-filled flotation devices, or foam products. Other measures include ulcer care, management of bacterial colonization and infection, surgical repair if necessary, continual education, adequate nutrition, management of pain, and provision of psychosocial support.

Ulcer care is critical. Debridement may be accomplished by sharp, mechanical, enzymatic, and autolytic measures, at least once weekly. In some patients, operative care will be required. Stable heel ulcers are an exception; debridement is unnecessary if only a dry eschar is present. Wounds should be cleaned initially and each dressing changed by a nontraumatic technique. Normal saline rather than peroxide or povidone-iodine is best. Selection of a dressing should ensure that the ulcer tissue remains moist and the surrounding skin dry.

Occlusive dressings include more than 300 products, generally classified as films, alginates, foams, hydrogels, hydrofibers, and hydrocolloid dressings. Transparent films are used only for stage II ulcers because they provide light drainage, whereas hydrofibers are used only for full-thickness stage III and IV ulcers. Surgical debridement and closure with flaps and reconstructive procedures may be necessary. Adjuvant therapies such as ultrasound, laser, UV radiation, hyperbaric oxygen, electrical stimulation, radiant heat, application of growth factors, cultured keratinocyte grafts, skin substitutes, and miscellaneous topical and oral agents are being investigated to determine their place in the treatment of these ulcers.

At times, anaerobic organisms colonize these ulcers and cause a putrid odor. The topical application of metronidazole eliminates this odor within 36 hours.

Friction Blisters

The formation of vesicles or bullae may occur at sites of combined pressure and friction and may be enhanced by heat and moisture. The feet of military recruits in training, the palms of oarsmen who have not yet developed protective calluses, and the fingers of drummers (drummer's digits) are examples of those at risk. The size of the bulla depends on the site of the trauma. If the skin is tense and uncomfortable, the blister should be drained, but the roof should not be completely removed because it may act as its own dressing.

In studies focusing on the prevention of friction blisters of the feet in long-distance runners and soldiers, acrylic fiber socks with drying action have been found to be effective. Additionally, pretreatment with a 20% solution of aluminum chloride hexahydrate for at least 3 days has been shown to reduce foot blisters significantly after prolonged hiking, but at the expense of skin irritation. Emollients decrease the irritation but reduce the overall effectiveness of the treatment.

Fracture Blisters

Fracture blisters overlie sites of closed fractures, especially the ankle and lower leg. The blisters appear a few days to 3 weeks after the injury and are thought to be caused by vascular compromise. Fracture blisters may create complications such as infection and scarring, especially if blood filled or in diabetic patients. The blisters generally heal spontaneously in 5–14 days but may cause delay of surgical reduction of the fracture.

Fig. 3.35 Sclerosing lymphangitis of penis.

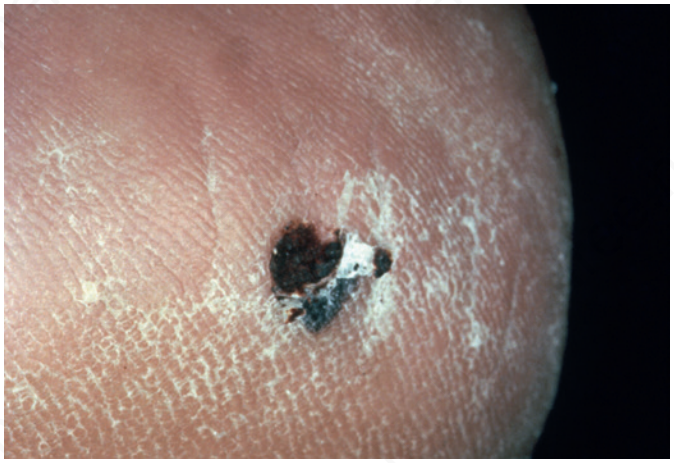

Fig. 3.36 Black heel.

Sclerosing Lymphangiitis

This lesion is a cordlike structure encircling the coronal sulcus of the penis or running the length of the shaft and has been attributed to trauma during vigorous sexual play (Fig. 3.35). Most if not all cases result from a superficial thrombophlebitis and thus has been renamed Mondor disease of the penis. Some early reports favor a lymphatic origin of some cases; CD31 and D240 stains will allow differentiation of future cases. Treatment is not necessary; sclerosing lymphangiitis follows a benign, self-limiting course.

Black Heel

Synonyms for black heel include talon noir and calcaneal petechiae. A sudden shower of minute, black, punctate macules occurs most often on the posterior edge of the plantar surface of one or both heels (Fig. 3.36), but sometimes distally on one or more toes. Black heel is often seen in basketball, volleyball, tennis, or lacrosse players. Seeming confluence may lead to mimicry of melanoma. The bleeding is caused by shearing stress of sports activities. Paring with a No. 15 blade and performing a guaiac test will confirm the diagnosis. Treatment is unnecessary.

Subcutaneous Emphysema

Free air occurring in the subcutaneous tissues is detected by the presence of cutaneous crepitations. Gas-producing organisms, especially *Clostridia*, and leakage of free air from the lungs or

Fig. 3.37 Subcutaneous emphysema. (Courtesy Curt Samlaska, MD.)

gastrointestinal tract are the most common causes (Fig. 3.37). Samlaska et al. reviewed the wide variety of causes of subcutaneous emphysema, including penetrating and nonpenetrating injuries, iatrogenic causes occurring during various procedures in hospitalized patients, spontaneous pneumomediastinum such as may occur with a violent cough, childbirth, asthma, Boerhaave syndrome (esophageal rupture after vomiting or the Heimlich maneuver), intraabdominal causes such as inflammatory bowel disease, cancer, perirectal abscess, pancreatitis or cystitis, dental procedures when using air pressure instruments and high-speed drills, and factitial disease.

Traumatic Asphyxia

Cervicofacial cyanosis and edema; multiple petechiae of the face, neck, and upper chest; and bilateral subconjunctival hemorrhage may occur after prolonged crushing injuries of the thorax or upper abdomen. Such trauma reverses blood flow in the superior vena cava or its tributaries.

Painful Fat Herniation

Also called painful piezogenic pedal papules, this rare cause of painful feet represents fat herniations through thin fascial layers of the weight-bearing parts of the heel (Fig. 3.38). These dermatoceles become apparent when weight is placed on the heel and disappear as soon as the pressure is removed. These fat herniations are present in many people, but the majority experience no symptoms. However, extrusion of the fat tissue together with its blood vessels and nerves may initiate pain on prolonged standing. Avoidance of prolonged standing will relieve this pain. Other options include taping of the foot, use of compression stockings, or use of plastic heel cups or padded orthotic devices to restrict the herniations. Laing et al. found that 76% of 29 patients had pedal papules, and interestingly, by placing pressure on the wrists, found 86% to have piezogenic wrist papules.

Narcotic Dermopathy

Heroin (diacetylmorphine) is a narcotic prepared for injection by dissolving the heroin powder in boiling water and then injecting

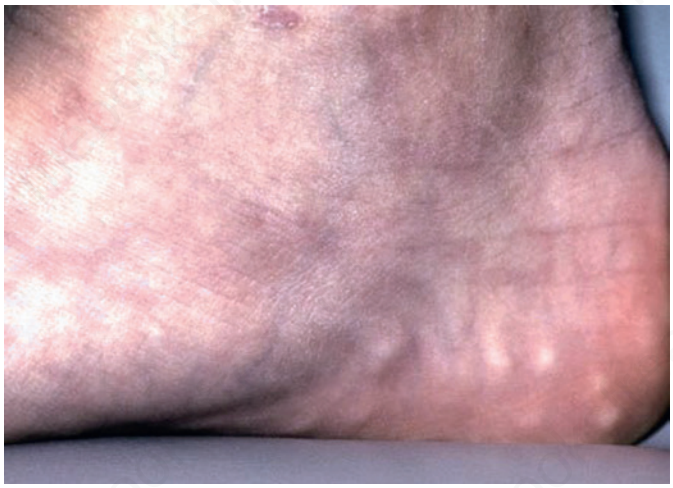

Fig. 3.38 Piezogenic papules. (Courtesy Paul Hong, MD.)

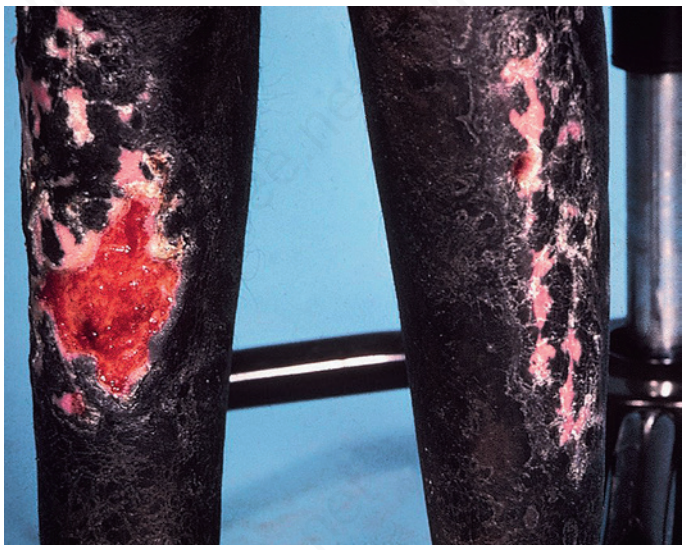

Fig. 3.39 Ulceration secondary to "skin popping."

it. The favored route of administration is intravenous. This results in thrombosed, cordlike, thickened veins at the sites of injection. Subcutaneous injection ("skin popping") can result in multiple, scattered ulcerations, which heal with discrete atrophic scars (Fig. 3.39). In addition, amphetamines, cocaine, and other drugs may be injected. Subcutaneous injection may result in infections, complications of bacterial abscess and cellulitis, or sterile nodules, apparently acute foreign body reactions to the injected drug or the adulterants mixed with it. These lesions may ulcerate. Chronic persistent firm nodules, a combination of scar and foreign body reaction, may result. If cocaine is being injected, it may cause ulcers because of its direct vasospastic effect. Addicts will continue to inject heroin and cocaine into the chronic ulcer bed. Cocaine-associated vasculitis caused by levamisole is discussed in Chapter 35.

The cutaneous manifestations of injection of heroin and other drugs also include camptodactylia, edema of the eyelids, persistent nonpitting edema of the hands, urticaria, abscesses, atrophic scars, and hyperpigmentation. Pentazocine abuse leads to a typical clinical picture of tense woody fibrosis, irregular punched-out ulcerations, and a rim of hyperpigmentation at injection sites. Extensive calcification may occur within the thickened sites.

FOREIGN BODY REACTIONS

Tattoo

Tattoos result from the introduction of insoluble pigments into the skin. They may be traumatic, cosmetic, or medicinal in nature and may be applied by a professional or an amateur. Pigment is applied to the skin, and needles pierce the skin to force the material into the dermis. Pigments used include carmine, indigo, vermilion, India ink, chrome green, magnesium (lilac color), Venetian red, aluminum, gold, titanium (white color) or zinc oxide, lead carbonate, copper, iron, logwood, azo and naptha-derived pigments, quinacridones, cobalt blue, cinnabar (mercuric sulfide), and cadmium sulfide. Cadmium, cobalt, mercury, and lead are not often used; however, occasional photosensitive reactions to cadmium, which was used for yellow color or to brighten the cinnabar red, are still seen. "Invisible tattoos," seen only under UV light, have ingredients such as polymethylmethacrylate and melamine that may cause granulomatous reactions.

Fig. 3.40 Red tattoo reaction. (Courtesy Curt Samlaska, MD.)

Tattoo-associated dermopathies may be reactive (allergic, lichenoid, granulomatous, or photosensitive) (Fig. 3.40) or infective (inoculation of syphilis, infectious hepatitis, tuberculosis, HIV, warts, molluscum, Hansen disease) or may induce a Koebner response in patients with active lichen planus or psoriasis. Discoid lupus erythematosus has been reported to occur in the red-pigmented portion of tattoos. Tattoos over nevi may delay the diagnosis of melanoma. Occasionally, the tattoo marks may become keloidal. Severe allergic reactions to "temporary tattoos" (painting of pigments such as henna on surface of skin) occur when the allergen *p*-phenylenediamine is added to make the color more dramatic.

Red tattoos are the most common cause of delayed reactions, with the histologic findings typically showing a lichenoid process. Occasionally, a pseudolymphomatous reaction may occur in red tattoos. Dermatitis in areas of red (mercury), green (chromium), or blue (cobalt) have been described in patients who are patch test positive to these metals. Sarcoidal, foreign body, and allergic granulomatous reactions may also occur within tattoos; aluminum may induce such reactions.

Treatment of such reactions is with topical or intralesional steroids. Excision is also satisfactory when the lesions are small enough and situated so that ellipsoid excisions are feasible. Reactions may also be successfully treated with Q-switched lasers, at times combined with ablative fractional resurfacing Generalized allergic reactions occasionally occur; prevention by treatment with oral

steroids and antihistamines has been suggested. Tattoo darkening can occur, as well as no response to laser treatment. Caution must be used when treating flesh-colored and pink-red tattoos because they may darken after treatment, likely caused by the reduction of ferric oxide to ferrous oxide. White ink, composed mostly of titanium dioxide, is often used to brighten green, blue, yellow, and purple tattoos. Laser irradiation reduces titanium to a blue-colored pigment. Test areas are recommended when treating light-colored facial tattoos. CO_2 resurfacing lasers used conservatively are an alternative to the Q-switched lasers in such patients (see Chapter 38).

Paraffinoma (Sclerosing Lipogranuloma)

Injection of oils into the skin for cosmetic purposes, such as the smoothing of wrinkles and the augmentation of breasts, was popular in the past. Paraffin, camphorated oil, cottonseed or sesame oil, mineral oil, and beeswax may produce plaquelike indurations with ulcerations within months and up to 40 years. Several reports document penile paraffinomas caused by self-injection. When petroleum jelly (Vaseline) gauze or a topical ointment is used to dress unsutured wounds, lipogranulomas or inflammatory mild erysipelas-like lesions with marked tenderness may occur. A radiofrequency device successfully treated a facial paraffinoma. Surgical removal must be wide and complete.

Granulomas

Silicone Granuloma

Liquid silicones, composed of long chains of dimethyl siloxy groups, are biologically inert. Silicones have been used for correcting wrinkles, reducing scars, and building up atrophic depressed areas of the skin. Many case reports detail granulomatous reactions to silicone, some with migration and reactive nodules at points distant from the injection site (Figs. 3.41 and 3.42). Acupuncture needles are coated with silicone, and granulomas may occur at the entry points. The incidence of the nodular swellings, which may be quite destructive and treatment resistant, remains unknown. It is clear that, if used off label, medical-grade silicone injected in small volume should be the rule, and it should not be injected into the penis or the glandular tissue of the breast.

For breast augmentation, silicone may be used as Silastic implants. If trauma causes rupture of the bag, subcutaneous fibrotic nodules often develop. Bioplastique consists of polymerized silicone particles dispersed in a gel carrier. When used for lip augmentation, nodules may develop. Histologically, these are foreign body granulomas.

Fig. 3.41 Silicone reaction.

Treatment of silicone granulomas is often not successful. Surgical removal may lead to fistulas, abscesses, and marked deformity. Both minocycline, 100 mg twice daily for several months, and imiquimod cream have been anecdotally useful.

Mercury Granuloma

Mercury may cause foreign body giant cell or sarcoidal-type granulomas (Fig. 3.43), pseudolymphoma, or membranous fat necrosis. It is usually identifiable as egg-shaped, extracellular, dark-gray to black, irregular globules. The gold lysis test is positive in tissues. Energy-dispersive radiographic spectroscopy may be done and will identify mercury by the characteristic emission spike. Such testing may be helpful in identifying any foreign substance suspected to have been implanted accidentally or intentionally by the patient. Systemic toxicity or embolus may develop from mercury and may result in death. Therefore excision is necessary and can be accomplished under x-ray guidance.

Beryllium Granuloma

Beryllium granuloma is seen as a chronic, persistent, granulomatous inflammation of the skin with ulceration that may follow accidental laceration, usually in an occupational setting.

Zirconium Granuloma

A papular eruption involving the axillae is sometimes seen as an allergic reaction in those shaving their armpits and using a

Fig. 3.42 Silicone granuloma.

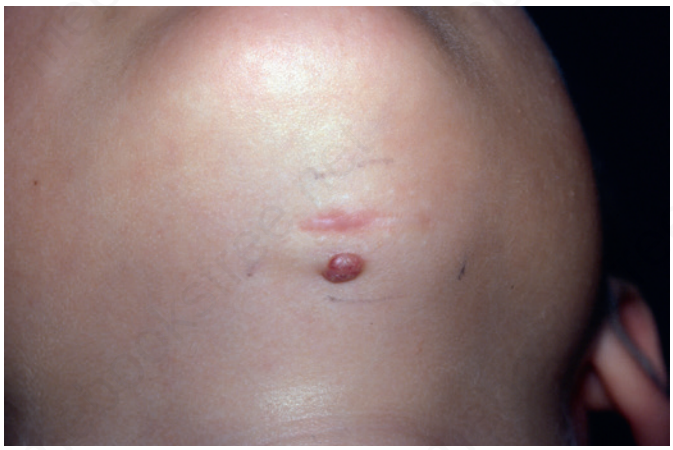

Fig. 3.43 Mercury granuloma from thermometer.

deodorant containing zirconium (Fig. 3.44). Although zirconium was eliminated from aerosol-type deodorants in 1978, aluminum-zirconium complex is present in some antiperspirants. Additionally, various poison ivy lotions contain zirconium compounds. The lesions are brownish red, dome-shaped, shiny papules. This is an acquired, delayed-type, allergic reaction resulting in a granuloma of the sarcoidal type. After many months, the lesions involute spontaneously.

Fig. 3.44 Aluminum-zirconium granuloma secondary to antiperspirant use.

Silica Granuloma

Automobile crashes and other types of trauma may produce tattooing of dirt (silicon dioxide) into the skin, which induces silica granulomas (Fig. 3.45). These typically present as black or blue papules or macules arranged in a linear fashion. At times, the granulomatous reaction to silica may be delayed for many years, with the ensuing reaction being both chronic and disfiguring. The granulomas may be caused by amorphous or crystalline silicon dioxide (quartz), magnesium silicate (talcum), or complex polysilicates (asbestos). Talc granulomas of the skin and peritoneum may develop after surgery from the talcum powder used on surgical gloves. Silica granulomas have a statistical association with systemic sarcoidosis, and silica may act as a stimulus for granuloma formation in patients with latent sarcoidosis.

Removal of these granulomas is fraught with difficulties. The best method of care is immediate and complete removal to prevent these reactions. Excision and systemic steroids have been used, but recurrences are common. Some reactions may subside spontaneously after 1–12 months. Dermabrasion or simple abrasion with a hard-bristled toothbrush is a satisfactory method for the removal of dirt accidentally embedded into the skin of the face or scalp.

Carbon Stain

Discoloration of the skin from embedded carbon usually occurs in children from improper use of firearms (Fig. 3.46) or fireworks or from a puncture wound by a pencil, which may leave a permanent black mark of embedded graphite, easily mistaken for a metastatic melanoma. Narcotic addicts who attempt to clean needles by flaming them with a lighted match may tattoo the carbon formed on the needle as it is inserted into the skin.

Carbon particles may be removed immediately after their deposition using a toothbrush and forceps. This expeditious and meticulous early care results in the best possible cosmetic result. If the particles are left in place long enough, they are best removed using the Q-switched Nd:YAG laser at 1064 nm. In one series

Fig. 3.47 Injected filler reaction.

success was reported in 50 of 51 treated tattoos with an average of 1.7 treatments. However, microexplosions producing poxlike scars have occurred with each laser pulse. Alternatively, dermabrasion may be used.

Injected Filler Substances

Injected or implanted filler substances used for facial rejuvenation may produce foreign body or sarcoidal granulomas. Palpable thickening and nodules (Fig. 3.47), which are occasionally painful, have been reported with collagen, hyaluronic acid and acrylic hydrogels, and polylactic acid, polyalkylimide, and polymethylmethacrylate microspheres. The reaction may be delayed for years; at times, patients are reluctant to admit to these prior cosmetic interventions and frequently cannot name the filler used. Topical, intralesional, or systemic steroids, sometimes augmented by tacrolimus, and minocycline or doxycycline have been reported to be helpful medical interventions.

4 Pruritus and Neurocutaneous Dermatoses

Bonus images for this chapter can be found online at expertconsult.inkling.com

PRURITUS

Pruritus, commonly known as itching, is a sensation exclusive to the skin. It may be defined as the sensation that produces the desire to scratch. Pruritogenic stimuli are first responded to by keratinocytes, which release a variety of mediators, and fine intraepidermal C-neuron filaments. Approximately 5% of the afferent unmyelinated C neurons respond to pruritogenic stimuli. Itch sensations in these nerve fibers are transmitted via the lateral spinothalamic tract to the brain, where a variety of foci generate both stimulatory and inhibitory responses. The sum of this complicated set of interactions appears to determine the quality and intensity of itch.

Itching may be elicited by many normally occurring stimuli, such as light touch, temperature change, and emotional stress. Chemical, mechanical, and electrical stimuli may also elicit itching. The brain may reinterpret such sensations as being painful or causative of burning or stinging sensations. A large group of neuromediators and their receptors have been identified. Some of the most important mediators are histamine and the H4 receptor, tryptase and its proteinase-activated receptor type 2, opioid peptides and the mu (μ) and kappa (κ) opioid receptors, leukotriene B4, prostaglandins such as PGE, thymic stromal lymphopoietin, acetylcholine, cytokines such as interleukin-31 (IL-31), and a variety of neuropeptides and vasoactive peptides (e.g., nerve growth factor, substance P) and their receptors (e.g., TRPV1). Investigation is ongoing to discover the relative importance of each of these mediators and to determine the clinical circumstances under which therapeutic targeting of these molecules will lead to relief of symptoms.

Itch has been classified into four primary categories, as follows:

- Pruritoceptive itch, initiated by skin disorders
- Neurogenic itch, generated in the central nervous system and caused by systemic disorders
- Neuropathic itch, caused by anatomic lesions of the central or peripheral nervous system
- Psychogenic itch, the type observed in parasitophobia

An overlap or mixture of these types may be causative in any individual patient.

Patterns of Itching

There are wide variations in itching from person to person, and a person may have a variation in reactions to the same stimulus. Heat will usually aggravate preexisting pruritus. Stress, absence of distractions, anxiety, and fear may all enhance itching. Itching tends to be most severe during undressing for bed.

Severe pruritus, with or without prior skin lesions, may be paroxysmal in character with a sudden onset, often severe enough to awaken the patient. It may stop instantly and completely as soon as pain is induced by scratching. However, the pleasure of scratching is so intense that the patient, despite the realization of damaging the skin, is often unable to stop short of inflicting such damage (Fig. 4.1). Itching of this distinctive type is characteristic of a select group of dermatoses: lichen simplex chronicus, atopic dermatitis, nummular eczema, dermatitis herpetiformis, neurotic excoriations, eosinophilic folliculitis, uremic pruritus, prurigo simplex, paraneoplastic itch (usually secondary to lymphoma), and prurigo nodularis. In general, only these disorders produce such intense pruritus and scratching as to induce bleeding. In individual cases, other diseases may manifest such severe symptoms.

Treatment

General guidelines for therapy of the itchy patient include keeping cool and avoiding hot baths or showers and wool clothing, which is a nonspecific irritant, as is xerosis. Many patients note itching increases after showers, when they wash with soap and then dry roughly. Using soap only in the axilla and inguinal area, patting dry, and applying a moisturizer can often help prevent such exacerbations. If itching is severe, a trial of "soaking and smearing" may provide significant relief (see winter itch later in this chapter). Patients often use an ice bag or hot water to ease pruritus; however, hot water can irritate the skin, is effective only for short periods, and over time exacerbates the condition.

Relief of pruritus with topical remedies may be achieved with topical anesthetic preparations. Many contain benzocaine, which may produce contact sensitization. Pramoxine in a variety of vehicles, lidocaine 5% ointment, eutectic mixture of lidocaine and prilocaine (EMLA) ointment, and lidocaine gel are preferred anesthetics that may be beneficial in localized conditions. EMLA and lidocaine may be toxic if applied to large areas. Topical antihistamines are generally not recommended, although doxepin cream may be effective for mild pruritus when used alone. Doxepin cream may cause contact allergy or a burning sensation, and somnolence may occur when doxepin is used over large areas. Topical lotions that contain menthol or camphor feel cool and improve pruritus. They may be kept in the refrigerator to enhance this soothing effect. Other lotions have specific ceramide content designed to mimic that of the normal epidermal barrier. Capsaicin, by depleting substance P, can be effective, but the burning sensation present during initial use frequently causes patients to discontinue its use. Topical steroids and calcineurin inhibitors effect a decrease in itching through their antiinflammatory action and therefore are of limited efficacy in neurogenic, psychogenic, or systemic disease–related pruritus.

Phototherapy with ultraviolet B (UVB), UVA, and psoralen plus UVA (PUVA) may be useful in a variety of dermatoses and pruritic disorders. Many oral agents are available to treat pruritus. Those most frequently used by nondermatologists are the antihistamines. First-generation H1 antihistamines, such as hydroxyzine and diphenhydramine, may be helpful in nocturnal itching, but their efficacy as antipruritics is disappointing in many disorders, except for urticaria and mastocytosis. Doxepin is an exception in that it can reduce anxiety and depression and is useful in several pruritic disorders. Sedating antihistamines should be prescribed cautiously, especially in elderly patients because of their impaired cognitive ability. The nonsedating antihistamines and H2 blockers are only effective in urticaria and mast cell disease. Opioids are involved in itch induction. In general, activation of μ-opioid receptors stimulates itch, whereas κ-opioid receptor stimulation inhibits itch perception; however, the interaction is complex. Additionally, opioid-altering agents such as naltrexone, naloxone, nalfurafine, and butorphanol have significant side effects and varying modes of delivery (intravenous, intranasal, oral). Initial reports of benefit in one condition are often followed by conflicting reports on further study. Specific recommendations in select pruritic

Fig. 4.1 Severe pruritus with excoriations.

conditions are detailed in those sections. These agents appear most useful for cholestatic pruritus. Central reduction of itch perception may be effected by anticonvulsants, such as gabapentin and pregabalin, and antidepressants, such as mirtazapine and the selective serotonin reuptake inhibitors (SSRIs). These take 8–12 weeks to attain full onset of action. Thalidomide, through a variety of direct neural effects, immunomodulatory actions, and hypnosedative effects, is also useful in select patients.

Internal Causes of Pruritus

Itching may be present as a symptom in a number of internal disorders. The intensity and duration of itching vary from one disease to another. The most important internal causes of itching include liver disease, especially obstructive and hepatitis C (with or without evidence of jaundice or liver failure), renal failure, diabetes mellitus, hypothyroidism and hyperthyroidism, hematopoietic diseases (e.g., iron deficiency anemia, polycythemia vera), neoplastic diseases (e.g., lymphoma [especially Hodgkin disease and cutaneous T-cell lymphoma], leukemia, myeloma), internal solid-tissue malignancies, intestinal parasites, carcinoid, multiple sclerosis, acquired immunodeficiency syndrome (AIDS), connective tissue disease (particularly dermatomyositis) and neuropsychiatric diseases, especially anorexia nervosa.

The pruritus of Hodgkin disease is usually continuous and at times is accompanied by severe burning. The incidence of pruritus is 10%–30% and is the first symptom of this disease in 7% of patients. Its cause is unknown. The pruritus of leukemia, except for chronic lymphocytic leukemia, has a tendency to be less severe than in Hodgkin disease.

Internal organ cancer may be found in patients with generalized pruritus that is unexplained by skin lesions. However, no significant overall increase of malignant neoplasms can be found in patients with idiopathic pruritus. A suggested workup for chronic, generalized pruritus includes a complete history, thorough physical examination, and laboratory tests, including complete blood count (CBC) and differential; thyroid, liver, and renal panels; fasting blood glucose; hepatitis C serology; human immunodeficiency virus (HIV) antibody (if risk factors are present); urinalysis; stool for occult blood; serum protein electrophoresis; and chest x-ray evaluation. Presence of eosinophilia on the CBC is a good screen for parasitic diseases, but if the patient has been receiving systemic corticosteroids, blood eosinophilia may not be a reliable screen for parasitic diseases, and stool samples for ova and parasites should be submitted. Additional radiologic studies or specialized tests are performed as indicated by the patient's age, history, and physical findings. A biopsy for direct immunofluorescence is occasionally helpful to detect dermatitis herpetiformis or pemphigoid.

Treatment of the itch associated with some of these internal conditions is discussed later in this chapter or under those specific diseases in other chapters; however, in other conditions listed previously treatment of the underlying disease state (e.g., treating the cancer, replacing thyroid hormone in hypothyroidism) causes relief of the pruritus. Be aware that disease specific therapies can exacerbate itching during treatment, for instance in cancer patients treated with biologic agents such as the anti EGFR monocolonal antibiodies.

Chronic Kidney Disease

Chronic kidney disease (CKD) is the most common systemic cause of pruritus; 20%–80% of patients with chronic renal failure have itching. The pruritus is often generalized, intractable, and severe; however, dialysis-associated pruritus may be episodic, mild, or localized to the dialysis catheter site, face, or legs.

The mechanism of pruritus associated with CKD is multifactorial. Xerosis, secondary hyperparathyroidism, increased serum histamine levels, hypervitaminosis A, iron deficiency anemia, and

Fig. 4.2 (A) Acquired perforating dermatosis of uremia. (B) Close-up view of A.

neuropathy have been implicated. Complications such as acquired perforating disease, lichen simplex chronicus, and prurigo nodularis may develop and contribute to the degree and severity of pruritus (Fig. 4.2).

Many patients have concomitant xerosis, and aggressive use of emollients, including "soaking and smearing" (see winter itch later in this chapter), may help. A trial of γ-linolenic acid cream twice daily was effective, as was one using baby oil. Gabapentin given three times weekly at the end of hemodialysis sessions can be effective, but its renal excretion is decreased in CKD, so a low initial dose of 100 mg after each session with slow upward titration is recommended. A mainstay of CKD-associated pruritus has been narrow-band (NB) UVB phototherapy, but a randomized controlled trial (RCT) failed to confirm its efficacy. Broad-band UVB may be best in the CKD patient. Naltrexone, topical tacrolimus, and ondansetron also were reported to be useful in initial trials, but subsequent studies indicated these agents are ineffective. Nalfurafine, 5 μg once daily after supper, has demonstrated improvement and was relatively well tolerated over a 1-year study. Thalidomide, intranasal butorphanol, and intravenous lidocaine are less practical options. Patients on peritoneal dialysis have a lower severity of pruritus than those on hemodialysis. Renal transplantation will eliminate pruritus.

Biliary Pruritus

Chronic liver disease with obstructive jaundice may cause severe generalized pruritus, and 20%–50% of patients with jaundice have pruritus. Intrahepatic cholestasis of pregnancy, primary sclerosing cholangitis, and hereditary cholestatic diseases such as Alagille syndrome all have pruritus in common. Another disease, primary biliary cirrhosis, is discussed separately next because of its many other cutaneous manifestations. Hepatitis C may be associated with pruritus as well.

Itching of biliary disease is probably caused by central mechanisms. The pathophysiology is not well understood, but it appears that lysophosphatidic acid, formed by the action of the enzyme autotaxin on lysophosphatidylcholine, is central. The serum conjugated bile acid levels do not correlate with the severity of pruritus, and the theory invoking endogenous opioids as the main cause has not been upheld.

Pruritus of chronic cholestatic liver disease is improved with cholestyramine, 4 to 16 g daily. Rifampin, 150 to 300 mg/day, may be effective but should be used with caution because it may cause hepatitis. Naltrexone, up to 50 mg/day, is useful but has significant side effects. If used, naltrexone should be started at ¼ tablet (12.5 mg) and increased by ¼ tablet every 3 to 7 days until pruritus improves. Sertraline, 75 to 100 mg/day, is another option. UVB phototherapy was effective in a small case series. Ursodeoxycholic acid is effective for the pruritus in intrahepatic cholestasis of pregnancy, but not for the itching from other causes. Liver transplantation is the definitive treatment for end-stage disease and provides dramatic relief from the severe pruritus.

Primary Biliary Cirrhosis. Primary biliary cirrhosis occurs almost exclusively in women older than 30. Itching may begin insidiously and may be the presenting symptom in a quarter to half of patients. With time, extreme pruritus develops in almost 80% of patients. This almost intolerable itching is accompanied by jaundice and a striking melanotic hyperpigmentation of the entire skin; the patient may turn almost black, except for a hypopigmented "butterfly" area in the upper back. Eruptive xanthomas, planar xanthomas of the palms (Fig. 4.3), xanthelasma, and tuberous xanthomas over the joints may be seen.

Dark urine, steatorrhea, and osteoporosis occur frequently. Serum bilirubin, alkaline phosphatase, serum ceruloplasmin, serum hyaluronate, and cholesterol values are increased. The antimitochondrial antibody test is positive. The disease is usually relentlessly progressive with the development of hepatic failure. Several cases have been accompanied by scleroderma.

Polycythemia Vera. More than one third of patients with polycythemia vera report pruritus; it is usually induced by temperature changes or several minutes after bathing. The cause is unknown.

Aspirin has been shown to provide immediate relief from itching; however, there is a risk of hemorrhagic complications. PUVA and NB UVB are also effective. A marked improvement is noted after an average of six treatments, with complete remission often occurring in 2–10 weeks. Paroxetine, 20 mg/day, produced clearing or near-complete clearing in a series of nine patients. Interferon (IFN) alpha-2 has been shown to be effective for treating the underlying disease and associated pruritus.

Saini KS, et al: Polycythemia vera–associated pruritus and its management. Eur J Clin Invest 2010; 40: 828.

PRURITIC DERMATOSES

Winter Itch

Asteatotic eczema, eczema craquelé, and xerotic eczema are other names for this pruritic condition. Winter itch is characterized by pruritus that usually first manifests and is most severe on the legs and arms. Extension to the body is common; however, the face, scalp, groin, axillae, palms, and soles are spared. The skin is dry with fine flakes (Fig. 4.4). The pretibial regions are particularly susceptible and may develop eczema craquelé, exhibiting fine cracks in the eczematous area that resemble the cracks in old porcelain dishes.

Frequent and lengthy bathing with plenty of soap during the winter is the most frequent cause. This is especially prevalent in elderly persons, whose skin has a decreased rate of repair of the epidermal water barrier and whose sebaceous glands are less productive. Low humidity in overheated rooms during cold weather contributes to this condition. In a study of 584 elderly individuals,

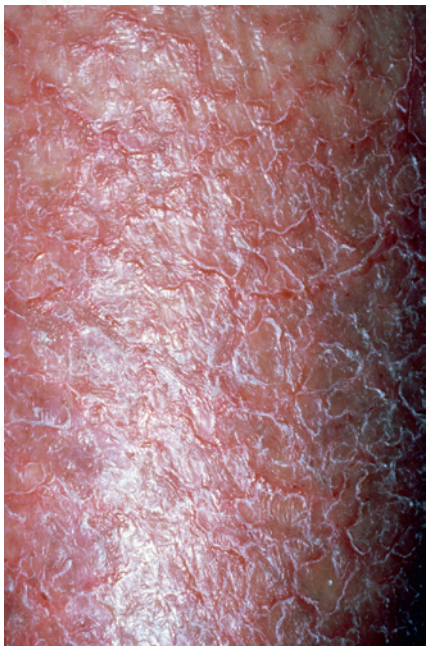

Fig. 4.4 Winter itch.

the prevalence of asteatosis (28.9%) was second only to seborrheic dermatitis as the most common finding.

Treatment consists of educating the patient on using soap only in the axillae and inguinal area and lubricating the skin with emollients immediately after showering. Preparations containing lactic acid or urea applied after bathing are helpful in some patients but may cause irritation and may worsen itching in patients with erythema and eczema.

For those with more severe symptoms, long-standing disease, or a significant inflammatory component, a regimen referred to as "soaking and smearing" is dramatically effective. The patient soaks in a tub of plain water at a comfortable temperature for 20 minutes before bedtime. Immediately on exiting the tub, without drying, triamcinolone, 0.025%–0.1% ointment, is applied to the wet skin. This will trap the moisture, lubricate the skin, and allow for excellent penetration of the steroid component. An old pair of pajamas is then donned, and the patient will note relief even on the first night. The nighttime soaks are repeated for several nights, after which the ointment alone suffices, with the maintenance therapy of limiting soap use to the axillae and groin, and moisturization after showering. Plain petrolatum may be used as the lubricant after the soaking if simple dryness without inflammation is present. Folliculitis may complicate this therapy.

Kimura N, et al: Prevalence of asteatosis and asteatotic eczema among elderly residents in facilities covered by long-term care insurance. J Dermatol 2013; 40: 770.

Pruritus Ani

Pruritus is often centered on the anal or genital area (less frequently in both), with minimal or no pruritus elsewhere. Anal neurodermatitis is characterized by paroxysms of violent itching, when the patient may tear at the affected area until bleeding is induced. Manifestations are identical to lichen simplex chronicus elsewhere on the body. Specific etiologic factors should always be sought and generally can be classified as dermatologic disease, local irritants (which may coexist with colorectal and anal causes), and infectious agents.

Allergic contact dermatitis is a common dermatologic cause or secondary complication of pruritus ani. It occurs from various medicaments, fragrance in toilet tissue, or preservatives in moist toilet tissue, with one study reporting 18 of 40 consecutive patients being patch test positive. Seborrheic dermatitis, psoriasis, lichen planus, lichen sclerosis, and atopic dermatitis all may cause perianal itching, and an examination of other classic sites of involvement with these conditions should be carefully undertaken. Extramammary Paget disease and Bowen disease, although not often itchy, may be present and will not improve with therapy. Biopsy of resistant dermatitic-appearing skin should be done in nonresponsive pruritus ani.

Irritant contact dermatitis from gastrointestinal contents, such as hot spices or cathartics, or failure to cleanse the area adequately after bowel movements may be causal. Anatomic factors may lead to leakage of rectal mucus on to perianal skin and thus promote irritation. Physical changes such as hemorrhoids, anal tags, fissures, and fistulas may aggravate or produce pruritus.

Mycotic pruritus ani is characterized by fissures and a white, sodden epidermis. Scrapings are examined directly with potassium hydroxide mounts, and cultures will usually reveal *Candida albicans*, *Epidermophyton floccosum*, or *Trichophyton rubrum*. Other sites of fungal infection, such as the groin, toes, and nails, should also be investigated. Erythrasma in the groin and perianal regions may also occasionally produce pruritus. The diagnosis is established by coral red fluorescence under the Wood's light. β-Hemolytic streptococcal infections have also been implicated, especially in young children. The use of tetracyclines may cause pruritus ani, most often in women, by inducing candidiasis. Diabetic patients are susceptible to perianal candidiasis.

Pinworm infestations may cause pruritus ani, especially in children and sometimes in their parents. Nocturnal pruritus is most prevalent. Other intestinal parasites, such as *Taenia solium*, *T. saginata*, amebiasis, and *Strongyloides stercoralis*, may produce pruritus. Pediculosis pubis may cause anal itching; however, attention is focused by the patient on the pubic area, where itching is most severe. Scabies may be causative but often will also involve the finger webs, wrists, axillae, areolae, and genitalia.

Lumbosacral radiculopathy also may be present with pruritus ani, as assessed by radiographs and nerve conduction studies; paravertebral blockade may help these patients.

Treatment

Meticulous toilet care should be followed, no matter what the cause of the itching. After defecation, the anal area should be cleansed whenever possible, washed with mild soap and water. Cleansing with wet toilet tissue is advisable in all cases. Medicated cleansing pads (Tucks) should be used regularly. A variety of moist toilet tissue products are now available. Contact allergy to preservatives in these products is occasionally a problem. An emollient lotion (Balneol) is helpful for cleansing without producing irritation.

Once the etiologic agent has been identified, a rational and effective treatment regimen may be started. Topical corticosteroids are effective for most noninfectious types of pruritus ani; however, use of topical tacrolimus ointment will frequently suffice and is safer. Pramoxine, a nonsteroidal topical anesthetic, is also often effective, especially in a lotion form combined with hydrocortisone. In pruritus ani, as well as in pruritus scroti and vulvae, it is sometimes best to discontinue all topical medications and treat with plain water sitz baths at night, followed immediately by plain petrolatum applied over wet skin. This soothes the area, provides a barrier, and eliminates contact with potential allergens and irritants.

Pruritus Scroti

The scrotum of an adult is a susceptible site for circumscribed neurodermatitis (lichen simplex chronicus) (Fig. 4.5). Psychogenic pruritus is probably the most frequent type of itching seen. Why it preferentially affects the scrotum, or in women the vulva (see pruritus vulvae), is unclear. Lichenification may result, can be extreme, and may persist for many years despite intensive therapy.

Infectious conditions may complicate or cause pruritus on the scrotum but are less common than idiopathic scrotal pruritus. Fungal infections, except candidiasis, usually spare the scrotum. When candidal infection affects the scrotum, burning rather than pruritus is frequently the primary symptom. The scrotum is eroded, weepy, or crusted. The scrotum may be affected to a lesser degree in cases of pruritus ani, but this pruritus usually affects the midline, extending from the anus along the midline to the base of the scrotum, rather than the dependent surfaces of the scrotum, where pruritus scroti usually occurs. Scrotal pruritus may be associated with allergic contact dermatitis from topical medications, including steroidal agents.

Topical corticosteroids are the mainstay of treatment, but caution should be exercised. The "addicted scrotum syndrome" may be caused by the use of high-potency topical steroidal agents. As with facial skin, after attempts to wean patients off the steroid, severe burning and redness may occur. Although usually seen after chronic use, this may occur even with short-term high-potency steroids. The scrotum is frequently in contact with inner thigh skin, producing areas of occlusion, which increases the penetration of topical steroid agents. Topical tacrolimus ointment is useful in overcoming the effects of overuse of potent topical steroids. Another alternative is gradual tapering to less potent corticosteroids. Other useful nonsteroidal alternatives include topical pramoxine, doxepin, and simple petrolatum, which is applied after a sitz bath as described for pruritus ani.

Tan ES, et al: Effective treatment of scrotal lichen simplex chronicus with 0.1% tacrolimus ointment. J Eur Acad Dermatol Venereol 2015; 29: 1448.

Pruritus Vulvae

The vulva is a common site for pruritus of different causes. Pruritus vulvae (Fig. 4.6) is the counterpart of pruritus scroti. In a prospective series of 141 women with chronic vulvar symptoms, the most common causes were unspecified dermatitis (54%), lichen sclerosus (13%), chronic vulvovaginal candidiasis (10%), dysesthetic vulvodynia (9%), and psoriasis (5%). In prepubertal children, such itching is most frequently irritant in nature, and girls generally benefit from education about improved hygienic measures.

Vaginal candidiasis is a frequent cause of pruritus vulvae. This is true especially during pregnancy and when oral antibiotics are taken. The inguinal, perineal, and perianal areas may be affected. Microscopic examination for *Candida albicans* and cultures for fungus should be performed. *Trichomonas vaginalis* infection may cause vulvar pruritus. For the detection of *T. vaginalis*, examination of vaginal secretions is often diagnostic. The organism is recognized by its motility, size (somewhat larger than a leukocyte), and piriform shape.

Contact dermatitis from sanitary pads, contraceptives, douche solutions, fragrance, preservatives especially in moist towelettes, colophony, benzocaine, corticosteroids, and a partner's condoms may account for vulvar pruritus. Urinary incontinence should also be considered. Lichen sclerosus is another frequent cause of pruritus in the genital area in middle-age and elderly women. Lichen planus may involve the vulva, resulting in pruritus and mucosal changes, including erosions and ulcerations, resorption of the labia minora, and atrophy.

When burning rather than itching predominates, the patient should be evaluated for signs of sensory neuropathy.

Treatment

Candidiasis and *Trichomonas* treatments are discussed in Chapters 15 and 20, respectively. Lichen sclerosus responds best to pulsed dosing of high-potency topical steroids or to topical tacrolimus or pimecrolimus. Topical steroidal agents and topical tacrolimus may be used to treat psychogenic pruritus or irritant or allergic reactions. The use of silk fabric underwear may limit irritation. Patch testing will assist in identifying the inciting allergen. High-potency topical steroids are effective in treating lichen planus, but other options are also available (see Chapter 12). Topical lidocaine, topical pramoxine, or an oral tricyclic antidepressant (TCA) may be helpful in select cases. Phototherapy using a comb light device may be effective. Any chronic skin disease that does not respond to therapy should prompt a biopsy.

Puncta Pruritica (Itchy Points)

"Itchy points" consists of one or two intensely itchy spots in clinically normal skin, sometimes followed by the appearance of seborrheic keratoses at exactly the same site. Curettage, cryosurgery, punch biopsy, or botulinum toxin A injection of the itchy points may cure the condition.

Salardini A, et al: Relief of intractable pruritus after administration of botulinum toxin A. Clin Neuropharmacol 2008; 31: 303.

Aquagenic Pruritus and Aquadynia

Aquagenic pruritus is itching evoked by contact with water of any temperature. Most patients experience severe, prickling discomfort within minutes of exposure to water or on cessation of exposure to water. There are two groups of patients: about one third consist of an older, primarily male population who have polycythemia vera, hypereosinophilic syndrome, or myelodysplastic syndrome, and two thirds are younger women who develop aquagenic pruritus as young adults and who have no known underlying disease and may have a family history of similar symptoms.

Aquagenic pruritus must be distinguished from xerosis as water may be perceived as an irritant in severely dry skin, and in these cases an initial trial of "soaking and smearing," as previously described for winter itch, is recommended. Treatment options for aquagenic pruritus include the use of antihistamines, sodium bicarbonate dissolved in bath water, propranolol, atenolol, SSRIs, acetylsalicylic acid (ASA, aspirin), pregabalin, montelukast, and NB UVB or PUVA phototherapy. One patient found tight-fitting clothing settled the symptoms after only 5 minutes.

Shelley et al. reported two patients with widespread burning pain that lasted 15–45 minutes after water exposure, calling this reaction "aquadynia" and considering the disorder a variant of aquagenic pruritus. Clonidine and propranolol seemed to provide some relief.

Shelley WB, et al: Aquadynia. J Am Acad Dermatol 1998; 38: 357.

Scalp Pruritus

Pruritus of the scalp, especially in elderly persons, is rather common. Lack of excoriations, scaling, or erythema excludes inflammatory causes of scalp pruritus such as seborrheic dermatitis, psoriasis, dermatomyositis, or lichen simplex chronicus. Most such cases remain are neuropathic or idiopathic, but some represent chronic folliculitis. Treatment with topical tar shampoos, salicylic acid shampoos, corticosteroid topical gels, mousse, shampoos, and liquids can be helpful. In patients who have severe scalp pruritus with localized itch, an intralesional injection of corticosteroid suspension may provide relief. Minocycline or oral antihistamines may be helpful. In other patients, low doses of antidepressants, such as doxepin, are useful.

Shumway NK, et al: Neurocutaneous disease: Neurocutaneous dysesthesias. J Am Acad Dermatol 2016; 74: 215.

Drug-Induced Pruritus

Medications should be considered a possible cause of pruritus with or without a skin eruption. For example, pruritus is frequently present after opioid use. Also, chloroquine and to a lesser degree other antimalarials produce pruritus in many patients, especially African Americans, treated for malaria. SSRIs and drugs causing cholestatic liver disease are other frequent causes.

Hydroxyethyl starch (HES) is used as a volume expander, a substitute for human plasma. One third of all patients treated will develop severe pruritus with long latency of onset (3–15 weeks) and persistence. Up to 30% of patients have localized symptoms. Antihistamines are ineffective.

Chronic Pruritic Dermatoses of Unknown Cause

Prurigo simplex is the preferred term for the chronic itchy idiopathic dermatosis described here. Papular dermatitis, subacute prurigo, "itchy red bump" disease, urticarial dermatitis, the eruption of senescence of Berger, and Rosen papular eruption in black men most likely represent variations of prurigo simplex. The term prurigo continues to lack nosologic precision.

Prurigo simplex is characterized by the lesion known as the prurigo papule, which is dome shaped and topped with a small vesicle. The vesicle is usually present only transiently because of its immediate removal by scratching, so that a crusted papule is more frequently seen. Prurigo papules are present in various stages of development and are seen mostly in middle-age or elderly persons of both genders. The trunk and extensor surfaces of the extremities are common sites, symmetrically distributed. Other areas include the face, neck, lower trunk, and buttocks. The lesions usually appear in crops, so that papulovesicles and the late stages of scarring may be seen at the same time. At times eczematous morphology may be intermixed.

The histopathology of prurigo simplex is nonspecific but often suggests an arthropod reaction. Spongiosis accompanied by a perivascular mononuclear infiltrate with some eosinophils is often found.

Many conditions may cause pruritic erythematous papules. Scabies, atopic dermatitis, insect bite reactions, papular urticaria, dermatitis herpetiformis, contact dermatitis, pityriasis lichenoides et varioliformis acuta (PLEVA), transient acantholytic dermatosis (TAD), papuloerythroderma of Ofuji, dermatographism, and physical urticarias should be considered. Biopsy may be helpful in differentiating dermatitis herpetiformis, PLEVA, TAD, and on occasion, unsuspected scabies.

Treatment

The medications for initial treatment of prurigo simplex and its variants should be topical corticosteroids and oral antihistamines. Early in the disease process, moderate-strength steroids should be used; if the condition is found to be unresponsive, a change to high-potency forms is indicated. "Soaking and smearing" may be necessary. Intralesional injection of triamcinolone will eradicate individual lesions. For more recalcitrant disease, UVB or PUVA therapy may be beneficial. If such interventions do not provide relief, low-dose azathioprine, mycophenolate, or methotrexate may be needed.

Prurigo Pigmentosa

Prurigo pigmentosa is a rare dermatosis of unknown cause characterized by the sudden onset of erythematous papules or vesicles that leave reticulated hyperpigmentation when they heal (Fig. 4.7). The condition mainly affects Japanese, although numerous cases

Fig. 4.7 Prurigo pigmentosa. (Courtesy Department of Dermatology, Keio University School of Medicine, Tokyo, Japan.)

have been reported in Caucasians. Women outnumber men 2:1. The mean age of onset is 25. It is associated with weight loss, dieting, anorexia, post bariatric surgery, pregnancy, diabetes, and ketonuria. It is exacerbated by heat, sweating, and friction and thus occurs most often in the winter and spring. The areas most frequently involved are the upper back, nape, clavicular region, and chest. Mucous membranes are spared. Histology of early lesions shows neutrophils in the dermal papillae and epidermis. Following this, a lichenoid dermatitis with variable psoriasiform hyperplasia occurs. Direct immunofluorescence yields negative findings. The cause is unknown. Minocycline, 100–200 mg/day, is the treatment of choice. Dapsone and alteration of the diet are also effective; topical steroids are not effective. Recurrence and exacerbations are common.

Papuloerythroderma of Ofuji

A rare disorder most often found in Japan, papuloerythroderma of Ofuji (PEO) is characterized by flat-topped, red-to-brown pruritic papules that spare the skinfolds, producing bands of uninvolved cutis, the so-called deck-chair sign. Almost all patients are over age 55, with clear male predominance. Frequently, there is associated blood eosinophilia. Skin biopsies reveal a dense lymphohistiocytic infiltrate, eosinophils in the papillary dermis, and increased Langerhans cells. Malignancies have occurred in 21% of reported cases, but the timing and course do not always often correlate with PEO. Reported malignancies include T-cell lymphomas, B-cell lymphomas, Sézary syndrome, and visceral carcinomas. Drugs (e.g., aspirin, ranitidine, furosemide) and infections (e.g., HIV, hepatitis C) may induce the condition. Severe atopic dermatitis and cutaneous T-cell lymphoma may present with identical morphologic finding of PEO. History will assist in making the diagnosis of atropic dermatitis, whereas biopsy may reveal findings diagnostic of eruptions.

Systemic steroids are the treatment of choice and may result in long-term remission. Topical or systemic steroids, tar derivatives, emollients, systemic retinoids, cyclosporine, UVB, and PUVA may also be therapeutic. UV therapy, with or without steroids, is favored.

Torchia D, et al: Papuloerythroderma 2009. Dermatology 2010; 220: 311.

Lichen Simplex Chronicus

Also known as circumscribed neurodermatitis, lichen simplex chronicus results from long-term chronic rubbing and scratching, more vigorously than a normal pain threshold would permit, with the skin becoming thickened and leathery. The normal markings of the skin become exaggerated (Fig. 4.8), so that the striae form a crisscross pattern, producing a mosaic in between composed of flat-topped, shiny, smooth quadrilateral facets. This change, known as lichenification, may originate on seemingly normal skin or may develop on skin that is the site of another disease, such as atopic or allergic contact dermatitis or ringworm. Such underlying etiologies should be sought and, if found, treated specifically. Paroxysmal pruritus is the main symptom.

Circumscribed, lichenified pruritic patches may develop on any part of the body; however, lichen simplex chronicus has a predilection for the back and sides of the neck, the scalp, the upper eyelid, the orifice of one or both ears, the palm, soles, or often the wrist and ankle flexures. The vulva, scrotum, and anal areas are common sites, although the genital and anal areas are seldom involved at the same time. The eruption may be papular, resembling lichen planus; and in other cases the patches are excoriated, slightly scaly or moist, and rarely, nodular. Persistent rubbing of the shins or upper back may result in dermal deposits of amyloid and the subsequent development of lichen or macular amyloidosis, respectively.

Fig. 4.8 Lichen simplex chronicus.

The onset of this dermatosis is usually gradual and insidious. Chronic scratching of a localized area may be a response to an inciting dermatitis; however, scratching of the localized site continues long after the original insult and becomes a habit. It may be associated with anxiety disorders and in depressed patients, with erectile dysfunction.

Treatment. Cessation of pruritus is the goal with lichen simplex chronicus. It is important to stress the need for the patient to avoid scratching the areas involved if the sensation of itch is ameliorated. Recurrences are frequent, even after the most thorough treatment, and in some cases the clearance of one lesion will see the onset of another elsewhere.

A high-potency steroid cream or ointment should be used initially but not indefinitely because of the potential for steroid-induced atrophy. Occlusion of medium-potency steroids may be beneficial. Use of a steroid-containing tape to provide both occlusion and antiinflammatory effects may have benefit. Treatment can be shifted to the use of medium- to lower-strength topical steroid creams as the lesions resolve. Topical doxepin, capsaicin, or pimecrolimus cream or tacrolimus ointment provides significant antipruritic effects and is a good adjunctive therapy.

Intralesional injections of triamcinolone suspension, using a concentration of 2.5–5 mg/mL, may be required. Too superficial an injection invites the twin risks of epidermal and dermal atrophy and depigmentation, which may last for many months. The suspension should not be injected into infected lesions because it may cause abscess. Botulinum toxin A injection may be curative. In

the most severe cases, complete occlusion with an Unna boot may break the cycle.

Prurigo Nodularis

Prurigo nodularis is a disease with multiple itchy nodules mainly on the extremities (Fig. 4.9), especially on the anterior surfaces of the thighs and legs. A linear arrangement is common. The individual lesions are pea sized or larger, firm, and erythematous or brownish. When fully developed, they become verrucous or fissured. The course of the disease is chronic, and the lesions evolve slowly. Itching is severe but usually confined to the lesions themselves. Bouts of extreme pruritus often occur when these patients are under stress. Prurigo nodularis is one of the disorders in which the pruritus is characteristically paroxysmal: intermittent, unbearably severe, and relieved only by scratching to the point of damaging the skin, usually inducing bleeding and often scarring.

The cause of prurigo nodularis is unknown; multiple factors may contribute, including atopic dermatitis, hepatic diseases (including hepatitis C), HIV disease, pregnancy, renal failure, lymphoproliferative disease, stress, and insect bites. Pemphigoid nodularis may be confused with prurigo nodularis clinically.

The histologic findings are those of compact hyperkeratosis, irregular acanthosis, multinucleated keratinocytes, and a perivascular mononuclear cell infiltrate in the dermis. Dermal collagen may be increased, especially in the dermal papillae, and subepidermal fibrin may be seen, both evidence of excoriation. In cases associated with renal failure, transepidermal elimination of degenerated collagen may be found.

Fig. 4.9 Prurigo nodularis. (Courtesy Debabrata Bandyopadhyay, MD.)

Treatment. The initial treatment of choice for prurigo nodularis is intralesional or topical administration of steroids. Usually, superpotent topical products are required, but at times, lower-strength preparations used with occlusion may be beneficial, as when administered as the "soak and smear" regimen. The use of steroids in tape (Cordran) and prolonged occlusion with semipermeable dressings, such as used for treating nonhealing wounds, can be useful in limited areas. Intralesional steroids will usually eradicate individual lesions, but unfortunately, many patients have too extensive disease for these local measures. PUVA, NB UVB, and UVA alone have been shown to be effective in some patients. The combination product containing calcipotriene and betamethasone dipropionate ointment, calcitriol ointment, or tacrolimus ointment applied topically twice daily may be therapeutic and steroid sparing. Isotretinoin, 1 mg/kg/day for 2–5 months, may benefit some patients. Managing dry skin with emollients and avoidance of soap, with administration of antihistamines, antidepressants, or anxiolytics, is of moderate benefit in allaying symptoms.

Good results have been obtained with thalidomide, lenalidomide, pregabalin, and cyclosporine. With thalidomide, onset may be rapid or slow, and sedation may occur; initial dose is 100 mg/day, titered to the lowest dose required. Patients treated with thalidomide are at risk for developing a dose-dependent neuropathy at cumulative doses of 40–50 g. Lenalidomide, an analog of thalidomide, has less problems with neuropathy but may cause myelosuppression, venous thrombosis, and Stevens-Johnson syndrome. Methotrexate, 7.5–20 mg weekly produced improvement in 10 of 13 treated patients. Pregabalin, 75 mg/day for 3 months, improved 23 of 30 patients in one study. Cyclosporine at doses of 3–4.5 mg/kg/day has also been shown to be effective in treating recalcitrant disease. Cryotherapy may be used adjunctively. Multimodal therapy, combining topical and systemic therapies, can improve results.

Psychodermatology

Some purely cutaneous disorders are psychiatric in nature, their cause being directly related to psychopathologic causes in the absence of primary dermatologic or other organic causes. Delusions of parasitosis, psychogenic (neurotic) excoriations, factitial dermatitis, and trichotillomania compose the major categories of psychodermatology. The differential diagnosis for these four disorders is twofold, requiring the exclusion of organic causes and the definition of a potential underlying psychological disorder.

Bromidrosiphobia is another delusional disorder. Body dysmorphic disorder is a spectrum of disease; some severely affected patients are delusional, whereas others have more insight and are less functionally impaired.

Psychosis is characterized by the presence of delusional ideation, which is defined as a fixed misbelief that is not shared by the patient's subculture. Monosymptomatic hypochondriacal disorder is a form of psychosis characterized by delusions regarding a particular hypochondriacal concern. In contrast to schizophrenia, there are no other mental deficits, such as auditory hallucination, loss of interpersonal skills, or presence of other inappropriate actions. Patients with monosymptomatic hypochondriacal psychosis often function appropriately in social settings, except for a single fixated belief that there is a serious problem with their skin or with other parts of their body.

Skin Signs of Psychiatric Illness

The skin is a frequent target for the release of emotional tension. Some of the signs described here may become repetitive compulsions that impair normal life functions and may be manifestations of an obsessive-compulsive disorder. Self-injury by prolonged, compulsive repetitious acts may produce various mutilations, depending on the act and site of injury.

Self-biting may be manifested by biting the nails (onychophagia) or recurrent manipulation of components of the nail unit (onychotillomania) (Fig. 4.10), skin (most frequently the forearms, hands, and fingers), and lip. Dermatophagia is a habit or compulsion, conscious or subconscious. Bumping of the head produces lacerations and contusions, which may be so severe as to produce cranial defects and life-threatening complications. Compulsive repetitive handwashing may produce an irritant dermatitis of the hands (Fig. 4.11).

Bulimia, with its self-induced vomiting, results in Russell sign—crusted papules on the dorsum of the dominant hand from cuts by the teeth. Clenching of the hand produces swelling and ecchymosis of the fingertips and subungual hemorrhage. Self-inflicted lacerations may be of suicidal intent. Lip licking produces increased salivation and thickening of the lips. Eventually, the perioral area becomes red and produces a distinctive picture resembling the exaggerated mouth makeup of a clown. Pressure produced by binding the waistline tightly with a cord will eventually lead to atrophy of the subcutaneous tissue.

Psychopharmacologic agents, especially the newer atypical antipsychotic agents, and behavioral therapy alone or in combination with these agents are the treatments of choice.

Delusional Infestation (Delusions of Parasitosis)

Delusional infestation (Ekbom syndrome) is a firm fixation in a person's mind that he or she suffers from a parasitic infestation of the skin. At times, close contacts may share the delusion (folie a deux or trios). The belief is so fixed that the patient often pick small pieces of epithelial debris from the skin and bring them to be examined, insisting that the offending parasite is contained in such material. Samples of alleged parasites enclosed in assorted containers, paper tissue, or sandwiched between adhesive tape are so characteristic that it is referred to as the "matchbox" or "ziplock" sign. Usually, the only symptom is pruritus or a stinging, biting, or crawling sensation. Intranasal formication, or a crawling sensation of the nasal mucosa, is common in this condition. Cutaneous findings may range from none to excoriations, prurigo nodularis, and frank ulcerations.

Frequently, these patients have paranoid tendencies. Women are affected 2:1 over men, often during middle or old age, although there is a bimodal peak, with some patients presenting in their 20s or 30s. The condition has been reported to be associated with schizophrenia, bipolar disorders, depression, anxiety disorders, and

Fig. 4.10 Onychophagia. (Courtesy Curt Samlaska, MD.)

Fig. 4.11 Irritant dermatitis from chronic handwashing.

obsessional states but is usually a monosymptomatic hypochondriacal disorder. A variety of organic conditions may be causative and should be considered. They include cocaine, alcohol, and amphetamine abuse; dementia and other neurologic conditions (e.g., multiple sclerosis, central nervous system tumors, epilepsy, Parkinson disease); malignancies, particularly lymphoma and leukemia; cerebrovascular disease; endocrine disorders; infectious diseases; pellagra; and vitamin B_{12} deficiency. A variety of medications, including gabapentin, antiparkinsonian and antihistaminic drugs, and corticosteroids, may also produce this condition. Some of these agents may produce cutaneous symptoms, particularly pruritus, which may contribute to the delusion.

The differential diagnosis is influenced by the cutaneous findings and history. Initial steps should be directed at excluding a true infestation, such as scabies, or an organic cause. A thorough history, particularly in reference to therapeutic and recreational drug use (e.g., amphetamines, alcohol, cocaine), review of systems, and physical examination should be performed. Many consider Morgellons disease simply to be another name for delusions of parasitosis. Patients complain of crawling, biting, burning, or other sensations that cause them to be intensely anxious. Often, granules or fibers are provided by the patient for analysis. Many patients have associated psychiatric conditions.

A skin biopsy is frequently performed, more to reassure the patient than to uncover occult skin disease. Screening laboratory tests to exclude systemic disorders should be obtained: CBC; urinalysis; liver, renal, and thyroid function tests; iron studies; serum glucose and serum B_{12}; folate; and electrolyte levels. Once organic causes have been eliminated, the patient should be evaluated to determine the cause of the delusions. Schizophrenia, monosymptomatic hypochondriacal psychosis, psychotic depression, dementia, and depression with somatization are considerations in the differential diagnosis.

Management of this difficult problem varies. Although referral to a psychiatrist may seem best, most frequently the patient will reject suggestions to seek psychiatric help. The dermatologist is cautioned against confronting the patient with the psychogenic nature of the disease. It is preferable to develop trust, which will usually require several visits. If pharmacologic treatment is undertaken, the patient may accept it if the medication is presented as one that will alter the perception of this bothersome sensation. Pimozide was the long-standing treatment of choice given at relatively low dosages, in the 1–4 mg range. Although this strategy has limited side effects, newer, atypical antipsychotic agents, such as risperidone (0.5–6 mg/day), olanzapine (2.5–20 mg/day), quetiapine (25–600 mg/day), and aripiprazole (2–30 mg/day), are safer and considered the appropriate first-line agents, although the experience with them is more limited. With appropriate pharmacologic intervention, at least 50% of patients will likely remit.

Fig. 4.12 Psychogenic excoriations. (Courtesy Steven Binnick, MD.)

Excoriation Disorder

This condition is also called psychogenic excoriations, neurotic excoriations or skin picking disorder. Many persons have unconscious compulsive habits of picking at themselves, and at times the tendency is so persistent and pronounced that excoriations of the skin result. The lesions are caused by picking, digging, or scraping and usually occur on parts readily accessible to the hands. These patients admit their actions induce the lesions but cannot control their behavior.

The excavations may be superficial or deep and are often linear. The bases of the ulcers are clean or covered with a scab. Right-handed persons tend to produce lesions on their left side and left-handed persons on their right side. There is evidence of past healed lesions, usually with linear scars, or rounded hyperpigmented or hypopigmented lesions, in the area of the active excoriations. The face, upper arms, and upper back are common sites for these excoriations (Fig. 4.12). Sometimes the focus is on acne lesions, producing acne excoriée.

Most of these patients are otherwise healthy adults leading normal lives. The organic differential diagnosis is vast and includes any condition that may manifest with excoriations. The most common psychopathologies associated with neurotic excoriations are depression, obsessive-compulsive disorder, and anxiety.

The treatment of choice is doxepin because of its antidepressant and antipruritic effects; doses are slowly increased to 100 mg or higher, if tolerated. Many alternatives to doxepin may be indicated, especially in those affected by an obsessive-compulsive component. *N*-acetylcysteine 1200 to 3000 mg/day is safe and tolerable option, which is now being studied in many psychodermatologic conditions. It has been shown to be effective in this excoriation disorder. Treatment is difficult, often requiring a combined psychiatric and pharmacologic intervention. It is important to establish a constructive patient-therapist alliance. Training in diversion strategies during "scratching episodes" may be helpful. An attempt should be made to identify specific conflicts or stressors preceding onset. The therapist should concentrate on systematic training directed at the behavioral reaction pattern. There should be support and advice given with regard to the patient's social situation and interpersonal relations.

Factitious Dermatitis and Dermatitis Artefacta

Factitious dermatitis is the term applied to self-inflicted skin lesions with the intent to elicit sympathy, escape responsibility, or collect disability insurance. Malingering applies to the latter two cases, where material gain is the objective. This contrasts with the usual dermatitis artefacta patient, who has an unconscious goal of gaining attention and assuming the sick patient role. Most patients are adults in midlife, with women affected three times more often than men. The vast majority have multiple lesions and are unemployed or on sick leave. These skin lesions are provoked by mechanical means or by the application or injection of chemical irritants and caustics. These patients often have a "hollow" history, unable to detail how the lesions appeared or evolved. The lesions may simulate other dermatoses but usually have a distinctive, geometric, bizarre appearance (Fig. 4.13), often with a shape and arrangement not encountered in other disorders. The lesions are generally distributed on parts easily reached by the hands, tend to be linear and arranged regularly and symmetrically, and are rarely seen on the dominant hand.

When chemicals are used, red streaks or guttate marks are often seen beneath the principal patch, where drops of the chemical have accidentally run or fallen on the skin. According to the manner of production, the lesions may be erythematous, vesicular, bullous, ulcerative, or gangrenous. The more common agents of destruction used are the fingernails, pointed instruments, hot metal, chemicals (e.g., carbolic, nitric, or acetic acid), caustic potash or soda, turpentine, table salt, urine, and feces. The lesions are likely to appear in crops. At times the only sign may be the indefinitely delayed healing of an operative wound, which is purposely kept open by the patient. Tight cords or clothing tied around an arm or leg may produce factitious lymphedema, which may be mistaken for postphlebitic syndrome or nerve injury, as well as other forms of chronic lymphedema.

Subcutaneous emphysema, manifesting as cutaneous crepitations, may be factitial in origin. Recurrent migratory subcutaneous emphysema involving the extremities, neck, chest, or face can be induced through injections of air into tissue with a needle and syringe. Circular pockets and bilateral involvement without physical findings, indicating contiguous spread from a single source, suggest a factitial origin. Puncturing the buccal mucosa through to facial skin with a needle and puffing out the cheeks can produce alarming results. Neck and shoulder crepitation is also a complication in manic patients that results from hyperventilation and breath holding.

Fig. 4.13 Factitial ulcers and scarring.

The organic differential diagnosis depends on the cutaneous signs manifested, such as gas gangrene for patients with factitious subcutaneous emphysema and the various forms of lymphedema for factitious lymphedema. A subset of these patients have Munchausen syndrome. They tend to cause lesions that closely simulate known conditions, and they create an intricate, often fantastic story surrounding the problem. Admissions to the hospital with extensive workup often result. Parents may induce lesions on their child to gain attention, so-called Munchausen by proxy, which is really child abuse. Considerations for psychopathology in dermatitis artefacta include borderline personality disorders and psychosis.

Proof of diagnosis is sometimes difficult. Occlusive dressings may be necessary to protect the lesions from ready access by the patient. It is usually best not to reveal any suspicion of the cause to the patient and to establish the diagnosis definitively without the patient's knowledge. If the patient is hospitalized, a resourceful, cooperative nurse may be useful in helping to establish the diagnosis. When injection of foreign material is suspected, examination of biopsy material by spectroscopy may reveal talc or other foreign material. Additionally epidermal multinucleated keratinocytes may be present as a clue.

Treatment should ideally involve psychotherapy, but typically the patient promptly rejects the suggestion and goes to another physician to seek a new round of treatment. It is best for the dermatologist to maintain a close relationship with the patient and provide symptomatic therapy and nonjudgmental support. SSRIs may address associated depression and anxiety. Very-low-dose atypical antipsychotics may also be added, if needed. Consultation with an experienced psychiatrist is prudent.

Trichotillomania

Trichotillomania (trichotillosis or hair pulling disorder) is characterized by an abnormal urge to pull out the hair. The sites involved are generally the frontal region of the scalp, eyebrows, eyelashes, and the beard. The classic presentation is the "Friar Tuck" form of vertex and crown alopecia. There are irregular areas of hair loss, which may be linear or bizarrely shaped. Infrequently, adults may pull out pubic hair. Hairs are broken and show differences in length (Fig. 4.14). The pulled hair may be ingested, and occasionally the trichobezoar will cause obstruction. When the tail extends from the main mass in the stomach to the small or large intestine, Rapunzel syndrome is the diagnosis. The nails may show evidence of onychophagy (nail biting), but no pits are present. The disease is seven times more common in children than in adults, and girls are affected 2.5 times more often than boys.

Trichotillomania often develops in the setting of psychosocial stress in the family, which may involve school problems, sibling rivalry, moving to a new house, hospitalization of a parent, or a disturbed parent-child relationship.

Differentiation from alopecia areata is possible because of the varying lengths of broken hairs present, the absence of nail pitting, and the microscopic appearance of the twisted or broken hairs in contrast to the tapered fractures of alopecia areata. Other organic disorders to consider are androgenic alopecia, tinea capitis,

Fig. 4.14 Trichotillomania.

monilethrix, pili torti, pseudopelade of Brocq, traction alopecia, syphilis, nutritional deficiencies, and systemic disorders such as lupus and lymphoma. Trichoscopy reveals broken hairs of varying lengths; some may be frayed, longitudinally split, or coiled. If necessary, a biopsy can be performed and is usually quite helpful. It reveals traumatized hair follicles with perifollicular hemorrhage, fragmented hair in the dermis, empty follicles, pigmented casts, and deformed hair shafts (trichomalacia). Multiple catagen hairs are typically seen. An alternative technique to biopsy, particularly for children, is to shave a part of the involved area and observe for regrowth of normal hairs. The differential diagnosis for this impulse control disorder should include underlying comorbid psychopathology, such as an obsessive-compulsive disorder (most common), depression, or anxiety.

In children, the diagnosis should be addressed openly, and referral to a child psychiatrist for cognitive-behavioral therapy (CBT) should be encouraged. Habit-reversal training is often part of the treatment. In adults with the problem, psychiatric impairment may be severe. Pharmacotherapy with clomipramine or olanzapine is the most effective of the studied medications, but SSRIs are most often prescribed and may help any associated depression or anxiety. *N*-acetylcysteine also shows promise especially in adults; it is available in health food stores and is relatively inexpensive and well tolerated. Trichobezoars require surgical removal.

Dermatothlasia

Dermatothlasia is a cutaneous neurosis characterized by a patient's uncontrollable desire to rub or pinch himself or herself to form bruised areas on the skin, sometimes as a defense against pain elsewhere.

Olfactory Reference Syndrome

Also called bromidrosiphobia or delusions of bromhidrosis, this is a monosymptomatic delusional state in which a person is convinced that his or her sweat has a repugnant odor that keeps other people away. The patient is unable to accept any evidence to the contrary. Three quarters of patients with bromidrosiphobia are male, with an average age of 25. Atypical antipsychotic agents or pimozide may be beneficial. It may be an early symptom of schizophrenia.

Body Dysmorphic Disorder (Dysmorphic Syndrome, Dysmorphophobia)

Body dysmorphic disorder is the excessive preoccupation of having an ugly body part. It is most common in young adults of either gender. The concern is frequently centered about the nose, mouth, genitalia, breasts, or hair. Objective evaluation will reveal a normal appearance or slight defect. These patients are usually seen in dermatologic practice, especially among those presenting for cosmetic surgery evaluation. Patients may manifest obsessional features, spending long periods inspecting the area. Associated depression and social isolation along with other comorbidities present a high risk of suicide. The SSRIs accompanied by CBT give the best results for those with this somatoform disorder. More severely affected patients have delusions that may lead to requests for repeated surgeries of the site and require antipsychotic medications.

CUTANEOUS DYSESTHESIA SYNDROMES

Cutaneous dysesthesia syndromes are characterized by pain and burning sensations without objective findings. Many patients report coexisting pruritus or transient pruritus associated with the dysesthesia.

Shumway NK, et al: Neurocutaneous disease: neurocutaneous dysesthesias. J Am Acad Dermatol 2016; 74: 215.

Scalp Dysesthesia

Scalp dysesthesia occurs primarily in middle-age to elderly women. Cervical spine degenerative disk disease is frequently present. The hypothesis is that chronic tension is placed on the occipitofrontalis muscle and scalp aponeurosis. In one series, gabapentin helped four of the seven patients seen in follow-up. A psychiatric overlay

is frequently associated, and treatment with low-dose antidepressants may also be helpful. If a history of a prior brow or face lift is elicited, surgical trauma to the face or scalp nerves may account for the symptoms.

Thornsberry LA, et al: Scalp dysesthesia related to cervical spine disease. JAMA Dermatol 2013; 149: 200.

Burning Mouth Syndrome (Glossodynia, Burning Tongue)

Burning mouth syndrome (BMS) is divided into two forms: a primary type characterized by a burning sensation of the oral mucosa, with no dental or medical cause, and secondary BMS, caused by a number of conditions, including lichen planus, candidiasis, vitamin or nutritional deficiencies (e.g., low B_{12}, iron, or folate), hypoestrogenism, parafunctional habits, diabetes, hypothyroidism, HIV, herpes simplex viral shedding, dry mouth, contact allergies, cranial nerve injuries, and medication side effects. Identification of the underlying condition and its treatment will result in relief of secondary BMS.

Primary BMS occurs most frequently in postmenopausal women. They are particularly prone to a feeling of burning of the tongue, mouth, and lips, with no objective findings. Symptoms vary in severity but are more or less constant. Patients with BMS often complain that multiple oral sites are involved. Management with topical applications of clonazepam, capsaicin, doxepin, or lidocaine can help. Oral administration of α-lipoic acid, SSRIs or TCAs, gabapentin, pregabalin, and benzodiazepines has been reported to be effective. The most common, best studied, and most successful therapy is provided by the antidepressant medications, because many patients are depressed as well.

Burning lips syndrome may be a separate entity; it appears to affect both men and women equally and occurs in individuals between ages 50 and 70. The labial mucosa may be smooth and pale, and the minor salivary glands of the lips are frequently dysfunctional. Treatment with α-lipoic acid showed improvement in 2 months in a double-blind controlled study.

Vulvodynia

Vulvodynia is defined as vulvar discomfort, usually described as burning pain, occurring without medical findings. It is chronic, defined as lasting 3 months or longer. Two subtypes are seen, the localized and generalized subsets. Both may occur only when provoked by physical contact, as a spontaneous pain, or mixed in type. Vulvar pain may be secondary to many specific underlying disorders, but when caused by infections (most often candidal or herpetic), inflammatory conditions (e.g., lichen planus, autoimmune blistering disease), neoplastic disorders (e.g., extramammary Paget disease, squamous cell carcinoma), neurologic etiologies (e.g., spinal nerve compression, herpetic neuralgia), or previous radiotherapy, these conditions are treated appropriately, and the patient's condition is not categorized as vulvodynia. Thus the diagnosis of vulvodynia is a diagnosis of exclusion.

The pain experienced may be debilitating. It may be accompanied by pelvic floor abnormalities, headaches, fibromyalgia, irritable bowel syndrome, and interstitial cystitis. Psychosocial problems result and may be exacerbated by stress, depression, or anxiety or may lead to such conditions over time. A male counterpart may be seen and has been called burning genital skin syndrome and dysesthetic penodynia or scrotodynia.

Treatment should always include patient and partner education and psychological support, including sex therapy and counseling, as appropriate. Spontaneous remission occurs in 90% of patients, but half recur within 6–30 months. Topical anesthetics and lubricants, such as petrolatum, applied before intercourse may be tried initially. Elimination of irritants, treatment of atopy with topical tacrolimus (allowing for the discontinuance of topical steroids, which have usually been tried without success), and the use of antihistamines for dermatographism may be helpful. Pelvic floor physical therapy and at times cognitive behavioral therapy may be useful. Vulvodynia is considered among the chronic pain syndromes that can have a psychological impact. Treatment then centers on the use of TCAs, SSRIs, and neuroleptics, chiefly gabapentin or pregabalin. Other interventions, such as botulinum toxin A and surgery, may be considered in individual patients, but the evidence for any of these therapies is limited.

Notalgia Paresthetica

Notalgia paresthetica is a unilateral sensory neuropathy characterized by infrascapular pruritus, burning pain, hyperalgesia, and tenderness, often in the distribution of the second to sixth thoracic spinal nerves. A pigmented patch localized to the area of pruritus is often found, caused by postinflammatory change. Macular amyloidosis may be produced by chronic scratching. In most patients, degenerative changes in the corresponding vertebrae are seen, leading to spinal nerve impingement. When this is present, physical therapy, nonsteroidal antiinflammatory drugs (NSAIDs), gabapentin, oxycarbazepine, and muscle relaxants may be helpful, as may paravertebral blocks.

Topical capsaicin, corticosteroids, tacrolimus, or lidocaine patch has been effective, but relapse occurs in most patients after discontinuing use. Botulinum toxin A injections were reported to be successful, although an RCT failed to show efficacy. When it was effective excellent long-term results may occur, and injections may be repeated as necessary. NB UVB is also an option.

Brachioradial Pruritus

This condition is characterized by itching localized to the brachioradial area of the arm. To relieve the burning, stinging, or even painful quality of the itch, patients will frequently use ice packs. The majority will have the sun-induced variety, a variant of polymorphous light syndrome that usually responds well to broad-spectrum sunscreens (see Chapter 3). In the remaining patients, cervical spine pathology is frequently found on radiographic evaluation. Searching for causes of the abnormality should include discussion of spinal injury, such as trauma, arthritis, or chronic repetitive microtrauma, whiplash injury, or assessment for a tumor in the cervical spinal column.

Gabapentin, botulinum A toxin, topical amitriptyline-ketamine or capsaicin 8% patch, aprepitant, carbamazepine, cervical spine manipulation, neck traction, antiinflammatory medications, physical therapy, and surgical resection of a cervical rib have all been successful in individual patients with brachioradial pruritus.

Meralgia Paresthetica (Roth-Bernhardt Disease)

Persistent numbness and periodic transient episodes of burning or lancinating pain on the anterolateral surface of the thigh characterize Roth-Bernhardt disease. The lateral femoral cutaneous nerve innervates this area and is subject to entrapment and compression along its course. Sensory mononeuropathies besides notalgia paresthetica and meralgia paresthetica include mental and intercostal neuropathy and cheiralgia, gonyalgia, and digitalgia paresthetica.

Meralgia paresthetica occurs most frequently in middle-age adults. Although some series show an association with obesity, others do not. Additionally, diabetes mellitus is twice as common in these patients than in the general population. Among diabetics, meralgia paresthetica is seven times more common than seen in patients without diabetes. Alopecia localized to the area innervated by the lateral femoral nerve may be a skin sign of this disease. The pelvic compression test and the Tinel test are two physical findings based on relieving pressure on the nerve, or percussing it which can help verify the diagnosis at the bedside. External compression may occur from tight-fitting clothing, cell phones, or other heavy objects in the pockets or worn on belts, or seat belt injuries from automobile crashes. Internal compression from arthritis of the lumbar vertebrae, a herniated disk, pregnancy, intraabdominal disease that increases intrapelvic pressure, iliac crest bone graft harvesting, diabetes, neuroma, and rarely a lumbar spine or pelvic tumor have been reported causes in individual patients.

The diagnostic test of choice is somatosensory-evoked potentials of the lateral femoral cutaneous nerve. Local anesthetics (e.g., lidocaine patch), NSAIDs, rest, avoidance of aggravating factors, and weight reduction may lead to improvement; indeed, 70% of patients have spontaneous improvement, aided by conservative measures. Gabapentin is useful in various neuropathic pain disorders. Pulsed frequency neuomodulation and acupuncture are other nonsurgical methods that may be helpful. If such interventions fail and a nerve block rapidly relieves symptoms, local infiltration with corticosteroids is indicated. Surgical decompression of the lateral femoral cutaneous nerve can produce good to excellent outcomes but should be reserved for patients with intractable symptoms who responded to nerve blocks but not corticosteroids. If the nerve block does not result in symptom relief, computed tomography (CT) scan of the lumbar spine as well as pelvic and lower abdominal ultrasound examinations to assess for tumors are indicated.

Complex Regional Pain Syndrome

Encompassing the descriptors reflex sympathetic dystrophy, causalgia, neuropathic pain, and Sudek syndrome, complex regional pain syndrome (CRPS) is characterized by burning pain, hyperesthesia, and trophic disturbances resulting from injury to a peripheral nerve. The continuing pain is disproportionate to the injury, which may have been a crush injury, laceration, fracture, hypothermia, sprain, burn, or surgery. It usually occurs in one of the upper extremities, although leg involvement is also common. The characteristic symptom is burning pain aggravated by movement or friction. The skin of the involved extremity becomes shiny, cold, and atrophic and may perspire profusely. Additional cutaneous manifestations include bullae, erosions, edema, telangiectases, hyperpigmentation, ulcerations, and brownish red patches with linear fissures (Fig. 4.15).

The intensity of the pain in CRPS patients varies from trivial burning to a state of torture accompanied by extreme hyperesthesia and frequently hyperhidrosis. Not only is the part subject to an intense burning sensation, but also a touch of the finger also causes exquisite pain. Exposure to the air is avoided with scrupulous care, and the patient walks carefully, carrying the limb tenderly with the sound hand. Patients are tremulous and apprehensive, and they keep the hand constantly wet, finding relief in the moisture rather than in the temperature of the application. A condition resembling permanent chilblains or even trophic ulcers may be present.

Fig. 4.15 Complex regional pain syndrome.

The syndrome usually begins with severe, localized, burning pain. focal edema, muscle spasm, stiffness or restricted mobility, and vasospasm affecting skin color and temperature. These may be followed by a diffusion of the pain and edema, diminished hair growth, brittle nails, joint thickening, and onset of muscle atrophy. Finally, irreversible trophic changes, intractable pain involving the entire limb, flexor contractures, marked atrophy of the muscles, severe limitation in joint and limb mobility, and severe osteoporosis result.

Not all patients will have all the features of CRPS, and an early diagnosis improves the chance of cure. The four major components are categorized as sensory, vasomotor, sudomotor/edema, and motor/trophic. Signs pertaining to at least two of these categories and symptoms relating to three are necessary to meet the Budapest diagnostic criteria. A three-phase technetium bone scan is helpful in confirming the diagnosis of CRPS.

Consultation with a neurologist or an anesthesiologist specializing in pain is advisable. Osteoporosis is a frequent complication, and studies using pamidronate, a powerful inhibitor of bone absorption, have been shown to improve symptoms of pain, tenderness, and swelling significantly. Pain relief which allows for physical mobilization and massage is helpful. Additionally psychological intervention with patients, their families, and caregivers is important as they often require ongoing support, education, and counseling.

Wertli M, et al: Prognostic factors in complex regional pain syndrome. J Rehabil Med 2013; 45: 225.

Trigeminal Trophic Syndrome

Interruption of the peripheral or central sensory pathways of the trigeminal nerve may result in a slowly enlarging, unilateral, uninflamed ulcer on ala nasi or adjacent cheek skin. The nasal tip is spared. It may infrequently occur elsewhere on the face, scalp, ear, or palate. The neck has been reported to be affected in the so-called cervical trophic syndrome, secondary to herpes zoster–associated nerve injury. Onset of ulceration varies from weeks to several years after nerve injury from trauma, herpes zoster, or stroke. Biopsy to exclude tumor or a variety of granulomatous or infectious etiologies is usually indicated. The cause is self-inflicted trauma to the anesthetic skin; the appropriate treatment is to prevent this by occlusion or with psychotropic medication, which is often successful. Scarring may be severe.

Sawada T, et al: Trigeminal trophic syndrome. J Dermatol 2014; 41: 525.

Fig. 4.16 Neuropathic ulcer of the hand in a diabetic patient.

Mal Perforans Pedis

Also known as neuropathic ulceration or perforating ulcer mal perforans is a chronic ulcerative disease seen on the sole or hand in conditions that result in loss of pain sensation at a site of constant trauma (Fig. 4.16). The primary cause lies in the posterolateral tracts of the cord (in arteriosclerosis and tabes dorsalis), lateral tracts (in syringomyelia), or peripheral nerves (in diabetes or Hansen disease).

In most patients, mal perforans begins as a circumscribed hyperkeratosis, usually on the ball of the foot. This lesion becomes soft, moist, and malodorous and later exudes a thin, purulent discharge. A slough slowly develops, and an indolent necrotic ulcer is left that lasts indefinitely. Whereas the neuropathy renders the ulceration painless and walking continues, plantar ulcers in this condition have a surrounding thick callus. Deeper perforation and secondary infection often lead to osteomyelitis of the metatarsal or tarsal bones.

Treatment consists of relief of pressure on the ulcer through use of a total-contact cast and debridement of the surrounding callosity. Removable off-loading devices were found to be significantly less effective in a systematic review and meta-analysis. Administration of local and systemic antibiotics is sometimes helpful.

Bus SA: The role of pressure offloading on diabetic foot ulcer healing and prevention of recurrence. Plast Reconstr Surg 2016; 138: 179S.

Morona JK, et al: Comparison of the clinical effectiveness of different off-loading devices for the treatment of neuropathic foot ulcers in patients with diabetes. Diabetes Metab Res Rev 2013; 29: 183.

Sciatic Nerve Injury

Serious sciatic nerve injury can result from improperly performed injections into the buttocks. Older patients are more susceptible to injection-induced sciatic nerve injury because of their decreased muscle mass or the presence of debilitating disease. The most common scenario for nerve damage is improper needle placement. Other common causes of sciatic neuropathy are hip surgery complications, hip fracture and dislocation, and compression by benign and malignant tumors. A paralytic footdrop is the most common finding. There is sensory loss and absence of sweating

over the distribution of the sciatic nerve branches. The skin of the affected extremity becomes thin, shiny, and often edematous.

Surgical exploration, guided by nerve action potentials, with repair of the sciatic nerve is worthwhile and is most successful if done soon after injury.

Topuz K, et al: Early surgical treatment protocol for sciatic nerve injury due to injection. Br J Neurosurg 2011; 25: 509.

Syringomyelia

Syringomyelia results from cystic cavities inside the cervical spinal cord caused by alterations of cerebrospinal fluid flow. Compression of the lateral spinal tracts produces sensory and trophic changes on the upper extremities, particularly in the fingers. The disease begins insidiously and gradually causes muscular weakness, hyperhidrosis, and sensory disturbances, especially in the thumb and index and middle fingers. The skin changes are characterized by dissociated anesthesia with loss of pain and temperature sense but retention of tactile sense. Burns are the most frequent lesions noted. Bullae, warts, and trophic ulcerations occur on the fingers and hands, and eventually contractures and gangrene occur. Other unusual features include hypertrophy of the limbs, hands, or feet and asymmetric scalp hair growth with a sharp midline demarcation. The disease must be differentiated chiefly from Hansen disease. Unlike Hansen disease, syringomyelia does not interfere with sweating or block the flare around a histamine wheal.

Early surgical treatment allows for improvement of symptoms and prevents progression of neurologic deficits.

Blegvad C, et al: Syringomyelia. Acta Neurochir (Wien) 2014; 156: 2127.

Hereditary Sensory and Autonomic Neuropathies

A number of inherited conditions are characterized by variable degrees of motor and sensory dysfunctions combined with autonomic alterations. From a dermatologic standpoint, altered pain and temperature sensation, trophic changes, sweating abnormalities, ulcers of the hands and feet, and, in some patients, self-mutilating behavior may be present. These five syndromes and their variants are now known to be secondary to disease-producing mutations in 12 genes.

Rotthier A, et al: Mechanisms of disease in hereditary sensory and autonomic neuropathies. Nat Rev Neurol 2012; 8: 73.

5 Eczema, Atopic Dermatitis, and Noninfectious Immunodeficiency Disorders

Bonus images for this chapter can be found online at expertconsult.inkling.com

ECZEMA

The word *eczema* seems to have originated in 543 AD and is derived from the Greek word *ekzein*, meaning to "to boil forth" or "to effervesce." The term encompasses such disorders as dyshidrotic eczema and nummular eczema (NE), but at times is used synonymously for atopic dermatitis (atopic eczema). The acute stage generally presents as a red edematous plaque that may have grossly visible, small, grouped vesicles. Subacute lesions present as erythematous plaques with scale or crusting. Later, lesions may be covered by a drier scale or may become lichenified. In most eczematous reactions, severe pruritus is a prominent symptom. The degree of irritation at which itching begins (the itch threshold) is lowered by stress. Itching is often prominent at bedtime and usually results in insomnia. Heat and sweating may also provoke episodes of itching.

Histologically, the hallmark of all eczematous eruptions is a serous exudate between cells of the epidermis (spongiosis), with an underlying dermal perivascular lymphoid infiltrate and exocytosis (lymphocytes present in overlying epidermis singly or in groups). Spongiosis is generally out of proportion to the lymphoid cells in the epidermis. This is in contrast to mycosis fungoides, which demonstrates minimal spongiosis confined to the area immediately surrounding the lymphocytes.

In most eczematous processes, spongiosis is very prominent in the acute stage, where it is accompanied by minimal acanthosis or hyperkeratosis. Subacute spongiotic dermatitis demonstrates epidermal spongiosis with acanthosis and hyperkeratosis. Chronic lesions may have minimal accompanying spongiosis, but acute and chronic stages may overlap because episodes of eczematous dermatitis follow one another. Scale corresponds to foci of parakeratosis produced by the inflamed epidermis. A crust is composed of serous exudate, acute inflammatory cells, and keratin. Eczema, regardless of cause, will manifest similar histologic changes if allowed to persist chronically. These features are related to chronic rubbing or scratching and correspond clinically to lichen simplex chronicus or prurigo nodularis. Histologic features at this stage include compact hyperkeratosis, irregular acanthosis, and thickening of the collagen bundles in the papillary portion of the dermis. The dermal infiltrate at all stages is predominantly lymphoid, but an admixture of eosinophils may be noted. Neutrophils generally appear in secondarily infected lesions. Spongiosis with many intraepidermal eosinophils may be seen in the early spongiotic phase of pemphigoid, pemphigus, and incontinentia pigmenti, as well as some cases of allergic contact dermatitis.

ATOPIC DERMATITIS (ATOPIC ECZEMA)

Atopic dermatitis (AD) is a chronic, inflammatory skin disease characterized by pruritus and a chronic course of exacerbations and remissions. It is associated with other atopic conditions, including food allergies, asthma, allergic rhinoconjunctivitis, eosinophilic esophagitis, and eosinophilic gastroenteritis. Because AD usually precedes the appearance of these other atopic conditions, it has been proposed that AD is the first step in an "atopic march" whereby sensitization to allergens through the skin may lead to allergic responses in the airways or digestive tract. Although this sequence of atopic conditions does occur in many children, whether the AD is causal in the development of the other manifestations of atopy is unproved but plausible. For this reason, early and effective treatment of AD is encouraged in an effort to prevent other atopic conditions. The genetic defect(s) predisposing at-risk individuals to the development of AD is the same for asthma and allergic rhinoconjunctivitis, and thus it has been difficult to prove that AD is causal in the development of other atopic conditions.

Epidemiology

The prevalence of AD, asthma, and allergic rhinoconjunctivitis increased dramatically in the last half of the 20th century, becoming a major health problem in many countries. The increase began first in the most developed nations, and as the standard of living has increased worldwide, so has the prevalence of AD. Rates of AD are about 30% in the most developed nations and exceed 10% in many countries, resulting in a worldwide cumulative prevalence of 20%. In the most developed nations, the rates of AD plateaued in the 1990s, whereas developing nations have rates that continue to increase. Factors associated with high rates of AD are high latitude (perhaps associated with low levels of annual sun exposure) and lower mean annual temperature. A role for exposure to allergens thought to "trigger" AD is not supported by epidemiologic studies. Iceland has a very high rate of AD (27%) yet has no dust mites, few trees, and low pet ownership. However, children in Iceland often have positive skin prick tests to environmental allergens (24%). This questions the value of such tests in predicting causal environmental allergens in AD. Girls are slightly more likely to develop AD. In the United States an increased risk of AD during the first 6 months of life is noted in infants with African and Asian race/ethnicity, male gender, greater gestational age at birth, and a family history of atopy, particularly a maternal history of eczema. Other factors that increase the risk for the development of AD early in childhood include consumption of a Western diet, birth order (first children at greater risk), and delivery by cesarean section, all of which alter the intestinal microbiome. Exposure to antibiotics prenatally during the first or second and third trimesters also increases risk of AD. Therefore biodiversity in the gut microbiome seems to be protective. Gut colonization with *Clostridium* cluster I is associated with development of AD. Dog ownership before age 1 year decreases the risk of developing AD by age 4, but cat ownership has no effect. The hygiene hypothesis suggests that being raised on a farm lowers the risk of AD whereas living in modernized, cleaner indoor environments leads to a higher risk of AD.

About 50% of cases of AD appear in the first year of life, the vast majority within the first 5 years of life, and the remaining cases of "adult" AD usually before age 30. Atopy is now so common in the population that most individuals have a family history of atopy. Elevated immunoglobulin E (IgE) levels are not diagnostic of atopic disease in the adult. Therefore elevated IgE and a family history of "atopy" in an adult with new-onset dermatitis should not be used to confirm the diagnosis of adult AD. Adult AD should only be considered when the dermatitis has a characteristic distribution and when other significant diagnoses, such as allergic contact dermatitis, photodermatitis, and cutaneous T-cell lymphoma, have been excluded. Rather, a dermatologist should infrequently make

the diagnosis of adult "atopic dermatitis" for a dermatitis appearing for the first time after age 30.

Genetic Basis and Pathogenesis

Eighty percent of identical twins show concordance for AD. A child is at increased risk of developing AD if either parent is affected. More than one quarter of offspring of atopic mothers develop AD in the first 3 months of life. If one parent is atopic, more than half the children will develop allergic symptoms by age 2. This rate rises to 79% if both parents are atopic. All of these findings strongly suggested a genetic cause for AD. Filaggrin is a protein encoded by the gene *FLG*, that resides in the epidermal differentiation complex (EDC) on chromosome 1q21. Filaggrin is processed by caspase 14 during terminal keratinocyte differentiation into highly hydroscopic pyrrolidone carboxylic acid and urocanic acid, collectively known as the "natural moisturizing factor" (NMF). Null mutations in *FLG* lead to reduction in NMF, which probably contributes to the xerosis that is almost universal in AD. Transepidermal water loss (TEWL) is increased. This may be caused by subclinical dermatitis, but also by abnormal delivery of lamellar body epidermal lipids (especially ceramide) to the interstices of the terminally differentiated keratinocytes. The resulting defective lipid bilayers retain water poorly, leading to increased TEWL and clinical xerosis. Ichthyosis vulgaris is caused by mutations in the *FLG* gene and is frequently associated with AD. Four *FLG* mutations have an estimated combined allelic frequency of 7%–10% in individuals of European descent. Different *FLG* gene mutations are associated with AD in other ethnicities although the rates do not necessarily match AD prevalence, demonstrating that the disease is multifactorial. Filaggrin 2 *(FLG2)*, also in the EDC and with similar function to *FLG*, is associated with persistent AD in African Americans. Inheriting one null *FLG* mutation slightly increases one's risk of developing AD, and inheriting two mutations, either as a homozygote or a compound heterozygote, dramatically increases one's risk. Between 42% and 79% of persons with one or more *FLG* null mutations will develop AD. However, 40% of carriers with *FLG* null mutations never have AD. *FLG* mutations are associated with AD that presents early in life, tends to persist into childhood and adulthood, and is associated with wheezing in infancy and with asthma. *FLG* mutations are also associated with allergic rhinitis and keratosis pilaris, independent of AD. Hyperlinear palms are strongly associated with *FLG* mutations, with a 71% positive predictive value (PPV) for marked palmar hyperlinearity. *LAMA3* gene mutations, encoding the alpha chain of laminin 5, may also predispose to AD. In murine models, decreased Claudin 3 expression can lead to leakage of sweat in the superficial dermis contributing to impaired sweating in atopic dermatitis.

Not all cases of AD are associated with *FLG* mutations. AD patients often demonstrate immunologic features consistent with a T-helper 2 (Th2) phenotype, with elevated IgE, eosinophils on skin biopsy, and positive skin tests and radioallergosorbent test (RAST). The cytokines, especially interleukin-4 (IL-4) and interleukin-13 (IL-13), that are released due to the Th2 immune response play an important role in AD by increasing inflammatory cell infiltration and stimulating the inflammatory feedback loop. Basophils and innate type 2 lymphoid cells can also secrete IL-4 and IL-13. Thymic stromal lymphopoietin (TSLP) is an important interleukin-7 (IL-7)–like cytokine that, through its interaction with Th2 cells, basophils, mast cells, and dendritic cells, promotes the secretion and production of Th2 cytokines and the development of inflammatory Th2 CD4+ T cells (through production of OL40L). TSLP is produced by keratinocytes and is found in high levels in AD skin lesions. In addition, interleukin-31 (IL-31) is produced by Th2 and Th22 cells. IL-31 binds directly to nerves leading to itching and also downregulates expression of filaggrin. The JAK-STAT pathway is also critical in causing overactivation of the TH2 response and itch. Interleukin-17 (IL-17) and interleukin-22 (IL-22), which are released by Th17 cells, are also elevated in AD. Thus AD appears to represent a disorder characterized by a barrier defect that activates a specific Th2 response leading to a cycle of inflammation mediated by various inflammatory signals. The cytokines produced then worsen the already defective barrier. This leads to a vicious cycle of barrier failure and progressive inflammation, producing a chronic, relapsing, pruritic disorder, and explains why moisturization alone is not enough once the inflammatory cascade has started.

Yamaga K, et al: Claudin-3 Loss Causes Leakage of Sweat from the Sweat Gland to Contribute to the Pathogenesis of Atopic Dermatitis. Journal of Investigative Dermatology 2018; 138(6): 1279-87.

Prevention in High-Risk Children

Extensive studies have been undertaken to determine whether it is possible to prevent the development of AD in children at high risk—those with parents or siblings with atopy. The most promising studies now repeated multiple times show that early moisturization, starting before 3 weeks of life, with thick emollient, may prevent AD in children at high risk of developing AD. Twice daily moisturization with various emollients such as petrolatum, sunflower seed oil, and others leads to an approximately 50% reduction in the expected rate of AD development in the first 6 months of life. This supports the idea that breaks in the skin barrier are an essential step in developing AD.

Switching to soy formula does not appear to reduce the risk of developing AD. Prolonged exclusive breastfeeding beyond 3–4 months of age is not protective for the development of AD. Extensively hydrolyzed casein formulas may be used as a supplement or substitute for breast milk during the first 4 months of life. Maternal allergen avoidance during pregnancy does not reduce the risk of AD in the offspring. Probiotic administration during and after pregnancy has been shown to decrease AD incidence by 14% based on data from a meta-analysis. However, the type of probiotic to use, exactly when to start, and the safety during pregnancy are not fully elucidated. House dust mite (HDM) avoidance does not reduce AD, even in sensitized individuals, and high levels of HDMs in the environment in early life reduce AD risk.

Food Allergy

The role of food allergy in AD is complicated, and the purported role of foods in AD has changed in recent years. Approximately 35% of children with moderate to severe AD have food allergies. However, 85% of children with AD will have elevated IgE to food or inhalant allergens, making a diagnosis of food allergy with serum or prick tests alone challenging due to the high false-positive rate of testing. Before food allergy testing is undertaken, treatment of the AD should be optimized. Parents are often seeking a "cause" for the child's AD, when in fact it could be controlled with appropriate topical measures. Food restriction diets can be difficult and could put the child at risk for malnourishment and possibly development of allergy and should never be pursued without the oversight of an allergist and nutritionist to ensure proper nutrition. Food allergy should be pursued only in younger children with moderate to severe AD in whom standard treatments have failed. These children should also have a history of possible triggering of AD by specific food exposures. Testing, if performed, should be targeted foods to which the child is likely to be exposed, but generally wheat, egg, soy, cow's milk, and peanut testing has been the most relevant to the AD. Double-blind placebo-controlled food challenges are

the "gold standard" for diagnosing food allergy. Skin prick tests have a high negative predictive value (>95%) but a PPV of only 30%–65%. For example, more than 8% of the U.S. population has a positive prick test to peanut, but only 0.4% are actually clinically allergic. Possible food allergy detected by testing should be confirmed by clinical history. A positive RAST or skin prick test for a food that the child rarely or never ingests is probably not causally relevant to the child's AD. Higher serum IgE levels and larger wheal sizes (>8–10 mm) are associated with greater likelihood of reacting to these foods when challenged. About 90% of food allergy is caused by a limited number of foods, as follows:

- Infants: cow's milk, egg, soybean, wheat
- Children (2–10 years): cow's milk, egg, peanut, tree nuts, fish, crustacean shellfish, sesame, kiwi fruit
- Older children: peanut, tree nuts, fish, shellfish, sesame, pollen-associated foods

Breastfeeding mothers must avoid the incriminated foods if their infant has been diagnosed with a food allergy.

There has been a rapid rise in peanut allergy in the United States. Recommendations to limit peanut exposure in childhood has been revised. A large randomized placebo control trial showed that early exposure in children at high risk for peanut allergy (due to strong family history of atopy) decreased the rate of development of peanut allergy by 86%. Therefore the revised guidelines that were developed in conjunction with dermatologists and allergists for peanut exposure are based on AD in the child. Of course a whole peanut should never be given to an infant due to choking hazard; therefore this was done with smooth peanut butter or the peanut snack Bamba (trademark).

1. Children with severe AD or egg allergy should be considered for peanut testing before exposure to peanuts around 4–6 months of age.
2. Mild to moderate AD: Introduce peanuts around 6 months.
3. No AD or food allergy: Introduce peanuts in accordance with family and cultural preferences.

Aeroallergens

It is debated how much of a role aeroallergens play in the pathophysiology of AD. Although early exposure to allergens may lessen the incidence of AD, exposure to dust mites, animal allergens, mold, pollen, tree allergens, and other airborne allergens in those who are allergic may exacerbate AD. Testing for IgE responses to aeroallergens may not be predictive of their effect on patients with AD. In patients who note worsening around specific allergens, they should avoid these. Common allergens to avoid if possible include tobacco smoke, pollen, house dust mites, cats, and dogs (if allergic) although early exposure to dogs may prevent AD. Reduction of dust mite exposure can be achieved through vacuuming with a filtered vacuum, using dust mite covers on mattresses, avoidance of stuffed animals, and wall-to-wall carpeting if feasible.

Clinical Manifestations

AD can be divided into three stages: infantile AD, occurring from 2 months to 2 years of age; childhood AD, from 2–10 years; and adolescent/adult AD. In all stages, pruritus is the hallmark. Itching often precedes the appearance of lesions, thus the concept that AD is "the itch that rashes." Useful diagnostic criteria include those of Hannifin and Rajka, the UK Working Party, and the American Academy of Dermatology's Consensus Conference on Pediatric Atopic Dermatitis (Boxes 5.1 and 5.2). These criteria have specificity at or above 90% but have much lower sensitivities (40%–100%). Therefore these criteria are useful for enrolling patients in studies and ensuring that they have AD, but less practical in diagnosing a specific patient with AD.

BOX 5.1 Criteria for Atopic Dermatitis

MAJOR CRITERIA

Must have three of the following:

1. Pruritus
2. Typical morphology and distribution
   - Flexural lichenification in adults
   - Facial and extensor involvement in infancy
3. Chronic or chronically relapsing dermatitis
4. Personal or family history of atopic disease (e.g., asthma, allergic rhinitis, atopic dermatitis)

MINOR CRITERIA

Must also have three of the following:

1. Xerosis
2. Ichthyosis/hyperlinear palms/keratosis pilaris
3. IgE reactivity (immediate skin test reactivity, RAST test positive)
4. Elevated serum IgE
5. Early age of onset
6. Tendency for cutaneous infections (especially *Staphylococcus aureus* and HSV)
7. Tendency to nonspecific hand/foot dermatitis
8. Nipple eczema
9. Cheilitis
10. Recurrent conjunctivitis
11. Dennie-Morgan infraorbital fold
12. Keratoconus
13. Anterior subcapsular cataracts
14. Orbital darkening
15. Facial pallor/facial erythema
16. Pityriasis alba
17. Itch when sweating
18. Intolerance to wool and lipid solvents
19. Perifollicular accentuation
20. Food hypersensitivity
21. Course influenced by environmental and/or emotional factors
22. White dermatographism or delayed blanch to cholinergic agents

HSV, Herpes simplex virus; *IgE,* immunoglobulin E; *RAST,* radioallergosorbent assay.

BOX 5.2 Modified Criteria for Children With Atopic Dermatitis

ESSENTIAL FEATURES

1. Pruritus
2. Eczema
   - Typical morphology and age-specific pattern
   - Chronic or relapsing history

IMPORTANT FEATURES

1. Early age at onset
2. Atopy
3. Personal and/or family history
4. IgE reactivity
5. Xerosis

ASSOCIATED FEATURES

1. Atypical vascular responses (e.g., facial pallor, white dermatographism)
2. Keratosis pilaris/ichthyosis/hyperlinear palms
3. Orbital/periorbital changes
4. Other regional findings (e.g., perioral changes/periauricular lesions)
5. Perifollicular accentuation/lichenification/prurigo lesions

Fig. 5.1 Atopic dermatitis.

Eichenfield LF, et al: Consensus conference on pediatric atopic dermatitis. J Am Acad Dermatol 2003; 49: 1088-95
Hanifin JM, et al: Diagnostic features of atopic dermatitis. Acta Derm Venereol (Stockh) 1980; (Suppl. 92): 44-7

Infantile Atopic Dermatitis

Fifty percent or more of AD cases present in the first year of life, but usually not until after 2 months. Widespread dermatitis in children under 2 months may be from an irritant, ichthyosis, or a hallmark of severe immunodeficiency. AD in infancy usually begins as erythema and scaling of the cheeks (Fig. 5.1). The eruption may extend to the scalp, neck, forehead, wrists, extensor extremities, and buttocks. There can be overlap with seborrheic dermatitis on the scalp and in the folds, but papular or nodular involvement in the axillae and inguinal folds is more typical of scabies infestation. Children with AD who have *FLG* gene mutations specifically have more cheek and extensor arm/hand involvement. There may be significant exudate; secondary effects from scratching, rubbing, and infection include crusts, infiltration, and pustules, respectively. Occlusion of saliva due to teething, extensive breastfeeding, and drooling may cause the cheeks and upper chest to flare and thick emollients can help prevent this. Breastfeeding should not be curtailed. The infiltrated plaques eventually take on a characteristic lichenified appearance. The infantile pattern of AD usually disappears by the end of the second year of life.

Worsening of AD is often observed in infants after immunizations and viral infections likely due to activation of the immune system. Partial remission may occur during the summer, with relapse in winter. This may relate to the therapeutic effects of ultraviolet (UV) B light and humidity in many atopic patients, as well as the aggravation by wool and dry air in the winter. Extensive airborne environmental allergies may lead to worsening in the warmer months.

Childhood Atopic Dermatitis

During childhood, lesions tend to be less exudative. The classic locations are the antecubital and popliteal fossae (Fig. 5.2), flexor wrists, ankles, eyelids, face, and around the neck. Lesions are often lichenified, indurated plaques. These are intermingled with isolated, excoriated, 2–4 mm papules that are scattered more widely over the uncovered parts. Nummular morphology and involvement of the feet are more common in childhood AD.

Pruritus is a constant feature, and most of the cutaneous changes are secondary to it. Itching is paroxysmal. Scratching induces lichenification and may lead to secondary infection. A vicious cycle may be established, the itch-scratch cycle, as pruritus leads to scratching, and scratching causes secondary changes that in them cause itching. Instead of scratching causing pain, in the atopic patient the "pain" induced by scratching is perceived as itch and induces more scratching. The scratching impulse is beyond the control of the patient. Severe bouts of scratching occur during sleep, leading to poor rest and chronic tiredness in atopic children. This can affect school performance. Parents often scold children who are scratching, and this leads to more anxiety and thus more scratching.

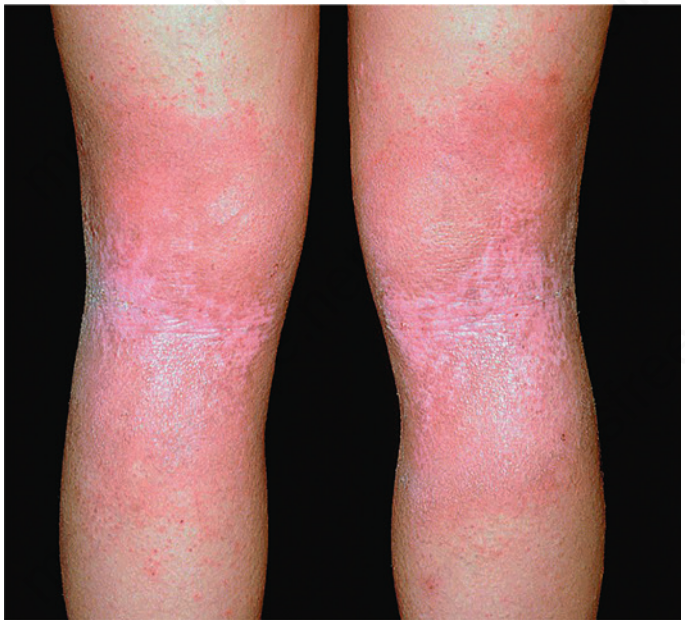

Fig. 5.2 Flexural involvement in childhood atopic dermatitis.

Fig. 5.3 Severe, widespread atopic dermatitis.

Severe AD involving a large percentage of the body surface area (BSA) can be associated with growth retardation (Fig. 5.3). Restriction diets and steroid use may exacerbate growth impairment. Aggressive management of such children with phototherapy or systemic immunosuppressive agents may allow for rebound growth. Children with severe AD may also have substantial psychological disturbances. Parents should be questioned with regard to school performance and socialization. Although using light therapy and systemic immunosuppressive or immunomodulatory therapy in children can be daunting for patients and practitioners, the benefits to quality of life can dramatically outweigh the risks.

Atopic Dermatitis in Adolescents and Adults

Most adolescents and adults with AD will give a history of childhood disease. AD will begin after age 18 years in only 6%–14% of patients diagnosed with AD. One exception is the patient who moves from a humid, tropical region to a more temperate area of higher latitude. This climatic change is often associated with the appearance of AD. In older patients, AD may occur as localized

Fig. 5.4 Prurigo-like papules in adult atopic dermatitis.

erythematous, scaly, papular, exudative, or lichenified plaques. In adolescents, the eruption often involves the classic antecubital and popliteal fossae, front and sides of the neck, forehead, and area around the eyes. In older adults, the distribution is generally less characteristic, and localized dermatitis may be the predominant feature, especially hand, nipple, or eyelid eczema. At times, the eruption may generalize, with accentuation in the flexures. The skin generally is dry and somewhat erythematous. Lichenification and prurigo-like papules are common (Fig. 5.4). Papular lesions tend to be dry, slightly elevated, and flat topped. They are almost always excoriated and often coalesce to form plaques. Staphylococcal colonization is common. In darker-skinned patients, the lesions are often hyperpigmented, frequently with focal hypopigmented areas related to healed excoriations.

Itching usually occurs in crises or paroxysms. Adults frequently complain that flares of AD are triggered by acute emotional upsets. Stress, anxiety, and depression reduce the threshold at which itch is perceived and result in damage to the epidermal permeability barrier, further exacerbating AD. Atopic persons may sweat poorly and may complain of severe pruritus related to heat or exercise. Physical conditioning and liberal use of emollients improve this component, and atopic patients can participate in competitive sports.

Even in patients with AD in adolescence or early adulthood, improvement usually occurs over time, and dermatitis is uncommon after middle life. In general, these patients retain mild stigmata of the disease, such as dry skin, easy skin irritation, and itching in response to heat and perspiration. They remain susceptible to a flare of their disease when exposed to a specific allergen or environmental situation. Photosensitivity develops in approximately 3% of AD patients and may manifest as either a polymorphous light eruption–type reaction or simply exacerbation of the AD by UV exposure. The average age for photosensitive AD is the middle to late thirties. Human immunodeficiency virus (HIV) infection can also serve as a trigger, and new-onset AD in an at-risk adult should lead to counseling and testing for HIV if warranted.

The hands, including the wrists, are frequently involved in adults, and hand dermatitis is a common problem for adults with a history of AD. It is common for irritant or atopic hand dermatitis to appear in young women after the birth of a child, when increased exposure to soaps and water triggers their disease. There is a new trend in children who can buy kits or mix their own various household liquids such as glue, borax, contact solution, baking soda and others to make "slime". This can lead to irritant dermatitis or worsening of hand atopic dermatitis. Wet work is a major factor in hand eczema in general, including those patients with AD.

Fig. 5.5 Atopic hand dermatitis.

Fig. 5.6 Periocular atopic dermatitis.

Atopic hand dermatitis can affect both the dorsal and the palmar surface (Fig. 5.5). Keratosis punctata of the creases, a disorder seen almost exclusively in black persons, is also more common in atopic patients. Patients with AD have frequent exposure to preservatives and other potential allergens in the creams and lotions that are continually applied to their skin. Contact allergy may manifest as chronic hand eczema. Patch testing can help differentiate an allergic contact dermatitis.

Eyelids are often involved (Fig. 5.6). In general, the involvement is bilateral and the condition flares with cold weather. As in hand dermatitis, irritants and allergic contact allergens must be excluded by a careful history and patch testing.

Gittler JK, et al: "Slime" May Not be so Benign: A Cause of Hand Dermatitis. The Journal of pediatrics. 2018.

Associated Features and Complications

Cutaneous Stigmata

A linear transverse fold just below the edge of the lower eyelids, known as the Dennie-Morgan fold, is indicative of the atopic diathesis, although it may be seen with any chronic dermatitis of the lower lids. In atopic patients with eyelid dermatitis, increased folds and darkening under the eyes is common. When there is extensive facial involvement, the nose is still typically spared. This is called the "headlight sign." The axillary vault and inguinal folds are also typically spared likely due to high humidity in these areas.

A prominent nasal crease may also be noted due to chronic upward wiping of the nose when there is rhinitis secondary to seasonal allergies. This is called the "nasal salute." When taken together with other clinical findings, these remain helpful clinical signs.

The less involved skin of atopic patients is frequently dry and slightly erythematous and may be scaly. Histologically, the apparently normal skin of atopic patients is frequently inflamed subclinically. The dry, scaling skin of AD may represent low-grade dermatitis. Pityriasis alba is a form of subclinical dermatitis, frequently atopic in origin. It presents as poorly marginated, hypopigmented, slightly scaly patches on the cheeks, upper arms, and trunk, typically in children and young adults with types III to V skin. It usually responds to emollients and mild topical steroids, preferably in an ointment base.

Keratosis pilaris (KP) consists of horny follicular lesions of the outer aspects of the upper arms, legs, cheeks, and buttocks and is often associated with AD, AD and occurs in patients with filagrin mutations. The keratotic papules on the face may be on a red background, a variant of KP called keratosis pilaris rubra faceii. KP is often refractory to treatment. Moisturizers alone are only partially beneficial. Some patients will respond to topical lactic acid, urea, or retinoids but they can easily irritate the skin of atopic patients and should be avoided in young children. If older patients desire, treatment should begin with applications only once or twice a week. KP must be differentiated from follicular eczema which tends to affect the trunk and is often more prominent in patients with skin types III-VI.

Thinning of the lateral eyebrows (Hertoghe sign) is sometimes present. This apparently occurs from chronic rubbing caused by pruritus and subclinical dermatitis. Hyperkeratosis and hyperpigmentation, which produce a "dirty neck" appearance, are also common in AD patients.

Vascular Stigmata

White dermatographism is blanching of the skin at the site of stroking or scratching. Chronic exposure to the vasoconstrictive effects of topical and oral steroids may lead to erythroderma due to vasodilation when steroids are tapered. This can lead to dysesthesias and belies the importance of using maintenance therapies that limit steroid exposure or lessen strength.

Atopic patients are at increased risk of developing various forms of urticaria, including contact urticaria. Episodes of contact urticaria may be followed by typical eczematous lesions at the affected site because skin that is scratched may flare with AD.

Ophthalmologic Abnormalities

Up to 10% of patients with AD develop cataracts, either anterior or posterior subcapsular. Posterior subcapsular cataracts in atopic individuals are indistinguishable from corticosteroid-induced cataracts. Development of cataracts is more common in patients with severe dermatitis. Keratoconus is an uncommon finding, occurring in approximately 1% of atopic patients. Contact lenses, keratoplasty, and intraocular lenses may be required to treat this condition. Environmental allergies may also lead to allergic rhinoconjunctivitis.

Susceptibility to Infection

Chronic eczematous lesions are often colonized with *Staphylococcus aureus. Staphylococcus epidermitis* may actually be protective as it is predominates in patients with fewer flares. In addition, the apparently normal nonlesional skin of atopic patients may also be colonized by *S. aureus*. The finding of increasing numbers of pathogenic staphylococci on the skin of a patient with AD is frequently associated with weeping and crusting of skin lesions, retroauricular and infraauricular and perinasal fissures, folliculitis, and adenopathy. In a flaring atopic patient, the possibility of secondary infection must be considered. IgE antibodies directed against *Staphylococcus* and its toxins have been documented in some atopic individuals. Staphylococcal production of superantigens is another possible mechanism for staphylococcal flares of disease. Treatment of lesions of AD with topical steroids is associated with reduced numbers of pathogenic bacteria on the surface, even if antibiotics are not used. Despite the frequent observation that the presence of staphylococcal infection of lesions of AD is associated with worsening of disease, it has not been proven that oral antibiotics make a long term difference in the course of AD. Nonetheless, treatment of the "infected" AD patient with oral antibiotics is a community standard of dermatologists worldwide.

With the widespread presence of antibiotic-resistant *S. aureus*, dermatologists have shifted from the chronic use of oral antibiotics in managing patients with frequent flares of AD associated with staphylococcal infection. Rather, dilute sodium hypochlorite (bleach) baths and reduction of nasal carriage have become the basis for preventing infection-triggered AD. The typical formula is one quarter of a US cup (approximately 60 milliliters) of plain, unscented, NOT concentrated, NOT splashproof bleach per 20 gallon bathtub of water. In patients with AD and frequent infections, chronic suppressive oral antibiotic therapy may stabilize the disease. Options include cephalosporins, trimethoprim-sulfamethoxazole (TMP-SMX), clindamycin, and (in older patients) doxycycline. Identifying and treating *S. aureus* carriers in the family and pets may also be of benefit. An unusual complication of *S. aureus* infection in patients with AD is subungual infection, with osteomyelitis of the distal phalanx. In atopic patients with fever who appear very toxic, the possibility of streptococcal infection must be considered. These children may require hospital admission and intravenous antibiotics. Group A streptococcal superinfection of AD typically presents with a more vesiculopustular look that may mimic herpes simplex virus (HSV). Culture of the skin can differentiate and guide therapy typically with a penicillin- or cephalosporin-based antibiotic.

Patients with AD have increased susceptibility to viral superinfection, especially from HSV, varicella-zoster virus (VZV), enteroviruses (Coxsackie), vaccinia, and molluscum. *Kaposi varicelliform infection* is a term used to describe an acute vesicular eruption on top of AD and is usually caused by HSV, VZV, or enterovirus superinfection. Eczema herpeticum is seen most frequently in young children and is usually associated with HSV type 1 transmitted from a caretaker or sibling. Once infected, there can be frequent flares of eczema herpeticum. Eczema herpeticum presents as the sudden appearance of vesicular, pustular, crusted, or eroded lesions concentrated in the areas of dermatitis (Fig. 5.7). The patients may have a fever and appear toxic. The lesions may continue to spread, and most of the skin surface may become involved. Secondary staphylococcal or streptococcal infection is common, and local edema and regional adenopathy frequently occur. If lesions of eczema herpeticum occur on or around the eyelids, ophthalmologic evaluation is recommended. The severity of eczema herpeticum is quite variable, but most cases require systemic antiviral therapy and an antistaphylococcal antibiotic. Delayed administration of acyclovir in hospitalized patients is associated with prolonged hospital stay. Genetic variants in TSLP and interferon regulatory factor 2 (IFR-2) in addition to DOCK 8 mutations are associated with AD and eczema herpeticum.

Recently a more virulent form of "hand foot and mouth" caused by enterovirus A6 instead of the typical A16 (also termed *Coxackie A16*) has been recognized and labeled "eczema coxsackium." Superinfection with the A6 strain often leads to very widespread papules and vesicles with low-grade fever. There will typically be at least a few lesions on the palms and soles and in the mouth but there is not the typical predominance in these areas compared with areas of AD. Therapy is supportive.

Vaccination against smallpox is contraindicated in persons with AD, even when the dermatitis is in remission. Widespread and even fatal vaccinia can occur in patients with an atopic diathesis.

Fig. 5.7 Recurrent herpes simplex in atopic dermatitis.

Atopic individuals may also develop extensive flat warts or molluscum contagiosum (MC). If the infection is extremely exuberant, an immunodeficiency such as DOCK-8 mutation should be ruled out. A common presentation of MC in children is a new patch of AD in an unusual area such as an axilla due to MC causing an immune response leading to a flare of AD. Chemical therapies such as salicylic acid and cantharidin may cause severe irritation within lesions of AD. Destruction with curettage (for molluscum), cryosurgery, or electrosurgery may be required to clear the lesions.

Differential Diagnosis

Typical AD in infancy and childhood is straightforward because of its characteristic morphology; predilection for symmetric involvement of the face, neck, and antecubital and popliteal fossae; and association with food allergy, asthma, and allergic rhinoconjunctivitis. Dermatoses that may resemble AD include seborrheic dermatitis (especially in infants), irritant or allergic contact dermatitis, nummular dermatitis, photodermatitis, scabies, and cases of psoriasis with an eczematous morphology. Certain immunodeficiency syndromes (see later discussion) may exhibit a dermatitis remarkably similar or identical to AD. In older patients with new onset dermatitis, cutaneous T cell lymphoma and allergic contact dermatitis should be considered.

Histopathology

The histology of AD varies with the stage of the lesion, with many of the changes induced by scratching. Hyperkeratosis, acanthosis, and excoriation are common. Staphylococcal colonization may be noted histologically. Although eosinophils may not be seen in the dermal infiltrate, staining for eosinophil major basic protein (MBP) reveals deposition in many cases.

General Management

Education and Support

Parental and patient education is of critical importance in the management of AD. In the busy clinic setting, dermatologists frequently have insufficient time to educate patients adequately regarding the multiple factors that are important in managing AD. Educational formats that have proved effective have been immediate nursing education on the correct use of medications, weekly evening educational sessions, and multidisciplinary day treatment venues. There are also now multiple online resources from major academic centers, professional societies, and associations that can be helpful. In all cases, "written action plans" outlining a "stepwise approach" have been important for parent/patient education. In addition, patients with chronic disease often become disenchanted with medical therapies or simply "burn out" from having to spend significant amounts of time managing their skin disease. The psychological support that can be incorporated into educational sessions can help motivate parents/patients and keep them engaged in the treatment plan. Having a child with AD is extremely stressful and generates significant stress within the family. Sleep is lost by both the patient and the parents. Supportive educational techniques and sometimes professional behavioral health consultation can help the family cope with this burden. In addition, the dermatologist must consider the complexity and time commitment of any prescribed regimen and ensure that the parents/patient understand and are committed to undertaking the treatments proposed.

Barrier Repair

AD patients have an impaired epidermal barrier. The cornerstone of treatment and prevention of AD lies in addressing this problem. Patients should moisturize daily, especially immediately after bathing, ideally while the skin is still damp within a few minutes of getting out of the water. This may be with petrolatum or a petrolatum-based product, an oil-based product, a dimethicone-based product, vegetable shortening, or a "barrier repair" moisturizer that contains the essential lipids of the epidermal barrier. These special barrier repair moisturizers have similar benefits in AD to low-potency topical steroids. They are easier to apply and, if available to the patient, may enhance compliance. Petrolatum and petrolatum-based moisturizers are most often recommended and are often the least expensive. However, men with significant body hair, AD patients triggered by heat, and the very rare patient with true allergic contact dermatitis to petrolatum may be unable to tolerate petrolatum-based agents. Moisturizers should ideally be fragrance and formaldehyde free because these are two of the most common allergens in patients with AD. The ratio and content of ceramides in the epidermis of patients with AD is abnormal. Moisturizers with ceramides added have been shown to provide some benefit beyond the actual emollient. Patients should be instructed on the barrier-damaging properties of soaps, hot water, and scrubbing. The pH of the skin that promotes normal epidermal function is slightly acidic (the acid mantle) so synthetic detergents that have a more acidic pH are preferred to more basic soaps that have a high concentration of surfactant. Detergent use should be restricted to the axilla, groin, face, soles, and scalp. Oil-based cleansers can be used to "wash" the skin without water. For flares of AD, the soak and smear technique (soak in tub, then seal in water with a heavy moisturizer or medicated ointments) or wet dressings (wet wraps) with topical steroids can be very effective. In dry climates, AD patients may note some benefit with humidifiers. α-Hydroxy acid–containing products (lactic acid, glycolic acid) can be irritating and can exacerbate inflamed AD. These products should only be used for the xerosis of AD when there is absolutely no inflammation or pruritus.

Antimicrobial Therapy

When the AD patient has evidence of infection, treatment with topical or systemic antibiotics may be appropriate. Rather than treating once an infection occurs, it appears that the key in AD is to reduce nasal staphylococcal carriage preemptively and to keep the skin decolonized from *Staphylococcus*. Dilute sodium hypochlorite (bleach) baths have rapidly become a mainstay in AD patients. Twice-weekly bathing in a tepid bath with one quarter of a US cup (approximately 60 ml) of standard household bleach (5–6%) diluted in 20 gallons of water dramatically improves AD on the trunk and extremities, but less so on the face. For a smaller baby bathtub this is typically 2.5 mL = ½ teaspoon per gallon of water. Many bleach manufacturers make splashless or double-concentrated bleach, which should be avoided. This treatment combines decolonization of the skin with hydration, addressing two of the major factors in worsening of AD. Dilute bleach baths have been shown to decrease Nuclear Factor (NF) kappa-beta and thus may serve a role as a primary antiinflammatory therapy as well. Adequate moisturizing after bathing is critical. Intranasal application of mupirocin is beneficial in reducing nasal carriage although resistance is emerging. In 80% of families, at least one parent is carrying the same staphylococcal strain as a colonized AD child. If the AD patient has recurrent infections, other carriers in the family and their pets are sought and treated aggressively. Recurrent infections, especially furunculosis, are a cardinal feature of children and adults with AD who have systemic immunologic abnormalities, especially hyper-IgE syndrome.

Environmental Factors

Stress, heat, sweating, and external irritants may precipitate an attack of itching and flare in the AD patient. Wool garments should be avoided. Addressing these triggers may improve the AD. Itch nerves are more active at higher temperatures, so overheating should be avoided. Irritants and allergens in the numerous products that AD patients may use can lead to flares of AD. Patients should avoid products that contain common allergens and should be evaluated for allergic contact dermatitis if a topical agent is associated with worsening of their AD.

Antipruritics

The primary treatment for the pruritus of AD is to reduce the severity of the AD. Antihistamines are frequently used for the pruritus of AD but are mainly beneficial for their sedative properties. If the patient has environmental allergies that lead to itch, the scratched skin can flare with AD, so in these patients long-acting histamine-2 blockers such as cetirizine, loratadine, and fexofenadine may help by decreasing the symptoms of the environmental allergies. Sedating antihistamines can lose some of their sedative effect if used consistently, so ideally they are only used when needed. Diphenhydramine, hydroxyzine, and doxepin can all be efficacious. Nonsedating antihistamines do not appear to benefit the pruritus of AD in standard doses. In some patients, gabapentin, selective serotonin reuptake inhibitors (SSRIs), mirtazapine, and even opiate antagonists may reduce pruritus. Applying ice during intense bouts of itch may help to "break" an itch paroxysm. Moisturizing lotions containing menthol, phenol, or pramoxine can be used between steroid applications to moisturize and reduce local areas of severe itch. More widespread use of topical doxepin (Sinequan) is limited by systemic absorption and sedation.

Specific Treatment Modalities

Topical Corticosteroid Therapy

Topical corticosteroids are the most common class of medications, along with moisturizers, used for the treatment of AD. They are effective and economical. Ointments are preferred because they can serve a double purpose as an emollient, they do not burn when applied, and they typically have fewer ingredients leading to lower of a chance of allergic contact dermatitis.

In infants, low-potency steroid ointments, are preferred. Regular application of emollients must be emphasized. Once corticosteroid receptors are saturated, additional applications of a steroid preparation contribute nothing more than an emollient effect. In most body sites, once-daily application of a corticosteroid is almost as effective as more frequent applications, at lower cost and with less systemic absorption and likely increased compliance. In some areas, twice-daily applications may be beneficial, but more frequent applications are almost never of benefit. Steroid phobia is common in parents and patients with AD. Less frequent applications of lower-concentration agents or intermittent use of steroids 2–5 times weekly, with emphasis on moisturizing, address these concerns. It can also be useful to point out that the human body must produce endogenous steroids daily to function. Application of topical corticosteroids under wet wraps or vinyl suit occlusion especially after soaking in a tub of water (soak and smear) can increase efficiency. For refractory areas, a stronger corticosteroid may be used. A more potent molecule is more appropriate than escalating concentrations of a weaker molecule because the effect of the latter plateaus rapidly as receptors become saturated, and the potent medication should be stopped when the flare subsides. Because AD is an inflammatory cascade that must be halted, it is important not to undertreat. Undertreatment leads to loss of faith on the part of the patient/parents and prolongs the suffering of the patient. For severe disease, using more potent topical steroids in short bursts of a few days to a week can help gain control of the disease. In refractory and relapsing AD, twice-weekly steroid application to the areas that commonly flare may reduce flares. Another maintenance method is to mix 1 part of hydrocortisone 2.5% ointment in with 1 to 4 parts of the patient's preferred emollient 2–5 days per week, lessening the amount this is used as tolerated.

In older children and adults, medium-potency steroids are often used, except on the face, where milder steroids or calcineurin inhibitors are preferred. For thick plaques and lichen simplex chronicus–like lesions, extremely potent steroids may be necessary. Ointments are more effective because of their moisturizing properties and require no preservatives, reducing the likelihood of allergic contact dermatitis. If an atopic patient worsens or fails to improve after the use of topical steroids and moisturizers, the possibility of allergic contact dermatitis to a preservative or the corticosteroids must be considered. Contact allergy to the corticosteroid itself can occur. Corticosteroid allergy seldom manifests as acute worsening of the eczema. Instead, it manifests as a flare of eczema whenever the corticosteroid is discontinued, even for a day. This may be difficult to differentiate from stubborn AD.

Although the potential for local and even systemic toxicity from corticosteroids is real, the steroid must be strong enough to control the pruritus and remove the inflammation. Even in small children, strong topical steroids may be necessary in weekly pulses to control severe flares. Monitoring of growth parameters should be carried out in infants and young children.

Ideally prevention of AD flares is with just emollients, but patients with more severe disease often need some consistent antiinflammatory medicines (similar to the paradigm used for asthma). Maintenance therapy with topical steroids as discussed earlier can be with twice-weekly application, mixing a low-potency steroid in with an emollient or with nonsteroidal antiinflammatory medications.

Topical Calcineurin Inhibitors

Topical calcineurin inhibitors (TCIs) such as tacrolimus or pimecrolimus offer an alternative to topical steroids. Systemic absorption is generally not significant with either of these agents.

Although a 0.03% tacrolimus ointment is marketed for use in children, it is unclear whether it really offers any safety advantage over the 0.1% formulation. Patients may experience a warm or stinging feeling in the skin when the medicines are first started. This tends to resolve and tolerability is improved if the ointment is applied to "bone-dry" skin. Patients experience less burning if eczematous patches are treated initially with a corticosteroid, with transition to a TCI after partial clearing. Improvement tends to be steady, with progressively smaller areas requiring treatment. TCIs are particularly useful on the eyelids and face, in areas prone to steroid atrophy, when steroid allergy is a consideration, or when systemic steroid absorption is a concern. Tacrolimus is more effective than pimecrolimus, with tacrolimus 0.1% ointment equivalent to triamcinolone acetonide 0.1%, and pimecrolimus equivalent to a class V or VI topical corticosteroid. There is a black box warning on calcineurin inhibitors in the United States, but a recent study that followed patients after marketing found no increase in malignancy in over 26,000 patient-years studied.

Topical Phosphodiesterase Inhibitors

Crisaborole is an antiinflammatory topical PDE4 inhibitor introduced in 2017 for AD in children over 2 years. It can be used on the face and skinfolds without concern for striae but may sting when applied. It may be most useful as a maintenance medication or for mild to moderate disease.

Tar

Crude coal tar 1%–5% in white petrolatum or hydrophilic ointment USP, or liquor carbonis detergens (LCDs) 5%–20% in hydrophilic ointment USP, is sometimes helpful for an area of refractory AD. Tar preparations are especially beneficial when used for intensive treatment for adults in an inpatient or day care setting, especially in combination with UV phototherapy. Goeckerman therapy with tar and UVB in a day treatment setting will lead to improvement in more than 90% of patients with refractory AD, and prolonged remission can be induced.

Phototherapy

If topical modalities fail to control AD, phototherapy is another step on the therapeutic ladder. Narrow-band (NB) UVB is highly effective and has replaced broadband UV for treating AD. When acutely inflamed, AD patients may tolerate UV poorly. Initial treatment with soak and smear topical steroids or a systemic immunosuppressive may cool off the skin enough to institute UV treatments. Patients with significant erythema must be introduced to UV at very low doses to avoid nonspecific irritancy and flaring of the AD. Often, the initial dose is much lower and the dose escalation much slower than in patients with psoriasis. In acute flares of AD, UVA I can be used. For patients unresponsive to NB UVB, photochemotherapy with psoralen plus UVA (PUVA) can be effective but the benefits must outweigh the risks. It requires less frequent treatments, and can be given either topically (soak/bath PUVA) or systemically (oral PUVA).

Systemic Therapy

Dupilumab is an IL-4 receptor inhibitor that thus blocks the function of IL-4 and IL-13. It is an injection given every 2 weeks after a loading dose and decreases pruritus and Eczema Area and Severity Index (EASI) scores. It is the first targeted systemic therapy for AD. The most common significant side effect is keratoconjunctivitis.

Systemic Corticosteroids. In general, systemic corticosteroids should be avoided due to concerns for reexacerbation when the steroids are stopped. Some will use systemic steroids to control acute exacerbations. In patients requiring systemic steroid therapy, short courses (≤3 weeks) are preferred. If repeated or prolonged courses of systemic corticosteroids are required to control the AD, phototherapy or a steroid-sparing systemic therapy should be considered. Chronic corticosteroid therapy for AD frequently results in significant steroid-induced side effects such as striae, infection, boney changes, and growth delay. Osteoporosis in women requires special consideration and should be addressed with a bisphosphonate early in the course of therapy when bone loss is greatest. Preventive strategies, such as calcium supplements, vitamin D supplementation, bisphosphonates, regular exercise, and smoking cessation, should be strongly encouraged. Dual-energy x-ray absorptiometry (DEXA) scans are recommended.

Cyclosporine

Cyclosporine (cyclosporin A) is highly effective in the treatment of severe AD, but the response is rarely sustained after the drug is discontinued. It is very useful to gain rapid control of severe AD. Cyclosporine has been shown to be safe and effective in both children and adults, although probably tolerated better in children. Potential long-term side effects, especially renal disease and hypertension, require careful monitoring, with attempts to transition the patient to a potentially less toxic agent if possible. The dose range is 3–5 mg/kg in children and 150–300 mg in adults, with a better and more rapid response at the higher end of the dose range. Cyclosporin should not be used long term due to risks of renal and other toxicity. Rebound flaring of AD is possible and can be significant after stopping cyclosporin A, and a plan should be in place for this eventuality.

Methotrexate

Methotrexate has a long history of safe use in children for other diseases. Recently studies have been published demonstrating that its efficacy is similar to cyclosporine, although the onset to action is significantly slower and it is not FDA approved for this indication. Doses are similar to what is used in psoriasis (0.3–0.6 mg/kg given once weekly (up to 25 mg) in children and 10–25 mg weekly in adults. Patients on methotrexate should take folic acid as well. The time to relapse with methotrexate may be longer than with cyclosporine. Switching from oral to subcutaneous administration may increase the benefit.

Other Immunosuppressive Agents

Several other immunosuppressive agents have demonstrated efficacy in patients with AD. They include axathioprine and mycophenolate mofetil. These agents do not appear to be as quick to work as cyclosporine. Patients with FLG mutations respond to azathioprine and methotrexate, but the response is slower than in those without FLG mutations. However, over time they may have a better safety profile, so patients requiring long-term immunosuppression may benefit from one of these agents. The dosing of azathioprine is guided by the serum thiopurine methyltransferase level. Mycophenolate mofetil (MMF) is generally well tolerated and, as with azathioprine, takes about 6 weeks to begin to reduce the AD. Unfortunately, the response of AD patients to MMF is variable, with 20%–40% not responding. If cyclosporin A is not to be used, the choice of steroid-sparing agent is personalized to the patient's risk factors and tolerance of the medication. Hydroxyurea, as used for psoriasis in the past, can be effective in AD if other steroid-sparing agents fail, as well as in the patient with liver disease.

Intravenous immune globulin (IVIG) has had some limited success in managing AD, but its high cost precludes it use, except when other reasonable therapeutic options have been exhausted. There are also reports of a dyshidrotic flare of dermatitis on the hands in patients on IVIG. Interferon-γ (IFN-γ) given by daily

injection has demonstrated efficacy in both children and adults with severe AD but is very rarely used. IFN-γ is well tolerated but can cause flulike symptoms. Omalizumab can be considered in refractory cases, but only 20% of patients achieve a 50% or greater reduction of their AD. Infliximab has not been beneficial in AD. Ustekinumab has been effective in a few reports, because the inflammatory cascade triggering and maintaining AD does involve Th17 cells.

Traditional Chinese herb mixtures have shown efficacy in children and in animal models for AD. The active herbs appear to be ophiopogon tuber and Schisandra fruit. Chinese herbs are usually delivered as a brewed tea to be drunk daily. Their bitter taste makes them difficult to palate, and there is a risk of allergy from herbal products.

Management of Acute Flare

Initially, the precipitating cause of the flare should be sought. Recent stressful events may be associated with flares. Secondary infection with *S. aureus* is one of the most common causes for flares and will manifest with pustules and honey-colored erosions. Less frequently, HSV or coxsackievirus may be involved. Pityriasis rosea may also cause AD to flare. The development of contact sensitivity to an applied medication or photosensitivity must be considered.

In the patient with an acute flare, treating triggers may lead to improvement (see earlier discussion). Soaking and smearing (wet wrapping) is recommended as first-line treatment. Often, 3–4 days of such intensive home therapy will break a severe flare. A short course of systemic corticosteroids may be of benefit as a last resort.

Regional Eczemas

Some eczema is different clinically based on location. Localized eczema can be from AD, contact dermatitis (both allergic and irritant), sebopsoriasis, and others as reviewed here.

Ear Eczema

Eczema of the ears or otitis externa may involve the helix, postauricular fold, and external auditory canal. By far the most frequently affected site is the external canal, where eczema is often a manifestation of seborrheic dermatitis or allergic contact dermatitis caused by topical medications, especially neomycin (Fig. 5.8), benzocaine, and preservatives or earphones. Secretions of the ear canal derive from the specialized apocrine and sebaceous glands, which form cerumen. Rubbing, wiping, scratching, and picking exacerbate the condition. Secondary bacterial colonization or infection is common. Infection is usually caused by staphylococci, streptococci, or *Pseudomonas*. *Pseudomonas aeruginosa* can result in malignant external otitis with ulceration and sepsis. Earlobe dermatitis in people with pierced ears is virtually pathognomonic for metal contact dermatitis (especially nickel).

Treatment should be directed at removal of causative agents, such as topically applied allergens. First, examine the ear with an otoscope and be sure there is not a perforated tympanic membrane. If there is drainage from a perforated tympanic membrane, management should be in consultation with an otolaryngologist. This purulent fluid can be the cause of an ear eczema—infectious eczematoid dermatitis. If the tympanic membrane is intact, scales and cerumen should be removed by gentle lavage with an ear syringe. A topical steroid otic solution can be used for noninfectious causes. For very weepy lesions, aluminum acetate optic solution (e.g., Domeboro) may be drying and beneficial.

Eyelid Dermatitis

Eyelid dermatitis is most often related to AD or allergic contact dermatitis, or both (see Chapter 6). Allergic conjunctivitis in an atopic patient may lead to rubbing and scratching of the eyelid and result in secondary eyelid dermatitis. Seborrheic dermatitis, psoriasis, and airborne dermatitis are other possible causes. Most patients with eyelid dermatitis are female. When an ocular medication contains an allergen, the allergen passes through the nasolacrimal duct, and dermatitis may also be noted below the nares in addition to the eyelids. Some cases of eyelid contact dermatitis are caused by substances transferred by the hands to the eyelids. If eyelid dermatitis occurs without associated AD, an allergen is detected in more than 50% of cases. More than 25% of patients with AD and eyelid dermatitis will also have allergic contact dermatitis contributing to the condition. Fragrances and balsam of Peru, metals (nickel and gold), paraphenylenediamine, quaternium 15, oleamidopropyl dimethylamine, thiuram (in rubber pads used to apply eyelid cosmetics), and tosylamide formaldehyde (in nail polish) are common allergens causing eyelid dermatitis. In medications, preservatives such as cocamidopropyl betaine and active agents such as phenylephrine hydrochloride, sodium cromoglycate, papain, and idoxuridine have all been implicated.

Eyelid dermatitis requires careful management, often in collaboration with an ophthalmologist. The most important aspect is to identify and eliminate any possible triggering allergens as noted previously. Patch testing for standard allergens, as well as the patient's ocular medications, is highly recommended. Preservative-free eye medications should be used. The ophthalmologist should monitor the patient for conjunctival complications, measure the intraocular pressure, and monitor for the development of cataracts, especially in patients with AD who have an increased risk for cataracts. Initially, topical corticosteroids and petrolatum-based emollients are recommended. If the dermatitis is persistent, the patient may be transitioned to TCIs or crisaborole to reduce the long-term risk of ocular steroid complications. The TCIs are often not initially tolerated on inflamed eyelids due to the burning. If there is an associated allergic conjunctivitis, or in patients who fail treatment with topical medications applied to the eyelid, ocular instillation of cyclosporine ophthalmic emulsion (Restasis) can be beneficial. Cromolyn sodium ophthalmic drops may be used to stabilize mast cells in the eyelid and reduce pruritus. In balsam of Peru–allergic patients, a balsam elimination diet may benefit.

Fig. 5.8 Ear eczema.

Breast Eczema (Nipple Eczema)

Eczema of the breasts usually affects the areolae and may extend onto the surrounding skin (Fig. 5.9). The area around the base of the nipple is usually spared, and the nipple itself is less frequently affected. The condition is more common in women but can be seen in infants as well. Usually, eczema of the nipples is of the moist type with oozing and crusting. Painful fissuring is frequently seen, especially in nursing mothers. AD is a frequent cause, and nipple eczema may be the sole manifestation of AD in adult women. It frequently presents during breastfeeding. The role of secondary infection with bacteria and *Candida* should be considered in breastfeeding women. Other causes of nipple eczema are allergic contact dermatitis and irritant dermatitis. Irritant dermatitis occurs from friction (jogger's nipples), or from poorly fitting brassieres with seams in women with asymmetric and large breasts. In patients in whom eczema of the nipple or areola has persisted for more than 3 months, especially if it is unilateral, a biopsy is mandatory to rule out the possibility of Paget disease of the breast. Topical corticosteroids or TCIs are often effective in the treatment of non-Paget eczema of the breast. Nevoid hyperkeratosis of the nipples is a chronic condition that may mimic nipple eczema, but it is not responsive to corticosteroids.

Nipple eczema in the breastfeeding woman is a therapeutic challenge and can be from AD, ACD, irritant dermatitis, infection or food allergy. A lactation consultant or nurse may be helpful in managing these patients, because poor positioning during breastfeeding is a common cofactor in the development of nipple eczema. The dermatitis may appear in an atopic woman when her child begins to ingest solid foods rarely due to contact dermatitis to a

Fig. 5.9 Nummular eczema of the breast.

food. Allergic contact dermatitis may develop to topical protective creams (containing vitamin A and E, aloe, lanolin, chamomile, or preservatives). Staphylococcal superinfection may develop and can be identified by culture. Oral antibiotics are the preferred treatment for bacterial secondary infection.

Candidal infection of the areola may present as normal skin, erythema, or an acute or chronic eczema. The area of the areola immediately adjacent to the nipple tends to be involved, sometimes with fine hairline cracks. Associated conditions include oral thrush in the infant, antibiotic use, and a personal history of vaginal candidiasis in mother. Cultures are typically positive from the affected areola/nipple. Oral thrush in the infant in the setting of nipple eczema in the mother would warrant treatment of the mother and infant. Patients frequently complain of severe pain, especially with nursing. Analgesia may be required, and breastfeeding may need to be suspended for a period. Pumping and the use of a silicone nipple shield may be helpful. Therapy with topical or systemic antifungal agents may be required. Topical gentian violet 0.5%, applied once daily to the nipple for up to 1 week, may be helpful but should not be ingested by the infant. Guaiazulene (Azulon) is a dark-blue hydrocarbon used in Europe for nipple "cracks" with breastfeeding.

Hand Eczema

Hand eczema is a common and important skin condition. The genetic risk factors for the development of hand dermatitis are unknown but patients with AD are more susceptible. The risk for persistence of the hand eczema is doubled if there is associated eczema at other sites at presentation, if there is a childhood history of AD, and if the onset of the hand eczema was before age 20. Atopic patients with the *FLG* null mutation may have a specific form of hand dermatitis characterized by dorsal hand and finger dermatitis, volar wrist involvement, and hyperlinear palms, but limited palmar dermatitis. Hand eczema is the most common occupational skin condition, accounting for more than 80% of all occupational dermatitides. About 1 per 1000 workers are affected annually. Women are at increased risk, most of which is accounted for by a "spike" in the rate of hand eczema in the 20–29 age-group, when increased environmental exposures increase women's risk (e.g., child care). As noted above, children with new hand dermatitis

Fig. 5.10 Hand eczema.

should be asked about making or handling "slime" which is an often home-made play substance that can cause irritant or allergic contact dermatitis.

Chronic hand eczema, especially if severe, significantly reduces the patient's quality of life and can be associated with symptoms of depression. Persons at high risk for hand eczema can be identified and counseled to avoid high-risk occupations such as those that involve consistent exposure to water or sensitizing chemicals such as hairdressers. If occupational hand eczema develops, some occupation-specific strategies can lead to improvement and prevent recurrence.

The evaluation and management of hand eczema has been hampered by the lack of a uniform classification system and a dearth of controlled therapeutic trials. The diagnostic dilemma in hand dermatitis is in part related to two factors. The clinical appearance of the skin eruption on the palms and soles may be very similar, independent of the etiology. In addition, virtually all chronic hand dermatitis demonstrates a chronic dermatitis histologically, again independent of pathogenic cause. For instance, psoriasis on the palms and soles may show the same spongiosis as a dermatitis (Fig. 5.10). As a result, the proposed classification schemes rely on a combination of morphologic features, history of coexistent illnesses, occupational exposure, and results of patch testing. The different types of hand eczema are as follows:

1. Allergic contact dermatitis (with or without an additional irritant component)
2. Irritant hand dermatitis
3. Atopic hand eczema (with or without an additional irritant component)
4. Recurrent vesicular (or vesiculobullous) hand eczema
5. Hyperkeratotic hand eczema
6. Pulpitis (chronic fingertip dermatitis)
7. Nummular dermatitis

A complete history, careful examination of the rest of the body surface, and frequently patch testing are essential in establishing a diagnosis. Patch testing is recommended in all patients with chronic hand eczema. Allergens in the environment, especially shower gels and shampoos, in the workplace, and in topical medications may be important in any patient. Patch testing must include broad screens of common allergens or allergic contact dermatitis may be missed.

The role of ingested nickel in the development of hand eczema in nickel-allergic patients is controversial. Some practitioners treat such patients with low-nickel diets and even disulfiram chelation with reported benefit. However, the risk of development of hand

eczema in adulthood is independent of nickel allergy. Similarly, the role of low-balsam diets in the management of balsam of Peru–allergic patients with hand eczema is unclear.

Wet work, defined as skin in liquids or gloves for more than 2 hours per day, or handwashing more than 20 times per day, is a strong risk factor for hand eczema. High-risk occupations include those that entail wet work and those with exposure to potential allergens. "high-risk" occupations include bakers, hairdressers, dental surgery assistants, kitchen workers/cooks, butchers, health care workers, cleaners, physicians/dentists/veterinarians, and laboratory technicians. In about 5% of patients with hand eczema, especially if severe, it is associated with prolonged missed work, job change, and job loss. In health care workers, the impaired barrier poses a risk for infection by blood-borne pathogens.

Almost one third of baker's apprentices develop hand dermatitis within 12 months of entering the profession. Among hairdressers, the incidence approaches 50% after several years. Both irritant dermatitis and allergic contact dermatitis are important factors, with glyceryl monothioglycolate and ammonium persulfate being the most common allergens among hairdressers. Cement workers have a high rate of hand dermatitis related to contact allergy, alkalinity, and hygroscopic effects of cement. Dorsal hand dermatitis in a cement worker suggests contact allergy to chromate or cobalt. The addition of ferrous sulfate to cement has no effect on irritant dermatitis, but reduces the incidence of allergic chromate dermatitis by two thirds.

Among patients with occupational hand dermatitis, atopic patients are disproportionately represented. Hand dermatitis is frequently the initial or only adult manifestation of an atopic diathesis. The likelihood of developing hand eczema is greatest in patients with AD, more common if the AD was severe, but is still increased in incidence in patients with only respiratory atopy. One third to one half of patients with hand eczema have atopy. Atopic patients should receive career counseling in adolescence to consider avoidance of occupations that are likely to induce hand dermatitis.

Contact urticaria syndrome may present as immediate burning, itching, or swelling of the hands, but a chronic eczematous phase may also occur. Latex is an important cause of the syndrome, but raw meat, lettuce, garlic, onion, carrot, tomato, spinach, grapefruit, orange, radish, fig, parsnip, cheese, or any number of other foods may be implicated.

Vesiculobullous Hand Eczema (Pompholyx, Dyshidrosis). Primary lesions of dyshidrosis are deep-seated multilocular vesicles resembling tapioca on the sides of the fingers (Fig. 5.11), palms, and soles. The eruption is symmetric and pruritic, with pruritus often preceding the eruption. Coalescence of smaller lesions may lead to bulla formation severe enough to prevent ambulation. Individual outbreaks resolve spontaneously over several weeks. Acute pompholyx, also known as cheiropompholyx if it affects the hands, presents with severe, sudden outbreaks of intensely pruritic vesicles. Idiopathic acute vesicular hand dermatitis is not related to blockage of sweat ducts, although palmoplantar hyperhidrosis is common in these patients, and control of hyperhidrosis improves the eczema. Bullous tinea or an id reaction from a dermatophyte should be excluded, and patch testing should be considered to rule out allergic contact dermatitis.

Chronic Vesiculobullous Hand Eczema. In chronic cases, the lesions may be hyperkeratotic, scaling, and fissured, and the "dyshidrosiform" pattern may be recognized only during exacerbations. The pruritic 1–2 mm vesicles tend to be most pronounced at the sides of the fingers. In long-standing cases, the nails may become dystrophic. The distribution of the lesions is, as a rule, bilateral and roughly symmetric.

Hyperkeratotic Hand Dermatitis. The eruption presents as hyperkeratotic, fissure-prone, erythematous areas of the middle or proximal palm. Vesicles are not seen. The volar surfaces of the fingers may also be involved (Fig. 5.12). Plantar lesions occur in about 10% of patients. Males outnumber females by 2 : 1, and the patients are usually older adults. Histologically, the lesions show chronic spongiotic dermatitis. The most important differential diagnosis is psoriasis, and some of the patients with chronic hyperkeratotic hand dermatitis will ultimately prove to be psoriatic. The presence of sharply demarcated plaques, nail pitting, or occasional crops of pustules is an important clue to psoriatic hand involvement.

Pulpitis (Fingertip Hand Dermatitis). This hyperkeratotic and fissuring eczema affects primarily the fingertips and may extend to merge with eczema of the palm. Vesicles can occur. Involvement of the three fingers of the dominant hand suggests a contact dermatitis (irritant or allergic), whereas similar involvement of the nondominant hand suggests vegetables and other items related to food preparation that are held in this hand for cutting (e.g., garlic).

Fig. 5.11 Pompholyx.

Fig. 5.12 Hyperkeratotic hand dermatitis.

Treatment. The hands are essential for work both in and out of the home. Treatment regimens must be practical and must allow patients to function as normally as possible. The efficacy of some of the treatments depends on the morphology of the eruption and the diagnostic classification (see previous discussion).

Protection. Vinyl gloves may be worn during wet work, especially when detergents are used. Although vinyl gloves protect against chemicals, they do not prevent exposure to heat through the glove or the macerating effect of sweat, which accumulates under the gloves. Wearing white cotton gloves under the vinyl gloves can prevent this. Vinyl gloves are also much less durable than rubber gloves. Rubber gloves may be used at home if patients do not exhibit allergy to rubber chemicals or latex. For rough work, such as gardening, wearing protective cloth or leather gloves is essential.

Barrier Repair. Moisturizing is a critical component of the management of hand dermatitis. Application of a protective moisturizing cream or ointment after each handwashing or water exposure is recommended. Creams require a preservative and have a higher risk of contact sensitivity and often burn when applied. Ointments tend to have few ingredients and do not generally require a preservative. At night, even during periods of remission, a heavy moisturizing ointment should be applied to the hands after soaking in water. If palmar dryness is present, occlusion of the moisturizer with a plastic bag or vinyl gloves is recommended. White petrolatum is inexpensive and nonsensitizing and remains a valuable agent in the treatment of hand dermatitis. Jars of moisturizers can be contaminated with *S. aureus.*

Topical Agents. Potent and ultrapotent topical corticosteroids are first-line pharmacologic therapy. Their efficacy is enhanced by presoaking and occlusion (soak and smear technique or wet dressings). A single application with occlusion at night is often more effective than multiple daytime applications. The treatment is continued until the hands are clear, and then either emollients are substituted or maintenance treatment with the topical steroid two or three times weekly is continued to prevent recurrence. In refractory cases, ultrapotent corticosteroids may be used for 2–3 weeks, then on weekends, with a milder corticosteroid applied during the week.

The TCIs may be of benefit in some mildly affected patients. Soaks with a tar bath oil or applications of 20% LCD or 2% crude coal tar in an ointment base may be of benefit, especially in patients with hyperkeratotic hand eczema. Bexarotene gel can be beneficial in up to 50% of patients with refractory hand eczema.

Phototherapy. Phototherapy in the form of high-dose UVA I, soak or cream PUVA, and oral PUVA can be effective but the risks of chronic photo damage and skin cancer must be discussed with patients.. Given the thickness of the palms, UVA irradiation should be delivered 30 minutes after soaking, as opposed to bath PUVA, which can be done immediately after bathing.

Grenz ray radiotherapy is rarely used due to long-term risk of malignancy.

Botulinum Toxin A. In patients with palmoplantar hyperhidrosis and associated hand eczema, treatment of the hyperhidrosis with intradermal injections of botulinum toxin A leads to both dramatic resolution of the sweating and clearing of the hand eczema. The hand eczema returns when the sweating returns.

Iontophoresis, which also reduces sweating, can similarly improve hand dermatitis. This illustrates the importance of wetness in the exacerbation of hand eczema.

Systemic Agents. The systemic agents used to treat severe chronic hand dermatitis are identical to those used for AD. Systemic steroids are recommended only to control acute exacerbations. For example, patients with infrequent but severe outbreaks of pompholyx may benefit from a few weeks of systemic steroids, starting at about 1 mg/kg/day. Patients with persistent, severe hand dermatitis should be considered for alternative, steroid-sparing therapy. Oral retinoids may have a place in the management of hand dermatitis. Alitretinoin (not available in the United States), may lead to complete or near-complete clearance of chronic refractory hand eczema in about 50% of patients, especially those with hyperkeratotic hand eczema. The onset of response is delayed, with some patients achieving optimal benefit only after more than 6 months of treatment. Acitretin, may have similar benefit and of course should not be used in women of childbearing potential.

Workplace Modifications. The incidence of hand dermatitis in the workplace can be reduced by identifying major irritants and allergens, preventing exposure through engineering controls, substituting less irritating chemicals when possible, enforcing personal protection and glove use, and instituting organized worker education. Hand eczema classes have been documented to reduce the burden of occupational dermatitis. It is important to note that prevention of exposure to a weak but frequent irritant can have more profound effects than removal of a strong but infrequently contacted irritant.

Proper gloves are essential in industrial settings. Nitrile gloves are generally less permeable than latex gloves. Gloves of ethylene vinyl alcohol copolymer sandwiched with polyethylene are effective against epoxy resin, methyl methacrylate, and many other organic compounds. Latex and vinyl gloves offer little protection against acrylates. The 4H (4 hour) glove and nitrile are best in this setting. As hospitals transition to nonlatex gloves, it is important to note that even low-protein, powder-free latex gloves reduce self-reported skin problems among health workers.

Diaper (Napkin) Dermatitis

Diaper dermatitis has dramatically decreased as a result of highly absorbable disposable diapers. Nonetheless, dermatitis of the diaper area in infants remains a common cutaneous disorder. The highest prevalence occurs between 6 and 12 months of age. Diaper dermatitis is also seen in adults with urinary or fecal incontinence who wear diapers.

Irritant diaper dermatitis is the most common type of dermatitis and is an erythematous dermatitis due to skin contact with urine and feces that is usually limited to the convex exposed surfaces. The folds remain unaffected, in contrast to intertrigo, inverse psoriasis, and candidiasis, where the folds are frequently involved. In severe cases of irritant dermatitis, there may be superficial erosion or even ulceration (Jacquet erosive diaper dermatitis), violaceous plaques and nodules (granuloma gluteal infantum), or pseudoverrucous papules and nodules; these three entities are part of a disease spectrum and can simulate herpetic infections or genital warts. The tip of the penis may become irritated and crusted, with the baby urinating frequently and spots of blood appearing on the diaper.

Excessive hydration with maceration of the skin is the primary causal factor in diaper dermatitis. The absence of diaper dermatitis in societies where children do not wear diapers clearly implicates the diaper environment as the cause of the eruption. Many parents will incorrectly switch to cloth diapers when diaper dermatitis occurs even though the superabsorbent modern diapers are much more effective at preventing diaper dermatitis by wicking urine and stool to some extent away from the skin. Moist skin is more easily abraded by friction of the diaper as the child moves. Wet skin is more permeable to irritants. Skin wetness also allows the growth of bacteria and yeast. Bacteria raise the local pH, increasing the activity of fecal lipases and proteases, which leads to more skin breakdown. *Candida albicans* is frequently a secondary invader and, when present, produces typical satellite erythematous lesions or pustules at the periphery as the dermatitis spreads. *S. aureus* and group A β-hemolytic streptococci can infect diaper dermatitis. Breastfeeding is associated with less frequent diaper dermatitis, and diarrhea is a risk factor.

Fig. 5.13 Napkin psoriasis.

The differential diagnosis of diaper dermatitis should include napkin psoriasis (Fig. 5.13), seborrheic dermatitis, AD, langerhans cell histiocytosis, tinea cruris, acrodermatitis enteropathica, aminoacidurias, biotin deficiency, and congenital syphilis. Allergic contact dermatitis is becoming more frequently recognized as a cause of dermatitis in the diaper area. Allergens include sorbitan sesequioleate, fragrances, disperse dye, cyclohexylthiopthalimide, and mercaptobenzothiazole (in rubber diaper covers). Given the skill of most pediatricians in the management of diaper dermatitis, dermatologists should think about these conditions in infants who have failed the standard interventions used by pediatricians. Refractory diaper dermatitis may require a biopsy to exclude some of these conditions.

Prevention is the best treatment. Diapers that contain superabsorbent gel have been proved effective in preventing diaper dermatitis in both neonates and infants. They work by absorbing the wetness away from the skin and by buffering the pH. Cloth diapers and regular disposable diapers are equal in their propensity to cause diaper dermatitis and are inferior to the superabsorbent gel diapers. The frequent changing of diapers is also critical: every 2 hours for newborns and every 3–4 hours for older infants. The renewed popularity of cloth and bamboo diapers as more natural and ecologic has led to a reemergence of severe diaper dermatitis in some European countries.

Protecting the skin of the diaper area is vital. Zinc oxide paste and petrolatum are both effective barriers, preventing the urine and stool from contacting the dermatitis. If simple improved hygiene and barrier therapy are not effective, the application of anticandidal agents in addition to a very-low-potency topical steroid for a few days can aid in healing.

Circumostomy Eczema

Eczematization of the surrounding skin frequently occurs after an ileostomy or colostomy. It is estimated that 75% of ileostomy patients have some postoperative sensitivity as a result of the leakage of intestinal fluid onto unprotected skin. As the consistency of the intestinal secretion becomes viscous, the sensitization subsides. Proprietary medications containing karaya powder have been helpful; 20% cholestyramine (an ion-exchange resin) in a petrolatum-based moisturizer and topical sucralfate as a powder or emollient are effective treatments. Absorbent silicone protective layers can be placed around the ostomy to provide protection against the tube rubbing and absorption of any leaking intestinal contents. Psoriasis may also appear at ostomy sites, especially in patients with inflammatory bowel disease (IBD) being treated with tumor necrosis factor (TNF) inhibitors who develop psoriasis as a complication. Topical treatment may be difficult because the appliance adheres poorly after the topical agents are applied. A topical corticosteroid spray may be used and will not interfere with appliance adherence. Contact dermatitis to the ostomy bag adhesive can be problematic, and even supposedly hypoallergenic ostomy bags may still trigger dermatitis in these patients.

Autosensitization (Id Reactions) and Conditioned Irritability

The presence of a localized, chronic, and usually severe focus of dermatitis may affect distant skin in two ways. Patients with a chronic localized dermatitis may develop dermatitis at distant sites from scratching or irritating the skin. This is called "conditioned irritability." The most common scenario is distant dermatitis in a patient with a chronic eczematous leg ulcer.

Autoeczematization (id reaction) refers to the spontaneous development of widespread dermatitis or dermatitis distant from a local inflammatory focus. The agent causing the local inflammatory focus is not the direct cause of the dermatitis at the distant sites. Autoeczematization most frequently presents as a generalized acute vesicular eruption with a prominent dyshidrosiform component on the hands. The most common associated condition is a chronic eczema of the legs, with or without ulceration. The "angry back" or "excited skin" syndrome observed with strongly positive patch tests, and the local dermatitis seen around infectious foci (infectious eczematoid dermatitis), may represent a limited form of this reaction.

Patients with a variety of infectious disorders may also present with an id reaction. The most classic pattern is characterized by symmetrically distributed minute papules that have a predilection for the face, upper ears, and trunk. The most common causes are tinea capitis or an allergic contact dermatitis. Therapy of tinea capitis with griseofulvin can lead to an id reaction soon after therapy that can be mistaken for an allergic reaction to griseofulvin. Proper management is to continue the griseofulvin and treat symptomatically with topical steroids or antihistamines if necessary. Id reactions can also be vesicular on the hands in response to an inflammatory tinea of the feet. Nummular eczematous lesions or pityriasis rosea–like lesions may occur in patients with head or pubic louse infestation. Id reactions clear when the focus of infection or infestation is treated, but topical or systemic antiinflammatory agents may be required until the triggering infection is eradicated.

Juvenile Plantar Dermatosis

Juvenile plantar dermatosis is an eczematous disorder of children from age 3 years to puberty although rarely it persists into adulthood. It usually begins as a patchy, symmetric, smooth, red glazed patch on the base or medial surface of the great toes, sometimes with fissuring and desquamation. Unlike tinea, it spares the interdigital spaces. Lesions evolve into red scaling patches involving the weight-bearing and frictional areas of the feet, usually symmetrically. The skin ends up appearing like parchment paper and it fissures easily. The forefoot is usually much more involved than the heel. The eruption is disproportionately more common in atopic children. In some patients, a similar eruption occurs on the fingers. Histologically, there is psoriasiform acanthosis and a sparse, largely lymphocytic infiltrate in the upper dermis, most dense around sweat ducts at their point of entry into the epidermis. Spongiosis is often present, and the stratum corneum is thin but compact.

The disease is caused by the repeated maceration of the feet due to occlusive shoes often worn without socks, especially athletic shoes, sandals, or rubber shoes, or by the abrasive effects of pool surfaces or diving boards. Thin, nonabsorbent, synthetic socks may contribute to the problem, but socks that soak up excess water must be changed when soaked.

The diagnosis of plantar dermatosis is clinical, especially if there is a family or personal history of atopy and the toe webs are spared. Treatment involves avoidance of maceration. Foot powders, thick absorbent socks, absorbent insoles, and having alternate pairs of shoes to wear to allow the shoes to dry out are all beneficial. Topical corticosteroid medications are of limited value and often are no more effective than occlusive barrier protection. Petrolatum or urea preparations can sometimes be of benefit. Most cases clear within 4 years of diagnosis.

Allergic contact dermatitis may play a significant role in plantar dermatoses in childhood. In one study from Scotland, 50% of children with "inflammatory dermatitis" of the soles had relevant positive patch tests, and 4 of 14 children with typical juvenile plantar dermatitis also had a relevant contact allergen. Refractory plantar dermatitis in childhood should suggest allergic contact dermatitis.

Xerotic Eczema

Xerotic eczema is also known as winter itch, eczema craquelé, and asteatotic eczema. These vividly descriptive terms are all applied to dehydrated skin showing redness, dry scaling, and fine crackling that may resemble crackled porcelain or the fissures in the bed of a dried lake. The primary lesion is an erythematous patch covered with an adherent scale. As the lesion enlarges, fine cracks in the epidermis occur (Fig. 5.14). Nummular lesions may occur. Xerotic "nummular" eczema is less weepy than classic nummular dermatitis. Favored sites are the anterior shins, extensor arms, and flank. Elderly persons are particularly predisposed, and xerosis is the most common cause of pruritus in older individuals. Xerotic eczema is seen most frequently during the winter, when there is low relative humidity. Bathing with hot water and harsh soaps contributes. The epidermal water barrier is impaired, and TEWL is increased. Epidermal barrier repair begins to decrease after age 55, correlated with an increase in epidermal pH (see later discussion). The loss of barrier repair ability is improved by acidifying the epidermis, showing the benefit of mild acids in treating xerosis. Heterozygous null mutation of the *FLG* gene is associated with xerosis.

Taking short tepid showers, limiting use of soap to soiled and apocrine-bearing areas, using acid pH synthetic detergents, and promptly applying an emollient after bathing are usually effective.

Fig. 5.14 Eczema craquelé.

White petrolatum and emollients containing 10% urea or 5% lactic acid are effective. Topical corticosteroids in ointment vehicles are useful for inflamed areas.

Pruritic Dermatitis in Elderly Persons

Pruritic skin conditions are common in elderly patients, appearing around age 55 and increasing in severity with age. Males are more often affected, and Asians and Caucasians more frequently have pruritus as seniors than African Americans or Hispanics.

The dermatoses seen in this age-group are typically eczematous or papular. The eczematous plaques may resemble nummular dermatitis, a feature recognized by Marion Sulzberger when he coined the phrase "exudative discoid and lichenoid chronic dermatitis," or "oid-oid disease." The pathogenic basis of this component of dermatitis in elderly persons may be related to barrier failure due to loss of acidification of the epidermis. In addition, patients often have urticarial papules on the trunk and proximal extremities that resemble insect bites. These lesions are termed *subacute prurigo* and histologically demonstrate features of an arthropod assault, with superficial and deep perivascular lymphohistiocytic infiltrates, dermal edema, and at times interstitial eosinophils. Lesions of transient acantholytic dermatitis or eosinophilic folliculitis may also occur. This component of the eruption may be related to the tendency of elderly individuals to have an immune system that skews toward Th2 because of loss of Th1 function parallel to what occurs in the setting of AD. For this reason, some practitioners consider this "adult atopic dermatitis." However, it is unknown whether these conditions have a genetic basis, or more likely, given the time of onset, are caused by acquired barrier and immune system abnormalities. In these patients, allergic contact dermatitis and photodermatitis may be present or develop. Patch testing may identify important allergens, avoidance of which leads to improvement.

Certain medication may also cause a similar eruption. Calcium channel blockers may be associated with pruritic dermatitis, but stopping them will clear only about one quarter of patients taking that class of medication. If there is widespread pruritic dermatitis, a biopsy should be performed to rule out cutaneous T-cell lymphoma. Treatment for these patients is similar to that of AD patients, with oral antipruritics, emollients, and topical corticosteroids (soak and smear) as first-line therapy. In refractory cases, phototherapy (UVB or PUVA), Goeckerman therapy (UVB plus crude coal tar) in a day treatment setting, and immunosuppressive agents can be effective. Inadvertent use of phototherapy in the patient with coexistent photosensitivity will lead to an exacerbation of pruritic dermatitis.

Nummular Eczema (Discoid Eczema)

NE usually begins on the lower legs, dorsa of the hands, or extensor surfaces of the arms. In younger adults, females predominate, but most patients older than 40 are male. Alcohol consumption has been associated with NE in adult males. A single lesion often precedes the eruption and may be present for some time before other lesions appear. The primary lesions are discrete, coin-shaped, erythematous, edematous, vesicular, and crusted patches (Fig. 5.15). Most lesions are 2–4 cm in diameter. Lesions may form after trauma (conditioned hyperirritability). As new lesions appear, the old lesions expand as tiny papulovesicular satellite lesions appear at the periphery and fuse with the main plaque. In severe cases, the condition may spread into palm-sized or larger patches. Pruritus is usually severe and of the same paroxysmal, compulsive quality and nocturnal timing seen in AD and prurigo nodularis.

AD frequently has nummular morphology in adolescents, but in atopy the lesions tend to be more chronic and lichenified. Histologically, NE is characterized by acute or subacute spongiotic dermatitis. The skin lesions of nummular dermatitis are frequently

Fig. 5.15 Nummular eczema. (Courtesy Steven Binnick, MD.)

colonized with *S. aureus*, in frequency similar to that seen in AD. Relevant positive patch tests are found in one quarter to one third of patients with NE. This may represent the primary cause of the dermatitis or a secondary allergy that developed from products used to treat the NE.

Initial treatment consists of simple soaking and greasing with an occlusive ointment, and once-daily or twice-daily application of a potent or superpotent topical corticosteroid cream or ointment then switched to a nonsteroidal topical medication such as a calcineurin inhibitor or crisaborole. Ointments are more effective, and occlusion may be necessary as nummular dermatitis can be very recalcitrant. If secondary staphylococcal infection is present, an antibiotic with appropriate coverage can be used. Stopping alcohol consumption may improve response. A sedating antihistamine, doxepin, or gabapentin at bedtime can help with sleep and reduce nighttime scratching. In some cases refractory to topical agents, intralesional or systemic corticosteroid therapy may be required. In patients unresponsive to topical steroids, phototherapy with NB UVB, bath (soak), or oral PUVA can be effective. For refractory plaques, the addition of topical tar as 2% crude coal tar or 20% LCD may be beneficial.

HORMONE-INDUCED DERMATOSES

Autoimmune progesterone dermatitis (APD) may appear as urticarial papules, deep gyrate lesions, papulovesicular lesions, an eczematous eruption, targetoid lesions, or a fixed drug reaction. Urticarial and erythema multiforme–like lesions are most characteristic. Lesions typically appear 5–7 days before menses, and improve or resolve a few days following menses. Pruritus is common. Onset is typically in the third and fourth decades of life. Familial cases have been reported. When urticaria is the predominant skin lesion, there is a generalized distribution, and it may be accompanied by laryngospasm and anaphylactoid reactions. Oral erosions may be present and cyclical, and a case of erythema multiforme associated with APD in an HIV patient has been reported. Many of the reported patients had received artificial progestational agents before the onset of the eruption. In some, it appeared during a normal pregnancy. The eruption may worsen or clear during pregnancy. Rarely, it can occur in males given progesterone and adolescent females. Progesterone luteal-phase support during in vitro fertilization has exacerbated the disease.

In most cases, diagnosis has been confirmed by intradermal testing with progesterone. A positive test may be immediate (30 minutes) or delayed (24–96 hours). Flares may be induced by intramuscular, intravaginal, or oral progesterone. Histopathology shows a perivascular infiltrate in most with some interstitial involvement in a third and the infiltrate is mostly lymphocytes, but a minority of patients had eosinophils or neutrophils admixed. The most common treatment is an oral contraceptive to suppress ovulation, thereby reducing progesterone levels. Topical corticosteroids for mild eczematous cases and antihistamines in urticaria cases can be beneficial. For more refractory cases or in patients with erythema multiforme, fixed drug, or anaphylaxis as the cause, suppression of progesterone production with conjugated estrogen and gonadotropin-releasing antagonists such as leuprolide acetate, danazol, and tamoxifen has been successful. Desensitization protocols may allow for use of progesterone during in vitro fertilization and pregnancy. Menopause and oophorectomy (except in one reported patient) have been curative.

Autoimmune estrogen dermatitis also presents as a cyclic skin disorder that may appear eczematous, papular, bullous, or urticarial. Pruritus is typically present. Skin eruptions may be chronic but are exacerbated premenstrually or occur only immediately before the menses. Characteristically, the dermatosis clears during pregnancy and at menopause. Intracutaneous skin testing with estrone produces a papule lasting longer than 24 hours or an immediate urticarial wheal (in patients with urticaria). Injections of progesterone yield negative results, ruling out autoimmune progesterone dermatitis. Tamoxifen is effective in some cases.

IMMUNODEFICIENCY SYNDROMES

Primary immunodeficiency diseases (PIDs) are important to the dermatologist. PIDs may present with skin manifestations, and the dermatologist may be instrumental in referring appropriate patients for immunodeficiency evaluation. These conditions have also given us tremendous insight into the genetic makeup and functioning of the immune system. The PIDs can be classified as those with predominantly antibody deficiency, impaired cell-mediated immunity (cellular immunodeficiencies, T cells, natural killer [NK] cells), combined B-cell and T-cell deficiencies, defects of phagocytic function, complement deficiencies, and well-characterized syndromes with immunodeficiency. More than 150 PIDs have been identified, as of the 2005 classification. Many of the original paradigms of PIDs have been refuted. PIDs are not rare, can be sporadic (not familial), can have adult onset, can be autosomal dominant, have incomplete penetrance, and may even spontaneously improve over time.

The dermatologist should suspect a PID in patients with chronic, severe, atypical or recalcitrant infections, and the type of immunodeficiency can at times be suggested by the clinical situation. Skin infections, especially chronic and recurrent bacterial skin infections, can be the initial manifestation of a PID with neutropenia, elevated IgE, or T-helper cell immunodeficiency. Fungal (especially *Candida*) and viral infections (warts, molluscum) suggest a PID of helper T cells or a specific monogenetic defect (STAT1 gain of function, IL-17, DOCK-8). Not all immunodeficiencies present with infections, but rather an inflammatory phenotype. Eczematous dermatitis and erythroderma, at times closely resembling severe atopic or seborrheic dermatitis, may affect the skin of PID patients due to maternal engraftment graft-versus-host disease (GVHD). They may be refractory to standard therapies. Granuloma formation, autoimmune disorders, and vasculitis are other cutaneous manifestations seen in some forms of primary immunodeficiency. The PIDs in which a specific infection or finding is the more common presentation are discussed in other chapters, including chronic mucocutaneous candidiasis (Chapter 15); Hermansky-Pudlak, Chédiak-Higashi, and Griscelli syndromes with pigmentary anomalies (Chapter 36); and cartilage-hair hypoplasia syndrome with disorders of hair (Chapter 27). The conditions described next are the most important PID conditions with which dermatologists should be familiar.

Schwartzfarb EM, et al: Pyoderma gangrenosum in a patient with Bruton's X-linked agammaglobulinemia. J Clin Aesthet Dermatol 2008; 1: 26.

Disorders of Antibody Deficiency

X-Linked Agammaglobulinemia

Also known as Bruton syndrome, X-linked agammaglobulinemia (XLA) is caused by mutations in the *BTK* gene (Bruton tyrosine kinase), which is essential for the development of B lymphocytes. XLA typically presents between 4 and 12 months of life, when maternal immunoglobulins wane. The affected boys present with infections of the upper and lower respiratory tracts, gastrointestinal (GI) tract, skin, joints, and central nervous system (CNS). The infections are usually caused by *Streptococcus pneumoniae*, *S. aureus*, *Haemophilus influenzae*, *Helicobacter*, and *Pseudomonas*. Recurrent skin staphylococcal infection may be a prominent component of this condition. Atopic-like dermatitis and pyoderma gangrenosum have been described. Hepatitis B, enterovirus, and rotavirus infections are common in XLA patients, and one third develop a rheumatoid-like arthritis. Enterovirus infection may result in a dermatomyositis-meningoencephalitis syndrome. Pyoderma gangrenosum has been reported in a patient, although this would absolutely be a diagnosis of exclusion because these patients can have such unusual skin infections. Kawasaki disease and polyarteritis nodosa have been reported in affected patients. An absence of palpable lymph nodes is characteristic.

Immunoglobulin A (IgA), IgM, IgD, and IgE are virtually absent from the serum, although IgG may be present in small amounts. The spleen and lymph nodes lack germinal centers, and plasma cells are absent from the lymph nodes, spleen, bone marrow, and connective tissues. In XLA, B cells usually only make up 0.1% of circulating peripheral blood lymphocytes (normal 5%–20%). More than 500 different mutations have been identified in the *BTK* gene in XLA patients. Some of these mutations only partially compromise the gene, so some patients may have milder phenotype and up to 7% circulating B cells, making differentiation from common variable immunodeficiency difficult. In addition to mutations in the *BTK* gene, mutations in other genes required for immunoglobulin production, such as *IGHM*, *CD79A*, *CD79B*, *IGLLa*, *BLNK*, and *LRRC8A*, can be responsible for panhypogammaglobulinemia.

Treatment with gamma globulin has enabled many patients to live into adulthood. The maintenance dose required can vary considerably from patient to patient. High-dose IVIG may also lead to improvement of pyoderma gangrenosum–like lower extremity ulcerations. Chronic sinusitis and pulmonary infection remain problematic because of the lack of IgA, and chronic sinopulmonary infections require repeated pulmonary function monitoring.

Isolated IgA Deficiency (OMIM 137100)

An absence or marked reduction of serum IgA (<7 mg/dL) is the most common immunodeficiency state. Patients with RAG-1 mutations can also present selective IgA deficiency. The incidence varies greatly based on ethnic background: about 1:150 in the Arab Peninsula and Spain, 1:225–1:300 in the United States, and 1:14,000–18,000 in Japan. Certain medications appear to induce selective IgA deficiency, including phenytoin, sulfasalazine, cyclosporine, nonsteroidal antiinflammatory drugs (NSAIDs), and hydroxychloroquine. The genetic cause in most cases is unknown.

From 10%–15% of all symptomatic immunodeficiency patients have IgA deficiency. Most IgA-deficient patients, however, are completely well. Of those with symptoms, half have repeated infections of the GI and respiratory tracts, and one quarter have autoimmune disease. Allergies such as anaphylactic reactions to transfusion or IVIG, asthma, and AD are common in the symptomatic group. There is an increased association of celiac disease, dermatitis herpetiformis, and IBD. Vitiligo, alopecia areata, and other autoimmune diseases (e.g., systemic lupus erythematosus [SLE], dermatomyositis, scleroderma, thyroiditis, rheumatoid arthritis, polyarteritis-like vasculitis, Sjögren syndrome) and ulcerative gingivitis have all been reported to occur in these patients. Malignancy is increased in adults with IgA deficiency.

Yel L: Selective IgA deficiency. J Clin Immunol 2010; 30: 10.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is a heterogeneous disorder and is the most common immunodeficiency syndrome after IgA deficiency. Patients have low levels of IgG and IgA, and 50% also have low levels of IgM. Lymphocyte counts may be normal or low. Multiple genetic defects have been found in CVID, including mutations in *ICOS* (CVID type 1), *TNFRSF13B* (type 2), *CD19* (type 3), *TNFRSF13C* (type 4), *MS4A1* (type 5), *CD81* (type 6), *CR2* (type 7), *LRBA* (type 8), *PRKCD* (type 9), and *NFKB2* (CVID 10). These patients do not form antibodies to bacterial antigens, and have recurrent sinopulmonary infections. They have a predisposition to autoimmune disorders, such as vitiligo and alopecia areata, GI abnormalities, lymphoreticular malignancy (10-fold increase of lymphoma), and gastric carcinoma. Noninfectious granulomas have been reported in as many as 22% of CVID (Fig. 5.16). In some patients with CVID and multiple other immunodeficiencies, vaccine strain rubella has been found within the granulomas. Therefore it is hypothesized that the granulomas form due to difficulty processing the live rubella vaccination that is often given before diagnosis of CVID. Seven percent of CVID patients with granulomas have cutaneous granulomas, and virtually all patients with cutaneous granulomas also have visceral granulomas. These patients are more often female and have higher risk for lymphoma than other CVID patients. The granulomas can show multiple histologic patterns: granuloma annulare-like, sarcoidal, and even caseating. They show a CD4/CD8 ratio of less than 1, distinguishing these granulomas from sarcoidosis. CVID patients who develop granulomas have more severe depletion of isotype-switched memory B cells and naïve T cells, an immunologic profile also seen in ataxia telangiectasia patients with cutaneous granulomas.

Replacement of the reduced immunoglobulins with IVIG may help reduce infections. Topical, systemic, and intralesional corticosteroids may be used for the granulomas, depending on their extent. Infliximab and etanercept have been effective in steroid-refractory cases.

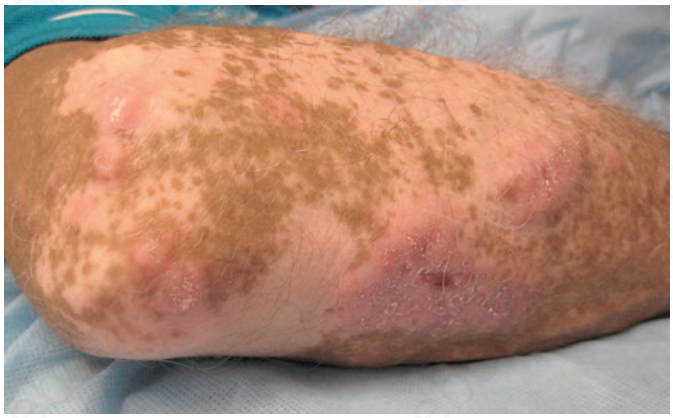

Fig. 5.16 Common variable immunodeficiency with granulomas in vitiligo.

Class-Switch Recombination Defects (Formerly Immunodeficiency With Hyper-IgM)

This group of diseases includes defects that are combined T-cell and B-cell abnormalities, such as CD40 deficiency *(CD40)* and CD40 ligand deficiency *(CD40LG)*, and disorders of primary B cells, such as cytidine deaminase *(AICDA)* and uracil-DNA glycosylase *(UNG)* deficiencies. Class-switch recombination defects are rare, and the different genetic diseases included in this group appear to have different clinical manifestations. These patients experience recurrent sinopulmonary infections, diarrhea, and oral and anogenital ulcers. Neutropenia may be associated with the ulcers. Recalcitrant human papillomavirus (HPV) infections (typically flat warts) may occur.

Hypomorphic mutations in *NEMO* or *IKBKG* are associated with hypogammaglobulinemia and elevated IgM and may be associated with anhidrotic ectodermal dysplasia with immunodeficiency. *NEMO* mutations cause X-linked recessive disorders with lymphocytosis and elevated CD3 and CD4 cells and low levels of NK cells. The mother may have mild stigmata of incontinentia pigmenti. These male infants present within the first few months of life with hypohidrosis, delayed tooth eruption, and immunodeficiency. Hair may be absent. Frequent infections of the skin and respiratory tract are common. The eruption has been characterized as an "atopic dermatitis–like eruption," although some patients may have prominent intertriginous lesions resembling seborrheic dermatitis. Treatment is bone marrow transplantation.

Qamar N, et al: The hyper IgM syndromes. Clin Rev Allergy Immunol 2014; 46: 120.

Thymoma With Immunodeficiency

Thymoma with immunodeficiency, also known as Good syndrome, occurs in adults in whom profound hypogammaglobulinemia and benign thymoma appear almost simultaneously. It is now classified predominantly as an antibody deficiency disorder. There is a striking deficiency of B and pre-B cells. One patient who developed vulvovaginal gingival lichen planus and severe oral herpes simplex has also been reported. Myelodysplasia and pure red blood cell aplasia may occur. Patients are at risk for fatal opportunistic pulmonary infections with fungi and *Pneumocystis*. Thymectomy does not prevent the development of the infectious or lymphoreticular complications. Supportive therapy with IVIG, granulocyte-macrophage colony-stimulating factor (GM-CSF), and transfusions may be required.

Moutasim KA, et al: A case of vulvovaginal gingival lichen planus in association with Good's syndrome. Oral Surg Oral Med Oral Pathol Oral Radiol Endod 2008; 105: e57.

Disorders With T-Cell Deficiency

T-cell deficiency states can result from lack of thymic tissue, enzyme defects toxic to T lymphocytes (purine nucleoside phosphorylase deficiency), failure to express surface molecules required for immune interactions (CD3, major histocompatibility complex [MHC] class I and II), or defects in signaling molecules.

Digeorge Syndrome

DiGeorge syndrome is an autosomal dominant disorder that in 50% of cases is caused by hemizygous deletion of 22q11-pter and rarely by deletions in 10p. Many cases are sporadic. Most DiGeorge syndrome patients have the congenital anomalies and only minor thymic anomalies. They present with hypocalcemia or congenital heart disease. The syndrome includes congenital absence of the parathyroids and an abnormal aorta. Aortic and cardiac defects are the most common cause of death. DiGeorge syndrome is characterized by a distinctive facies: notched, low-set ears, micrognathia, shortened philtrum, and hypertelorism. Patients with these DiGeorge congenital malformations and complete lack of thymus are deemed to have "complete DiGeorge syndrome." Cell-mediated immunity is absent or depressed, and few T cells with the phenotype of recent thymus emigrants are found in the peripheral blood or tissues. Opportunistic infections are common despite normal immunoglobulin levels. Maternally derived GVHD may occur in these patients. A small subset of patients with complete DiGeorge syndrome develop an eczematous dermatitis, lymphadenopathy, and an oligoclonal T-cell proliferation. The condition may present as an atopic-like dermatitis, severe and extensive seborrheic dermatitis, or an erythroderma. This is called "atypical complete DiGeorge syndrome." Biopsies show features of a spongiotic dermatitis with eosinophils, necrotic keratinocytes with satellite necrosis, and characteristically perieccrine and intraeccrine inflammation. This resembles the histology of grade 1 or 2 GVHD, lichen striatus, and some cases of mycosis fungoides. One African American patient with DiGeorge syndrome developed a granulomatous dermatitis. The treatment for complete DiGeorge syndrome is thymic transplantation.

Miscellaneous T-Cell Deficiencies and Severe Combined Immunodeficiency

IPEX Syndrome

The immune dysregulation, polyendocrinopathy, enteropathy, X-linked recessive (IPEX) syndrome is a rare disorder presenting neonatally with the classic triad of autoimmune enteropathy, endocrinopathy (diabetes, thyroiditis), and eczematous dermatitis affecting males. Elevated IgE levels, eosinophilia, and food allergies, plus the eczematous dermatitis, all are manifestations of Th2 skewing of the immune system. Patients present with diffuse and severe erythematous exudative plaques resembling AD. Secondary infection is common, and staphylococcal septicemia can occur. The skin eruption may be follicularly based or may lead to prurigo nodularis. The scalp develops hyperkeratotic psoriasiform plaques. Cheilitis and onychodystrophy can occur. Alopecia areata, chronic urticaria, and bullous pemphigoid are cutaneous autoimmune manifestations of IPEX syndrome.

The IPEX syndrome is caused by mutations in *FOXP3* (forkhead box P3 protein), the master control gene for regulatory T-cell (Treg) development. IPEX like disease may also be caused by loss-of-function mutations in *CD25*, *STAT5b*, and *ITCH* and gain-of-function mutations in *STAT1* (signal transducer and activator of transcription 1). *FOXP3* is necessary for the development of Tregs, which are required to maintain immune homeostasis and mediate peripheral tolerance to "self" and nonself antigens. The enteropathy may be driven by autoantibodies to villin, and

these autoantibodies can be used diagnostically. Treatment is immunomodulator therapy or bone marrow transplantation.

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) is a heterogeneous group of genetic disorders characterized by severely impaired cellular and humoral immunity. Severe T-cell deficiency and low lymphocyte count are found in virtually all SCID patients. Candidiasis (moniliasis) of the oropharynx and skin, intractable diarrhea, and pneumonia are the triad of findings that usually lead to the diagnosis of SCID. In addition, severe recurrent infections may occur, caused by *Pseudomonas*, *Staphylococcus*, Enterobacteriaceae, or *Candida*. Overwhelming viral infections are the usual cause of death. Engraftment of maternally transmitted or transfusion-derived lymphocytes can lead to GVHD. The initial seborrheic dermatitis–like eruption may represent maternal engraftment GVHD. This cutaneous eruption may be asymptomatic but tends to generalize. Infants with a widespread dermatitis but who lack any palpable lymph nodes should raise suspicion for SCID. More severe eczematous dermatitis and erythroderma may develop with alopecia. Cutaneous granulomas have been reported. In addition a higher rate of dermatofibroma sarcoma protuberans (DFSP) had been reported in SCID due to adenosine deaminase.

Deficiency or total absence of circulating T lymphocytes characterizes SCID. Immunoglobulin levels are consistently very low, but B-cell numbers may be reduced, normal, or increased. The thymus is very small; its malformed architecture at autopsy is pathognomonic.

The inheritance is either autosomal recessive or X-linked. Forty percent of SCID cases are X-linked and caused by deficiency of a common γ-chain that is an essential component of the IL-2 receptor. Twenty percent are caused by adenosine deaminase (ADA) deficiency and 6% from *Jak3* mutations.

Prenatal diagnosis and carrier detection are possible for many forms of SCID. The definitive treatment is hematopoietic stem cell transplantation (HSCT, bone marrow transplantation). This should ideally be carried out before age 3½ months for optimal outcome. The success rate approaches 90%. In utero HSCT has been successful in X-linked SCID. SCID patients rarely live longer than 2 years without transplantation. On average, 8 years after successful HSCT, SCID patients may develop severe HPV infection with common warts, flat warts, or even epidermodysplasia verruciformis. The development of HPV infections in SCID patients after HSCT is only seen in patients with either *Jak3* or γ-chain (gamma c) deficiency, but more than 50% of these patients may develop this complication.

Miscellaneous Genetic Disorders of Cellular Immunity

The *TAP1* and *TAP2* gene deficiencies are extremely rare autosomal recessive disorders that result in severe reduction of MHC class I expression on the surface of cells. CD8 cells are decreased, but CD4 cells are normal, as are B-cell numbers and serum immunoglobulins. Three forms of disease occur. The patient with the first phenotype develops severe bacterial, fungal, and parasitic infection and dies by age 3. The patient with the second phenotype is completely asymptomatic. The third group is the most common. Group 3 patients present in childhood with recurrent and chronic bacterial respiratory infections. These lead to bronchiectasis and eventually fatal respiratory failure in adulthood. The skin abnormalities appear in late childhood or more frequently in young adulthood (after age 15). Necrotizing granulomatous lesions appear as plaques or ulcerations on the lower legs and on the midface around the nose. The perinasal lesions are quite destructive and resemble "lethal midline granuloma" or Wegener granulomatosis. Nasal polyps with necrotizing granulomatous histology also occur. One patient also developed leukocytoclastic vasculitis.

The ZAP-70 (ζ-chain [TCR]–associated protein kinase of 70 kD) deficiency is an autosomal recessive disorder of considerable heterogeneity. This enzyme is required for T-cell receptor (TCR) intracellular signaling. Patients present before age 2 years with recurrent bacterial, viral, and opportunistic infections, diarrhea, and failure to thrive. They have a lymphocytosis with normal CD4, NK, and B cells and decreased CD8 cells. Some patients develop an exfoliative erythroderma, eosinophilia, and elevated IgE levels.

Omenn syndrome (OMIM 603554; histiocytic medullary reticulosis) is a rare disorder that presents at birth or in the neonatal period. Classic Omenn was caused by defects in molecules involved in the variable diversity and joining V(D)J process. It is also caused by hypomorphic mutations in some of the genes that cause SCID. Both antibody production and cell-mediated immune function are impaired. Genetic mutations causing Omenn syndrome occur in *RAG1* and *RAG2 (*90% of cases, classic Omenn), *DCLRE1C* (encoding ARTEMIS), *DNA-ligIV, IL7Rα, IL2Rγ, CHD7, ADA*, and *RNRP.* These mutations all result in defective T-cell development and oligoclonal, abnormally activated T cells. Clinical features include severe exfoliative erythroderma, eosinophilia, alopecia, *Pneumocystis jiroveci* and viral pneumonias, colitis, hepatosplenomegaly, lymphadenopathy, hypogammaglobulinemia, and elevated IgE.

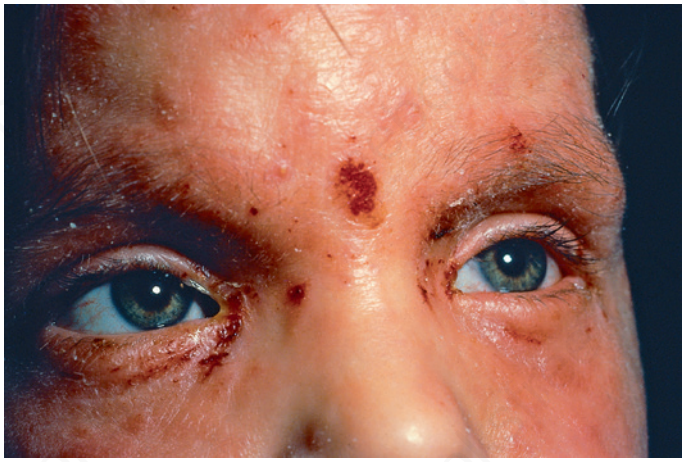

Fig. 5.17 Eczematous eruption with purpura in Wiskott-Aldrich syndrome.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome, an X-linked recessive syndrome, consists of a triad of chronic eczematous dermatitis resembling AD (Fig. 5.17); increased susceptibility to bacterial infections, such as pyoderma or otitis media; and thrombocytopenic purpura with small platelets. Levels of IgM are variable, IgA is normal to high, and IgE is elevated, as is IgG. On a complete blood cell count the mean platelet volume (MPV) is decreased. T cells (especially naïve T cells) are low in infancy and progressively decline in number and activity over time. Untreated survival is about 15 years, with death from infection, bleeding, or lymphoma (25% of patients).

The genetic cause of Wiskott-Aldrich syndrome is a mutation in the *WASP* gene. This gene codes for a protein called WASP, which is universally expressed in hematopoietic cells and is critical in the reorganization of the actin cytoskeleton in hematopoietic cells in response to external stimuli. The hematopoietic cells of affected patients cannot polarize or migrate in response to physiologic stimuli, accounting for the protean clinical features of the syndrome. Wiskott-Aldrich syndrome occurs when mutations in *WASP* lead to absence or truncation of the WASP protein (WASP – mutations). Mutations that result in normal length but some loss of function in the WASP protein (WASP + mutations) result in two different syndromes: X-linked thrombocytopenia (XLT) and intermittent X-linked thrombocytopenia. Gain-of-function mutations in WASP cause X-linked neutropenia. Patients with XLT may also have an atopic-like dermatitis, but this is usually milder than the severe and difficult to control eczema affecting patients with the full Wiskott-Aldrich syndrome. WASP/XLT patients may also develop autoimmune disease, especially autoimmune hemolytic anemia, vasculitis, Henoch-Schönlein–like purpura, and IBD. High IgM is associated with the development of autoimmune disease.

Treatment is with platelet transfusions, antibiotics, and IVIG, if required. Low dose IL2 is in trials and targeted gene therapy has been attempted. Often, splenectomy is performed to help control bleeding, but this leads to increased risk of sepsis and is not routinely recommended. Immunosuppressive therapy or rituximab may be used to control autoimmune complications. Bone marrow transplantation from a human leukocyte antigen (HLA)–identical sibling as early as possible in the disease course provides complete reversal of the platelet and immune dysfunction, as well as improvement or clearing of the eczematous dermatitis. Survival at 7 years with a matched sibling donor transplant approaches 90%.

Fig. 5.18 Granulomatous lesions in ataxia teleangiectasia.

Massaad MJ, et al: Wiskott-Aldrich syndrome. Ann NY Acad Sci 2013; 1285: 26.

Ataxia Telangiectasia

Ataxia telangiectasia is an autosomal recessive condition caused by mutations in a single gene on chromosome 11 *(ATM)*, which encodes a protein called ATM. When ATM is absent, the cell cycle does not stop to repair DNA damage, particularly double-stranded breaks, or for B(D)J recombination of immunoglobulin and TCR genes. This results in immunodeficiency and an increased risk for malignancy. The initial prominent skin feature is progressive ocular and cutaneous telangiectasias starting at age 3–6 years. These begin on the bulbar conjunctiva but later develop on the eyelids, ears, and flexors of the arms and legs. The ATM protein seems to be important in maintaining mitochondrial homeostasis, and this defect may be responsible for the premature aging (with loss of subcutaneous fat and graying of hair) and neurodegeneration.

Cutaneous noninfectious granulomas may occur and can be ulcerative and painful (Fig. 5.18). Rubella virus has been recovered by PCR from active ulcerations. Live vaccinations such the measles mumps and rubella vaccination should not be given to immunodeficient children, but because AT presents typically after age 1, children are often already vaccinated. Therefore the likely mechanism of granuloma formation is the ineffective processing of the rubella (or other infectious antigens) in live vaccinations. The granulomas tend to worsen with biopsy and manipulation. Other cutaneous features include large, irregular segmental café au lait spots, vitiligo, seborrheic dermatitis, AD, recurrent impetigo, and acanthosis nigricans. Late tightening of the skin can occur and resembles acral sclerosis. Sinopulmonary infections are common, especially otitis media, sinusitis, bronchitis, and pneumonia. Varicella (at times severe), herpes simplex, molluscum contagiosum, and herpes zoster can occur. Refractory warts occur in more than 5% of patients. Aside from candidal esophagitis, unusual opportunistic infections are rare.

Lymphopenia is common, with reduction of both B and T cells occurring in the majority of patients. Th-cell counts can be less than 200. IgA, IgG4, IgG2, and IgE deficiencies can all be present. Paradoxically, IgM, IgA, and IgG can be elevated in some patients, including the presence of monoclonal gammopathy in more than 10%. The immunologic abnormalities are not progressive. Lymphoma risk is increased more than 200-fold (especially B-cell lymphoma), and leukemia (especially T-cell chronic lymphocytic leukemia) is increased 70-fold. Treatment includes high vigilance for infection and malignancy. In patients with low CD4 counts, prophylaxis to prevent *Pneumocystis* pneumonia can be considered. When IgG deficiency is present and infections are frequent, IVIG may be beneficial. IVIG and intralesional corticosteroids may be used for the cutaneous granulomas. Carriers of ataxia telangiectasia have an increased risk for breast cancer. Because of the accumulation of chromosomal breaks after radiation exposure, both the ataxia telangiectasia patients and the carriers should minimize radiation exposure.

Primary Immunodeficiency Diseases Associated With Warts

Depressed T-cell function, either iatrogenic or genetic, is associated with an increased risk of HPV infection. However, a few PIDs are associated with a particular burden of HPV infection, and HPV infection may be an initial or prominent component of the syndrome. HPV vaccine may activate the immune system to help clear recalcitrant verrucae in some patients. Epidermodysplasia verruciformis is discussed in Chapter 19.

WHIM Syndrome

The warts, hypogammaglobulinemia, infections, and myelokathexis (WHIM) syndrome is an autosomal dominant disorder with hypogammaglobulinemia, reduced B-cell numbers, and neutropenia. The most common genetic cause is a gain of function mutation of the *CXCR4* gene. Additional mutations that are not in the *CXCR4* gene can also cause WHIM, but all of them lead to functional hyperactivity of *CXCR4*. *CXCR4* causes retention of neutrophils in the bone marrow and is the basis of the neutropenia and myelokathexis (increased apoptotic neutrophils in bone marrow). There is profound loss of circulating CD27+ memory B cells, resulting in hypogammaglobulinemia, with the observation that WHIM patients have normal antibody response to certain antigens but fail to maintain this antibody production. However, normal immunoglobulin levels do not exclude the diagnosis of WHIM. Almost 80% of WHIM patients have warts at the time of their diagnosis (Fig. 5.19). These include common and genital wart types. A significant number of female WHIM patients have cervical and vulval dysplasia, which can progress to carcinoma. WHIM patients have disproportionately more HPV infections than SCID patients but have little problem resolving other viral infections. However, they may develop Epstein-Barr virus (EBV)–induced lymphomas. The vast majority of patients in early childhood have recurrent sinopulmonary infections, skin infections, osteomyelitis, and urinary tract infections. Recurrent pneumonias lead to bronchiectasis. There is a CXCR4 antagonist in trials but standard treatment is G-CSF, IVIG, prophylactic antibiotics, and aggressive treatment of infections. There is one report recently of a cure of WHIM by chromothripsis in a hematopoietic stem cell. Chromothripsis is a catastrophic disruption of chromosomes

Fig. 5.19 Warts in WHIM syndrome.

in a cell in this case the new stem cell had a selective advantage due to the lack of the WHIM mutation. Untreated, the HPV infections can progress to fatal carcinomas, and therefore male patients must be regularly examined by dermatologists and female patients by gynecologists; a low threshold for biopsy of genital lesions is required.

DOCK8 Deficiency

Deficiency in DOCK8 (dedicator of cytokinesis 8) are associated with hyper-IgE syndrome (see later discussion). However, unlike other genetic causes of hyper-IgE, DOCK8 deficiency is uniquely associated with a susceptibility to cutaneous viral infections, including HSV, molluscum contagiosum, and HPV (Fig. 5.20). Warts can be flat or verrucous and affect about two thirds of patients.

GATA2 Deficiency (WILD Syndrome)

GATA2 is an important transcription factor involved in hematopoiesis maintenance of the stem cell compartment. GATA2 deficiency leads to a constellation of syndromes characterized by myelodysplasia, opportunistic infections, and leukemia. Patients have profound monocytopenia, often neutropenia, and NK, B, and dendritic cell lymphocytopenia. T-cell counts are variable. More than 75% of patients have severe or disseminated HPV infection, usually verruca plana or verruca vulgaris, and the HPV infection is first manifestation in the majority of patients, usually in adolescence or early adulthood. Severe cervical HPV infection can also occur and may lead to cancer. Thirty percent of patients develop a corticosteroid-responsive panniculitis. GATA2 has a role in lymphatic development and when the constellation includes lymphedema, it has been named WILD syndrome (warts,

Fig. 5.20 Warts in DOCK8 immunodeficiency. (Courtesy Edward W. Cowen, MD.)

immunodeficiency, lymphedema, and dysplasia). The genetic defect in WILD patients can be missed on typical sanger sequencing because the mutation can be large and extend into exons. The WILD syndrome is rare and presents at age 6 months with lower extremity lymphedema that is progressive and later may involve the upper extremities and groin. Venous thrombosis occurs in 25% and lymphedema in 11% of patients of all patients with GATA2 mutations. Allogeneic HSCT seems to be curative.

Defects of Phagocyte Number, Function, or Both

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is a rare disorder caused by mutations in one of the genes that encode the subunits of the superoxide-generating phagocyte NADPH oxidase system responsible for the respiratory burst involved in organism killing. CGD is characterized by repeated and recurrent bacterial and fungal infections of the lungs, skin, lymph nodes, and bones. Gingivostomatitis (aphthous-like ulcerations) and a seborrheic dermatitis of the periauricular, perinasal, and perianal area are characteristic. The dermatitis is frequently infected with *S. aureus*, and regional adenopathy and abscesses may complicate the infections. The term *suppurative dermatitis* is used in the immunology literature to describe this seborrheic-like dermatitis with secondary infection, analogous to the "infective dermatitis" seen in human T-cell lymphotropic virus (HTLV)–1 infection. In addition to *S. aureus*, *Serratia* species are often isolated from skin abscesses and osteomyelitis. *Aspergillus* is the most common agent causing pneumonia in CGD patients. In tuberculosis-endemic areas, CGD patients frequently develop active tuberculosis or prolonged scarring, abscesses, or disseminated infection following bacille Calmette-Guérin (BCG) immunization.

There are four types of CGD, one X-linked and three autosomal recessive. The X-linked form is the most common (65%–75% of CGD patients) and is caused by a mutation in the *CYBB* gene, which leads to a total absence of NADPH oxidase activity. In autosomal recessive forms, mutations in the genes encoding for the remaining three oxidase components have been described: p22-phox *(CYBA)*, p47-phox *(NCF1)*, and p67-phox *(NCF2)*. One patient with a mutation in p40-phox *(NCF4)* has been described. The X-linked variant has the most severe phenotype. Compared with the autosomal recessive CGD patients, the X-linked patients present at an earlier age (14 vs. 30 months) and are diagnosed at an earlier age (3–5 vs. 6–13 years). The lack of superoxide generation apparently causes disease, not because the bacteria are not being killed by the superoxide, but because the superoxide is required to activate proteases in phagocytic vacuoles that are needed to kill infectious organisms.

Granuloma formation is characteristic of CGD and can occur in the GI tract, liver, bladder, bone, and lymph nodes. Up to 40% of biopsies from these organs will demonstrate granulomas, at times with identifiable fungal or mycobacterial organisms. These patients are often receiving prophylactic antibiotics, however, so organisms are frequently not found. Subcorneal pustular eruptions can also be seen in CGD patients. In the intestinal tract, the GI symptoms and granuloma formation can present in a similar fashion to inflammatory bowel disease.

The diagnosis of CGD is made by demonstrating low reduction of yellow nitroblue tetrazolium (NBT) to blue formazan in the "NBT test." Dihydrorhodamine 123 flow cytometry (DHR), chemiluminescence production, and the ferricytochrome *c* reduction assay are also confirmatory. Western blot analysis for NADPH oxidase expression and DNA sequencing can pinpoint the genetic mutation.

Female carriers of the X-linked form of CGD have a mixed population of normal and abnormal phagocytes and therefore show intermediate NBT reduction and two discrete populations with DHR testing. The majority of carriers have skin complaints including a malar rash, discoid lupus erythematosus (DLE)–like lesions, adult acne and skin abscesses. The lesions are clinically DLE-like, but histologically, the interface component is often absent, and the lesions resemble tumid lupus. Direct immunofluorescence examination is usually negative, as is common in tumid lupus erythematosus (LE). Less frequently, CGD patients themselves have been described as having similar LE-like lesions, or "arcuate dermal erythema." Despite these findings, the vast majority of patients with LE-like skin lesions, both carriers and CGD patients, are antinuclear antibody (ANA) negative. Raynaud phenomenon can occur. More than half will report a photosensitive dermatitis, 40% have oral ulcerations, and one third have joint complaints.

Treatment of infections should be early and aggressive. There should be a low threshold to biopsy skin lesions, as they may reveal important and potentially life-threatening infections. Patients usually receive chronic TMP-SMX prophylaxis, chronic oral anti-*Aspergillus* agent (such as itraconazole, posaconazole or voriconazole), and IFN-γ injections. Voriconazole can lead to severe photodamage and skin malignancy, so chronic therapy in CGD patients should be used with extreme caution. Thalidomide has been used for the colitis. Bone marrow or stem cell transplantation has been successful in restoring enzyme function, reducing infections, and improving the associated bowel disease. However, survival is *not* increased with bone marrow transplantation, so this is not routinely undertaken. Recently IL-1 blockade was found to be effective at decreasing the inflammation of CGD.

Leukocyte Adhesion Deficiency

This rare autosomal recessive disorder has three types. Leukocyte adhesion deficiency (LAD) type I is caused by a mutation in the common chain (CD18) of the β2-integrin family (*ITGB2).* It is characterized by recurrent bacterial infections of the skin and mucosal surfaces, especially gingivitis and periodontitis. The remnant umbilical cord is often delayed in separation during infancy. Skin ulcerations from infection may continue to expand. Cellulitis and necrotic abscesses, especially in the perirectal area, can occur. Minor injuries may lead to pyoderma gangrenosum–like ulcerations that heal slowly. Infections begin at birth, and omphalitis with delayed separation of the cord is characteristic. Neutrophilia is marked, usually 5–20 times normal, and the count may reach up to 100,000 during infections. Despite this, there is an absence of neutrophils at the sites of infection, demonstrating the defective migration of neutrophils out of the blood vessels in these patients. LAD type I patients are affected either severely (<1% of normal CD18 expression) or moderately (2.5%–10% of normal expression.) Patients with moderate disease have less severe infections and survive into adulthood, whereas patients with severe disease often die in infancy.

LAD type II is caused by a mutation in *SLC35C1*, which results in a general defect in fucose metabolism which results in decreased fucosylation of selectin ligands on leukocytes. This leads to impaired tethering and rolling on activated endothelial cells. Severe mental retardation, short stature, a distinctive facies, and the rare hh blood phenotype are the features. Initially, these patients have recurrent cellulitis with marked neutrophilia, but the infections are not life threatening. After age 3 years, infections become less of a problem and patients develop chronic periodontitis.

LAD type III is caused by a mutation in the gene *FERMT3* and is characterized by severe recurrent infections, bleeding tendency (from impaired platelet function), and marked neutrophilia.

LAD1 patients can have abnormal IL12 and 23 activity and thus ustekinumab was recently tried with excellent success. Bone marrow transplantation is an option for patients with severe LAD type I and LAD type III.

Hyperimmunoglobulinemia E Syndrome

There are at least multiple defined mutations that cause hyperimmunoglobulinemia E syndrome (HIES; also called hyper-IgE syndrome). The autosomal dominant form is caused by a mutation in *STAT3*, and the autosomal recessive form by mutations in *DOCK8* and rarely in tyrosine kinase 2 (TYK2) or phosphoglucomutase 3 (PGM3). The autosomal recessive forms of HIES are clinically somewhat different and are described separately.

Autosomal dominant HIES was first called Job syndrome or Buckley syndrome. The classic triad is an AD-like eczematous dermatitis, recurrent skin and lung infections, and high serum IgE, although IgE is elevated in atopy generally. The skin disease is the first manifestation of STAT3 deficiency and begins at birth in 19% of cases, within the first week of life in more than 50%, and in the first month in 80%. This is very helpful clinically because AD does not usually start until the second or third month of age. The initial eruption is noted first on the face or scalp, but quickly generalizes to affect the face, scalp, and body. The rash favors the shoulder, arms, chest, and buttocks. The newborn rash begins as pink papules and pustules that coalesce into crusted plaques that may initially be diagnosed as "neonatal acne." Histologically, these papules are intraepidermal eosinophilic pustules. The dermatitis evolves to bear a close resemblance to AD, often very severe, and occurs in 100% of autosomal dominant HIES patients. Staphylococcal infection of the dermatitis is common. There can be "cold" abscesses due to the lack of inflammation typically present to fight infection. IgE levels are above 2000 in 95% of patients with autosomal dominant HIES, but since only a small percentage of children with IgE levels above 2000 actually have HIES, other features must be used to confirm the diagnosis. Recurrent pyogenic pneumonia is the rule, starting in childhood. Because of the lack of neutrophilic inflammation in abscesses and pneumonia, symptoms may be lacking and lead to a delay in diagnosis. Although antibiotic treatment clears the pneumonia, healing is abnormal, with the formation of bronchiectasis and pneumatoceles, a characteristic feature of HIES. Mucocutaneous candidiasis is common, typically thrush, vaginal candidiasis, and candidal onychomycosis. Musculoskeletal abnormalities are common, including scoliosis, osteopenia, minimal trauma fractures (55%), and hyperextensibility, leading to premature degenerative joint disease. Retention of some or all of the primary teeth is a characteristic feature. Other oral manifestations include median rhomboid glossitis, high-arch palate, and abnormally prominent wrinkles on the oral mucosa. Arterial aneurysms are common, including Chiari 1 malformation (40%) and coronary vascular abnormalities (60%). The latter can cause myocardial infarction. Autosomal dominant HIES patients have a characteristic facies, developing during childhood and adolescence. Features include facial asymmetry, broad nose, deep-set eyes, and a prominent forehead. The facial skin is rough, with large pores. There is an increased risk of malignancy, predominantly B-cell non-Hodgkin lymphoma, but cutaneous squamous cell carcinoma has also been reported. Laboratory abnormalities are limited to eosinophilia and an elevated IgE. In adults, IgE levels may become normal. Functional Th17 studies can help in diagnosis. A scoring system developed at the National Institutes of Health (NIH) can accurately identify patients with HIES, selecting those in whom genetic testing could be considered.

Autosomal recessive HIES is caused by *DOCK8*, TYK2, or PGM3 mutations and is less common. Patients with *DOCK8* mutations also have severe eczema and recurrent skin and lung infections, although the lung infections resolve without pneumatoceles (except in PGM3). TYK2 has only been described in a small number of patients who had high IgE and atopy. Food allergies are often present in autosomal recessive HIES caused by *DOCK8* mutation, as is decreased IgM. The main cutaneous difference is patients with *DOCK8* mutations are predisposed to exuberant cutaneous viral infections, especially warts, molluscum contagiosum, herpes simplex, and varicella-zoster, as well as systemic viral infections, including EBV and cytomegalovirus (CMV). They also develop mucocutaneous candidiasis. Neurologic disease is much more common in autosomal recessive HIES, ranging from facial paralysis to hemiplegia. Autosomal recessive HIES patients have normal facies, no fractures, and normal shedding of primary dentition, but a dramatic increase in malignancy, especially leukemia.

Treatment for HIES is aimed at decreasing infection and maintaining skin barrier. Infections are suppressed with bleach baths and chronic antibiotic prophylaxis (usually with TMP-SMX); antifungal agents may be used for candidal infections of the skin and nails. Topical antiinflammatories are used to manage the eczema, and in severe cases, systemic therapy can be considered but should be used with caution. Bisphosphonates are used for osteopenia. The role of IVIG, antihistamines, dupilumab, and omalizumab (antibody against IgE) is unknown. In patients with autosomal recessive HIES, hematopoietic cell transplantation (HCT) is recommended because of the high risk of malignancy and CNS infarction. Autosomal dominant HIES patients with malignancy should be considered for HCT because it can reverse the HIES, reducing the infectious complications following HCT.

Complement Deficiency

The complement system is an effector pathway of proteins that results in membrane damage and chemotactic activity. Four major functions result from complement activation: cell lysis, opsonization/phagocytosis, inflammation, and immune complex removal. In the "classical" complement pathway, complement is activated by an antigen-antibody reaction involving IgG or IgM. Some complement components are directly activated by binding to the surface of infectious organisms; this is called the "alternate" pathway. The central component common to both pathways is C3. In the classical pathway, antigen-antibody complexes sequentially bind and activate three complement proteins, C1, C4, and C2, leading to the formation of C3 convertase, an activator of C3. The alternate pathway starts with direct activation of C3. From activated C3, C5–C9 are sequentially activated. Cytolysis is induced mainly through the membrane attack complex (MAC), which is made up of the terminal components of complement. Opsonization is mainly mediated by a subunit of C3b, and inflammation by subunits of C3, C4, and C5.

Inherited deficiencies of complement are usually autosomal recessive traits. Deficiencies of all 11 components of the classical pathway, as well as inhibitors of this pathway, have been described. Genetic deficiency of the C1 inhibitor is the only autosomal dominant form of complement deficiency and results in hereditary angioedema (see Chapter 7). In general, deficiencies of the early components of the classical pathway result in autoimmune connective tissue diseases, whereas deficiencies of the late components of complement lead to recurrent neisserial sepsis or meningitis. Overlap exists, and patients with late-component deficiencies may exhibit connective tissue diseases, and patients with deficiencies of early components, such as C1q, may manifest infections. Deficiency of C3 results in recurrent infections with encapsulated bacteria such as *Pneumococcus*, *H. influenzae*, and *Streptococcus pyogenes.* C3 inactivator deficiency, as with C3 deficiency, results in recurrent pyogenic infections. Properdin (component of alternate pathway) dysfunction is inherited as an X-linked trait and predisposes to fulminant meningococcemia. Deficiency of C9 is the most common complement deficiency in Japan but is uncommon in other countries. Most patients appear healthy. MASP2 deficiency, resulting in absent hemolytic activity by the lectin pathway, is considered a complement deficiency and results in a syndrome resembling SLE and increased pyogenic infection. Factor I deficiency results in recurrent infections, including *Neisseria meningitides.* Partially deficient family members may also have increased infections.

C2 deficiency is the most common complement deficiency in the United States and Europe. Most patients are healthy, but SLE-like syndromes develop in 10%. C1q-, C3-, and C4-deficient patients have SLE at rates of 90%, 31%, and 75%, respectively, and C1r deficiency was recently reported in early-onset SLE. Complement deficiency–associated SLE typically has early onset, photosensitivity, less renal disease, and Ro/La autoantibodies in two thirds of patients. C2- and C4-deficient patients with LE typically have subacute annular morphology (Fig. 5.21), Sjögren syndrome, arthralgias, and oral ulcerations. CH50 is a functional assay of the complement system and is typically low in active systemic lupus. Cell-bound complement activity products such as C4d and C3d, which are the byproducts of complement activation, are deposited on other cells such as erythrocytes and can be detected to monitor systemic lupus disease activity. Frequent infections, anaphylactoid purpura, dermatomyositis, vasculitis, and cold urticaria may be seen. A patient with C1q deficiency presented with macrophage activating syndrome. Renal disease, anti-dsDNA antibodies, and anticardiolipin antibodies are uncommon. Patients with C4 deficiency may have lupus and involvement of the palms and soles.

Fig. 5.21 Subacute lupus erythematosus as can be seen in complement deficiency disorders.

Many of the complement component deficiencies can be acquired as an autoimmune phenomenon or a paraneoplastic finding. Examples include acquired angioedema, as when C1 inhibitor is the target, or lipodystrophy and nephritis, when C3 convertase is the target.

When complement deficiency is suspected, a useful screening test is a CH50 (total hemolytic complement) determination, because deficiency of any of the complement components will usually result in CH50 levels that are dramatically reduced or zero.

Graft-Versus-Host Disease

GVHD occurs most frequently in the setting of HSCT but may also occur following organ transplantation or in the rare situation of transfusion of active lymphoid cells into an immunodeficient child postpartum or even in utero. Blood transfusions with active lymphocytes (nonradiated whole blood) from family members or in populations with minimal genetic variability, given to an immunodeficient patient, can result in GVHD. HSCT from a monozygotic twin (syngeneic) or even from the patient's own stem cells (autologous) can rarely induce a mild form of GVHD.

Development of GVHD requires three elements. First, the transplanted cells must be immunologically competent. Second, the recipient must express tissue antigens that are not present in the donor and therefore are recognized as foreign. Third, the recipient must be unable to reject the transplanted cells. Immunologic competence of the transplanted cells is important, because ablating them too much may lead to failure of engraftment, or, more often, incomplete eradication of the recipient's malignancy (graft-vs.-tumor effect). Therefore some degree of immunologic competence of the transplanted cells is desired. For this reason, the prevalence of GVHD still remains about 50% after HSCT. Another important factor in determining the development and severity of the GVHD is the preconditioning regimen. Chemotherapy and radiation cause activation of dendritic cells (antigen-presenting cells [APCs]) in tissues with high cell turnover—the skin, gut, and liver. These APCs increase their expression of HLA and other minor cell surface antigens, priming them to interact with transplanted lymphoid cells. Host APCs are important in presenting these antigens to the active lymphoid donor cells. Cytokines, especially IL-2, TNF-α, and IFN-γ, are important in enhancing this host-donor immunologic interaction. Reducing this early inflammatory component in GVHD can delay the onset of the GVHD but may not reduce the prevalence. The indications for HSCT, age limits, and allowable degree of HLA incompatibility have resulted in greater use of HSCT, increasing the number of persons at risk for GVHD.

Fig. 5.22 Acute graft-versus-host disease. (Courtesy Jennifer Huang, MD.)

Initially, only reactions that occurred within the first 100 days after transplantation were considered acute GVHD, but it is now recognized that classic acute GVHD can occur up to 1 year or more after HSCT, especially with tapering of anti-GVHD immunosuppressives. Acute GVHD is based on the clinical presentation, *not* the time of onset after transplantation. In acute GVHD, the cutaneous eruption typically begins between the 14th and 42nd days after transplantation, with a peak at day 30 (Fig. 5.22). Acute GVHD is characterized by an erythematous morbilliform eruption of the face and trunk, which may become confluent and result in exfoliative erythroderma. Ear involvement is common. It often begins with punctate lesions corresponding to hair follicles and eccrine ducts, resembling keratosis pilaris. In many cases, a fine scale can be appreciated on the skin lesions. GVH is often described as more monomorphous than similar-appearing morbilliform drug eruptions, and tends to involve the upper back, rather than the lower back and dependent areas. GVHD is staged clinically, with stage 1 as less than 25% BSA, stage 2 as 25%–50% BSA, stage 3 as greater than 50% BSA, and stage 4 as erythroderma with bullae. In children, the diaper area is often involved. The eruption may appear papular and eczematous, involving web spaces, periumbilical skin, and ears, and bears some resemblance to scabies.

The differential diagnosis for the eruption of acute GVHD includes the eruption of lymphocyte recovery, engraftment syndrome, viral exanthem, and drug eruption. The cutaneous histology in the early phases of acute GVHD may not be able to completely distinguish these entities. Grade IV GVHD is characterized by full-thickness slough and may resemble toxic epidermal necrolysis, and it may be impossible to distinguish the two entities clinically or histologically. The mucous membranes and the conjunctivae can be involved as well, which can be difficult to distinguish from chemotherapy-induced and infectious mucositis. Often, about the same time, the patient develops the other characteristic features of acute GVHD: cholestatic hepatitis with elevated bilirubin and high-volume diarrhea. Autologous GVHD usually involves only the skin and is self-limited, and it is thought to occur from preconditioning regimen–induced loss of "self-tolerance."

The "eruption of lymphocyte recovery" is a mild, self-limited morbilliform eruption that may be associated with a brief fever, occurring when lymphocyte counts first return following chemotherapy. This can closely resemble GVHD, though without liver or gut involvement; patients may progress to overt aGVHD. Engraftment syndrome is a combination of symptoms that occur about the time of engraftment and neutrophil recovery. Patients

develop fever (without infectious source), diarrhea, pulmonary infiltrates with hypoxia, and capillary leak syndrome with edema and weight gain. It occurs as soon as 7 days after autologous HSCT and 11–16 days after allogeneic transplants. The associated skin eruption is clinically and histologically identical to acute GVHD. Ocular involvement with keratitis can occur. This syndrome occurs in 7%–59% of post-HSCT patients and is a significant cause of morbidity and mortality in autologous peripheral blood progenitor cell transplant patients. It is mediated by cytokine production and neutrophil infiltration of the organs damaged by the conditioning chemotherapy, especially the lungs. Administration of G-CSF and autologous transplantation are risk factors for its development. Treatment is high-dose systemic corticosteroids.

With improved support for GVHD patients after HSCT, more are surviving, and 60%–70% develop chronic GVHD (cGVHD). It is the second most common cause of death in HSCT patients. It is unclear whether cGVHD is mediated by the same pathologic mechanisms as acute GVHD. Certain conditioning regimens may increase risk of cGVHD, particularly total body irradiation and the risk of scleroderma-like cGVHD. Chronic disease has features more typical of an autoimmune disease. Diagnostic criteria have been adopted, with "diagnostic" and "distinctive" cutaneous manifestations. The most common diagnostic feature, occurring in 80% of patients who develop cGVHD, is a lichen planus–like eruption. It typically occurs 3–5 months after grafting, usually beginning on the hands and feet but becoming generalized. It may present with a malar rash resembling LE. The chronic interface dermatitis can leave the skin with a poikilodermatous appearance. Similar lichen planus–like lesions may occur on the oral mucosa and can result in pain and poor nutrition. Lichen sclerosus–like lesions can also occur. Involvement of the vaginal or esophageal mucosa can result in severe scarring and strictures. About 20% of men with cGVHD have genital skin changes, and 13% have cGVHD of the penis. cGVHD of the skin and oral mucosa is associated with genital involvement. Lichen sclerosus–like lesions, phimosis, and inflammatory balanitis are most common; 80% of men with penile cGVHD report erectile dysfunction. Patients may underreport their genital cGVH, and a thorough physical and history is important.

Sclerosis is the other "diagnostic" family of skin lesions. This can include lesions resembling superficial morphea, which can have overlying lichen sclerosus–like changes. The morphea-like lesions demonstrate an isomorphic response, favoring areas of pressure, especially the waistband and brassiere-band areas. Deeper sclerotic lesions resembling eosinophilic fasciitis (resulting in joint contractures, Fig. 5.23) and restriction of the oral commissure due to sclerosis can occur. These sclerotic plaques may ulcerate.

Fig. 5.23 Chronic graft-versus-host disease.

The extent of involvement of the deep tissues, such as muscle and fascia, cannot be easily defined by clinical examination and may be aided by magnetic resonance imaging. Rarely, the myositis of cGVHD may be accompanied by a skin eruption similar to dermatomyositis. Other features of GVHD may include depigmentation resembling vitiligo; scarring or nonscarring alopecia; nail dystrophy (e.g., longitudinal ridging, brittle thin nails, pterygium, nail loss); and xerostomia and other, Sjögren-like mucosal symptoms. Atypical forms of GVHD resembling Pityriasis Rubra Pilaris (PRP), psoriasis, eczematous eruptions, isolated follicular hyperkeratosis, and Pityriasis Rosea (PR)-like eruptions have been reported. GVHD associated angiomatosis, with vascular lesions within sclerotic-type cGVHD, is a newly described and challenging subtype of cGVHD.

Biopsy may not be necessary to diagnose GVHD, particularly aGVHD. Punch biopsy is generally adequate, unless evaluating scleroderma-like disease, where incisional biopsy is preferred. Histologically, aGVHD demonstrates vacuolar interface dermatitis. Individual keratinocyte necrosis with adjacent lymphocytes (satellite necrosis) is typically present, suggesting cell-mediated cytotoxicity. The height and extent of keratinocyte necrosis, bulla formation, and slough are used in grading schemes (grade 0 is normal, grade 1 is basal vacuolization, grade 2 includes necrotic epidermal cells, grade 3 has clefting, and grade 4 has bulla formation). Eosinophils may be more common in drug reactions, but can be seen in GVH and cannot be used to distinguish the two. GVHD inflammation histologically often involves follicles, corresponding to the characteristic clinical perifollicular inflammation. Elafin has been proposed as a possible marker for GVHD but cannot reliably distinguish GVHD from drug reactions, though high levels of elafin may correspond to a poorer prognosis. The histologic findings in early disease may be nonspecific, and many treatment protocols do not depend on histologic features to initiate therapy. A background of epidermal disorder and atypia may be present in later lesions of acute GVHD, but similar epidermal changes may be seen after chemotherapy and may be unreliable in distinguishing GVHD from drug reactions. Chronic GVHD demonstrates lichenoid dermatitis or dermal sclerosis with hyalinization of collagen bundles and narrowing of the space between bundles.

Acute GVHD is managed on the skin with topical corticosteroids, TCIs, and rarely UV phototherapy. Most patients have associated systemic symptoms, in which case systemic corticosteroids, tacrolimus, and occasionally other suppressive agents are instituted. When aGVH is not responsive to steroids, multidisciplinary discussions and individual regimens based on comorbidities, infectious history, and status of underlying disease are often necessary. Mesenchymal stem cells, antithymocyte globulin, and extracorporeal photopheresis (ECP) are novel options being evaluated. TNF inhibitors, rituximab, and targeted small molecule inhibitors are also being studied. Ruxolitinib and other JAK inhibitors have shown promise in early studies and are being actively evaluated for both acute and chronic GVHD. For cGVHD, ECP can be considered as a nonsuppressive, disease-stabilizing, steroid-sparing agent for patients unresponsive to these first-line therapies. Phototherapy, particularly UVA-based regimens (PUVA with or without retinoids, UVA1), may improve sclerotic cGVHD. Rituximab has shown some benefit in steroid-refractory cGVHD. Sirolimus and everolimus appear to have activity against fibrosis and may be useful in fibrotic cGVHD. Imatinib may also be useful in cGVHD with fibrosis. Hydroxychloroquine has also been reported. In cGVHD, topical steroids may help lichen planus–like disease but are unlikely to affect scleroderma-like disease. Physical therapy is essential in patients with sclerosis, especially if it involves joints.

Graft-Versus-Host Disease in Solid-Organ Transplantation

Transplantation of a solid organ into a partially immunosuppressed host may result in GVHD, because the organ may contain immune

cells. The prevalence of GVHD after solid-organ transplantation is extremely low, about 1% at one center over 15 years with more than 2000 transplants. The risk for developing GVHD after solid-organ transplantation is related to the type of organ transplanted and depends on the amount of lymphoid tissue that the organ contains. The risk profile is small intestine > liver/pancreas > kidney > heart. In liver and small intestine transplants the risk is 1%–2%, but when it occurs the mortality rate is 85%. Close matching increases the risk of GVHD in organ transplantation, because the immunocompetent recipient cells are less likely to recognize the donor lymphocytes as nonself and destroy them. Also, African American race and CMV infection increase the risk The onset is usually 1–8 weeks following transplantation but can be delayed for years. Fever, rash, and pancytopenia are the cardinal features, with pancytopenia a frequent cause of mortality. The skin is the first site of involvement, and only cutaneous disease occurs in 15% of cases. Both acute and chronic GVHD skin findings can occur. Skin biopsies tend to show more inflammation than in HSCT-associated GVHD. In GVHD accompanying liver transplantation, the liver is unaffected because it is syngeneic with the donor lymphocytes. The diagnosis of GVHD in patients receiving organ transplantation can be aided by documenting macrochimerism in the peripheral blood and skin after the first month of transplantation.

6 Contact Dermatitis and Drug Eruptions

Bonus images for this chapter can be found online at expertconsult.inkling.com

CONTACT DERMATITIS

There are two types of dermatitis caused by substances coming in contact with the skin: irritant dermatitis and allergic contact dermatitis. Irritant dermatitis is an inflammatory reaction in the skin resulting from exposure to a substance that causes an eruption in most people who come in contact with it. Allergic contact dermatitis is an acquired sensitivity to various substances that produce inflammatory reactions only in those persons who have been previously sensitized to the allergen.

Irritant Contact Dermatitis

Many substances act as irritants that produce a nonspecific inflammatory reaction of the skin. This type of dermatitis may be induced in any person if there is contact with a sufficiently high concentration. No previous exposure is necessary, and the effect is evident within minutes, or a few hours at most. The concentration and type of toxic agent, duration of exposure, and condition of the skin at the time of exposure produce the variation in severity of the dermatitis from person to person, or from time to time in the same person. The skin may be more vulnerable because of maceration from excessive humidity or exposure to water, heat, cold, pressure, or friction. Dry skin, as opposed to wet skin, is less likely to react to contactants, although in chronic xerosis, as seen in elderly patients, increased sensitivity to irritants results. Thick skin is less reactive than thin skin. Atopic patients are predisposed to irritant hand dermatitis. Repeated exposure to some of the milder irritants may produce a hardening effect over time. This process makes the skin more resistant to the irritant effects of a given substance. Symptomatically, pain and burning are more common in irritant dermatitis, contrasting with the usual itch of allergic reactions. Avoidance, substitution of nonirritating agents when possible, and protection, most often by wearing gloves or using barrier creams, are the mainstays of treatment.

Alkalis

Irritant dermatitis is often produced by alkalis such as soaps, cement, detergents, bleaches, ammonia preparations, lye, drain pipe cleaners, and toilet bowl and oven cleansers (Fig. 6.1). Alkalis penetrate and destroy deeply because they dissolve keratin. Strong solutions are corrosive, and immediate application of a weak acid such as vinegar, lemon juice, or 0.5% hydrochloric acid solution will lessen their effects.

The principal compounds are sodium, potassium, ammonium, and calcium hydroxides. Occupational exposure is frequent among workers in soap manufacturing. Sodium silicate (water glass) is a caustic used in soap manufacture and paper sizing and for the preservation of eggs. Alkalis in the form of soaps, bleaching agents, detergents, and most household cleansing agents figure prominently in the causes of hand eczema. Alkaline sulfides are used as depilatories. Calcium oxide (quicklime) forms slaked lime when water is added. Severe burns may be caused in plasterers.

Acids

The powerful acids are corrosive, whereas the weaker acids are astringent. Hydrochloric acid produces burns that are less deep and more liable to form blisters than injuries from sulfuric and nitric acids (Fig. 6.2). Hydrochloric acid burns are encountered in those who handle or transport the product and in plumbers and those who work in galvanizing or tin-plate factories. Sulfuric acid produces a brownish charring of the skin, beneath which is an ulceration that heals slowly. Sulfuric acid is used more widely than any other acid in industry; it is handled principally by brass and iron workers and by those who work with copper or bronze. Nitric acid is a powerful oxidizing substance that causes deep burns; the tissue is stained yellow. Such injuries are observed in those who manufacture or handle the acid or use it in the making of explosives in laboratories. At times, nitric acid or formic acid is used in assaults secondary to interpersonal conflicts, resulting in scarring most prominently of the face, with the complication of renal failure present in a small number of cases.

Hydrofluoric acid is used widely in rust remover, in the semiconductor industry, and in germicides, dyes, plastics, and glass etching. It may act insidiously at first, starting with erythema and ending with vesiculation, ulceration, and finally necrosis of the tissue. Hydrofluoric acid is one of the strongest inorganic acids, capable of dissolving glass. Hypocalcemia, hypomagnesemia, hyperkalemia, and cardiac dysrhythmias may complicate hydrofluoric acid burns. Fluorine is best neutralized with hexafluorine solution, followed by 10% calcium gluconate solution or magnesium oxide.

Oxalic acid may produce paresthesia of the fingertips, with cyanosis and gangrene. The nails become discolored yellow. Oxalic acid is best neutralized with limewater or milk of magnesia to produce precipitation. Titanium hydrochloride is used in the manufacture of pigments. Application of water to the exposed part will produce severe burns. Therefore treatment consists only of wiping away the noxious substance.

Phenol (carbolic acid) is a protoplasmic poison that produces a white eschar on the surface of the skin. It can penetrate deep into the tissue. If a large surface of the skin is treated with phenol for cosmetic peeling effects, the absorbed phenol may produce glomerulonephritis and arrhythmias. Locally, temporary anesthesia may also occur. Phenol is readily neutralized with 65% ethyl or isopropyl alcohol.

Chromic acid burns, which may be seen in electroplating and dye production occupations, may result in extensive tissue necrosis and acute renal damage. Excision of affected skin down to the fascia should be accomplished rapidly, and hemodialysis to remove circulating chromium should start in the first 24 hours. Other strong acids that are irritants include acetic, trichloracetic, arsenious, chlorosulfonic, fluoroboric, hydriodic, hydrobromic, iodic, perchloric, phosphoric, salicylic, silicofluoric, sulfonic, sulfurous, tannic, and tungstic acids.

Treatment of acid burns consists of immediate rinsing with copious amounts of water and alkalization with sodium bicarbonate, calcium hydroxide (limewater), or soap solutions. Phosphorus burns should be rinsed off with water, followed by application of copper sulfate to produce a precipitate.

Fig. 6.1 Cement burns. (Courtesy Steven Binnick, MD.)

Fig. 6.2 Drip burn from acid solution.

Airbag Dermatitis

Airbags are deployed as a safety feature on cars when rapid deceleration occurs. Activation of a sodium azide and cupric oxide propellant cartridge releases nitrogen gas, which expands the bag at speeds exceeding 160 km/hour (96 miles/hour). Talcum powder, sodium hydroxide, and sodium carbonate are released into the bag. Abrasions, thermal, friction, and chemical burns and an irritant contact dermatitis may result. Superficial erythema may respond well to topical steroids, but full-thickness burns may occur and require debridement and grafting.

Other Irritants

Metal salts that act as irritants include the cyanides of calcium, copper, mercury, nickel, silver, and zinc and the chlorides of calcium and zinc. Bromine, chlorine, fluorine, and iodine are also irritants. Occupational exposure to methyl bromide may produce erythema and vesicles in the axillary and inguinal areas. Insecticides, including 2,2-dichlorovinyl dimethyl phosphate used in roach powder and fly repellents and killers, can act as irritants.

Fiberglass Dermatitis

Fiberglass dermatitis is seen after occupational or inadvertent exposure. The small spicules of glass penetrate the skin and cause severe irritation with tiny erythematous papules, scratch marks, and intense pruritus. Usually, there is no delayed hypersensitivity reaction. Wearing clothes that have been washed together with fiberglass curtains, handling air conditioner filters, or working in the manufacture of fiberglass material may produce severe folliculitis, pruritus, and eruptions that may simulate scabies or insect bites. Fiberglass is also used in thermal and acoustic installation, the wind industry, padding, vibration isolation, curtains, draperies, insulation for automobile bodies, furniture, gasoline tanks, and spacecraft. Talcum powder dusted on the flexure surfaces of the arms before exposure makes the fibers slide off the skin. A thorough washing of the skin after handling fiberglass is helpful. Patch testing to epoxy resins should be done when evaluating workers in fiberglass and reinforced-plastics operations, because an allergic contact dermatitis may be difficult to discern from fiberglass dermatitis.

Dusts

Some dusts and gases may irritate the skin in the presence of heat and moisture, such as perspiration. The dusts of lime, zinc, and arsenic may produce folliculitis. Dusts from various woods, such as teak, may incite itching and dermatitis. Dusts from cinchona bark, quinine, and pyrethrum produce widespread dermatitis. Tobacco dust in cigar factories, powdered orris root, lycopodium, and dusts of various nutshells may cause swelling of the eyelids and dermatitis of the face, neck, and upper extremities, the distribution of an airborne contact dermatitis. Dusts formed during the manufacture of high explosives may cause erythematous, vesicular, and eczematous dermatitis that may lead to generalized exfoliative dermatitis.

Capsaicin

Hand irritation produced by capsaicin in hot peppers used in Korean and North Chinese cuisine (Hunan hand) may be severe and prolonged, sometimes necessitating stellate ganglion blockade and gabapentin. Pepper spray, used by police in high concentrations and by civilians in less concentrated formulas, contains capsaicin and may produce severe burns. Cold water is not much help; capsaicin is insoluble in water. Acetic acid 5% (white vinegar) or antacids (Maalox) may completely relieve the burning, even if applied an hour or more after the contact. Application should be continued until the area can be dried without return of the discomfort.

Tear Gas Dermatitis

Lacrimators such as chloroacetophenone in concentrated form may cause dermatitis, with a delayed appearance about 24–72 hours after exposure. Irritation or sensitization, with erythema and severe vesiculation, may result. Treatment consists of lavage of the affected skin with sodium bicarbonate solution and instillation of boric acid solution into the eyes. Contaminated clothing should be removed.

Sulfur mustard gas, also known as yperite (dichlorodiethyl sulfide), has been used in chemical warfare. Erythema, vesicles, and bullae result from mild to moderate exposure (Fig. 6.3). Toxic epidermal necrolysis (TEN)–like appearance may follow more concentrated contact. The earliest and most frequently affected sites are areas covered by clothing and humidified by sweat, such as the groin, axillae, and genitalia.

Fig. 6.3 Mustard gas burn. (Courtesy James WD: Textbook of Military Medicine. Office of the Surgeon General, United States Army, 1994.)

Fig. 6.4 Mace-induced reaction.

Mace is a mixture of tear gas (chloroacetophenone) in trichloroethane and various hydrocarbons resembling kerosene. It is available in a variety of self-defense sprays. Mace is a potent irritant and may cause allergic sensitization (Fig. 6.4). Treatment consists of changing clothes, then washing with oil or milk, followed by washing with copious amounts of water.

Chloracne

Workers in the manufacture of chlorinated compounds may develop chloracne, with small, straw-colored follicular plugs and papules, chiefly on the malar crescent, retroauricular areas, earlobes, neck, shoulders, and scrotum. Histologically, there is a loss of sebaceous glands and the formation of cystic structures. The synthetic waxes chloronaphthalene and chlorodiphenyl, used in the manufacture of electric insulators and in paints, varnishes, and lacquers, predispose workers engaged in the manufacture of these synthetic waxes to chloracne. Exposure to 2,6-dichlorobenzonitrile during the manufacture of a herbicide, and to 3,4,3′,4′-tetrachloroazoxybenzene, which is an unwanted intermediate byproduct in the manufacture of a pesticide, may also produce chloracne.

A contaminant in the synthesis of herbicides and hexachlorophene, 2,3,7,8-tetracholorodibenzo-*p*-dioxin, produces a chemical burn in the acute stage, but chloracne, hyperpigmentation, hirsutism, and skin fragility (with or without criteria for porphyria cutanea tarda) are manifestations of chronic toxicity. Gastrointestinal tract cancer and malignancies of the lymphatic and hematopoietic systems are suspected to result. Although direct contact is the usual method of exposure, inhalation, ingestion, or contact with contaminated clothing may also result in chloracne. Chloracne may persist for long periods because dioxin is stored in the liver and released slowly into the circulation. Treatment is with medications used in acne vulgaris, including isotretinoin.

Hydrocarbons

Many hydrocarbons produce skin eruptions. Crude petroleum causes generalized itching, folliculitis, or acneiform eruptions. The irritant properties of petroleum derivatives are directly proportional to their fat-solvent properties and inversely proportional to their viscosity. Oils of the naphthalene series are more irritating than those of the paraffin series. Refined fractions from petroleum are less irritating than the unrefined products, although benzene, naphtha, and carbon disulfide may cause a mild dermatitis.

Lubricating and cutting oils are causes of similar cutaneous lesions. They represent a frequent cause of occupational dermatoses in machine tool operators, machinists, layout men, instrument makers, and setup men. Insoluble (neat) cutting oils are responsible for a follicular acneiform eruption on the dorsa of the hands, the forearms, face, thighs, and back of the neck. Hyperpigmentation, keratoses, and scrotal cancer have been found in those exposed to insoluble cutting oils. Soluble oils and synthetic fluids used in metalworking do not result in acne, but rather an eczematous dermatitis, usually of the dorsal forearms and hands. Approximately 50% of the time it is irritant and in the remainder it is allergic. Allergic contact dermatitis arises from various additives, such as biocides, coloring agents, and deodorizers.

Coal briquette makers develop dermatitis as a result of a tarry residue from petroleum used in their trade. Paraffin exposure leads to pustules, keratoses, and ulcerations. Shale oil workers develop an erythematous, follicular eruption that eventually leads to keratoses, which may become the sites of carcinoma. It is estimated that 50% of shale oil workers have skin problems.

Impure and low-grade paraffins and mineral oils cause similar skin eruptions. Initially, the skin changes are similar to those in chloracne. Over time, a diffuse erythema with dappled pigmentation develops. Gradually, keratoses appear, and after many years, some of these are the sites of carcinoma. Melanoderma may occur from exposure to mineral oils and lower-grade petroleum from creosote, asphalt, and other tar products. Photosensitization may play a role. Creosote is a contact irritant, sensitizer, and photosensitizer. Allergy is demonstrated by patch testing with 10% creosote in oil.

Petrolatum dermatitis may appear as a verrucous thickening of the skin caused by prolonged contact with impure petroleum jelly or, occasionally, lubricating oil. A follicular-centered process may occur in which erythematous horny nodules are present, usually on the anterior and inner aspects of the thighs. There are no comedones, and the lesions are separated by apparently normal skin.

Acne corne consists of follicular keratosis and pigmentation resulting from crude petroleum, tar oils, and paraffin. The dorsal aspects of the fingers and hands, the arms, legs, face, and thorax are the areas usually involved. The lesions are follicular horny papules, often black, and are associated at first with a follicular erythema and later with a dirty brownish or purplish spotty pigmentation, which in severe cases becomes widespread and is especially marked around the genitals. This syndrome may simulate pityriasis rubra pilaris or lichen spinulosus.

Coal tar and pitch and many of their derivatives produce photosensitization and an acneiform folliculitis of the forearms, legs, face, and scrotum. Follicular keratoses (pitch warts) may

develop and later turn into carcinoma. Soot, lamp black, and the ash from peat fires produce dermatitis of a dry, scaly character, which over time forms warty outgrowths and cancer. Chimney sweep's cancer occurs under a soot wart and is usually located on the scrotum, where soot, sebum, and dirt collect in the folds of the skin. This form of cancer has virtually disappeared.

Acquired perforating disease may occur in oil field workers who use drilling fluid containing calcium chloride. Patients develop tender, umbilicated papules of the forearms that microscopically show transepidermal elimination of calcium.

Solvents

The solvents cause approximately 10% of occupational dermatitis. When solvents are applied to the hands to cleanse them, the surface oil is dissolved, and a chronic fissured dermatitis results. Additionally, peripheral neuropathy and chemical lymphangitis may occur after the solvents are absorbed through the fissured skin. Solvent sniffers may develop an eczematous eruption around the mouth and nose; erythema and edema occur. This is a direct irritant dermatitis caused by the inhalation of the solvent placed on a handkerchief.

Trichloroethylene is a chlorinated hydrocarbon solvent and degreasing agent also used in the dry-cleaning and refrigeration industry. Inhalation may produce exfoliative erythroderma, mucous membrane erosions, eosinophilia, and hepatitis.

Allergic contact dermatitis caused by alcohol is rarely encountered with lower-aliphatic alcohols. A severe case of bullous and hemorrhagic dermatitis on the fingertips and deltoid region was caused by isopropyl alcohol. Although rare, ethyl alcohol dermatitis may also be encountered. Cetyl and stearyl alcohols may provoke contact urticaria.

Allergic Contact Dermatitis

Allergic contact dermatitis results when an allergen comes into contact with previously sensitized skin. It is caused by a specific acquired hypersensitivity of the delayed type, also known as cell-mediated (type IV) hypersensitivity. These sensitizers do not cause demonstrable skin changes on initial contact. Persons may be exposed to allergens for years before finally developing hypersensitivity. Genetic variability in the immunologic processes leading to sensitization and other factors, such as concentration of the allergen applied, its vehicle, timing and site of the exposure, presence of occlusion, age, gender, and race of the patient, and presence of other skin or systemic disorders, likely determine whether any given exposure will result in sensitization. Once sensitized, however, subsequent outbreaks may result from extremely slight exposure.

Childhood exposures do result in allergy, and the frequency of allergy in this age group is increasing. The most common relevant allergens in young children are nickel, cobalt, fragrance, lanolin, and neomycin. In adolescents potassium dichromate and Myroxylon pereirae become significant. Sensitivity is rarely lost over the years; older patients have similar rates of allergy as adults.

Occasionally, dermatitis may be induced when the allergen is taken internally by a patient first sensitized by topical application, as with substances such as cinnamon oil or various medications. The anamnestic response is termed systemic contact dermatitis. It may appear first at the site of the prior sensitization or past positive patch test, but may spread to a generalized morbilliform or eczematous eruption. Additional morphologic patterns include vesicular hand eczema, urticaria, erythema multiforme, vasculitis, or symmetric drug-related intertriginous and flexural exanthema (SDRIFE). Formerly called baboon syndrome, SDRIFE is a deep-red-violet eruption on the buttocks, genital area, inner thighs, and sometimes the axillae.

The most common causes of contact dermatitis in the United States are toxicodendrons (poison ivy, oak, or sumac), nickel, balsam of Peru *(Myroxylon pereirae)*, neomycin, fragrance, formaldehyde and the formaldehyde-releasing preservatives, bacitracin, and rubber compounds. Frequent positive reactions to gold and thimerosal do not often correlate with the clinical exposure history. Gold reactions, which may be prolonged, can be correlated in some cases with oral gold exposure or occupational dermatitis, but in most cases, the relevance is questionable. Thimerosal reactions are probably related to its use as a preservative in common vaccines and skin-testing material. It also serves as a marker for piroxicam photosensitivity.

Eczematous delayed-type hypersensitivity reaction, as exemplified by allergic contact dermatitis and the patch test, must be distinguished from immediate-type hypersensitivity reaction. The latter presents within minutes of exposure with urticaria and is proved with a scratch test. It should be kept in mind, however, that persons who develop contact urticaria to a substance may concomitantly have a type IV delayed-type sensitization and eczema from the same allergen.

In some patients, impetigo, pustular folliculitis, and irritation or allergic reactions from applied medications are superimposed on the original dermatitis. A particularly vexing situation is when allergy to topical corticosteroids complicates an eczema, in which case the preexisting dermatitis usually does not flare, but simply does not heal as expected. The cutaneous reaction may also provoke a hypersusceptibility to various other, previously innocuous substances, which continues the eczematous inflammatory response indefinitely.

These eruptions resolve when the cause is identified and avoided. For acute generalized allergic contact dermatitis, treatment with systemic steroidal agents is effective, beginning with 40–60 mg/day of prednisone in a single oral dose, and tapering slowly to topical steroids. When the eruption is limited in extent and severity, local application of topical corticosteroid creams, lotions, or aerosol sprays is preferred.

Testing for Sensitivity

Patch Test. The patch test is used to detect hypersensitivity to a substance that is in contact with the skin so that the allergen may be determined and corrective measures taken. So many allergens can cause allergic contact dermatitis that it is impossible to test a person for all of them. In addition, a good history and observation of the pattern of the dermatitis, its localization on the body, and its state of activity are helpful in determining the cause. The patch test is confirmatory and diagnostic, but only within the framework of the history and physical findings; it is rarely helpful if it must stand alone. Interpretation of the relevance of positive tests and the subsequent education of patients are challenging in some cases. The Contact Allergen Management Program (CAMP) provides names of alternative products that may be used by patients when an allergen is identified. This is available through the American Contact Dermatitis Society.

The patch test consists of application of substances suspected to be the cause of the dermatitis to intact uninflamed skin. Patch testing may be administered by the thin-layer rapid-use epicutaneous (TRUE) test or by individually prepared patches. The TRUE test has resulted in more screening for allergic contact dermatitis than in the past, but if it does not reveal the allergen for a highly suspect dermatitis, testing with an expanded series will on average yield relevant allergens in more than half of these patients. Dermatitis originating in the workplace will almost always require individualized testing.

Test substances are applied usually to the upper back, although if only one or two are applied, the upper outer arm may be used. Each patch should be numbered to avoid confusion. The patches are removed after 48 hours (or sooner if severe itching or burning occurs at the site) and read. The patch sites need to be evaluated again at day 4 or 5 because positive reactions may not appear earlier. Some allergens may take up to day 7 to show a reaction, and the patient should be advised to return if such a delayed reaction occurs. Erythematous papules and vesicles with edema are indicative of allergy (Fig. 6.5). Occasionally, patch tests for potassium iodide, nickel, or mercury will produce pustules at the site of the test application. Usually no erythema is produced; therefore the reaction has no clinical significance.

Fig. 6.5 Positive patch test reaction.

Strong patch test reactions may induce a state of hyperirritability ("excited skin syndrome") in which adjacent tests that would otherwise be negative appear as weakly positive. Weakly positive tests in the presence of strong tests do not prove sensitivity. The skin and mucous membranes vary widely in the ability to react to antigens. The oral mucosa is more resistant to primary irritants and is less liable to be involved in allergic reactions. This may be because the keratin layer of the skin more readily combines with haptens to form allergens. Also, the oral mucosa is bathed in saliva, which cleanses and buffers the area and dilutes irritants. However, patch testing for various types of oral signs and symptoms, such as swelling, tingling and burning, perioral dermatitis, and the appearance of oral lichen planus, is useful in determining a cause in many cases.

Potent topical corticosteroids, ultraviolet (UV) light, prednisone, and the acquired immunodeficiency syndrome (AIDS) have been reported to interfere with the reliability of patch testing. Expert opinion regarding patch testing while on other immunosuppressants (e.g., methotrexate, azathioprine, biologics) is that these are less likely to produce unreliable testing. However, with all of these, false-negative reactions may result; the value of testing in such circumstances is that if a positive reaction occurs, a diagnosis may be made. Vitiliginous skin is less reactive than normally pigmented adjacent skin.

Provocative Use Test. The provocative use test may be used to screen products used by the patient. Products that are made to stay on the skin once applied (as opposed to shampoos or soaps) are rubbed on normal skin of the inner aspect of the forearm several times daily for 5 days. A pink itchy patch will indicate the need to avoid the product. Further testing to its individual ingredients will help identify replacement products. This test may also confirm a positive closed patch test reaction to ingredients of the personal care product.

Photopatch Test. The photopatch test is used to evaluate for contact photoallergy to such substances as sulfonamides, phenothiazines, *p*-aminobenzoic acid, oxybenzone, 6-methyl coumarin, musk ambrette, and tetrachlorosalicylanilide. A standard patch test is applied for 48 hours; this is then exposed to 5 to 15 J/m^2 of UVA and read after another 48 hours. To test for 6-methyl coumarin sensitivity, the patch is applied in the same manner but for only 30 minutes before light exposure, rather than for 48 hours. A duplicate set of nonirradiated patches is used in testing for the presence of routine delayed hypersensitivity reactions. Also, a site of normal skin is given an identical dose of UVA to test for increased sensitivity to light without prior exposure to chemicals. There is a steady increase in incidence of photoallergy to sunscreening agents and a decreasing incidence of such reactions to fragrance.

Regional Predilection

Familiarity with certain contactants and the typical dermatitis they elicit on specific parts of the body will assist in diagnosis of the etiologic agent.

Head and Neck. The scalp is relatively resistant to the development of contact allergies; however, involvement may be caused by hair dye, hair spray, shampoo, or permanent wave solutions. The surrounding glabrous skin, including the ear rims and backs of the ears, may be much more inflamed and suggestive of the cause. Persistent otitis of the ear canal may be caused by sensitivity to neomycin, an ingredient of most aural medications. The eyelids are the most frequent site for nail polish dermatitis. Volatile gases, false-eyelash adhesive, fragrances, eye medications, preservatives,

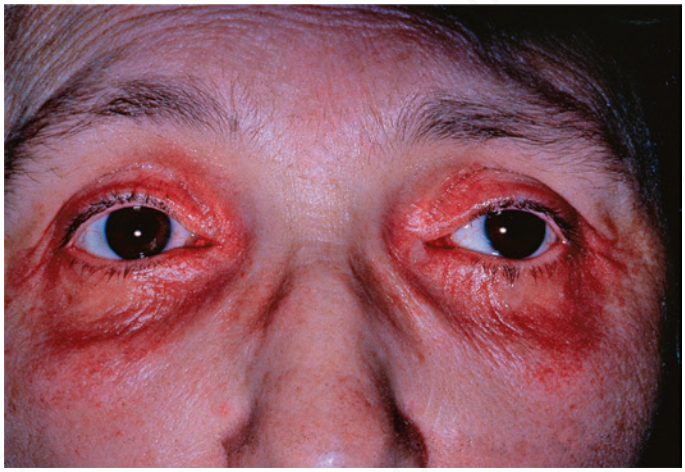

Fig. 6.6 Eyelid dermatitis.

mascara, rubber in sponges used to apply cosmetics, and eye shadow are also frequently implicated (Fig. 6.6). Perioral dermatitis and cheilitis may be caused by flavoring agents in dentifrices and gum, as well as fragrances, shellac, medicaments, and sunscreens in lipstick and lip balms. Perfume dermatitis may cause redness just under the ears or on the neck. Earlobe dermatitis is indicative of nickel sensitivity. Photocontact dermatitis may involve the entire face and may be sharply cut off at the collar line or extend down on to the sternum in a V shape. There is a typical clear area under the chin where there is little or no exposure to sunlight. The left cheek and left side of the neck (from sun exposure while driving) may be the first areas involved.

Trunk. The trunk is an infrequent site; however, the dye or finish of clothing may cause dermatitis. The axilla may be the site of deodorant dermatitis and clothing-dye dermatitis; involvement of the axillary vault suggests the former; of the axillary folds, the latter. In women, brassieres cause dermatitis from the material itself, the elastic, or the metal snaps or underwires.

Arms. The wrists may be involved because of jewelry or the backs of watches and clasps, all of which may contain nickel. Wristbands made of leather are a source of chrome dermatitis.

Hands. Innumerable substances may cause allergic contact dermatitis of the hands, which typically occurs on the backs of the hands and spares the palms. Florists will often develop fingertip or palmar lesions. A hand dermatitis that changes from web spaces to fingertips or from palms to dorsal hands should trigger patch testing. Poison ivy and other plant dermatitides frequently occur on the hands and arms. Rubber glove sensitivity must be kept constantly in mind. Usually, irritancy is superimposed on allergic contact dermatitis of the hands, altering both the morphologic and histologic clues to the diagnosis.

Abdomen. The abdomen, especially the waistline, may be the site of rubber dermatitis from the elastic in pants and undergarments. The metallic rivets in blue jeans may lead to periumbilical dermatitis in nickel-sensitive patients, as may piercings of the umbilicus.

Groin. The groin is usually spared, but the buttocks and upper thighs may be sites of dermatitis caused by dyes. The penis is frequently involved in poison ivy dermatitis. Condom dermatitis may also occur. The perianal region may be involved from the "caine" medications in suppositories, as well as preservatives and fragrances in cleansing materials. Almost half of women with pruritus vulvae have one or more relevant allergens; often these are medicaments, fragrances, or preservatives.

Lower Extremities. The shins may be the site of rubber dermatitis from elastic stockings. Feet are sites for shoe dermatitis, most often attributable to rubber sensitivity, chrome-tanned leather, dyes, or adhesives. Application of topical antibiotics to stasis ulcers frequently leads to sensitivity and allergic contact dermatitis.

Dermatitis Resulting From Plants

A large number of plants, including trees, grasses, flowers, vegetables, fruits, and weeds, are potential causes of dermatitis. Eruptions from them vary considerably in appearance but are usually vesicular and accompanied by marked edema. After previous exposure and sensitization to the active substance in the plant, the typical dermatitis results from reexposure. The onset is usually a few hours or days after contact. The characteristic linearly grouped

Fig. 6.7 Acute poison ivy reaction.

lesions are probably produced by brushing the skin with a leaf edge or a broken twig or by carriage of the allergen under the nails. Contrary to popular belief, the contents of vesicles are not capable of producing new lesions.

***Toxicodendron* (Poison Ivy).** *Toxicodendron* dermatitis includes dermatitis from members of the Anacardiaceae family of plants: poison ivy (*T. radicans*, or *Rhus radicans*), poison oak *(T. diversilobum*, *R. diversaloba)*, poison sumac *(T. vernix*, *R. vernix)*, Japanese lacquer tree, cashew nut tree (allergen in nutshell), mango (allergen in rind, leaves, or sap), Rengas tree, and Indian marking nut tree. The ginkgo (allergen in fruit pulp), spider flower or silver oak, *Gluta* species of trees and shrubs in Southeast Asia, Brazilian pepper tree, also known as Florida holly, and poisonwood tree contain almost identical antigens.

Toxicodendron dermatitis appears within 48 hours of exposure of a person previously sensitized to the plant. It usually begins on the backs of the fingers, interdigital spaces, wrists, and eyelids, although it may begin on the ankles or other parts that have been exposed. Marked pruritus is the first symptom; inflammation, vesicles, and bullae may then appear. The vesicles are usually grouped and often linear (Fig. 6.7). Large bullae may be present, especially on the forearms and hands. The eyelids are puffy and worse in the morning, improving as the day progresses (Fig. 6.8). Pruritus ani and involvement of the genital areas occur frequently. A black lacquer deposit may occur in which the sap of the plant has been oxidized after being bound to the stratum corneum (Fig. 6.9). Untreated *Toxicodendron* dermatitis usually lasts 2–3 weeks.

The fingers transfer the allergen to other parts, especially the forearms and the male prepuce, which become greatly swollen. However, once the causative oil has been washed off, there is no spreading of the allergen. Some persons are so susceptible that direct contact is not necessary, the allergen apparently being carried by objects with prior exposure to the catechol. Occasionally, eating the allergen, as occurred in a patient who ingested raw cashew

Fig. 6.8 Acute poison ivy reaction.

Fig. 6.9 Black dot sign in poison ivy reaction.

nuts in an imported pesto sauce, may result in SDRIFE (see earlier) or a systematized allergic contact dermatitis with the morphology of a generalized erythematous papular eruption.

The cause is an oleoresin known as urushiol, of which the active agent is a mixture of catechols. This and related resorcinol allergens are present in many plants and also in *Philodendron* species, wood from *Persoonia elliptica*, wheat bran, and marine brown algae.

The most striking diagnostic feature is the linearity of the lesions. It is rare to see vesicles arranged linearly except in plant-induced dermatitis. A history of exposure in the country or park to plants that have shiny leaves in groups of three, followed by the appearance of vesicular lesions within 2 days, usually establishes the diagnosis.

Eradication of plants having grouped "leaves of three" growing in frequented places is one easy preventive measure, as is recognition of the plants to avoid. An excellent resource is a pamphlet available from the American Academy of Dermatology. If the individual is exposed, washing with soap and water within 5 minutes may prevent an eruption. Protective barrier creams are available that are somewhat beneficial. Quaternium-18 bentonite has been shown to prevent or diminish experimentally produced poison ivy dermatitis.

Innumerable attempts have been made to immunize against poison ivy dermatitis by oral administration of the allergen or subcutaneous injections of oily extracts. To date, no accepted method of immunization is available. Repeated attacks do not confer immunity, although a single severe attack may achieve this by what has been called massive-dose desensitization.

When the diagnosis is clear and the eruption severe or extensive, systemic steroidal agents are effective, beginning with 40–60 mg of prednisone in a single oral dose daily, tapered off over a 3-week period. When the eruption is limited in extent and severity, local application of topical corticosteroid creams, lotions, or aerosol sprays is preferred. Time-honored calamine lotion without phenol is helpful and does no harm. Antihistaminic ointments should be avoided because of their sensitization potential. This also applies to the local application of the "caine" topical anesthetics.

Other *Toxicodendron*-Related Dermatitides. Lacquer dermatitis is caused by a furniture lacquer made from the Japanese lacquer tree, used on furniture, jewelry, or bric-a-brac. Antique lacquer is harmless, but lacquer less than 1 or 2 years old is highly antigenic. Cashew oil is extracted from the nutshells of the cashew tree *(Anacardium occidentale)*. This vesicant oil contains cardol, a phenol similar to urushiol in poison ivy. The liquid has many commercial applications, such as the manufacture of brake linings, varnish, synthetic glue, paint, and sealer for concrete.

Mango dermatitis is uncommon in natives of mango-growing countries (e.g., Philippines, Guam, Hawaii, Cuba) who have never been exposed to contact with *Toxicodendron* species. Many persons who have been so exposed, however, whether or not they had dermatitis from it, are sensitized by one or a few episodes of contact with the peel of the mango fruit. The palms carry the allergen, so the eyelids and the male prepuce are often early sites of involvement.

Ginkgo tree dermatitis simulates *Toxicodendron* dermatitis with its severe vesiculation, erythematous papules, and edema. The causative substances are ginkgolic acids from the fruit pulp of the ginkgo tree. Ingestion of the ginkgo fruit may result in perianal dermatitis. Ginkgo biloba given orally for cerebral disturbances is made from a leaf extract so it does not elicit a systemic contact allergy when ingested.

Flowers and Houseplants. Among the more common houseplants, the velvety-leafed philodendron, *Philodendron crystallinum* (and its several variants), known in India as the "money plant," is a frequent cause of contact dermatitis. The eruption is often seen on the face, especially the eyelids, carried there by hands that have watered or cared for the plant. English ivy follows philodendron in frequency of cases of occult contact dermatitis. Primrose dermatitis affects the fingers, eyelids, and neck with a punctate or diffuse erythema and edema. Formerly found most frequently in Europe, the primrose is now a common U.S. houseplant. Primin, a quinone, is the causative oleoresin abounding in the glandular hairs of the plant *Primula obconica*.

The popular cut flower, the Peruvian lily, is the most common cause of allergic contact dermatitis in florists. When handling flowers of the genus *Alstroemeria*, the florist uses the thumb and second and third digits of the dominant hand. Because it is chronic, fissured hyperkeratotic dermatitis results, identical to the "tulip fingers" seen among sensitized tulip workers (see Fig. 6.10). Testing is done with the allergen tuliposide A. It does not penetrate nitrile gloves. The geranium, scorpion flower (*Phacelia crenulata* or *P. campanularia*), hydrangea, creosote bush *(Larvia tridentata)*, *Heracula*, daffodil, foxglove, pooja, lisianthus, lilac, lady slipper, magnolia, and tulip and narcissus bulbs are other flowers that commonly cause allergic reactions among florists. The poinsettia and oleander almost never cause dermatitis, despite their reputation for it, although they are toxic if ingested.

Chrysanthemums frequently cause dermatitis, with the hands and eyelids of florists most often affected. The α-methylene portion of the sesquiterpene lactone molecule is the antigenic site, as it is in the other genera of the Compositae family.

A severe inflammatory reaction with bulla formation may be caused by the prairie crocus (*Anemone patens* L.), the floral emblem of the province of Manitoba. Several species of ornamental "bottle brush" from Queensland *(Grevillea banksii*, *G. Robyn Gordon*, *G. robusta)*, may cause allergic contact dermatitis. It is exported to the United States and other Western countries. The allergen is a long-chain alkyl resorcinol. Cross-sensitivity to *Toxicodendron* has been demonstrated. Treatment of all these plant dermatitides is the same as that recommended for toxicodendron dermatitis.

Fig. 6.10 Chronic fissured fingertip dermatitis in a florist.

Contact dermatitis may be caused by handling many other flowers, such as the geranium, scorpion flower (*Phacelia crenulata* or *P. campanularia*), hydrangea, creosote bush *(Larvia tridentata)*, *Heracula*, daffodil, foxglove, lilac, lady slipper, magnolia, and tulip and narcissus bulbs. The poinsettia and oleander almost never cause dermatitis, despite their reputation for it, although they are toxic if ingested.

Parthenium hysterophorus is a photosensitizing weed. The well-deserved reputation for harmfulness of dieffenbachia, a common, glossy-leafed house plant, rests on the high content of calcium oxalate crystals in its sap, which burn the mouth and throat severely if any part of the plant is chewed or swallowed. Severe edema of the oral tissues may result in complete loss of voice, thus its common nickname, "dumb cane." It does not appear to sensitize. The castor bean, the seed of *Ricinus communis*, contains ricin, a poisonous substance (phytotoxin). Its sap contains an antigen that may cause anaphylactic hypersensitivity and also dermatitis.

Fruit and Vegetables. Many vegetables may cause contact dermatitis, including asparagus, carrot, celery, cow-parsnip, cucumber, garlic, Indian bean, mushroom, onion, parsley, tomato, and turnip. Onion and celery, among other vegetables, have been incriminated in the production of contact urticaria and even anaphylaxis. Several plants, including celery, fig, lime, and parsley, can cause a phototoxic dermatitis because of the presence of psoralens. Phototoxic contact dermatitis from plants is discussed more fully in Chapter 3.

Trees. Trees with timber and sawdust that may produce contact dermatitis include ash, birch, cedar, cocobolo, elm, Kentucky coffee tree, koa, mahogany, mango, maple, mesquite, milo, myrtle, pine, and teak. The latex of fig and rubber trees may also cause dermatitis, usually of the phototoxic type. Melaleuca oil (tea tree oil), which may be applied to the skin to treat a variety of maladies, can cause allergic contact dermatitis, primarily through the allergen D-limonene (Fig. 6.11). The exotic woods, especially cocobolo and rosewood are prominent among allergens that may produce erythema multiforme (EM) after cutaneous exposure. *Toxicodendron*, tea tree oil, various medicaments, and a variety of other allergens may induce this reaction.

Tree-Associated Plants. Foresters and lumber workers can be exposed to allergenic plants other than trees. Lichens are a group

Fig. 6.11 Tea tree oil dermatitis. (Courtesy Glen Crawford, MD.)

of plants composed of symbiotic algae and fungi. Foresters and wood choppers exposed to these lichens growing on trees may develop severe allergic contact dermatitis. Exposure to the lichens may also occur from firewood, funeral wreaths, and also fragrances added to aftershave lotions (oak moss and tree moss). Sensitization is produced by D-usnic acid and other lichen acids contained in lichens. The leafy liverwort *(Frullania nisquallensis)*, a forest epiphyte growing on tree trunks, has produced allergic dermatitis in forest workers. The eruption is commonly called "cedar poisoning." It resembles *Toxicodendron* dermatitis; its attacks are more severe during wet weather. The allergen is sesquiterpene lactone.

Pollens and Seeds. The pollens in ragweed are composed of two antigens. The protein fraction causes the respiratory symptoms of asthma and hay fever, and the oil-soluble portion causes contact dermatitis. Ragweed oil dermatitis is a seasonal disturbance seen mainly during the ragweed growing season from spring to fall. Contact with the plant or with wind-blown fragments of the dried plant produces the typical dermatitis. The oil causes swelling and redness of the lids and entire face, and a red blotchy eruption on the forearms that, after several attacks, may become generalized, with lichenification. It closely resembles chronic atopic dermatitis, with lichenification of the face, neck, and major flexures, and severe pruritus. The distribution also mimics that of photodermatitis, with ragweed dermatitis differentiated by its involvement of the upper eyelids and the retroauricular and submental areas. Chronic cases may continue into the winter, although signs and symptoms are most severe at the height of the season. Sesquiterpene lactones are the cause. Coexistent sensitization to pyrethrum may account for prolongation of ragweed dermatitis. Men outnumber women in hypersensitivity reactions; farmers outnumber patients of all other occupations.

Marine Plants. Numerous aquatic plants are toxic or produce contact dermatitis. Algae are the worst offenders. Freshwater plants are rarely of concern. Seaweed dermatitis is a type of swimmer's eruption produced by contact with a marine blue-green alga, *Lyngbya majuscula Gomont*. The onset is within a few minutes of leaving the ocean, with severe itching and burning, followed by dermatitis, blisters, and deep, painful desquamation that affects the areas covered by the bathing suit, especially the scrotum, perineum, and perianal areas and occasionally the breasts in women). Patch tests with the alga are neither necessary nor helpful because it is a potent irritant. Bathing in fresh water within 10 or 15 minutes of leaving the ocean may prevent the dermatitis. The Bermuda fire sponge may produce contact erythema multiforme. Trawler fishermen in the Dogger Bank area of the North Sea develop allergic dermatitis after contact with *Alcyonidium hirsutum*. This seaweed-like animal colony becomes caught in nets and produces erythema, edema, and lichenification on the fishermen's hands and wrists.

Plant-Associated Dermatitis. The residua of various insecticides on plants may also produce dermatitis. This is especially true of sprays containing arsenic and malathion. Randox (2-chloro-*N*,*N*-diallyl-acetamide) has been reported as the cause of hemorrhagic bullae on the feet of farmers. Lawn care companies spray herbicides and fungicides throughout the spring, summer, and fall. Dryene, thiuram, carbamates, and chlorothalonil are potential sensitizers in these workers, whose clothing frequently becomes wetted while spraying.

Barbs, bristles, spines, thorns, spicules, and cactus needles are some of the mechanical accessories of plants that may produce dermatitis. Sabra dermatitis is an occupational dermatitis resembling scabies. It is seen among pickers of the prickly pear cactus plant. It also occurs in persons handling Indian figs in Israel, where the condition is seen from July to November. The penetration of minute, invisible thorns into the skin is the cause. *Agave americana* is a low-growing plant used for ornamental purposes in many southwestern U.S. communities. Trimming during landscaping can induce an irritant dermatitis caused by calcium oxalate crystals. The stinging nettle is a common weed that bears tiny spines with biologically active substances such as histamine that produce itching and urticaria within minutes of contact.

Plant Derivatives. Sensitizing substances derived from plants are found in the oleoresin fractions that contain camphors, essential oils, phenols, resins, and terpenes. The chief sensitizers are the essential oils. These may be localized in certain parts of the plant, such as in the peel of citrus fruits, leaves of the eucalyptus tree, and bark of the cinnamon tree. Aromatherapy, an increasingly popular treatment for relief of stress, involves either inhaling or massaging with essential oils; this may cause allergic contact dermatitis in therapists or clients. Exposure to botanical extracts through many cosmetics and homeopathic remedies has resulted in an increasing number of reports of allergic contact sensitivity to individual ingredients, especially tea tree oil.

Cinnamon oil (*Cassia* oil) is a common flavoring agent, especially in pastries. Hand dermatitis in pastry bakers is often caused by cinnamon. It is also used as a flavor for lipstick, bitters, alcoholic and nonalcoholic beverages, toothpaste, and chewing gum. Perioral dermatitis may be caused by cinnamon in chewing gum. A 5% cinnamon solution in olive oil is used for patch testing. Eugenol, clove oil, and eucalyptus oil are used by dentists, who may acquire contact dermatitis from them. Anise, peppermint, and spearmint oils may cause sensitization.

Nutmeg, paprika, and cloves are causes of spice allergy. Fragrance mix is a useful indicator allergen. Lemon oil from lemon peel or lemon wood may cause sensitization in the various handlers of these substances. Citric acid may cause dermatitis in bakers. Lime oil in lime-scented shaving cream or lotion may cause photoallergy. *Myroxylon pereirae* contains numerous substances, including essential oils similar to the oil of lemon peel. It is known to cross-react with vanilla, cinnamon, and many other substances. Vanillin is derived from the vanilla plant and frequently produces contact dermatitis, vanillism, in those connected with its production and use.

Turpentine frequently acts as an irritant and as an allergic sensitizer (carene). It is contained in paints, paint thinners, varnishes, and waxes.

Dermatitis From Clothing

A predisposition to contact dermatitis from clothing occurs in persons who perspire freely or who are obese and wear clothing that tends to be tight. Depending on the offending substance, various regions of the body will be affected. Regional location is helpful in identifying the sensitizing substance. The axillary folds are often involved; the vaults of the axillae are usually spared. Sites of increased perspiration and sites where evaporation is impeded, such as the intertriginous areas, will tend to leach dyes from fabrics to produce dermatitis. Areas where the material is tight against the skin, such as the waistband or neck, are frequently involved (Fig. 6.12). The thighs are affected when pants contain the offending allergen. The hands, face, and undergarment sites are usually spared, but otherwise these reactions may be scattered and generalized. Secondary changes of lichenification and infection occur frequently because of the chronicity of exposure.

Cotton, wool, linen, and silk fabrics were used exclusively before the advent of synthetic fabrics. Most materials are now blended in definite proportions with synthetics to produce superior lasting and esthetic properties. Dermatitis from cotton is virtually nonexistent. In most cases, there is no true sensitization to wool. Wool acts as an irritant because of the barbs on its fibers. These barbs may produce severe pruritus at points of contact with the skin, especially in the intertriginous areas. In persons with sensitive skin, such as those with atopic dermatitis, the wearing of wool is not advisable because of its mechanical irritative properties. Silk is a sensitizer, but rarely; the nature of the allergen is not known. Many patients believe their detergent is the source of a dermatitis, but this is rarely the case.

Numerous synthetic fibers are available for clothing and accessory manufacture, all of which again are remarkably free of sensitizing properties. Polyvinyl resins are the plastics used in such apparel as raincoats, rainhoods, wristbands, suspenders, plastic mittens, and gloves. These also are only infrequently found to be causes of contact dermatitis.

Fig. 6.12 Waistband clothing dermatitis.

The most common causes of clothing dermatitis are the fabric finishers, dyes, and rubber additives. Fabric finishers are used to improve the durability, appearance, and feel of a material. Antiwrinkling and crease-holding chemicals are mostly resins, which are incorporated into the fibers as they are being manufactured or applied to the finished fabric. Fabrics are treated to make them less vulnerable to the effects of perspiration and ironing. Clothing may be treated with these substances to make it dry rapidly after washing. They are used to make clothing fabrics shrink resistant and water and stain repellent. When all these uses are taken into consideration, the low incidence of dermatitis from these formaldehyde resin materials is remarkable.

Ethylene urea melamine formaldehyde resin and dimethylol dihydroxyethylene urea formaldehyde resin are the best screening agents. Many persons also react to formaldehyde and the formaldehyde-releasing preservatives such as quaternium 15. Avoidance of exposure of the skin to formaldehyde resin is most difficult. New clothes should be thoroughly washed twice before wearing the first time. Even with this precaution, however, allergens may still be present in sufficient quantities to continue the dermatitis. T-shirts, sweat-shirts and pants, white underclothes suitable for bleaching, and garments of mixed synthetic fibers with cotton fibers added to make them drip-dry are most likely to cause problems in these patients.

Synthetic fabrics such as polyester and acetate liners in women's clothing are also prime causes, and women are more affected than men. Even infants may be affected, however, with dyes in diapers accounting for some cases. Many patients do not react to paraphenylene diamine, but only to the disperse dye allergens. The best screening agents are disperse blue 106 and 124. Lymphomatoid contact allergy may result from clothing dye reactivity.

Suspected fabrics may be soaked in water for 15 minutes and applied under a patch for 72–96 hours. Jeans, Spandex, silk, 100% linen, 100% nylon, and 100% cotton that is not wrinkle resistant or colorfast are best tolerated. Spandex is a nonrubber (but elastic) polyurethane fiber. It is widely used for garments such as girdles,

brassieres, and socks, but is generally safe in the United States because it is free of rubber additives.

Shoe Dermatitis

Footwear dermatitis may begin on the dorsal surfaces of the toes and may remain localized to that area indefinitely (Fig. 6.13). There is erythema, lichenification, and, in severe cases, weeping and crusting. Secondary infection is frequent. In severe cases, an id reaction may be produced on the hands, similar to the reaction from fungal infection of the feet. A diagnostic point is the normal appearance of the skin between the toes, which has no contact with the offending substance. In fungal infections, the toe webs are usually involved. Another pattern seen is involvement of the sole with sparing of the instep and flexural creases of the toes. Also, purpuric reactions may occur to components of black rubber mix. Hyperhidrosis and atopy predispose to development of shoe allergy.

Shoe dermatitis is most frequently caused by the rubber accelerators mercaptobenzothiazole, carbamates, and tetramethylthiuram disulfide. Potassium dichromate in leather and the adhesives used in synthetic materials (especially *p*-tert-butylphenol formaldehyde resin) are also common shoe allergens. Diisocyanates are used in making foam rubber padding for athletic shoes and may cause allergy. Dimethyl fumarate is a preservative used in antihumidity sachets. It is a volatile substance and may deposit on shoes during its transport. Dimethyl fumarate is highly allergenic, and several outbreaks of shoe dermatitis in Europe have occurred secondary to this allergen. Other causative agents are felt, cork liners, formaldehyde, dyes, asphalt, and tar. Shoe refresher sprays may also induce allergy. Patch testing with pieces of various shoe parts may be done by soaking them for 15 minutes in water and applying them to the back for 72–96 hours. Once the allergen has been identified, selection of shoes without the offending substance will lead to resolution. Unfortunately, this is a difficult process, because most shoes are made in areas without mandatory labeling requirements, and plastic, wooden, or fabric shoes that contain fewer allergens are often impractical.

Dermatitis From Metals and Metal Salts

Metal dermatitis is most frequently caused by nickel and chromates. Usually, with the exception of nickel, the pure metals generally do not cause hypersensitivity; only when they are incorporated into salts do they cause reactions. Most objects containing metal or metal salts are combinations of several metals, some of which may have been used to plate the surface, thereby enhancing its attractiveness, durability, or tensile strength. For this reason, suspected metal-caused dermatitis should be investigated by doing patch tests to several of the metal salts.

Patients have developed a variety of dermatoses, most often eczematous in type, after placement of an orthopedic, gynecologic, or dental implant or a pacemaker/defibrillator or endovascular device. When patients are symptomatic with an eczematous process after implantation, patch testing will allow evaluation of allergy by testing with an extended tray, metals, and bone cement. A positive diagnosis of allergy at a minimum requires the appearance of a chronic dermatitis after placement, no other cause, a positive patch test for the suspected metal (or with drug-eluting stents, the drug), and healing after removal. This scenario is exceedingly uncommon; the removal of the foreign material needs to be judged as necessary, reasonable, and safe, and no objective criteria exist to determine the necessity. Dental and gynecologic implants are more frequently replaced; some patients do improve. Patch testing before placement does not seem to predict complications and is therefore not recommended.

Black Dermatographism. Black or greenish staining under rings, metal wristbands, bracelets, and clasps is caused by the abrasive effect of cosmetics or other powders containing zinc or titanium oxide on gold jewelry. This skin discoloration is black because of the deposit of metal particles on skin that has been powdered and that has metal, such as gold, silver, or platinum, rubbing on it. Abrasion of the metal results because some powders are hard (zinc oxide) and can abrade the metal.

Nickel. Because we are all constantly exposed to nickel, nickel dermatitis is a frequent occurrence. Although still most common among women, sensitization is increasing among men. A direct relationship between prevalence of nickel allergy and number of pierced sites has been documented. Nickel produces more cases of allergic contact dermatitis than all other metals combined.

Fig. 6.14 Nickel dermatitis caused by earring.

Erythematous and eczematous eruptions, sometimes with lichenification, appear beneath earrings (Fig. 6.14), bracelets, rings, wrist watches, clasps, and jeans buttons. The snaps on clothing have been implicated in producing allergy in children; nickel is the most common cause of allergic contact dermatitis in children as well as adults. Laptop computers, cell phones, electronic cigarettes, and microneedling devices are newer products capable of causing nickel dermatitis. Metals, including nickel, are increasingly being recognized as a cause of cosmetic allergies. Nickel ranks highly on lists of occupationally induced allergic contact dermatitis.

Nickel dermatitis is seen most frequently on the earlobes. Piercing the earlobes with nickel-plated instruments or wearing nickel-plated jewelry readily induces nickel sensitivity. Earlobes should be pierced only with stainless steel instruments, and only stainless steel earrings should be worn until the ears have healed. Exposure to the metal may not be readily apparent most of the time. Even with gold jewelry, the clasps and solder may contain nickel. Nickel objects may be plated with chrome but may still cause nickel dermatitis through the leaching of some of the nickel through the small pores of the chromium plating.

Nickel oxides in green paints may produce nickel dermatitis. Homeopathic and complementary medicaments may also contain enough nickel to produce a contact allergy. Sweat containing sodium chloride may combine with nickel to form nickel chloride. This affects the degree of nickel dermatitis, being more severe in persons who perspire profusely.

The diagnosis is established by a positive patch test reaction to nickel sulfate. Nickel may be detected by applying dimethylglyoxime solution to the test object. In the presence of nickel, the cotton swab used to apply the solution will turn orange-pink. A positive test always means that nickel is present, but a negative test does not rule out its presence. Sweat, blood, or saline may leach nickel from stainless steel.

Prophylactic measures should include the reduction of perspiration in those sensitive to nickel. Topical corticosteroids applied before exposure to nickel, such as before putting on a wristband, may be successful. Clasps and other objects are available in plastic material so that some of the exposure to nickel may be decreased. Polyurethane varathane 91 applied in three coats will give protection for several months. Treatment of nickel dermatitis consists of the application of topical corticosteroids. In Europe, laws regulating the maximum content of nickel in jewelry have led to a marked decrease in sensitization. Dr. Sharon Jacob is leading an effort to have a similar law passed in the United States.

Hand eczema and pompholyx in nickel-sensitive or cobalt-sensitive patients have rarely been aggravated by ingested metals in the diet. In severe, treatment-resistant dermatitis, a specific diet low in nickel and cobalt may be tried.

Chromium. The chromates are strongly corrosive and irritating to the skin and may act as primary irritants or as sensitizers to produce allergic contact dermatitis. Besides affecting employees in chromate works, chrome dermatitis is encountered among tanners, painters, dyers, photographers, polishers, welders, aircraft workers, diesel engine workers, and those involved with the bleaching of crude oils, tallows, and fats. Traces of dichromates in shoe leather and gloves may cause eczema of the feet and hands. Many zippers are chromium plated, and the nickel underneath may be the causative agent. Chromium metal and stainless steel do not produce contact dermatitis.

Zinc chromate paint is a source of dermatitis. Matches, hide glues, chrome alloys, cigarette lighters, and leather hatbands, sandals, or camera cases may cause chrome dermatitis. Anticorrosion solutions used for refrigeration and other recirculation systems often contain chromates that produce dermatitis. Most workers in the cement industry who have cement eczema show positive patch tests to dichromates. Cement eczema is often a primary irritant dermatitis complicated by allergic contact dermatitis to the hexavalent chromates. The incidence of cement dermatitis has decreased significantly over the years, believed to be the result of the addition of ferrous sulfate, delivery of premixed cement to the job site, and improved education.

The skin changes are multiform, ranging from a mild follicular dermatitis to widespread nodular and crusted eruptions, all being worse on exposed parts. Often the eruptions are slow to clear up, lasting from a few weeks to 6 months after contact has ceased. Heavy exposure of industrial workers to chromates may produce chrome ulcers on the backs of the hands and forearms, usually beginning around a hair follicle, or in the creases of the knuckles or finger webs. The hole begins as a small abrasion that deepens and widens as its edges grow thick, eventually forming a conical, indolent ulceration. Chrome ulcers may also arise on—and perforate—the nasal septum. Arsenic exposure may result in similar ulcers.

Diagnosis of chrome sensitivity is made by a positive patch test to potassium dichromate in petrolatum. The hexavalent chrome compounds are the most frequent cause of chrome dermatitis because these penetrate the skin more easily than the trivalent form. Both forms are sensitizers. Even with avoidance of chromate-containing materials, chromate-induced dermatitis is often persistent.

Mercury. The mercurials may act not only as irritants but also as sensitizers. Thimerosal is a mercuric-containing preservative; it is an allergen that is rarely relevant. Allergy to this compound is likely to have been caused by exposure during childhood vaccinations and to tincture of merthiolate antiseptic. In general, these patients tolerate repeated vaccinations well. Most individuals are sensitized to the ethyl mercuric component of thimerosal; however, those who react to the thiosalicylic acid portion develop photodermatitis to piroxicam. Mercury in amalgam dental fillings has been shown in multiple large studies to cause oral lichenoid eruptions. The relationship is especially strong when the oral lesion, often with a painful erosion present, is apposed to a gold or amalgam filling. In many cases, when sensitivity is proved by patch testing and fillings are replaced, involution of the oral findings occurs.

Cobalt. Cobalt is frequently combined with nickel as a contaminant, and patients allergic to cobalt typically are also allergic to nickel. The metals have similar properties but do not produce cross-reactions. Cobalt dermatitis may occur in those involved in the manufacture of polyester resins and paints, hard metals used for cutting and drilling tools, and cement. Cobalt dermatitis may also occur in producers of pottery, ceramics, metal alloys, glass, carbides, and pigments. Individuals may be exposed to cobalt in hair dye, flypaper, and vitamin B_{12}. Blue tattoo pigment contains

Fig. 6.15 Oral lichenoid dermatitis due to gold.

cobalt oxide. Rarely, cobalt chloride may cause nonimmunologic local release of vasoreactive materials, with a local urticarial response.

Gold. Gold dermatitis may rarely occur from the wearing of gold jewelry. A predisposing factor in such patients is the presence of dental gold. Oral lichenoid eruptions have also been reported with gold, similar to the situation with mercury-containing amalgams (Fig. 6.15). It is not uncommon to see positive reactions to gold when patch-testing patients with facial, eyelid, or widespread dermatitis of unknown cause. Although it is difficult to make a direct clinical correlation with any one piece of jewelry, occasionally patients will clear if they stop wearing all gold jewelry. One possible explanation is that titanium dioxide in sunscreen products may liberate gold particles from jewelry. In most patients, however, there is a lack of relevance. Gold reactions on patch testing may be delayed in onset and remain inflamed for months.

Other Metals. Most other common metals are not important in causing contact dermatitis. Platinum dermatitis may occur from exposure to platinum salts and sprays in industry. Platinum rings, earrings, white gold spectacles, clasps, and other jewelry cause eruptions resembling those caused by nickel. Zinc, aluminum, copper sulfate, titanium, and antimony dermatitis rarely occur, although these metals may act as irritants.

Contact Stomatitis

The role of contact allergy in oral symptomatology is significant. Approximately 30% of patients with oral symptoms will have relevant allergens, most frequently metals used in dental fillings, food additives (flavorings and antioxidants), and dental products (acrylic monomers, epoxy resins, hardeners used in prosthodontics and dental impression materials). Chewing gums and dentifrices may also produce contact stomatitis. Ingredients responsible for this are hexylresorcinol, thymol, dichlorophen, oil of cinnamon, and mint.

Clinical signs may be bright erythema of the tongue and buccal mucosa with scattered erosions. Angular cheilitis may also develop. Oral lichenoid lesions may be caused by sensitization to metals in dental fillings and gold caps or crowns.

Rubber Dermatitis

Rubber dermatitis generally occurs on the hands from wearing rubber gloves, as by surgeons, nurses, and homemakers. The eruption is usually sharply limited to the gloved area but may spread up the forearms. Rubber dermatitis also develops from exposure to condoms, diaphragms, swim goggles (Fig. 6.16), caps and scuba masks, wet suits, bandages for chronic leg ulcers, respirators, gas

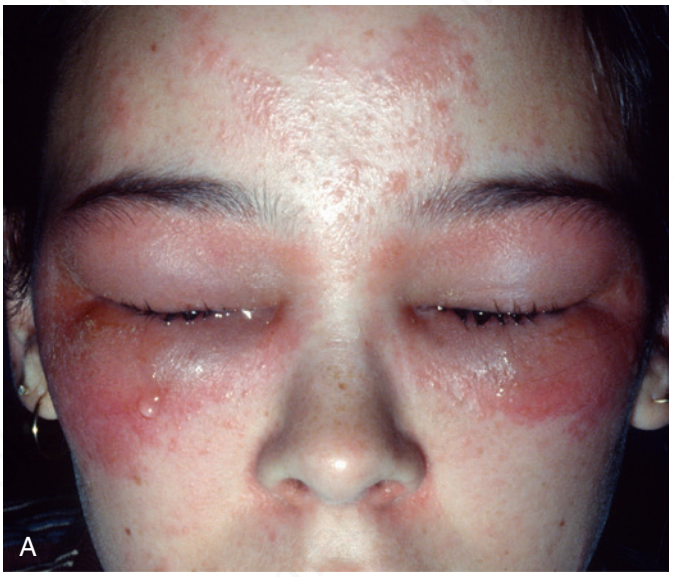

Fig. 6.16 Rubber dermatitis from swim goggles.

masks, rubber sheets, and cosmetic sponges. Shoe dermatitis may be caused by rubber allergy to insoles or sneakers.

Natural and synthetic rubbers are used separately or in combination to make the final rubber product. The chemicals added in the rubber manufacturing process, most importantly the accelerators and antioxidants, are the common causes of allergic contact dermatitis. A similar list of additives is present in neoprene, a synthetic rubber, but also includes the dialkyl thioureas. These are not in the standard patch trays and thus may escape detection unless applied as a supplemental allergen. Elastic in underwear is chemically transformed by laundry bleach into a potent sensitizing substance. The allergen is permanent and cannot be removed by washing. The offending garments must be thrown out and the use of bleaches interdicted.

Accelerators. During the manufacturing process, chemicals are used to hasten the vulcanization of rubber. Among the numerous chemicals available, tetramethylthiuram disulfide, mercaptobenzothiazole, and diphenylguanidine are frequently used. Tetramethylthiuram disulfide and its analogs, known as disulfiram and thiuram, may produce contact dermatitis when moist skin is exposed to the finished rubber product. In a 10-year study of 636 cases of allergy to rubber additives, thiuram mix was by far the most common sensitizer. Mercaptobenzothiazole is most often the cause in shoe allergy and thiuram in glove allergy.

Antioxidants. Antioxidants are used to preserve rubber. Amine antioxidants, such as phenyl-α-naphthylamine, are most effective. Hydroquinone antioxidants may cause depigmentation of the skin, as well as allergic contact dermatitis. A frequent antioxidant sensitizer, propyl *p*-phenylenediamine, is used in tires, heavy-duty rubber goods, boots, and elastic underwear.

Adhesive Dermatitis

Cements, glues, and gums may cause adhesive dermatitis. Formaldehyde resin adhesives contain free formaldehyde, naphtha, glue, and disinfectants. Synthetic resin adhesives contain plasticizers; hide glues may contain chromates from the tanned leather, and other glues incorporate preservatives such as formaldehyde. Dental bonding adhesives may contain acrylic monomers and epoxy resins and hardeners. Pressure-sensitive adhesives contain rubber and acrylates, and anaerobic adhesives have primarily acrylates.

Vegetable gums, such as gum tragacanth, gum arabic, and karaya, may be used in denture adhesives, hair wave lotions, topical medications, toothpastes, and depilatories, and many cause contact dermatitis. Resins are used in adhesive tapes and in various adhesives such as tincture of benzoin. Turpentine is frequently found in rosin; abietic acid in the rosin is the causative sensitizer.

Adhesive tape reactions are frequently irritant in nature. Allergic reactions to adhesive tape itself are caused by the rubber components, accelerators, antioxidants, and various resins or turpentine. Some adhesive tapes contain acrylate polymers rather than rubber adhesives. These acrylates may cause allergic contact dermatitis. Pressure-sensitive adhesives are increasingly used. Allergens present in these adhesives include rosin, rubber accelerators, antioxidants, acrylates, hydroquinones, lanolin, thiourea compounds, and *N*-dodecylmaleamic compounds.

Synthetic Resin Dermatitis

The many varieties of synthetic resins preclude adequate discussion of each. The reactions during the manufacture of these substances are more common than those in their finished state.

Epoxy Resins. The epoxy resins in their liquid (noncured, monomer) form may produce severe dermatitis, especially during the manufacturing process. The fully polymerized or cured product is nonsensitizing. Nonindustrial exposure is usually to epoxy resin

glues, nail lacquers, and artificial nails. Epoxy resins are used in the home as glues and paints (bathtub and refrigerator). Artists and sculptors frequently use epoxy resins.

Epoxy resins consist of two or more components, the resin and the curing agent. Approximately 90% of allergic reactions are to the resin and 10% to the hardener. The numerous curing agents include the amines, phenolic compounds, peroxides, and polyamides. These may be irritants and/or allergens. The resin, based on an acetone and phenol compound known as bisphenol A, in its raw state may cause allergic contact dermatitis. BIS-GMA, a combination of bisphenol A and glycidyl methacrylate, is the main allergen in dental bonding agents. Epoxy resins are used also as stabilizers and plasticizers. Their use in the manufacture of polyvinyl chloride (plastic) film has caused dermatitis from plastic handbags, beads, gloves, and panties.

Polyester Resins. Ordinarily, completely cured or polymerized resins are not sensitizers. The unsaturated polyester resins are dissolved and later copolymerized with vinyl monomers. Such polyester resins are used for polyester plasticizers, polyester fibers (Dacron), and polyester film (Mylar). The unsaturated polyester resins, on the other hand, will produce primary irritation in their fabrication or among sculptors. The dermatitis occurs typically as an eczematous eruption on the back of the hands, wrists, and forearms. Polyester resins are incorporated into other plastic material as laminates to give them strength; applications include boat hulls, automobile body putty, safety helmets, fuel tanks, lampshades, and skylights.

Acrylic Monomers. Cyanoacrylates are used widely as adhesives in a variety of home and commercial products. They are generally a rare cause of contact dermatitis. Multifunctional acrylic monomers may produce allergic or irritant contact dermatitis. Pentaerythritol triacrylate, trimethylolpropane triacrylate, and hexanediol diacrylate are widely used acrylic monomers. Printers handling multifunctional acrylic monomers in printing inks and acrylic printing plates may present with an erythematous, pruritic eruption, mainly of the hands and arms, swelling of the face, and involvement of the eyelids.

Orthopedic surgeons experience contact dermatitis from the use of acrylic bone cement (methyl methacrylate monomer) used in mending hip joints. Dentists and dental technicians are exposed when applying this to teeth. The sensitizer passes through rubber and polyvinyl gloves and may additionally cause paresthesias. In patients who are allergic to their acrylate dental prosthesis, coating this with UV light–cured acrylate lacquer may allow it to be worn without adverse effects.

Benzoyl peroxide is a popular acne remedy. It is also used for bleaching flour and edible oils and for curing plastics, such as acrylic dentures. Infrequently, an allergic contact dermatitis may result.

Cosmetic Dermatitis

Cutaneous reactions to cosmetics may be divided into irritant, allergic, and photosensitivity reactions. More than half the reactions occur on the face and are caused primarily by skin care products, nail cosmetics, shaving preparations, and deodorants. The leading cause of allergic contact dermatitis associated with cosmetics is from fragrance. A close second is preservatives, such as methylchloroisothiazolinone/methyllisothiazolinone, 2-bromo-2-nitropropane-1,3-diol, quaternium 15, methyldibromo glutaronitrile, and imidazolidinyl urea. The third leading cause is *p*-phenylenediamine in hair dye. It is recommended that patch testing with the patient's own product, as long as it is applied to the skin as a leave-on product, be part of the evaluation.

Fig. 6.17 Fragrance allergy, lyral.

Fragrances. Almost all cosmetic preparations, skin care products, and many medications contain fragrance; even those labeled "nonscented" often contain a masking fragrance that may be a sensitizer. Even "fragrance-free" products have been documented to contain the raw fragrance ingredients, such as rose oil in "all-natural" products. Fragrances are the most common cosmetic ingredient causing allergic contact dermatitis. Photodermatitis, irritation, contact urticaria, and dyspigmentation are other types of reactions that fragrances may produce.

The most common individual allergens identified are cinnamic alcohol, oak moss, cinnamic aldehyde, hydroxy citronellal, musk ambrette, isoeugenol, geraniol, coumarin, lyral (Fig. 6.17), and eugenol. Hyperperoxides of linalool and oxidized limonene are newer important fragrance allergens. Frequently, unspecified allergens are the cause, because they are not listed on labels, and fragrances are combinations of many different ingredients. *Myroxylon pereirae* (balsam of Peru) will identify approximately half of those often unsuspected cases of allergic dermatitis, and additional testing with the fragrance mixes will identify over 90%. Additionally, a natural fragrance mixture of jasmine absolute, ylang-ylang oil, narcissus absolute, spearmint oil, and sandalwood oil is recommended. Other essential oils may be missed if not individually tested. Fragrance mixes should be prepared the day of application as evaporation may compromise their reliability. New products should be tested for tolerance in patients with a history of fragrance sensitivity.

At least 1% of the population have fragrance sensitivity. Women still outnumber men, but as the frequency of fragrance contact reactions has increased over the years, men have shown a steeper increase in sensitivity. Fragrance is one allergen that may be transferred by skin-to-skin contact to a sensitive person, causing connubial contact dermatitis. Ingestion of balsam-related foods, such as tomatoes, citrus fruits, and spices, may cause a flare in some sensitive patients. In particularly difficult-to-treat patients, balsam-restricted diets may be beneficial but are not easy to follow.

Fig. 6.18 Hair dye allergy.

Hair Dyes. Permanent hair dyes incorporate *p*-phenylenediamine (PPDA), a popular but potent sensitizer that may cross-react with many chemicals. In rinses and tints, the azo dyes, acid violet 6B, water-soluble nigrosine, and ammonium carbonate may sensitize and cross-react with PPDA. Workers in the manufacture of PPDA, furriers, hairdressers, and those in the photographic and rubber vulcanization industries develop eruptions first on the back of the hands, wrists, forearms, eyelids, and nose, consisting of an eczematous, erythematous, oozing dermatitis. It will penetrate most protective gloves, but not nitrile gloves. Lichenification and scaling are seen in the chronic type. In those with dyed hair, sensitivity is manifested by itching, redness, and puffiness of the upper eyelids, tops of the ears, temples, and back of the neck (Fig. 6.18). Beard/mustache dermatitis may be caused by coloring of the facial hair and eyelid dermatitis by dying eyelashes. PPDA added to temporary henna tattoos to make them darker has resulted in acute vesicular allergic reactions, some with scarring and hyperpigmentation. Kumkum is a common cosmetic in India, primarily smeared on the forehead of women to denote their marital status; one of many reported allergens in the product is PPDA.

For those sensitive to this type of hair dye, use of semipermanent or temporary dyes might be the solution. In the case of sensitivity to these alternatives, vegetable dyes such as henna may be tried. Metallic dyes are usually not favored by women but are frequently used by men as "hair color restorers." The metallic hair dyes may contain nickel, cobalt, chromium, or lead. Hair dyes containing FD&C and D&C dyes often do not cross-react with PPDA and 70% of PPDA-sensitive patients exposed to a dye containing the less allergenic PPDA derivative 2-methoxymehtyl-PPD tolerated it.

Other Hair Products. Hair bleach products incorporate peroxides, persulfates, and ammonia, which may act as primary irritants. Hair bleaches that contain ammonium persulfate, a primary irritant, may produce a local urticarial and a generalized histamine reaction.

Several types of permanent wave preparations exist. The alkaline permanent wave preparations, which use ammonium thioglycolate, are rarely if ever sensitizers and usually cause only hair breakage and irritant reactions. The hot type, or acid perm, is a common sensitizer, the allergen being glyceryl monothioglycolate. Cosmetologists are at risk for development of hand dermatitis. The glyceryl monothioglycolate persists in the hair for at least 3 months after application and may cause a long-lasting dermatitis. It readily penetrates rubber and vinyl gloves. A more neutral pH permanent wave solution is less allergenic than the acid perms; however, allergy to cysteamine hydrochloride found in neutral permanent wave products may occur. This allergen does not penetrate household-weight latex gloves, and hair waved with it does not produce allergic reactions in sensitized individuals. Also, it is an amine salt, not a thioglycolate, so cross-reactivity is unlikely.

Hair straighteners using greases and gums are not sensitizers; however, the perfume incorporated in these preparations can be sensitizing. Thioglycolates are also used, and hair breakage may occur with these products.

Hair sprays may contain shellac, gum arabic, sunscreens, and synthetic resins as sensitizers, and allergic reactions occur infrequently. Lanolin is frequently incorporated into aerosol sprays.

Chemical depilatories containing calcium thioglycolate and the sulfides and sulfhydrates may cause primary irritant dermatitis. Mechanical hair removers include the mercaptans, waxes, and resins; resins may produce allergic dermatitis.

Hair tonics and lotions with tincture of cinchona produce allergic sensitization; tincture of cantharidin and salicylic acid cause primary irritation. Resorcin, quinine sulfate, and perfumes such as bay rum are also sensitizers.

Nail Products. Nail lacquers may contain tosylamide/formaldehyde resin and are a frequent cause of eyelid and neck dermatitis. Polishes free of this resin are available. Nail polish removers are solvents such as acetone, which can cause nail brittleness. The acrylic monomers in artificial nails, as well as the ethyl cyanoacrylate glue required to attach the prosthetic nail, may produce allergic sensitivity. Photoinitiating agents, such as benzophenone, used in photo-bonded acrylic sculptured nails are other potential allergens.

Lipsticks. Various R and C dyes, sunscreens, shellac, flavoring agents, preservative, and lipstick perfumes may cause sensitization reactions. Lipsticks are tested as is. Lip plumpers may cause contact urticaria in those being kissed. Propolis is found in many so-called natural products, including lip balms, toothpastes, lotions, shampoos, and other cosmetics. Its main allergens are two types of caffeates.

Eye Makeup. In mascara, eye shadow, and eyeliners, preservatives, shellac, metals, base wax, and perfumes are the components that may produce sensitization, but this occurs rarely. False-positive reactions to some mascaras occur when a closed patch test is used. This is caused by the irritative qualities of the solvents. An open or nonocclusive patch test is recommended. A provocative use test in the antecubital fossae may ultimately be necessary. The rubber sponges used to apply eye makeup, nickel in the tools used, or cocamidopropylbetaine in eye makeup remover also cause eyelid dermatitis.

Sunscreens. *p*-Aminobenzoic acid (PABA) and its derivatives (e.g., padimate O, padimate A, glycerol PABA), dibenzoylmethanes, salicylates, cinnamates, and benzophenones are photosensitizers as well as sensitizers. The benzophenones (most often benzophenone-3) and dibenzoylmethanes are the most common sunscreen allergens and photoallergens. These agents frequently are found in various other cosmetic products. The physical blockers titanium dioxide and zinc oxide do not cause allergy. If allergy to PABA exists, its derivatives should be avoided, and the patient should be aware that thiazides, sulfonylurea antidiabetic medication, azo dyes, *p*-aminosalicylic acid, benzocaine, and PPDA all may cause dermatitis from cross-reactions.

Bleaching Creams. Hydroquinones are occasional sensitizers. Ammoniated mercury is a sensitizing agent formerly used in bleaching creams.

Lanolin. The fatty alcohol lanolin is rarely a sensitizer on normal skin, so it usually does not produce dermatitis when exposure is with cosmetic and skin care products. It provokes allergic reactions more frequently in therapeutic agents used by atopic patients and in emollient products that may be used postsurgically.

Dentifrices and Mouthwashes. Dentifrices and mouthwashes contain sensitizers, such as the essential oils used as flavoring agents, preservatives, formalin, antibiotics, and antiseptics. Circumoral dermatitis and cheilitis may be caused by tartar-control types of dentifrice.

Axillary Antiperspirants. Aluminum salts, such as aluminum chloride and chlorhydroxide, and zinc salts, such as zinc chloride, act as primary irritants and may rarely produce a folliculitis. Aluminum chlorhydrate is considered to be the least irritating antiperspirant. Zirconium salt preparations, now removed from all antiperspirants, produced a granulomatous reaction. Zirconium-aluminum complexes, however, are often used as the active ingredient in topical antiperspirants and may produce granulomas. Quaternary ammonium compounds in some roll-on deodorants may produce allergic contact dermatitis.

Axillary Deodorants and Feminine Hygiene Sprays. Fragrances, bacteriostats, and propellants cause the majority of the reactions seen with these products. Deodorants that contain cinnamic aldehyde can induce irritation on axillary skin even when tolerated on healthy skin in other sites.

Cosmetic Intolerance Syndrome. Occasionally, a patient will complain of intense burning or stinging after applying any cosmetic. The patient usually has only subjective symptoms, but objective inflammation may also be present. The underlying cause may be difficult to document, even after thorough patch, photopatch, and contact urticaria testing. Endogenous disease, such as seborrheic dermatitis, rosacea, or atopic dermatitis, may complicate the assessment. Avoidance of all cosmetics, with only glycerin being allowed, for 6–12 months is often necessary to calm the reactive state. Adding back cosmetics one at a time, no more frequently than one a week, may then be tolerated.

Preservatives

Preservatives are added to any preparation that contains water to kill microorganisms and prevent spoilage. Such products include moist materials such as baby wipes, which when used in either infants or adults can produce reactions caused by preservatives. The most important class is formaldehyde and the formaldehyde-releasing compounds, including quaternium 15 (the leading preservative sensitizer in the United States), imidazolidinyl urea, diazolidinyl urea, DMDM hydantoin, and 2-bromo-2-nitropropane-1,3-diol.

Kathon CG, or methylchloroisothiazolinone/methylisothiazolinone (MCI/MI), and Euxyl K 400 (methyldibromoglutaronitrile and phenoxyethanol in 1:4 ratio) are other important preservative allergens. MCI/MI is widely used in cosmetics and personal care products such as baby wipes and moist towelettes, but may be found in medical devices, and in industrial products such as cutting oils, household detergents, paints, and glues. MCI is a stronger allergen, however use of MI alone in high concentrations has led to a increase in primary sensitization to it. Testing should be to each chemical separately. In Euxyl K 400, the methyldibromoglutaronitrile component produces the allergic response. This preservative may produce false-negative results on testing, so

repeat open testing is indicated if a specific leave-on product is suspected of causing allergy. European regulations limit exposure to methyldibromoglutaronitrile. As with similar laws regulating nickel in Europe, allergy to this preservative is also lowering in incidence over time.

Tea tree oil is an additive to some natural products that may serve as an antimicrobial. It is a frequent sensitizer as many products include this oil as a "natural" antimicrobial agent. Sorbic acid is a rare sensitizer among the preservatives; however, it is a cause of facial flushing and stinging through its action as an inducer of nonimmunologic contact urticaria. Benzalkonium chloride is widely used but a rare sensitizer. Triclosan and benzyl alcohol are weak sensitizers. Thimerosal is discussed earlier.

Formaldehyde and Formaldehyde-Releasing Agents. Formaldehyde is used rarely, primarily in shampoos. Because it is quickly diluted and washed away, sensitization through this exposure is rare. Formaldehyde releasers are polymers of formaldehyde that may release small amounts of formaldehyde under certain conditions. Allergy may be to the formaldehyde-releasing preservatives (which act as antibacterial and antifungal agents in their own right) or to the released formaldehyde. Cross-reactivity among them is common, so when allergy is proved to one compound and avoidance does not clear the eruption, screening for clinically relevant reactions to the others is indicated. This may be done by repetitive open application testing to the leave-on product or by extended patch testing.

Parabens. Allergic contact dermatitis may develop from parabens, which are used in cosmetics, foods, drugs, dentifrices, and suppositories. The paraben esters (methyl, ethyl, propyl, and butyl *p*-hydroxybenzoates) are used in low concentrations in cosmetics and rarely cause dermatitis. They are found in higher concentration in topical medicaments and may be the cause of allergic reactions. Parabens, which are frequently used as bacteriostatic agents, are capable of producing immunologically mediated, immediate systemic hypersensitivity reactions. Cross-reactivity to *p*-phenylenediamine and benzocaine occurs in some individuals.

Other Important Preservatives. Iodopropynyl butylcarbamate is a wood and paint preservative that is being used more commonly in cosmetics and personal care products. This accounts for its reported higher importance among preservative allergens. The hands are the most frequent area sensitized. Gallates are antioxidant preservatives that are also emerging as important allergens; propyl gallate is the most commonly reported gallate allergen. It usually produces hand and facial eruptions as it is most commonly encountered by patients in cosmetics and personal care products. *p*-Chloro-metaxylenol (PCMX), a chlorinated phenol antiseptic is used in many over-the-counter products with the disinfectant properties of *p*-chloro-metacresol to which it is cross-reactive.

Vehicles

Formulation of topically applied products is complex, and additives are blended to make a pleasant base for carriage of the active ingredient to the skin. Various emulsifiers, humectants, stabilizers, surfactants, and surface active agents are used to make esthetically pleasing preparations. These may cause irritation, erythema, and allergy. The surfactant cocamidopropyl betaine produces dermatitis of the head and neck in consumers and the hands in hairdressers, often from its presence in shampoos. Sorbitan sesquioleate is an emulsifier in the fragrance I mix. It may produce false-positive results to fragrance in the few patients sensitive to it. Propolis and lanolin are discussed previously under "Cosmetic Dermatitis."

Propylene Glycol. Propylene glycol is widely used as a vehicle for topical medications, cosmetics (especially antiperspirants), and various emollient lotions. It is used in the manufacture of automobile brake fluid and alkyd resins, as a lubricant for food machinery, and as an additive for food colors and flavoring agents. Propylene glycol must be considered as a sensitizer able to produce contact dermatitis, and it can cause a flare of the contact dermatitis when ingested. It is tested as a 4% aqueous solution, but irritant reactions or false-negative results are common. A use test of the implicated propylene glycol–containing products may be required.

Ethylenediamine. Ethylenediamine is used as a stabilizer in medicated creams. It may cause contact dermatitis and cross-react with internally taken aminophylline, which consists of theophylline and ethylenediamine. Hydroxyzine is a piperazine derivative that is structurally based on a dimer of ethylenediamine, to which patients sensitive to the stabilizer may develop a generalized itchy, red eruption that recurs each time hydroxyzine is taken orally.

Topical Drug Contact Dermatitis

Drugs, in addition to their pharmacologic and possible toxic action, also possess sensitizing properties. Sensitization may occur not only from topical application (Fig. 6.19) but also from ingestion, injection, or inhalation. Some drugs, such as the antihistamines, including topical doxepin, sensitize much more frequently when applied topically than when taken orally. With the advent of transdermal patches for delivery of medications (e.g., nitroglycerin, hormones, nicotine, clonidine, fentanyl, lidocaine, and scopolamine)

Fig. 6.19 Contact dermatitis to eyedrops. (Courtesy Shyam Verma, MBBS, DVD.)

reports of sensitization have been increasing. Clonidine induces the highest rate of allergic reactions. At times, EM-like reactions may occur with transdermally applied drugs.

Some drugs may produce sensitization of the skin when applied topically; if the medication is taken later internally, an acute flare at the site of the contact dermatitis may result. This anamnestic (recalled) eruption or systemic contact dermatitis can occur with antihistamines, sulfonamides, and penicillin. The same is true of the local anesthetic ointments containing "caine" medications, but not as a rule with lidocaine allergy. Usually, if sensitization occurs when using transdermal patches, the drugs do not cause systemic contact dermatitis when taken orally. The important topical medications that cause irritation or allergic contact dermatitis are discussed next.

Local Anesthetics. Physicians and dentists may develop allergic contact dermatitis from local anesthetics. In addition, the continued use of these local anesthetics as antipruritic ointments and lotions causes sensitization of the skin. Benzocaine is a frequently used topical antipruritic and is the most common topical sensitizer of this group. Itchy dermatitis of the anogenital area may be caused by a topical anesthetic.

Local anesthetics may be divided into two groups. The first group includes the *p*-aminobenzoic acid esters, such as benzocaine, butethamine, chloroprocaine, procaine (Novacaine), and tetracaine. The second group, which sensitizes much less frequently, includes the amides, such as dibucaine (Nupercainal), lidocaine (Lido-Mantle, EMLA, Lidoderm patch, LMX, Xylocaine), mepivacaine (Carbocaine), and prilocaine. In addition, the preservative methylparaben, frequently found in these prepared solutions, may cause hypersensitivity reactions that can easily be misattributed to the local anesthetics. It should be kept in mind that numerous cross-reactions are seen in benzocaine-sensitive individuals. These are discussed earlier in the sections on sunscreens and preservatives. Lidocaine can induce contact urticaria as well. Finally pramoxine has a distinctive structure and is not an amide nor an ester anesthetic. It may rarely induce contact allergy of both the immediate and delayed types.

Antimicrobials. Physicians, dentists, nurses, and other medical personnel, as well as patients, especially those with chronic leg ulcers, may develop contact dermatitis from various antibiotics. Neomycin and bacitracin are the most common sensitizers in the United States. Neomycin sulfate has been incorporated into innumerable ointments, creams, and lotions, including underarm deodorants, otic and ophthalmologic preparations, and antibiotic creams and ointments available without prescription. The signs of neomycin sensitivity may be those of a typical contact dermatitis but are often signs of a recalcitrant skin eruption that has become lichenified and even hyperkeratotic. This may result because many topical agents contain several types of antibiotic but also often have corticosteroids present. This picture may be seen in persistent external otitis, lichen simplex chronicus of the nuchal area, or dermatophytosis between the toes. A late-appearing reaction on patch testing can occur, so an assessment at day 7 is recommended.

Allergy to bacitracin increased dramatically because of its use after minor surgical procedures. After clean surgical procedures, white petrolatum is as effective in wound healing as antibiotic ointment and does not carry the allergenic potential. Petrolatum should be used after clean cutaneous surgery; antibiotic ointments are not necessary. There is a high rate of co-reaction (not cross-reaction) with neomycin because of simultaneous exposures. Contact urticaria and anaphylaxis are reported more often with bacitracin than with other antibiotics.

Mafenide acetate, the topical antimicrobial found in Sulfamylon, a burn remedy, may cause allergic contact dermatitis, as can metronidazole. Polymyxin B is an uncommon sensitizer.

Antifungal Agents. Allergic contact dermatitis to imidazole and other antifungal agents may occur. There is a high cross-reactivity rate among miconazole, isoconazole, clotrimazole, and oxiconazole because of their common chemical structure.

Corticosteroids. Numerous reports of large series of patients who have developed allergy to common corticosteroid preparations emphasize the need for a high index of suspicion when treating patients with chronic dermatitis who fail to improve, or who worsen, when topical steroidal agents are used. Once sensitized to one type of corticosteroid, cross-sensitization may occur. The corticosteroids have been separated into the following four structural classes:

- Class A is the hydrocortisone, tixocortol pivalate group.
- Class B is the triamcinolone acetonide, budesonide group.
- Class C is the betamethasone group.
- Class D is the hydrocortisone-17-butyrate group.

There are frequent cross-reactions between classes B and D. Tixocortol pivalate and budesonide have been found to be the best screening agents, finding 93% of steroid allergies. Patch testing to the implicated leave-on product may be useful. An empiric trial of desoximetasone (Topicort) or mometasone (Elocon) in the absence of patch testing will give the best chance of selecting a topical steroid with an extremely low risk of sensitization.

Occupational Contact Dermatitis

Workers in various occupations are prone to contact dermatitis from primary irritants and allergic contactants. In certain occupations, it is a common occurrence. Irritant contact dermatitis occurs more frequently in the workplace, but it tends to be less severe and less chronic than allergic contact dermatitis. Occupational skin disease has declined over the past 30 years but still constitutes approximately 10% of all occupational disease cases. Agriculture, forestry, and fishing have the highest incidence of occupational skin disease, with the manufacturing and health care sectors contributing many cases as well.

Irritant contact dermatitis is often present in wet-work jobs, and allergy occurs in hairdressers, machinists, and many others with unique exposures to multiple sensitizing chemicals. The hands are the parts most affected and are involved in 60% of allergic reactions and 80% of irritant dermatitis. Epoxy resin is an allergen overrepresented when evaluating occupational patients. The allergens most frequently encountered in occupational cases are carba mix, thiuram mix, epoxy resin, formaldehyde, and nickel.

Management

Occupational contact dermatitis is managed by eliminating contact of the skin with irritating and sensitizing substances. The work environment should be carefully controlled, with use of all available protective devices to prevent accidental and even planned exposures. Personal protective measures, such as frequent clothing changes, cleansing showers, protective clothing, and protective barrier creams, should be used as appropriate. Hand-cleansing procedures should be thoroughly surveyed, with particular attention to the soaps available and the solvents used.

Treatment of the dermatitis follows closely that recommended for *Toxicodendron* dermatitis. Topical corticosteroid preparations are especially helpful in the acute phase. For dry, fissured hands, soaking them in water for 20 minutes at night followed immediately on removing (without drying them) with triamcinolone 0.1% ointment will help hydrate and heal. Topical tacrolimus ointment and pimecrolimus cream may assist in maintenance therapy, along with high-lipid content moisturizing creams. When rubber and polyvinyl gloves cannot be used against irritant and allergenic substances, protective skin creams may offer a solution but are often impractical. A wide variety is available, but two main types are used: for "wet work," to protect against acids, alkalis, water-based paints, coolants, and cutting oils with water; and for "dry work," to protect against oils, greases, cutting oils, adhesive, resins, glues, and wood preservatives.

Unfortunately, despite the best efforts at treatment and prevention, the prognosis for occupational skin disease is guarded. One third to one quarter heal, and another one third to one half improve, with the remainder the same or worse. A change or discontinuance of the job does not guarantee relief; many individuals continue to have persistent postoccupational dermatitis. The importance of thorough patient education cannot be overemphasized. Atopic patients, males with chromate allergy, females with nickel allergy, those with a delay in diagnosis before institution of treatment, and construction industry workers fare the worst, whereas irritation from metalworking fluids, reactions to urushiols in foresters, and allergic contact dermatitis to acrylic monomers or amine curing agents is usually short-lived.

Contact Urticaria

Contact urticaria may be defined as a wheal and flare reaction occurring when a substance is applied to the intact skin. Urticaria is only one of a broad spectrum of immediate reactions, including pruritus, dermatitis, local or general urticaria, bronchial asthma, orolaryngeal edema, rhinoconjunctivitis, gastrointestinal distress, headache, or anaphylactic reaction. Any combination of these is subsumed under the expression "syndrome of immediate reactions."

Contact urticaria may be nonimmunologic (no prior sensitization), immunologic, or of unknown mechanism. The nonimmunologic type is the most common and may be caused by direct release of vasoactive substances from mast cells. The allergic type tends to be the most severe, because anaphylaxis is possible. The third type has features of both other types.

Nonimmunologic Mechanism. The nonimmunologic type of reaction induces contact urticaria in almost all exposed individuals. Examples of this type of reaction are seen with nettle rash (plants), dimethyl sulfoxide (DMSO), sorbic acid, benzoic acid, cinnamic aldehyde, cobalt chloride, and Trafuril.

Immunologic Mechanism. The immunologic reaction is of the immediate (immunoglobulin E [IgE]–mediated) type of hypersensitivity. Latex, potatoes, phenylmercuric propionate, and many other allergens have been reported to cause this type.

Uncertain Mechanism. The uncertain type of reaction occurs with agents that produce contact urticaria and a generalized histamine type of reaction but lack a direct or immunologic basis for the reaction.

Substances Causing Contact Urticaria. Many different substances can elicit such a reaction. Universal precautions not only led to a marked increase in delayed-type hypersensitivity reaction to rubber additives, but also to many reports of contact urticaria and anaphylaxis to latex. Most of these reactions occur in health professionals. Reactions are characterized by itching and swelling of the hands within a few minutes of donning the gloves, usually resolving within an hour after removing them. In patients with continued exposure, the eruption may eventually appear as chronic eczema. Glove powder may aerosolize the allergen and produce more generalized reactions. Although these reactions may occur on the job, many cases present as death or near-death events when sensitized individuals undergo surgery or other procedures, especially when there is mucosal exposure (e.g., dental care, rectal examination, childbirth).

In addition to health care workers, who have a reported incidence of 3%–10%, atopic persons and spina bifida patients are other risk groups for the development of type I allergy to latex protein. The sensitized individual should also be aware that up to 50% of patients have a concomitant fruit allergy to foods such as banana, avocado, kiwi, chestnut, and passion fruit.

Contact urticaria is seen in homemakers and food workers who handle raw vegetables, raw meats and fish, shellfish, and other foods. Raw potatoes have been shown to cause not only contact urticaria but also asthma at the same time. It has been seen in hairdressers who handle bleaches and hair dyes containing ammonium persulfate, in whom the contact urticaria is accompanied by swelling and erythema of the face, followed by unconsciousness. Caterpillars, moths, and hedgehogs may cause contact urticaria just by touching the skin.

Additional substances inducing this reaction are oatmeal, flour, meat, turkey skin, calf liver, banana, lemon, monoamylamine, benzophenone, nail polish, tetanus antitoxin, streptomycin, cetyl alcohol, stearyl alcohol, estrogenic cream, cinnamic aldehyde, sorbic acid, benzoic acid, castor bean, lindane, carrots, spices, wool, silk, dog and cat saliva, dog hairs, horse serum, ammonia, sulfur dioxide, formaldehyde, acrylic monomers, exotic woods, wheat, cod liver oil, and aspirin.

Bacitracin ointment may cause anaphylactic reactions when applied topically, especially to chronic leg ulcers; however, it may rarely occur after application to acute wounds (Fig. 6.20).

Testing. The usual closed patch tests do not show sensitivity reactions. Instead, open patch tests are performed for eliciting immediate-type hypersensitivity. The substance is applied to a 1-cm^2 area on the forearm and observed for 20–30 minutes for erythema that evolves into a wheal and flare response. When foods are tested, a small piece of the actual food is placed on the skin. Rubber glove testing can be done by applying one finger of a latex glove to a moistened hand for 15 minutes. If no reaction is observed, the entire glove is worn for another 15–20 minutes. The radioallergosorbent test (RAST) detects 75% of latex-allergic individuals. Prick, scratch, or intradermal testing is undertaken only when there are problems of interpretation of the open patch tests. These tests have produced anaphylactic reactions and should only be attempted when support for this complication is available.

Fig. 6.20 Contact urticaria caused by bacitracin applied to punch biopsy site.

Management. Avoidance of the offending substance is best, but if this is not possible, antihistamines are of benefit. If generalized urticaria or asthmatic reactions occur, systemic glucocorticoids are best. For anaphylaxis, epinephrine and supportive measures are needed.

DRUG REACTIONS

Epidemiology

Adverse drug reactions (ADRs) are a common cause of dermatologic consultation. In a large French study, about 1 in 200 inpatients on medical services developed a drug eruption, compared with 1 in 10,000 on surgical services. In the United States, similar studies have shown a reaction rate of 2%–3% for medical inpatients. In only about 55% of patients who were carefully evaluated was it possible to attribute a specific medication definitely as the cause of the eruption. Simple exanthems (75%–95%) and urticaria (5%–6%) account for the vast majority of drug eruptions. Females are 1.3–1.5 times more likely to develop drug eruptions, except in children under age 3 years, with boys more likely to be affected than girls. Aminopenicillins cause drug eruptions in 1.2%–8% of exposures and trimethoprim-sulfamethoxazole (TMP-SMX) in 2.8%–3.7%. About 20% of emergency department visits for adverse

events caused by medications are related to antibiotics, mainly penicillins and cephalosporins. Nonsteroidal antiinflammatory drugs (NSAIDs) have a reaction rate of about 1 in 200. In contrast, reaction rates for digoxin, lidocaine, prednisone, codeine, and acetaminophen are less than 1 in 1000.

Patients with immune dysregulation (lupus, HIV, bone marrow transplant) and multiple drug exposures have higher rates of reactions. Patients with human immunodeficiency virus (HIV) or Epstein-Barr virus (EBV) infection have dramatically increased rates of exanthematous reactions to certain antibiotics. Hypersensitivity syndromes from multiple drug classes have been associated with reactivation of latent viral infections, primarily human herpesvirus (HHV) 6 and HHV-7, but also EBV and cytomegalovirus (CMV). Certain human leukocyte antigen (HLA) types in specific populations, may increase risk for drug reactions for specific medications, with personalized pharmacogenomics emerging as a strategy to prevent ADRs

Evaluation

All patients with a suspected drug reaction should be evaluated for primary lesion morphology and distribution of the rash, checked for concerning, atypical, or high-risk features, and examined for any extracutaneous manifestations. Four basic rules should always be applied in evaluating the patient with a suspected ADR, as follows:

1. The patient is probably on unnecessary medications, and all of these should be stopped. Pare down the medication list to the bare essentials.
2. The patient must be asked about nonprescription medications and pharmaceuticals delivered by other means (e.g., eyedrops, suppositories, implants, injections, patches, dialysates, radiocontrast agents, recreational drugs, herbal supplements, vitamins, minerals, and more).
3. Regardless of how atypical the patient's cutaneous reaction, always consider medication as a possible cause. In patients with unusual reactions, searching the medical literature and calling the manufacturer for prior reports may be useful.
4. The timing of drug administration must correlate with the appearance of the eruption. A drug chart lists all the drugs given to the patient in the left column, with the dates along the lower axis, and the course of the drug eruption at the top. Lines extend from left to right for the dates of administration of each medication. These are directly below the course of the eruption. This graphic representation of the timing of medication administration and eruption is a very handy tool in assigning plausibility to a certain medication causing an eruption. It is important to consider dose changes, concomitant medications that may affect drug levels, comorbid illnesses that may affect metabolism (i.e., kidney injury), and whether patients have changed from brand name to generic drug types.

An important step in evaluating a patient with a potential ADR is to diagnose the cutaneous eruption by clinical pattern (e.g., exanthema, urticaria, vasculitis, pustular, hypersensitivity syndrome). Regularly updated manuals (e.g., Litt) or similar Internet databases are strongly recommended as reference sources for this information. Attribution scoring systems exist, but are generally used in clinical research settings (Naranjo scale, Kramer criteria). The following questions provide a framework for evaluation:

- Has the suspected medication been reported to cause the reaction the patient is experiencing? How frequently? Has the patient had a previous reaction to any medications?
- What are other possible causes of the patient's eruption? For example, an exanthem could be related to an associated viral illness, not the medication.
- When did the eruption appear relative to the administration of the suspected medication?
- Certain reactions are known to be related to rate of administration (vancomycin red man syndrome) or cumulative dose (lichenoid reactions to gold). Could the rate or dose be causing this patient's reaction?
- Does the eruption clear when the suspected medication is stopped? Because certain eruptions may clear with continuation of the drug, however, this is a useful, but not irrefutable, criterion to ascribe a specific reaction to a medication.
- Does the reaction recur with rechallenge?

Skin testing may be useful in evaluating type I (immediate) hypersensitivity reactions. It is most frequently used in evaluating adverse reactions to penicillin, local anesthetics, insulin, and vaccines. RAST has demonstrated a 20% false-negative rate in penicillin type I allergy; thus, in their current form, RASTs cannot replace skin testing. Intradermal, skin prick, and patch testing are also reported to be beneficial in some patients with morbilliform reactions, acute generalized exanthematous pustulosis, drug reaction with eosinophilia and systemic symptoms (DRESS), or, if done within the site of the eruption, fixed-drug reaction. Lymphocyte transformation tests reveal T-cell sensitization to drugs by measuring the response of peripheral blood mononuclear cells, although false-positive (and negative) results are possible, depending on the type of eruption and timing of testing. The enzyme-linked immunospot (ELISpot) assay, cytokine profiling, and ELISA testing for cytotxic mediators are also utilized in research settings. These are typically utilized for severe cutaneous adverse reactions (SCARs), such as anticonvulsant or sulfonamide hypersensitivity reaction or Stevens-Johnson syndrome (SJS). Serum measurement of drug-specific IgEs may also be used in some cases.

The patient should be given concrete advice about the reaction. The primary concern is whether the patient can continue on or retake the medication in question. This requires carefully weighing the severity of the eruption, likelihood of true reaction, risks and benefits of reexposure, and alternate treatment options (and risk of cross-reactivity) for the condition for which the drug was prescribed. Unusual reactions should be reported to regulatory agencies and the manufacturer for pharmacovigiliance and postmarketing identification of potentially important reaction patterns.

Pathogenesis

The pathogenesis of the various ADRs varies by subtype. Most common cutaneous ADRs are type I (urticarial reactions, IgE mediated) or type IV (delayed). Type IV, delayed-type reactions, can be subdivided into type IVa (T-helper 1 [Th1] cells, interferon [IFN]-γ/tumor necrosis factor–α [TNF-α] mediated), type IVb (T-helper 2 [Th2], interleukin [IL]-4/IL-5/IL-13), type IVc (cytotoxic T cells, granzyme), and type IVd (neutrophils, CXCL-8, granulocyte-macrophage colony-stimulating factor [GM-CSF]), which correlates with the clinical morphologic pattern of the ADR. T cells in the dermis in acute generalized exanthematous pustulosis (AGEP, an example of a type IVd reaction) secrete IL-8, a neutrophil-attracting chemokine. In drug rash (reaction) with eosinophilia and systemic symptoms (DRESS, a type IVb reaction), they secrete IL-5 and eotaxin, recruiting eosinophils. As a consequence of T-helper cell activation, memory T cells are produced, resulting in recurrence of many eruptions on rechallenge.

Large molecules, such as rat- or mouse-derived antibodies, can be immunogenic. Most medications, however, are too small to be recognized as antigens by immunologically active cells. The medication is the hapten, and the immunologically active molecule is a medication-protein complex or hapten-carrier complex. Some medications, such as penicillin, are active enough to bind directly to proteins. Most, however, need to be metabolized to more active or more immunogenic forms to bind to proteins and cause an

Fig. 6.21 Morbilliform (exanthematous) drug eruption caused by exposure to an antibiotic.

immunologic reaction. The drug metabolites can also be toxic to cells, causing direct cell damage. Drug metabolism varies by drug class, but frequently occurs in the cytochrome P450 system in the liver.

There has also been a proposed model for ADRs in which the drug or a metabolite binds directly to T cells or Langerhans cells in close opposition to sentinel T cells in the skin. This direct binding could activate the T cell–Langerhans cell interactive unit, resulting in the production of biologically active molecules. This would explain how some drug eruptions occur soon after exposure or with the first exposure to a medication. It could also explain a dose-dependent effect in drug eruptions. Also, a systemic viral infection may have already activated the immune cells in the skin, reducing their threshold for activation by drug binding. Once the T cell is activated, it may produce a variety of reactions, as follows:

1. T cells stimulate IFN-γ production and a Th1 response. This type of reaction could be "bullous" but without extensive epidermal necrosis (contact dermatitis).
2. T cells could be activated to function in a Th2 manner and stimulate eosinophil ingress through Th2 cytokines (DRESS).
3. T cells could activate cytotoxic (CD8+) T cells, which would secrete perforin/granzyme B and Fas ligand, resulting in keratinocyte apoptosis (SJS/ toxic epidermal necrolysis [TEN]).
4. T cells, through chemokine (CXCL8) and cytokine (IL-8, GM-CSF) production, recruit neutrophils, resulting in pustular exanthems (AGEP).

Th17 cells are implicated in many drug eruptions, and sulfamethoxazole induces a T-cell switch mechanism based on the TCRVβ20-1 domain altering peptide–HLA recognition. Dermal CD4+/CD25+/Foxp3 regulatory T cells (Tregs) are reduced in severe bullous drug eruptions such as TEN. Circulating Tregs expressing skin-homing molecules are increased in early drug-induced hypersensitivity syndrome (DIHS, DHS). The cells are immunologically active early in the course of the eruption, enter the skin, and can effectively suppress the immune response. However, they become functionally deficient later, perhaps explaining the occasional development of autoimmune phenomena months after DIHS, as well as the tendency of DIHS reactions to relapse, recur, or fail to resolve. In severe drug reactions, micro-RNA-18a-5p downregulates the expression of the antiapoptotic B-cell lymphoma/leukemia-2–like protein 10 (BCL2L10), promoting apoptosis.

Clinical Morphology

Cutaneous drug reactions are initially discussed here by morphologic pattern. In addition to the cutaneous eruption, some reactions may be associated with other systemic symptoms or findings. The modifier "simple" is used to describe reactions without systemic symptoms or internal organ involvement. "Complex" reactions are those with systemic findings. This includes drug induced hypersensitivity syndrome (DIHS, DHS), which is synonymous with drug reaction with eosinophilia and systemic symptoms (DRESS), and drug induced delayed multiorgan hypersensitivity syndrome.

Drug reactions may cause cutaneous lesions and findings identical to a known disease or disorder. These may be of similar or disparate pathogenesis. For example, true serum sickness caused by the injection of foreign proteins, such as antithymocyte globulin, is associated with circulating immune complexes. Medications, notably cefaclor, induce a serum sickness–like reaction not associated with circulating immune complexes. Vancomycin-induced linear IgA bullous disease is nearly identical to the de novo disease. Calcium channel blockers (CCBs) and IFN are associated with eczematous eruptions.

Exanthems (Morbilliform or Maculopapular Reactions)

Exanthems are the most common form of adverse cutaneous drug eruption. They are characterized by erythema, often with small papules throughout. Exanthems tend to occur within the first 2 weeks of treatment but may appear later, or even up to 10 days after the medication has been stopped. Lesions tend to appear first proximally, especially in the groin and axilla, generalizing within 1 or 2 days. The face is typically spared; facial involvement should prompt consideration for DRESS. Pruritus is usually prominent, helping to distinguish a drug eruption from a viral exanthema or graft-versus-host disease. Antibiotics, especially semisynthetic penicillins and TMP-SMX, are the most common causes of this reaction pattern (Fig. 6.21). Ampicillin-amoxicillin given during EBV infection causes an exanthem in 29%–69% of adults and 100% of children. TMP-SMX given to AIDS patients causes exanthems in about 40%. Antimalarials given to patients with dermatomyositis cause exanthems in 25%. Certain quinolones cause exanthems at a high rate: 4% overall and 30% in young women.

Morbilliform eruptions may rarely be restricted to a previously sunburned site, the so-called "UV recall–like" phenomenon. The sunburn may have occurred 1–7 months before the drug eruption. This pattern of eruption must be distinguished from a true UV recall caused by antimetabolites (see later section, "Adverse Reactions to Chemotherapeutic Agents").

In the case of simple exanthems, treatment is supportive. The eruption will clear within 2 weeks of stopping the offending medication, and it may clear even if the drug is continued. Topical corticosteroids and antipruritics may be of benefit and allow the course of therapy to be completed. Rechallenge usually results in the reappearance of the eruption, except in the setting of HIV. In many HIV-infected patients with simple reactions to TMP-SMX, reexposure by slow introduction or full-dose reexposure may be tolerated. Infrequently in HIV patients, however, and rarely in persons with normal immune function, rechallenge may result in a more severe blistering reaction. The use of patch and intradermal testing for the confirmation of the incriminated drug in morbilliform exanthems is not standardized. Only 2%–10% of patients who experience the eruption on rechallenge will have a positive patch or intradermal test.

Cutaneous findings identical to simple exanthems may occur as part of DRESS. Most patients with DRESS will have facial involvement, facial edema, ear involvement, and many will have hand edema, all of which are uncommon in simple exanthems. In contrast to simple exanthems, in complex exanthems the inciting agent must be stopped immediately, and rechallenge should rarely be undertaken. Even outside the setting of DRESS, higher eosinophil counts correlate with more severe ADRs.

Drug-Induced Hypersensitivity Syndrome or Drug Reaction With Eosinophilia and Systemic Symptoms

DIHS/DRESS is a severe cutaneous eruption with associated systemic involvement, where host genetic factors, medication exposure, plus frequent viral reactivation, lead to activated T cells and create a multiorgan inflammatory reaction. The overall incidence of DRESS is between 1/1000 and 1/10,000 individuals. Genetic factors appear to play an important role in DRESS. Polymorphisms in drug metabolizing enzymes (CYP450, N-acetyltransferase) can lead to reduced activity and increased active drug metabolites. Specific HLA-alleles are associated with the development of DRESS in certain populations.

All patients with DRESS share the characteristic features of fever, rash, and internal organ involvement. Characteristic features include the following:

- Rash developing late (>2, often 4–8 weeks) after the inciting medication is started
- Long-lasting symptoms after discontinuation of the causative drug
- Fever (>38°C)
- Multiorgan involvement
- CBC abnormalities (usually an eosinophilia, but may have activated lymphocytosis instead):
  - Eosinophilia (>1500 absolute eosinophilia; criteria vary, with some groups citing counts greater than 1500/μL and others more than 700/μL or above 10% if the leukocyte count is lower than 4000/μL)
  - Lymphocyte activation (lymphocytosis, atypical lymphocytosis, lymphadenopathy)
- Frequent reactivation of HHV-6, HHV-7, EBV, and CMV (60%–80% of cases demonstrate HHV family reactivation)

Seven major medications/classes of medication are commonly implicated, though DRESS may occur with drugs from almost any category: (1) anticonvulsants—phenytoin, carbamazepine, phenobarbital, and lamotrigine primarily (can occur with the other antiepileptic agents as well); (2) long-acting sulfonamides—sulfamethoxazole, sulfadiazine, and sulfasalazine (but *not* all sulfa-containing medications—sulfonylureas, thiazine diuretics, furosemide, and acetazolamide); (3) allopurinol; (4) nevirapine; (5) abacavir; (6) dapsone; and (7) minocycline.

DRESS has been reported with multiple other agents as well, including, but not limited to, antimicrobial agents (vancomycin, cephalosporins, fluoroquinolones, antituberculosis agents, other antibiotics), biologic agents (tocilizumab, IL-1 inhibitors, and more), targeted chemotherapeutics (vismodegib, imatinib, and more), other antiviral agents (telaprevir for hepatitis C before its removal from the market, raltegravir, and others), antipyretic agents (acetaminophen, ibuprofen, diclofenac, celecoxib), and more. Diagnosis of DRESS should be made based on clinical and laboratory features, and drug exposure history, with consideration given to any potential inciting agent, regardless of drug class.

The skin eruption accompanying DRESS/DIHS is typically morbilliform (with variable follicular accentuation [Fig. 6.22] and occasional 2-zone targetoid lesions), and can vary from faint and mild to severe with exfoliative erythroderma. Facial erythema and edema with periorbital sparing often accompanies the skin eruption, and there may be impetigo-like crusting on the chin and/or superficial fine pustules, especially on the face. Mucositis is uncommon but may occur, typically in the mouth and milder than that of SJS. Patients with DRESS, AGEP, and SJS/TEN may share overlapping features and these SCARs may coexist; patients should be managed based on which features predominate and are most severe. In DRESS, adverse prognostic indicators include tachycardia, leukocytosis, tachypnea, coagulopathy, thrombocytopenia, and gastrointestinal bleeding. The internal organ involvement described in DRESS can be divided into two types: (1) organ dysfunction occurring during or immediately associated with the acute episode and (2) delayed involvement/late sequelae, possibly with an autoimmune basis. The first category includes hepatitis, interstitial nephritis, interstitial pneumonitis, and myocarditis, with rare other organ involvement (colitis/intestinal bleeding, encephalitis/aseptic meningitis, sialadenitis). Late sequelae include delayed myocarditis, autoimmune diseases from 4.8% up to 10% of patients (thyroiditis/Graves, type 1 diabetes, vitiligo), syndrome of inappropriate secretion of antidiuretic hormone (SIADH), or rarely Systemic lupus erythematosus (SLE). Mortality rates from DRESS are cited as 5% to up to 10% of patients, usually from complications of fulminant hepatic involvement, myocarditis, or renal/lung disease. It is important to note that the manifestations of the syndrome may vary by drug (and possibly ethnicity, as patients of certain backgrounds are more likely to develop DRESS from certain agents); dapsone hypersensitivity has a weaker association with eosinophilia, and allopurinol hypersensitivity has more renal involvement, whereas minocycline-associated DRESS may have more pulmonary involvement.

Skin biopsy is not required to confirm a diagnosis of DRESS. The histopathologic features may vary, with epidermal spongiosis, interface dermatitis, superficial epidermal pustules (resembling

AGEP), and apoptotic keratinocytes (resembling EM) reported. Atypical lymphocytes can be seen; eosinophils may be observed but are not required. Small studies suggest a more severe histopathologic phenotype (with EM-like features) may be more associated with a severe illness.

First-line treatment for DRESS involves identifying and stopping the causative agent, and initiation of antiinflammatory therapy, generally with high dose systemic corticosteroids (1–2 mg/kg/day, sometimes administered in divided doses). Pulse intravenous (IV) steroids, intravenous immune globulin (IVIG), cyclosporine, and other agents have been employed in severe or recalcitrant cases. Patients often require a long, slow steroid taper over weeks to months after initial onset.

Anticonvulsant Hypersensitivity Syndrome

The terms anticonvulsant hypersensitivity syndrome is now thought of as a subset of DRESS, and can be seen with phenytoin, phenobarbital, carbamazepine, lamotrigine, zonisamide, levetiracetam and other anticonvulsants. The estimated incidence of this condition is 1:1000 to 1:10,000 patients treated with these medications. Carbamazepine is currently the most common anticonvulsant causing DRESS, because it is also used to treat neuropathic pain, bipolar disorder, and schizophrenia, though lamotrigine has a higher rate on an individual basis (and patients with DRESS from lamotrigine may be less likely to develop an eosinophilia). Anticonvulsant hypersensitivity syndrome may occur at any dose, though slow upward titration of these agents may be associated with lower rates of severe reactions. Coadministration of valproate may increase the risk of DRESS with other agents. Certain HLA-haplotypes confer increased risk of DRESS (carbamazepine HLA A*31:01), and there are evolving recommendations existing for pretreatment genetic testing in some populations (such as exists in testing for HLA B*1502 in patients before carbamazepine therapy to prevent SJS).

Because many of the anticonvulsants are metabolized through the same pathway, cross-reactions are frequent, making selection of an alternative agent quite difficult. The rate of cross-reactivity among phenytoin, phenobarbital, and carbamazepine is 70%. In vitro tests are commercially available and may aid in selecting an agent to which the patient will not cross-react. Valproate, levetiracetam, and newer antiepileptics are generally considered safer alternatives for patients sensitive to aromatic anticonvulsants.

Allopurinol Hypersensitivity Syndrome

Allopurinol hypersensitivity syndrome typically occurs in patients with preexisting renal failure, or in those who develop acute kidney injury and whose dosing of allopurinol is not adjusted. Often, affected patients are treated unnecessarily for asymptomatic hyperuricemia, with clear indications for therapy present in only about one third of these patients. They are often given a dose not adjusted for their coexisting renal disease and are frequently taking a thiazide diuretic. Weeks to many months (average 7 weeks) after the allopurinol is begun, the patient develops a morbilliform eruption (50% of cases) that often evolves to an exfoliative erythroderma (20%) (Fig. 6.23). Bullae may occur, especially on the palms and soles, and oral ulcers may be present. Associated with the dermatitis are fever, eosinophilia, sometimes hepatitis (70% of cases), and typically worsening of renal function (40%–80%, the higher percentage in those with preexisting renal disease). Lung involvement and adenopathy occur infrequently. About 25% of patients die as a result of this syndrome, often from cardiovascular complications. Dialysis does not appear to accelerate the resolution of the eruption, suggesting that if a drug metabolite is responsible, it is not dialyzable. There is a strong association between HLA-B-5801 and the development of allopurinol hypersensitivity syndrome in the Han Chinese, but not in other races. HHV reactivation may be associated. This syndrome may be steroid responsive but is extremely slow to resolve, frequently lasting for months after allopurinol has been stopped. Very gradual tapering of systemic corticosteroids with monitoring of eosinophil count and renal function is essential. Too rapid tapering may lead to relapse of the syndrome.

Fig. 6.23 Allopurinol hypersensitivity syndrome.

Sulfonamide Hypersensitivity Syndrome

Fewer than 0.1% of treatment courses with sulfonamides are complicated by a hypersensitivity syndrome. It typically begins 3 weeks after starting the medication but may occur as soon as 1 week, faster than most other DRESS reactions. The skin eruption is similar to others, though patients may be erythrodermic. Patients are often slow acetylators, unable to detoxify the toxic and immunogenic metabolites generated during the metabolism of the sulfonamides. Patients with sulfonamide hypersensitivity syndrome may develop antibodies that recognize microsomal proteins to which the reactive metabolite of the sulfonamides binds. Hepatitis, nephritis/nephropathy, pneumonitis, myocarditis or pericarditis, and pancreatitis can all occur as a part of the syndrome. The hepatitis may be fulminant and life threatening. Patients who are allergic to antimicrobial sulfonamides are usually tolerant of other types of sulfa moieties, and should not all be labeled allergic to "sulfa." Zonisamide, a sulfonamide anticonvulsant, cross-reacts with sulfonamides but not other anticonvulsants.

Minocycline Hypersensitivity Syndrome

Minocycline hypersensitivity syndrome occurs in young adults, sometimes in the context of acne therapy. Deficiency of glutathione *S*-transferases is common in affected individuals and is more common in persons of African Caribbean descent. Females are more often affected. Minocycline may be detected in the blood of these patients up to 17 months after its discontinuation, suggesting that slow metabolism and persistent levels of medication may play a role. Minocycline hypersensitivity syndrome usually

begins 2–4 weeks after starting the minocycline, and demonstrates typical skin findings of DRESS. Headache and cough are common complaints. Liver involvement occurs in 75% of patients and renal disease in 17%. Minocycline hypersensitivity is particularly associated with pneumonitis. This may progress to respiratory distress syndrome. It can be life threatening, but most patients survive. Myocarditis has also been reported. Patients with minocycline-induced DRESS may be at higher risk of developing long-term/delayed autoimmune sequelae.

Dapsone Hypersensitivity Syndrome

Dapsone hypersensitivity syndrome occurs in less than 1% of patients given this medication. It usually begins 4 weeks or more after starting dapsone. Hemolytic anemia and methemoglobinemia may be present. A morbilliform eruption that heals with desquamation is most characteristic. Icterus and lymphadenopathy occur in 80% of patients. Eosinophilia is typically *not* present. Liver involvement is a mixture of hepatocellular and cholestatic. The bilirubin is elevated in 85%, partly attributable to the hemolysis, and hypoalbuminemia is characteristic. Liver involvement is often severe and may be fatal. As with the hypersensitivity syndromes previously discussed, corticosteroids are the mainstay of treatment.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

SJS and TEN (Lyell syndrome, nonstaphylococcal scaled skin syndrome) exist on a continuum, representing different levels of severity of an acute blistering drug eruption. The term *erythema multiforme* is a source of some confusion. Historically, EM minor refers to the syndrome of true 3-zone target lesions, often symmetrically on acral surfaces, with mild mucositis of one site; this is now generally seen in association with HSV (see Chapter 7), termed *herpes-associated EM* (HAEM). Most historical cases of EM major/majus are now simply referred to as SJS. An SJS-like illness with severe mucositis can be seen due to mycoplasma, particularly in children, which some have referred to as mycoplasma-induced rash and mucositis (suggesting it is a distinct entity from SJS or EM; Fuchs syndrome may also refer to this entity). EM and SJS/TEN appear to be distinct entities with largely unrelated pathophysiology and demographics, and many are moving away from use of the term EM minor, EM major/majus, and EM-like drug eruption.

SJS, SJS/TEN overlap, and TEN are related, severe, potentially fatal SCARs. Fortunately, these are uncommon reactions, with an incidence of 0.4–1.2 per million person-years for TEN and 1.2–6.0 per million person-years for SJS. SJS is defined as <10% epidermal detachment, TEN as >30% epidermal detachment, and SJS/TEN overlap as 10%–30% detachment, measured at the worst extent of the disease.

- Both SJS and TEN are most frequently induced by the same medications.
- Patients initially presenting with SJS may progress to extensive skin loss resembling TEN.
- The histologic findings of TEN and SJS are indistinguishable.
- Both are increased by the same magnitude in HIV infection.

There are specific HLA-haplotypes that confer an increased risk in some ethnic populations for the development of these SCARs. In Taiwan, carbamazepine causes up to one third of cases, but only 5% in Europe. In Han Chinese, the HLA haplotype HLA-B*1502 is present in the vast majority of carbamazepine-induced SJS/TEN patients and is present in about 10% of the Han Chinese population in general; this haplotype has also been shown to confer risk in other Asian populations. HLA typing should be performed in all Asians before starting carbamazepine, because the prevalence of HLA-B*1502 is 5%–10% in Asians in the United States and Asia, and testing before drug administration may markedly decrease or eliminate the risk of SJS in this setting.

More than 100 medications have been reported to cause SJS and TEN. In adults, common inciting medications are TMP-SMX (1–3 : 100,000), sulfadoxine plus pyrimethamine (Fansidar-R) (10 : 100,000), nevirapine, lamotrigine (1 : 1000 adults and 3 : 1000 children), and carbamazepine (14 : 100,000). Antibiotics (especially long-acting sulfa drugs and penicillins), other anticonvulsants, antiinflammatories (NSAIDs), and allopurinol are also frequent causes. Currently, in Europe, allopurinol is the most common cause of SJS and TEN. In children SJS/TEN is most often caused by sulfonamides and other antibiotics, antiepileptics, and acetaminophen. SJS/TEN from TMP-SMX is significantly more common in the spring. Establishing causality of a drug can sometimes be difficult; the ALDEN score has been proposed as a tool to help establish causality. Rechallenge can be dangerous and is discouraged, so in vitro methods have been developed. Lymphocyte granulysin expression, Granzyme B-ELISpot, and IFN-γ production assays together provided a sensitivity of 80% and specificity of 95% but are still used primarily in a research setting. It is important to identify the causative agent; if the culprit is stopped within 24 hours of blister development, mortality is reduced from 26% to 5%. As many patients are on multiple agents, similar principles apply as outlined in the introduction section. It is important to note classes of medications with relatively low rates of SCAR: β-blockers, angiotensin-converting enzyme (ACE) inhibitors, CCBs, diuretics, and most antidiabetic agents.

The clinical presentation may start with fever and influenza-like symptoms preceeding the eruption by a few days. Skin lesions appear on the face and trunk and rapidly spread, usually within 4 days, to their maximum extent. Initial lesions are often deep-red/dusky macules, sometimes with a central nonblanching zone (2-zone lesions, targetoid lesions, atypical targets, "SJS with spots"); these may centrally desquamate or may form atypical targets with purpuric centers that coalesce, form bullae (Fig. 6.24), then slough. In SJS virtually always, two or more mucosal surfaces are inflamed, with peeling, erosions, and hemorrhagic crust forming. The oral mucosa and conjunctiva are most frequently affected (Fig. 6.25), but physical examination should include thorough inspection of

Fig. 6.24 Bullous drug reaction.

Fig. 6.25 Stevens-Johnson syndrome.

all mucosal surfaces (oral, ocular, urethral, vaginal, anal). The patient may have photophobia, difficulty with swallowing, rectal erosions, dysuria, and/or cough, indicative of ocular, alimentary, urinary, and respiratory tract involvement, respectively. In other patients, dusky macular erythema is present in a local or widespread distribution over the trunk. Mucosal involvement may not be found. The epidermis in the areas of macular erythema rapidly becomes detached from the dermis, leading to extensive skin loss, often much more rapidly than occurs in the patients with atypical targets and extensive mucosal involvement. "Pure TEN" is a conceptual way of thinking of such patients. Rarely, SJS/TEN patients may present with lesions predominantly in sun-exposed areas, with a clear history of a recent significant sun exposure. This suggests that, in rare cases, SJS/TEN may be photo induced or photo exacerbated. Patients with SJS/TEN may have internal involvement similar to patients with DRESS/DIHS. These most frequently include eosinophilia, hepatitis, and worsening renal function.

Keratinocyte death in SJS and TEN is proposed to occur through more than one potential mechanism, and the relative importance of each of these mechanisms in SJS and TEN is not known. There is likely an immune response triggered to a drug-tissue complex. Activated cytotoxic T cells and natural killer (NK) cells produce granulysin, TNF-α, TRAIL, and perforin-granzyme B, all of which can induce keratinocyte necrosis. T-cell, NK-cell, and NKT-cell–derived granullysin is a key mediator of tissue damage, and serum (and blister) granulysin levels may correlate with disease severity. Effector memory CD8+ T cells, regulatory T cells, NK cells, and Th17 cells appear to play a role in mediating the disease. In addition, keratinocyte necrosis can be induced by the binding of soluble Fas ligand (sFasL) to Fas (also known as the death receptor or CD95). Soluble Fas ligand is elevated in the blood of patients with TEN, and its level correlates with body surface area (BSA) involvement. In addition, the peripheral blood mononuclear cells of patients with TEN secrete Fas ligand on exposure to the incriminated drug. The sera of patients with TEN induce necrosis of cultured keratinocytes, and a monoclonal antibody to Fas ligand in a dose-dependent manner inhibits keratinocyte necrosis exposed to TEN patient sera.

A skin biopsy is usually performed. Frozen-section analysis may lead to a rapid diagnosis, either by submitting the roof of a blister or portion of sloughed skin, or performing a biopsy of an area of impending necrosis. The histology of TEN and SJS is similar. There is a lymphocytic infiltrate at the dermoepidermal junction (DEJ) with necrosis of keratinocytes that at times may be full thickness. There is typically cellular necrosis out of proportion to the infiltrate. Paraneoplastic pemphigus may be excluded with direct immunofluorescence (DIF). Patients with graft-versus-host disease (GVHD) may also demonstrate a TEN-like picture with identical histology, although prominent follicular involvement may occasionally be a clue favoring GVHD.

Management of SJS/TEN patients is complex and requires multidisciplinary, coordinated care, often in an experienced intensive care unit or burn unit. There exists some controversy over optimal supportive care and therapeutic interventions, with little high quality evidence to guide decision making. Patients with SJS/TEN have fluid and electrolyte imbalances, hypercatabolism, and sometimes acute respiratory distress syndrome (ARDS), may be hypercoaguable, and are at risk for bacteremia from loss of the protective skin barrier, Their metabolic and fluid requirements are less than in burn victims (generally fluid resuscitation is approximately two thirds that of a burn victim's requirements based on the Parkland formula for skin loss), but nutritional support and monitoring for sepsis are critical. In addition to extent of skin loss, age, known malignancy, tachycardia, renal failure (particularly patients requiring dialysis), hyperglycemia, and low bicarbonate are all risk factors for having a higher mortality risk with SJS/TEN. SCORTEN, the most common model used to predict mortality, gives 1 point for each of these findings, with a 3.2% mortality rate for 0–1 points, and a 90% mortality rate for 5 or more points. However, respiratory tract involvement, not included in the SCORTEN, is also a poor prognostic sign. About one quarter of TEN patients have bronchial involvement. In TEN, epithelial detachment of the respiratory mucosae and associated ARDS are associated with a mortality rate of 70%. Supportive care is essential. Appropriate consultation with specialists to manage any affected mucosa is advised (ophthalmology for eyes and often amniotic membranes, gynecology for vaginal, urology consideration for severe urethral inflammation). When mucosal surfaces are eroded, they can adhere and scar; this is particularly common in the eyes or vaginal area, and care should be taken to separate eroded sites with nonstick dressings. General principles of skin care include limiting trauma and avoiding tape-to-skin, placing IV lines at uninvolved sites, keeping the skin moist to assist in healing, and using nonstick dressings. Silver-impregnated dressings may be used, and skin substitutes have been explored as well. Generally it is advised to leave involved epidermis in place to serve as a natural biologic dressing.

In the past corticosteroids were used, but more recently there exists controversy. Many European experts use cyclosporine (3-6mg/kg/day divided dosing), whereas in the United States many use IVIG (1 g/kg/day for 4 days) with or without corticosteroids. Early, high-dose steroids for a short period may be helpful in some cases. Etanercept has recently been reported as beneficial in a moderate sized randomized study in Asia. There exists no consensus for the optimal systemic intervention for SJS/TEN.

Fig. 6.26 Phenytoin plus radiation-induced reaction.

The proposed mechanism of action of IVIG in TEN is by IVIG blocking the binding of sFasL to Fas, stopping keratinocyte apoptosis. The presence of cytotoxic T lymphocytes and NK cells within the dermis subjacent to the necrotic epidermis suggests that immunosuppressive agents that block immune function could also be effective in SJS or TEN. Cyclosporine is the most promising agent. If considered, immunosuppressive treatment should be used as soon as possible, given as a short trial to see if the process may be arrested, and then tapered rapidly to avoid the risk of continued immunosuppression in a patient with substantial loss of skin. A prospective trial of thalidomide was discontinued because of excessive mortality rates in the active treatment arm. Data are mixed regarding systemic corticosteroid therapy for skin disease, and there is a clear risk of sepsis and potential for steroids to impair wound healing. Systemic and topical steroid therapy for ocular involvement may improve outcomes, as may topical cyclosporine. In patients with SJS/TEN who also have systemic involvement, as seen in DIHS (considered by some as SJS/TEN representing the cutaneous eruption of DIHS), systemic corticosteroids should be given early and tapered as rapidly as possible.

For patients who survive, the average time for epidermal regrowth is 3 weeks. The most common sequelae are ocular scarring and vision loss. The only predictor of eventual visual complications is the severity of ocular involvement during the acute phase. A sicca-like syndrome with dry eyes may also result, even in patients who never had clinical ocular involvement during the acute episode. Other complications include cutaneous scarring, altered taste, eruptive melanocytic lesions, hair, sweating, and nail abnormalities. Transient, widespread verrucous hyperplasia resembling confluent seborrheic keratoses has also been reported.

Radiation-Induced Epidermal Necrolysis

This rare reaction may occur if phenytoin is given prophylactically in neurosurgical patients who are receiving whole-brain radiation therapy and systemic steroids. As the dose of steroids is being reduced, erythema and edema initially appear on the head in the radiation ports. This evolves over 1 or 2 days to lesions with the clinical appearance and histology of SJS or even TEN. The eruption spreads caudad, and mucosal involvement may occur (Fig. 6.26). A similar syndrome has been reported with the use of amifostine, phenobarbital, or levetiracetam during radiation for head and neck cancers. This EM syndrome can rarely be seen with radiation therapy alone. If amifostine is used to reduce acute and chronic, radiation-associated head and neck xerostomia, there is a significant risk of SJS/TEN.

Human Immunodeficiency Virus Disease and Drug Reactions

Patients infected with HIV, especially those with Th-cell counts between 25 and 200, are at increased risk for the development of adverse reactions to medications, which may adversely affect

treatment adherence. Morbilliform reactions to TMP-SMX occur in 45% or more of AIDS patients being treated for *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia. In two thirds of patients without life-threatening reactions, TMP-SMX treatment can be continued with simple conservative support, and the eruption may resolve. Associated hepatitis or neutropenia may require discontinuation of the drug. A similar increased rate of reaction to amoxicillin-clavulanate is also seen, and patients have been described with sensitivity to multiple antituberculosis agents, especially streptomycin and ofloxacin. If the dermatitis is treatment limiting but the eruption is not life threatening, low-dose rechallenge/desensitization may be attempted. It is successful in 65%–85% of patients in the short term and in more than 50% in the long term. In fact, initial introduction of TMP-SMX for prophylaxis by dose escalation reduces the rate of adverse reactions as well. However, rechallenge at full dose may have the same rate of recurrent eruptions as does introduction by dose escalation. Low-dose rechallenge is usually safe, but severe acute reactions may occur, including marked hypotension. Although most ADRs occur in the first few days of rechallenge, reactions may appear months after restarting TMP-SMX and may be atypical in appearance. The mechanism of this increased adverse reaction to TMP-SMX is unknown.

Severe bullous reactions, SJS, and TEN are 100–1000 times more common per drug exposure in patients with AIDS. These reactions are usually caused by sulfa drugs, especially long-acting ones, but may be caused by many agents. Nevirapine, a nonnucleoside reverse transcriptase inhibitor, has been associated with a high rate of severe drug eruptions, including SJS/TEN. Most of these ADRs are cutaneous and occur in the first 6 weeks of treatment. This high rate of reaction can be reduced by starting with a lower lead-in dose and by concomitant treatment with prednisone during the induction period. Nevirapine hypersensitivity syndrome presents with fever, hepatitis, or rash. More than 1% of patients will develop SJS/TEN. Multiple HLA-alleles in different populations have been reported as conferring elevated risk for nevirapine-associated SCARs (C*04:01 in Malawi, DRB1*01:01 in Europeans, and B*35 in Asian groups). Hepatitis, but not cutaneous reactions, is seen more often in patients with CD4 counts above 200 to 250. Fixed drug eruptions (FDEs) are also frequently seen in patients with HIV infection. Abacavir is associated with a potentially life-threatening hypersensitivity syndrome (DRESS-like, with fever, rash, and gastrointestinal or pulmonary symptoms) in 8% of patients. It usually occurs in the first 6 weeks of treatment but can occur within hours of the first dose. Rechallenge in these patients may lead to life-threatening hypotension and death. Abacavir hypersensitivity usually occurs in patients who are HLA-B*5701 positive, and screening of patients for this HLA type and not exposing patients with this HLA type to abacavir has decreased the number of cases of abacavir hypersensitivity syndrome. Patch testing is very sensitive and can be used to confirm abacavir hypersensitivity.

Aciclovir, nucleoside and nonnucleoside reverse transcriptase inhibitors (except nevirapine), and protease inhibitors are uncommon causes of ADRs. Many reactions attributed to these agents may actually be coexistent HIV-associated skin disorders, especially folliculitis, which are common in patients with AIDS. Regarding HAART-specific cutaneous adverse reactions, older antiretroviral agents were more likely to cause lipodystrophy (Stavudine, protease inhibitors) than newer regimens. HAART agents have been reported to cause hyperpigmentation (Emtricitabine), including of the nails (Zidovudine), and injection site reactions (ISRs; Enfuvirtide).

Fixed Drug Reactions (Eruptions)

Fixed drug reactions are common. FDEs are so named because they recur at the same site with each exposure to the medication. The time from ingestion of the offending agent to the appearance of symptoms is between 30 minutes and 8 hours, averaging 2 hours. In most patients, six or fewer lesions occur, and often only one. Infrequently, FDEs may be multifocal with numerous lesions (generalized) and can blisters, termed *generalized bullous fixed drug eruption* (GBDFE), which can mimic SJS/TEN (Fig. 6.27). They may present anywhere on the body, but half occur on the oral and genital mucosa. FDEs represent 2% of all genital ulcers evaluated at clinics for sexually transmitted diseases and can occur in young boys. In males, lesions are usually unifocal and can affect the glans or shaft of the penis. FDE of the vulva is often symmetric, presenting as an erosive vulvitis, with lesions on the labia minora and majora and extending to the perineum. Other unusual variants of FDE include eczematous, urticarial, papular, purpuric, linear, giant, and psoriasiform. At times, some lesions of FDE will not reactivate with exposure because of a presumed "refractory period" that may last from weeks to months.

Clinically, an FDE begins as a red round/oval patch that can develop a dusky, intensely inflamed central portion and resemble an iris or target lesion similar to erythema multiforme, which may blister and erode. Lesions of the genital and oral mucosae usually present as erosions. Most lesions are 1 to several cm in diameter, but larger plaques may occur, mimicking cellulitis. Characteristically, prolonged or permanent postinflammatory hyperpigmentation results, although a nonpigmenting variant of an FDE is recognized. With repeated or continued ingestion of the offending medication, new lesions may be added, sometimes eventuating in a clinical picture similar to SJS with similar morbidity and mortality. Histologically, an interface dermatitis occurs with subepidermal vesicle formation, necrosis of keratinocytes, and a mixed superficial and deep infiltrate of neutrophils, eosinophils, and mononuclear cells. Pigment incontinence is usually marked, correlating with the pigmentation resulting from repeated FDEs at the same site. Because biopsies are generally performed during the acute stage of a recurrence, the stratum corneum is normal. Papillary dermal fibrosis and deep perivascular pigment incontinence are often present from prior episodes.

Fig. 6.27 Fixed drug reactions caused by aspirin.

Medications inducing FDEs are usually those taken intermittently. Many of the NSAIDs, especially pyrazolone derivatives, paracetamol, naproxen, oxicams, and mefenamic acid, cause FDE, with a special predilection for the lips. Sulfonamides, trimethoprim, and TMP-SMX are now responsible for the majority of genital FDEs. Barbiturates, tetracyclines, fluconazole, fluoroquinolones, phenolphthalein, acetaminophen, cetirizine, celecoxib, dextromethorphan, hydroxyzine/cetirizine/levocetirizine, quinine, lamotrigine, phenylpropanolamine, erythromycin, metformin, sildenafil, mycophenolate, chemotherapeutic agents, and Chinese and Japanese herbs are also among the long list of possible causes. The risk of developing a FDE has been linked to HLA-B22. Patch tests with various concentrations of the offending medication can reproduce the lesion when placed on affected, but not on unaffected, skin. Tape-stripping the skin before applying the suspected medication in various vehicles may increase the likelihood of a positive patch test.

Occasionally, FDEs do not result in long-lasting hyperpigmentation. The so-called nonpigmenting FDE is distinctive and has two variants. The pseudocellulitis or scarlatiniform type is characterized by large, tender, erythematous plaques that resolve completely within weeks, only to recur on reingestion of the offending drug. Pseudoephedrine hydrochloride is by far the most common culprit. The second variant is SDRIFE (formerly baboon syndrome; see "Allergic Contact Dermatitis" earlier). SDRIFE preferentially affects the buttocks, groin, and axillae with erythematous, fixed plaques, and is most commonly due to antibiotic agents, particularly aminopenicillins. Histologically, a giant cell lichenoid dermatitis can be seen in this setting. Fixed sunlight eruption has been reported as multiple FDE-like lesions occurring in response to sunlight.

The diagnosis of FDE is often straightforward and is elucidated by the history. Antibiotics manufactured overseas are readily available in many ethnic markets, including reports of such agents as trimethoprim/sulfamethoxazole in over-the-counter cold medications, and the formulations may not be carefully regulated. In some patients, the reaction may be to a dye in a medication rather than the active ingredient. Fixed drug reaction may rarely be related to foods, including residual antibiotics in meat products and quinine contained in tonic water. Confirmation with provocation tests can be performed. Because of the "refractory period," provocation tests need to be delayed at least 2 weeks from the last eruption. If an oral provocation test is considered, the initial challenge should be 10% of the standard dose, and patients with widespread lesions (SJS/TEN–like) should not be challenged. Patch testing using a drug concentration of 10%–20% in petrolatum or water applied to a previously reacted site is the recommended approach. In most patients, the treatment is simply to stop the medication. Desensitization can be successful.

Lesions of an FDE contain intraepidermal CD8+ T cells with the phenotypic markers of resident memory T cells. Tissue resident memory T cells are thought to remain in the skin to provide immunity to infection (e.g., herpes simplex virus). In FDE, once the medication is stopped, the abundant CD4+/FoxP3 T cells (Tregs) are believed to downregulate the eruption. In SJS/TEN patients, such Tregs are found in much fewer numbers than in FDE, which may explain the progression of SJS/TEN even after stopping the trigger. Resident mast cells in lesions of FDE may be the cells initially activated with drug exposure, explaining the rapid onset of the lesion.

Acute Generalized Exanthematous Pustulosis

Also known as toxic pustuloderma and pustular drug eruption, AGEP is an uncommon reaction with an incidence of 1–5 cases per million per year. The average age in Europe is in the fifties and about one decade younger in Israel and Taiwan. Children can be affected. Women have been affected slightly more than men until recently, when a strong female predominance was suggested. There may be a genetic predisposition, with HLA*B51, DR11, and DQ3 more association with AGEP. Drugs are the most common cause of this reaction pattern, although AGEP has also been reported after mercury exposure. AGEP following infections and insect bites, such as from the *Loxosceles* spider (e.g., brown recluse), has been reported, but some of these patients have also received antibiotics. A localized variant, "acute localized exanthematous pustulosis" (ALEP), has been rarely reported, usually acutely after antibiotic exposure.

The eruption is of sudden onset, within 1 day in many cases associated with antibiotics, and averaging 11 days in other cases. The rash is accompanied by fever in most patients. Initially, there is a scarlatiniform erythema. The eruption evolves and disseminates rapidly, consisting usually of more than 100 nonfollicular pinpoint pustules less than 5 mm in diameter; dermoscopy may aid in identifying pustules in some early cases (Fig. 6.28). The face and flexural folds are commonly affected first, with extension to the trunk and limbs. Nikolsky sign may be positive. Facial edema may be seen, and mucous membrane involvement is uncommon, and if present usually affects only one surface and is nonerosive. Laboratory abnormalities typically include a leukocytosis with neutrophilia (90%) and at times an eosinophilia (30%). Typically, the entire self-limited episode lasts up to 15 days. Characteristically, widespread superficial desquamation occurs as the eruption clears. AGEP can recur with seconder-exposure to the medication.

In more than 90% of patients, drugs are the cause of AGEP. Frequently implicated medications include antibiotics (penicillin and macrolide classes in particular, plus clindamycin, minocycline, sulfonamides, antimycotic agents, vancomycin, and quinolones), antiepileptic agents, and antihypertensives, particularly CCBs

Fig. 6.28 Acute generalized exanthematous pustulosis.

(especially diltiazem, though cross-reactivity between CCBs has been described). Hydroxychloroquine is frequently implicated, including in atypical, prolonged courses, but may also induce psoriasis, and it is important to distinguish the two. Corticosteroids, allopurinol, oxicam NSAIDs, pseudoephedrine, terazosin, omeprazole, and sennoside have also caused AGEP. Chemotherapeutic agents, including small molecule/multikinase inhibitors and other targeted agents, are being reported as inciting agents with increasing frequency. Radiocontrast material and some forms of dialysates have been shown to cause AGEP. Infectious agents implicated include viruses (enteroviruses, CMV, EBV, hepatitis), rarely vaccinations, and other infections (mycoplasma, and other bacterial infections), though concomitant antibiotics were occasionally employed and may have been the inciting agent.

In the classic case, the diagnosis is straightforward, with the characteristic sudden and rapid onset, widespread pustulation, and self-limited course. Due to the severity of the eruption and potential for widespread erythroderma, patients with certain comorbidities may be at risk for complications such as high output heart failure. The facial edema and pustulation can simulate DRESS/DIHS from anticonvulsants. Cases of overlap between SJS/TEN, DRESS, an dAGEP exist, and patients with mixed features should be evaluated for each and treated based on the most severe features. Pustular psoriasis, especially pustular psoriasis of pregnancy, can be difficult to differentiate from AGEP. If there are no characteristic lesions of psoriasis elsewhere and no prior personal or family history of psoriasis, distinguishing these two entities may be impossible, and the patient may need to be followed for a final diagnosis to be made. A microbial pustulosis in the setting of a connective tissue disease can also resemble AGEP, but lesions are usually localized to the flexors, and the course is more chronic.

Histologically, early lesions show marked papillary edema, neutrophil clusters in the dermal papillae, and perivascular eosinophils. There may be an associated leukocytoclastic vasculitis. Well-developed lesions show intraepidermal or subcorneal spongiform pustules. Severe cases may demonstrate an interface dermatitis similar to EM. The presence of eosinophils and the marked papillary edema help to distinguish this eruption from pustular psoriasis, though pustular psoriasis of pregnancy is often associated with tissue eosinophilia.

Patch testing with the suspected agent may reproduce a pustular eruption on an erythematous base at 48 hours in about 50% of patients. Patch testing rarely will result in a recrudescence of AGEP. AGEP is mediated by T cells, and shares overlapping features and inflammatory pathways with pustular psoriasis, with dermal IL-17 and IL-23 and epidermal IL-8. IFN-γ, IL-4/IL-5, and GM-CSF are also increased. *IL36RN* gene mutations have been demonstrated in both AGEP and pustular psoriasis patients.

Most patients with AGEP can be managed with topical corticosteroids and antihistamines. In over one third of cases, systemic corticosteroids may be required. In severe cases, cyclosporine, infliximab, or etanercept have rapidly stopped the pustulation and appeared to have hastened the resolution of the eruption.

Drug-Induced Pseudolymphoma

At times, exposure to medication may result in cutaneous inflammatory patterns that resemble lymphoma. These pseudolymphomatous drug eruptions may resemble either T-cell or B-cell lymphomas. The most common drug-induced pseudolymphoma is one resembling cutaneous T-cell lymphoma (CTCL) clinically and histologically. The most common setting in which these pseudolymphomas occur is a drug-induced hypersensitivity syndrome (DRESS/DIHS), in which infrequently the histology may resemble CTCL. More rarely, medications may induce plaques or nodules, usually in elderly white men after many months of treatment. Lymphadenopathy and circulating Sézary cells may also be present. CD30+ cells may be present in the infiltrate. Usually, other features (e.g., keratinocyte necrosis, dermal edema) help to distinguish these reactions from true lymphoma. Importantly, T-cell receptor gene rearrangements in the skin and blood may be positive (or show pseudoclones) in these drug-induced cases, representing a potential pitfall for the unwary physician. Importantly, patients with angioimmunoblastic T-cell lymphoma can very closely resemble patients with DRESS, leading to delays in diagnosis. Pseudolymphoma resolves with discontinuation of the medication. The medication groups primarily responsible are anticonvulsants, antimicrobial agents (sulfa drugs, vancomycin, rifampin, others), antihypertensives (ACE inhibitors, β-blockers, CCBs, thiazides), and antidepressants or anxiolytics. Vaccinations and herbal supplements can also induce pseudolymphoma.

Mangana J, et al: Angioimmunoblastic T-cell lymphoma mimicking drug reaction with eosinophilia and systemic symptoms (DRESS Syndrome). Case Rep Dermatol 2017; 9: 74–79.

Urticaria/Angioedema

Urticarial drug eruptions are the second most common type of cutaneous adverse drug eruption, and can be induced by immunologic and nonimmunologic mechanisms. In either case, clinically the lesions are pruritic wheals or angioedema (Fig. 6.29). Urticaria, especially extensive disease, around the face or mouth, may be part of a more severe anaphylactic reaction with bronchospasm, laryngospasm, or hypotension. Immediate hypersensitivity skin testing and sometimes RAST is useful in evaluating risk for these patterns of reaction. Most patients are acutely managed with antihistamine therapy, with severe cases requiring systemic corticosteroids.

Aspirin and NSAIDs are the most common causes of nonimmunologic urticarial reactions. They alter prostaglandin metabolism, enhancing degranulation of mast cells. They may therefore also exacerbate chronic urticaria of other causes. The nonacetylated salicylates (trilisate and salsalate) do not cross-react with aspirin in patients experiencing bronchospasm and may be safe alternatives. Some patients have urticaria to only one medication in this family, without cross-reaction with other NSAIDs, suggesting that specific IgE-mediated mechanisms may also be possible in NSAID-induced urticaria. Other agents causing nonimmunologic urticaria include radiocontrast material, opiates, tubocurarine, and polymyxin B. Pretesting does not exclude the possibility of anaphylactoid reaction

Fig. 6.29 Angioedema. (Courtesy Steven Binnick, MD.)

to radiocontrast material. The use of low-osmolarity radiocontrast material and pretreatment with antihistamines, systemic steroids, and in those with a history of asthma, theophylline, may reduce the likelihood of reaction to radiocontrast material.

Immunologic urticaria is most often associated with penicillin and related β-lactam antibiotics and relates to the minor determinants rather than the β-lactam ring. It is associated with IgE antibodies to penicillin or its metabolites. Skin testing with major and minor determinants is useful in evaluating patients with a history of urticaria associated with penicillin exposure. Patients with penicillin allergy have an increased rate of reaction to cephalosporins. In the case of cefaclor, half of anaphylactic reactions occur in patients with a history of penicillin allergy. Third-generation cephalosporins, especially cefdinir, are much less likely to induce a reaction in a penicillin-allergic patient than are first- or second-generation agents.

Bupropion is often used for depression and smoking cessation. It can induce urticaria, which may be severe and associated with hepatitis and a serum sickness like syndrome. Two antihistamines, cetirizine and hydroxyzine, may induce urticaria, an apparent paradox that may lead to confusion in the clinical setting.

Angioedema is a known complication of the use of ACE inhibitors and angiotensin II antagonists. Blacks are at almost 5 times greater risk than whites. Lisinopril and enalapril produce angioedema more frequently than captopril. Angioedema typically occurs within a week of starting therapy but may begin after months of treatment. The episodes may be severe, requiring hospitalization in up to 45% of patients, intensive care in up to 27%, and intubation in up to 18%. One quarter of patients affected give a history of previous angioedema. The angioedema appears to be dose dependent, because it may resolve with decreased dose. All these factors suggest that the angioedema may represent a consequence of a normal pharmacologic effect of the ACE inhibitors. The blocking of kininase II by ACE inhibitors may increase tissue kinin levels, enhancing urticarial reactions and angioedema. Although this is dose dependent, ACE inhibitor users with one episode of angioedema have a 10-fold risk of a second episode, and the recurrent episodes may be more severe. The treatment of urticaria is discussed in Chapter 7.

Red Man Syndrome

The IV infusion of vancomycin may be complicated by a characteristic reaction called "red man syndrome." With rapid infusions, due to a direct toxic effect of vancomycin on mastocytes, rapid degranulation may occur. A macular eruption appears initially on the back of the neck, sometimes spreading to the upper trunk, face, and arms. Angioedema has been described. There is associated pruritus and "heat," as well as hypotension that may be severe enough to cause cardiac arrest. Oral vancomycin has caused a similar reaction in a child. Children with systemic juvenile idiopathic arthritis (JIA) may have potentially fatal macrophage activation syndrome during or after a "red man reaction" from vancomycin, and thromboses have occurred in patients with sickle cell disease. The red man reaction is caused by elevated blood histamine. Red man syndrome can be prevented in most patients by reducing the rate of infusion of the antibiotic, or by pretreatment with H1 and H2 antihistamines. Although typically reported with vancomycin, similar "anaphylactoid" reactions have been seen with ciprofloxacin, cefepime, amphotericin B, rifampin, infliximab, and teicoplanin.

Photosensitivity Reactions (Photosensitive Drug Reactions)

Medications may cause phototoxic, photoallergic, and lichenoid reactions, accelerated photoaging, and photodistributed telangiectasias, as well as pseudoporphyria. The mechanisms of photosensitivity are discussed in Chapter 3. In many cases, the mechanism for drug-induced photosensitivity is unknown, though some have speculated damage occurs through the generation of reactive oxygen species. Most medication-related photosensitivity is triggered by radiation in the UVA range, partly because (1) most photosensitizing drugs have absorption spectra in the UVA and short-visible range (315–430 nm), and (2) UVA penetrates into the dermis where the photosensitizing drug is present. The most common causes of photosensitivity are NSAIDs, TMP-SMX, thiazide diuretics and related sulfonylureas, quinine and quinidine, phenothiazines, and certain tetracyclines; some less commonly prescribed medications have very high per-patient rates of photosensitivity and toxicity, such as voriconazole and vemurafenib. Numerous other medications in many classes induce photosensitivity less frequently.

Phototoxic reactions are related to the dose of both the medication and the UV irradiation. Reactions can occur in anyone if sufficient thresholds are reached and do not require prior exposure or participation by the immune system. Persons of higher skin types are at lower risk of developing phototoxic eruptions in some studies. There is individual variation in the amount of photosensitivity created by a standard dose of medication, independent of serum concentration. This remains unexplained but reflects the clinical setting, where interindividual variability in development of phototoxic eruptions is seen. Reactions can appear from hours to days after exposure. Tetracyclines, amiodarone, and NSAIDs are common culprits. The reaction may present as immediate burning with sun exposure (amiodarone, chlorpromazine) or exaggerated sunburn (fluoroquinolone antibiotics, chlorpromazine, amiodarone, thiazide diuretics, quinine, tetracyclines). Hyperpigmentation may complicate phototoxic reactions and may last for many months.

Fig. 6.30 Amiodarone hyperpigmentation.

Treatment may include dose reduction and photoprotection by a sunblock with strong coverage through the whole UVA spectrum.

Photoallergic reactions are typically eczematous and pruritic, may first appear weeks to months after drug exposure, and involve the immune system. Unfortunately, in the patient with photoallergy to systemic medications, photopatch testing is infrequently positive and of limited clinical value. In general, photoallergic reactions are not as dependent on drug dose as phototoxic reactions. Photosensitivity of both the phototoxic and the photoallergic type may persist for months to years after the medication has been stopped. Photosensitivity reactions to various drugs are discussed individually next, emphasizing the characteristic patterns seen with each medication group.

Amiodarone photosensitivity develops in up to 75% of treated patients and occurs after a cumulative dose of 40 g and at least 4 months on therapy. A reduced minimal erythema dose (MED) to UVA, but not UVB, occurs, and gradually returns to normal between 12 and 24 months after stopping the medication. Stinging and burning may occur as soon as 30 minutes after sun exposure. Less frequently, a dusky, blue-red erythema of the face and dorsa of the hands occurs (Fig. 6.30). At times, papular reactions are also seen. This reaction may be dose dependent, and acute burning may be relieved by dose reduction; amiodarone has a long half-life and can persist for weeks to months after stopping. Narrow-band UVB may desensitize patients with persistent phototoxicity after stopping amiodarone.

The NSAIDs, especially piroxicam, are frequently associated with photosensitivity (Fig. 6.31). The characteristic reaction is a vesicular eruption of the dorsa of the hands, sometimes associated with a dyshidrosiform pattern on the lateral aspects of the hands and fingers. In severe cases, even the palms may be involved. Histologically, this reaction pattern shows intraepidermal spongiosis, exocytosis, and perivascular inflammatory cells—a pattern typical of photoallergy. However, this reaction may occur on the initial exposure to the medication, but phototoxicity tests in animals and humans have been negative. Patients with photosensitivity to piroxicam may also react to thiosalicylic acid, a common sensitizer in thimerosal. Half of patients having a positive patch test to thimerosal with no prior exposure to piroxicam test positive to piroxicam. This suggests that piroxicam reactions seen on initial exposure to the medication may be related to sensitization during prior thimerosal exposure.

Sulfonamide antibiotics, related hypoglycemic agents, and the sulfonylurea diuretics may all be associated with photosensitivity reactions. Notably, patients may tolerate one of the medications from this group, but when additional members of the group are added, clinical photosensitivity occurs. The typical pattern is erythema, scale, and, in chronic cases, lichenification and hyperpigmentation.

Fig. 6.31 Piroxicam photosensitivity.

Fluoroquinolone antibiotics are frequently associated with photosensitivity reactions. Sparfloxacin is highly photosensitizing; enoxacin, ciprofloxacin, and sitafloxacin are mildly photosensitizing; and levofloxacin rarely, if ever, causes photosensitivity.

Photodistributed lichenoid reactions have been reported most often from thiazide diuretics, quinidine, and NSAIDs, but also occur from diltiazem and clopidogrel bisulfate. They present as erythematous patches and plaques. Sometimes, typical Wickham striae are observed in the lesions. Histologically, photodistributed lichenoid reactions are often indistinguishable from idiopathic lichen planus. Marked hyperpigmentation may occur, especially in persons of higher skin types (IV–VI) and diltiazem-induced cases. The lichenoid nature of the eruption may not be clinically obvious, and histology is required to confirm the diagnosis. This hyperpigmentation may persist for months. UVA-associated phototoxicity is also common with vemurafenib, with reduced UVA MED in 94% of those tested.

Azathioprine can cause photosensitivity to UVA, and there are scattered reports of antimalarial agents inducing photosensitivity. These reactions rare reactions are important to keep in mind as the diseases for which these agents may be prescribed, such as connective tissue disorders, can also exhibit photosensitivity.

Some newer medications have generated multiple reports of photosensitivity, including combination antivirals for hepatitis C, particularly simeprevir; newer chemotherapeutic agents (discussed at length later in the chapter), including vemurafenib, which is strikingly photosensitizing; and emerging reports with other agents (imatinib, ibrutinib, vandetanib, EGF-receptor inhibitors, and more). Flutamide has been reported to induce photoleukomelanoderma, a mosaic mix of hypopigmentation and hyperpigmentation after erythema in sun-exposed areas.

Voriconazole, a second-generation triazole, has been associated with an unusual combination of photosensitive phenomena. Photosensitivity occurs in 8%–10% of patients taking voriconazole for more than 12 weeks. It appears to be UVA induced, and is not dose dependent. Usually, the photosensitivity is mild, with facial erythema and chelitis, and may resemble a sunburn. In these cases, with the use of sun protection and topical treatment, voriconazole can be continued. Occasionally, more severe reactions occur. Pseudoporphyria, eruptive lentigines, atypical nevi, premature

aging, and even the development of melanoma and highly aggressive and potentially fatal squamous cell carcinomas (SCCs) have been reported. Multiple studies, including a large 20-year retrospective study of lung cancer patients, have shown that voriconazole is an independent risk factor for SCC development, and 17% can be unusually aggressive. Any exposure to voriconazole is associated with a 2.6-fold increased risk of SCC, and the risk increases with cumulative exposure. Affected patients can closely resemble patients with xeroderma pigmentosa. Photodistributed granuloma annulare has also been seen. This severe form of photosensitivity rapidly resolves on stopping voriconazole. Patients with aggressive SCC or melanoma are advised to stop voriconazole and transition to an alternate agent if possible; posaconazole can be an effective alternative. Emerging studies suggest hydrochlorothiazide may be associated with an increased risk of skin cancer.

Photodistributed telangiectasia is a rare complication of CCBs (nifedipine, felodipine, amlodipine). UVA appears to be the action spectrum. Cefotaxime has also been reported to produce this reaction. Corticosteroids, oral contraceptives, isotretinoin, IFNs, lithium, thiothixene, methotrexate, and other medications may induce telangiectasia, but not through photosensitivity.

Pseudoporphyria is a photodistributed bullous reaction clinically and histologically resembling porphyria cutanea tarda (Fig. 6.32). Patients present with blistering on sun-exposed skin of the face and hands and skin fragility. Varioliform scarring occurs in 70% of patients. Facial scarring is especially common in children with pseudoporphyria. Hypertrichosis is rarely found; dyspigmentation and sclerodermoid changes are not reported. Porphyrin studies are normal. The blistering usually resolves gradually once the offending medication is stopped. However, skin fragility may persist for years. Naproxen is the most frequently reported cause. Up to 12% of children with JIA treated with NSAIDs may develop pseudoporphyria. Pseudoporphyria has also been reported to other NSAIDs (oxaprozin, nabumetone, ketoprofen, mefenamic acid; but not piroxicam), tetracycline, furosemide, nalidixic acid, isotretinoin, acitretin, 5-fluorouracil, bumetanide, dapsone, oral contraceptives, rofecoxib, celecoxib, cyclosporine, imatinib, vemurafenib, voriconazole, and pyridoxine. Tanning booth (sunbed) exposure and even excessive sun exposure can produce pseudoporphyria. Cases in women outnumber men by 24:1. Some women with sunbed-induced pseudoporphyria are taking oral contraceptives. Patients on dialysis may develop pseudoporphyria, and *N*-acetylcysteine in doses up to 600 mg twice daily may lead to improvement in these cases. Histologically, a pauciinflammatory subepidermal vesicle is seen. DIF may show immunoglobulin and complement deposition at the DEJ and perivascularly, as seen in porphyria cutanea tarda.

Anticoagulant-Induced Skin Necrosis

Both warfarin and heparin induce lesions of cutaneous necrosis, although by different mechanisms. Obese, postmenopausal women are predisposed, and lesions tend to occur in areas with abundant subcutaneous fat, such as the breast, abdomen, thigh, or buttocks. The clinical appearance overlaps with calciphylaxis, and patients with warfarin-induced calciphylaxis have been described.

Warfarin-induced skin necrosis (WISN) usually occurs 3–5 days after therapy is begun, and a high initial dose increases the risk. Patients with a much more delayed onset (up to 15 years) are ascribed to noncompliance, drug-drug interactions, or liver dysfunction. WISN occurs in 1:1000 to 1:10,000 patients treated with warfarin. Hereditary or acquired deficiency of protein C, and less often protein S, is associated with warfarin necrosis. Other hypercoaguable states, such as antithrombin III or factor V Leiden mutations, or lupus anticoagulant syndrome may be associated as well. Lesions begin as red, painful plaques that develop petechiae, then form a large bulla (Fig. 6.33). Necrosis follows. Priapism can complicate warfarin necrosis. A less common variant seen in patients

Fig. 6.32 Sixteen-year-old with scarring from pseudo–porphyria cutanea tarda reaction to tetracycline.

Fig. 6.33 Warfarin-induced necrosis. (Courtesy Steven Binnick, MD.)

with a deep venous thrombosis (DVT) of an extremity is necrosis of a distal extremity, usually the one with the DVT. Warfarin-induced venous limb necrosis is most often seen in cancer patients, but also in the setting of heparin-induced thrombocytopenia (HIT) and antiphospholipid syndrome.

Early in warfarin treatment, the serum levels of the vitamin K–dependent antithrombotic protein C fall. Because the half-life of antithrombotic protein C is shorter than that of the vitamin K–dependent prothrombotic factors II, X, and IX, an acquired state of reduced protein C level occurs before the clotting factors are reduced. This creates a temporary prothrombotic state. This is more likely to occur if the levels of protein C are already low, if other antithrombotic proteins are deficient, or if the patient has an associated hypercoagulable state. This explains why the syndrome does not always recur with gradual reinstitution of warfarin, and why it has been reported to resolve with continued warfarin treatment. Histologically, noninflammatory thrombosis with fibrin in the vessels is seen. Treatment is to stop the warfarin, administer vitamin K to reverse the warfarin, and begin heparin or low-molecular-weight (LMW) heparin. Administration of purified protein C can rapidly reverse the syndrome, as well as associated priapism. Other vitamin K antagonists, such as fluindione, may cause a similar reaction. Rivaroxaban, a direct inhibitor of activated factor X that does not inhibit other vitamin K–dependent proteins, may be considered an alternative anticoagulant. Dabigatran etexilate has been suggested for prevention of WISN in the patient with protein C deficiency.

Heparin induces necrosis both at the sites of local injections and in a widespread pattern when infused intravenously or given by local injection. Local reactions are the most common. Heparin can also induce local allergic reactions at injection sites, which are distinct from the necrosis syndrome. Independent of its method of delivery, heparin-induced skin necrosis lesions present as tender red plaques that undergo necrosis, usually 6–12 days after the heparin treatments are started. Intraepidermal hemorrhagic bullae have also been described. Unfractionated heparin is more likely to cause this complication than fractionated LMW heparin, and postsurgical patients are at greater risk than medical patients. Even the heparin used for dialysis or to flush arterial catheters may be associated with cutaneous necrosis.

Some necrotic reactions to local injections, and most disseminated reactions occurring with IV heparin, are associated with HIT. Patients with underlying prothrombotic conditions, such as factor V Leiden and prothrombin mutations or elevated levels of factor VIII, may develop severe skin lesions if they develop HIT and heparin necrosis. A heparin-dependent antiplatelet antibody is the pathogenic basis of HIT and apparently of heparin-induced skin necrosis. This antibody causes both the thrombocytopenia and the aggregation of platelets in vessels, leading to thrombosis (white clot syndrome). The antibody may appear up to 3 weeks after the heparin has been discontinued, so the onset of the syndrome may be delayed. Histologically, fibrin thrombi are less reproducibly found in affected tissues, because the vascular thrombosis is the result of platelet aggregation, not protein deposition. The process may not only produce infarcts in the skin, but also cause arterial thrombosis of the limbs, heart, lung, and brain, resulting in significant morbidity or mortality. Bilateral adrenal necrosis caused by hemorrhagic infarction can occur and, if not detected early, may lead to death from acute addisonian crisis. The syndrome must be recognized immediately in any patient receiving heparin with late-developing thrombocytopenia. The treatment is to stop the heparin and give a direct thrombin inhibitor and vitamin K. After the platelet count has returned to normal, warfarin therapy is typically given for 3–6 months. Patients with HIT cannot be treated with warfarin immediately, as the warfarin would be ineffective in stopping the thrombosis (it is *not* antithrombotic) and may worsen the thrombosis by enhancing coagulation. The diagnosis of HIT can be delayed because the antiplatelet antibody may not be present while the platelet count is falling. Adding warfarin at this time can lead to disastrous widespread acral thrombosis resembling disseminated intravascular coagulation (DIC).

Skin necrosis has also been associated with other anticoagulants, such as fluindione enoxaparin. Patients with cancer, an acquired prothrombotic state, are at increased risk for DVT. If they are treated with heparin and develop HIT, patients are at extreme risk for development of a prothrombotic state if treated with warfarin. In this setting, digital and limb gangrene has occurred in the face of normal peripheral pulses and supertherapeutic anticoagulation by standard measures (international normalized ratio). The consumptive coagulopathy induced by the cancer is the underlying trigger.

Vitamin K Reactions

Several days to 2 weeks after injection of vitamin K, an allergic reaction at the injection site may occur (Fig. 6.34). Most affected patients have liver disease and are being treated for elevated prothrombin time. The lesions are pruritic red patches or plaques that can be deep seated, involving the dermis and subcutaneous tissue. There may be superficial vesiculation. Lesions occur most often on the posterior arm and over the hip or buttocks. Plaques on the hip tend to progress around the waist and down the thigh, forming a "cowboy gunbelt and holster" pattern. Small, generalized eczematous papules may occur on other skin sites in severe reactions. These reactions usually persist for 1–3 weeks, but may persist much longer, or resolve only to recur spontaneously. On testing, patients with this pattern of reaction are positive on intradermal testing to the pure vitamin K_1.

In Europe a second pattern of vitamin K reaction has been reported. Subcutaneous sclerosis with or without fasciitis appears at the injection site many months after vitamin K treatment. There may have been a preceding acute reaction as previously described. Peripheral eosinophilia may be found. These pseudosclerodermatous reactions have been termed *Texier disease* and last several years.

The addition of vitamin K_1 to cosmetics has led to allergic contact dermatitis from the vitamin K, confirmed by patch testing.

Fig. 6.34 Vitamin K allergy.

Injection Site Reactions

In addition to allergic reactions, as described with vitamin K, cutaneous necrosis may occur at sites of medication injections. These are of two typical forms: those associated with IV infusions and those related to intramuscular (IM) injections. Pharmacologic agents that extravasate into tissue during IV infusion may cause local tissue necrosis, resulting from inherent tissue-toxic properties. These include chemotherapeutic agents (fluorouracil in particular, but multiple agents), calcium salts, radiocontrast material, and nafcillin. IM injections may produce a syndrome called embolia cutis medicamentosa, livedoid dermatitis, or Nicolau syndrome. Immediately after injection, local intense pain occurs and the overlying skin blanches (ischemic pallor). Within minutes to hours, the site develops an erythematous macule that evolves into a livedoid violaceous patch with dendrites. This becomes hemorrhagic, then ulcerates, often forming a deep ulcer many centimeters in diameter. Eventually, over weeks to months, the ulcer heals with an atrophic scar. Muscle and liver enzymes may be elevated, and neurologic symptoms and sequelae occur in one third of patients. The circulation of the limb may be affected, rarely leading to amputation. Nicolau syndrome has been seen with injection of many unrelated agents, including NSAIDs, local anesthetics, corticosteroids, antibiotics, IFN-α, sedatives, vaccines, and medroxyprogesterone acetate (Depo-Provera). There may be a particular risk with refrigerated medications that may contain crystals, which are meant to be warmed before injection. It appears to be caused by periarterial injection leading to arterial thrombosis. IFN-β injections into subcutaneous tissue of the abdomen, buttocks, or thighs of patients with multiple sclerosis has resulted in similar lesions. Patient education and autoinjectors can prevent this complication. Biopsy of the IFN ISRs resembles lupus panniculitis. Vitamin B_{12} also produces localized sclerodermoid reactions. Treatment of Nicolau syndrome is conservative: dressing changes, debridement, bed rest, and pain control. Surgical intervention is rarely required.

IFN injections, as well as subcutaneous injections of pain medication, allergy shots, and Depo-Provera, have also been reported to cause subcutaneous sarcoid-like granulomatous lesions. Fusion inhibitors, such as enfuvirtide, have very high rates of local ISRs. TNF inhibitors and other biologic agents, particularly anakinra, may frequently induce localized injection-site reactions, which in some cases can be severe enough to be treatment limiting. Calcinosis cutis may develop at injection sites, including from antithrombotic agents. Injection-site dermatitis has been reported with agents such as diclofenac, docetaxel, ketoprofen, piroxicam and others. Insulin pumps and injections have led to localized panniculitis-like nodules. One case of injection-site pseudolymphoma has been reported from a GM-CSF–producing tumor cell vaccine.

Drug-Induced Pigmentation

Pigmentation of the skin may result from drug administration. The mechanism may be postinflammatory hyperpigmentation in some patients but frequently is related to actual deposition of the drug in the skin.

Minocycline induces many types of hyperpigmentation, which may occur in various combinations. Classically, three types of pigmentation are described. Type I is a blue-black discoloration appearing in areas of prior inflammation, often acne, sarcoidal plaques, or surgical scars (Fig. 6.35). This may be the most common type seen by dermatologists. It does not appear to be related to the total or daily dose of exposure. In all other types of pigmentation resulting from minocycline, the incidence increases with total dose, with up to 40% of treated patients experiencing hyperpigmentation with more than 1 year of therapy. The second type (type II) is the appearance of a similar-colored pigmentation on the normal skin of the anterior shins. In most cases, types I and II minocycline pigmentation occur after 3 months to several years of treatment. Generalized black hyperpigmentation has occurred after several days or a few weeks of treatment in Japanese patients. In type I and type II minocycline hyperpigmentation, histologic evaluation reveals pigment granules within macrophages in the dermis and at times in the fat, resembling a tattoo. These granules usually stain positively for both iron and melanin. At times, the macrophages containing minocycline are found only in the subcutaneous fat. Stains for iron may be negative in some cases. Calcium stains may also be positive because minocycline binds calcium. The least common type (type III) is generalized, muddy-brown hyperpigmentation, accentuated in sun-exposed areas. Tigecycline may produce similar hyperpigmentation. Histologic examination reveals only increased epidermal and dermal melanin. This may represent the consequence of a low-grade photosensitivity reaction.

In addition to the skin, minocycline types I and II pigmentation may also involve the sclera, conjunctiva, bone, thyroid, ear cartilage (simulating alkaptonuria), nail bed, oral mucosa, and permanent teeth (Fig. 6.36). Black veins have been reported following sclerotherapy in a patient on minocycline. Tetracycline staining of the teeth is usually related to childhood or fetal exposure, is brown, and is accentuated on the gingival third of the teeth. Dental hyperpigmentation caused by minocycline, in contrast, occurs in adults, is gray or gray-green, and is most marked in the midportion of the tooth. Some patients with affected teeth do not have hyperpigmentation elsewhere. The blue-gray pigmentation of the skin may be improved with the Q-switched ruby laser and pulsed dye laser, or fractional photothermolysis.

Chloroquine, hydroxychloroquine, and quinacrine all may cause a blue-black pigmentation of the face, extremities, ear cartilage,

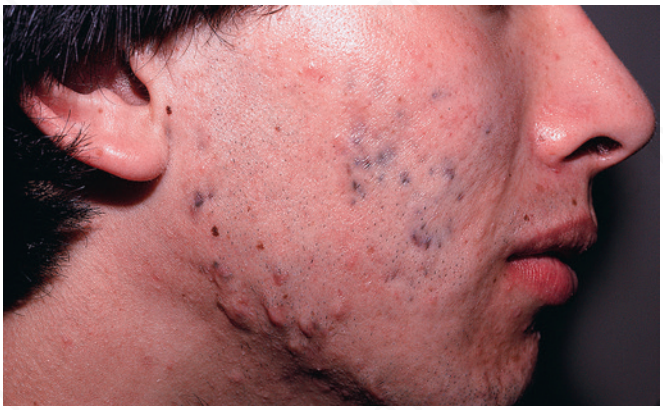

Fig. 6.35 Minocycline-induced hyperpigmentation.

Fig. 6.36 Minocycline hyperpigmentation.

Fig. 6.37 Chlorpromazine hyperpigmentation.

oral mucosa, and nails, in up to 29% of patients. Generally this occurs after long duration or higher cumulative dose (over 300 g). Pretibial hyperpigmentation is the most common pattern and is similar to that induced by minocycline. The gingiva or hard palate may also be discolored. Quinidine may also rarely cause such a pattern of hyperpigmentation. Quinacrine is yellow and concentrated in the epidermis. Generalized yellow discoloration of the skin and sclera (mimicking jaundice) occurs reproducibly in patients but fades within 4 months of stopping the drug. In dark-skinned patients, this color is masked and less significant cosmetically. Histologically pigment granules are present within macrophages in the dermis.

Amiodarone causes photosensitivity in 30%–57% of treated patients after 3–6 months. In 1%–10% of patients, a slate-gray hyperpigmentation develops in the areas of photosensitivity. The pigmentation gradually fades after the medication is discontinued. Histologically, periodic acid–Schiff (PAS)–positive, yellow-brown granules are seen within the cytoplasm of macrophages in the dermis. Electron microscopy reveals membrane-bound structures resembling lipid-containing lysosomes. It responds to treatment with the Q-switched ruby laser.

Clofazimine treatment is reproducibly complicated by the appearance of a pink discoloration that gradually becomes reddish blue or brown and is concentrated in the lesions of patients with Hansen disease. This pigmentation may be disfiguring and is a major cause of noncompliance with this drug in the treatment of Hansen disease. Histologically, a PAS-positive, brown, granular pigment is variably seen within foamy macrophages in the dermis. This has been called "drug-induced lipofuscinosis."

Zidovudine causes a blue or brown hyperpigmentation that is most frequently observed in the nails. The lunula may be blue, or the whole nail plate may become dark brown. Diffuse hyperpigmentation of the skin, pigmentation of the lateral tongue, and increased tanning are less common. It occurs in darkly pigmented persons, is dose dependent, and clears after zidovudine is discontinued. Hydroxyurea causes a similar pattern of hyperpigmentation, including the melanonychia.

Chlorpromazine, thioridazine, imipramine, and clomipramine may cause a slate-gray hyperpigmentation in sun-exposed areas after long periods of ingestion (Fig. 6.37). Frequently, corneal and lens opacities are also present, so all patients with hyperpigmentation from these medications should have an ophthalmologic evaluation. The pigmentation from the phenothiazines fades gradually over years, even if the patient is treated with another phenothiazine. The corneal, but not the lenticular, changes also resolve. Imipramine hyperpigmentation has been reported to disappear within 1 year. Histologically, in sun-exposed but not sun-protected skin, numerous refractile golden-brown granules are present within macrophages in the dermis, along with increased dermal melanin. The slate-gray color comes from a mixture of the golden-brown pigment of the drug and the black color of the melanin viewed in the dermis.

The heavy metals gold, silver, and bismuth produce blue to slate-gray hyperpigmentation. Pigmentation occurs after years of exposure, predominantly in sun-exposed areas, and is permanent. Silver is by far the most common form of heavy metal–induced pigmentation seen by dermatologists. It occurs in two forms, local or systemic. Local argyria typically follows the topical use of silver sulfadiazine or silver-containing dressings (Acticoat). Blue-gray pigmentation occurs at the site of application. Implantation into the skin by needles or pierced jewelry may lead to focal areas of argyria. Systemic argyria can also arise from topical application to the skin (in burn and epidermolysis bullosa patients), by inhalation, by mucosal application (nose drops or eyedrops), or by ingestion. Patients may purchase or build devices that allow them to make colloidal silver solutions, which they then ingest in the belief that it will improve their health. After several months of such exposure, the skin becomes slate-gray or blue-gray, primarily in areas of sun exposure. Histologically, granules of silver are found in basement membranes around adnexal (especially eccrine) and vascular structures. Sun exposure leads to the silver binding to either sulfur or selenium in the skin, increasing deposition. The deposited silver activates tyrosinase, increasing pigmentation. Most patients with argyria have no systemic symptoms or consequences of the increased silver in their body. Q-switched 1064-nm neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser may be used. Gold deposition was more common when gold was used as a treatment for rheumatoid arthritis. Cutaneous chrysiasis also presents as blue-gray pigmentation, usually after a cumulative dose of 8 g. Chrysiasis is also more prominent in sun-exposed sites. Dermatologists should remain aware of this condition, because patients treated with gold, even decades earlier, may develop disfiguring hyperpigmentation after Q-switched laser therapy for hair removal or lentigines lightening. Chrysiasis has been treated effectively in one patient using repeated 595-nm pulsed dye laser therapy. Bismuth also pigments the gingival margin. Histologically, granules of the metals are seen in the dermis and around blood vessels. Arsenical melanosis is characterized by black, generalized pigmentation or by a pronounced truncal hyperpigmentation that spares the face, with scattered depigmented macules that resemble raindrops.

The CCB diltiazem can cause a severe photodistributed hyperpigmentation. This is most common in African American or Hispanic women and occurs about 1 year after starting therapy. The lesions are slate-gray or gray-blue macules and patches on the face, neck, and forearms. Perifollicular accentuation is noted.

Histology shows a sparse lichenoid dermatitis with prominent dermal melanophages. The action spectrum of the drug appears to be in the UVB range, but hyperpigmentation is induced by UVA irradiation. The mechanism appears to be postinflammatory hyperpigmentation from a photosensitive lichenoid eruption rather than drug or drug metabolite deposition. Treatment is broad-spectrum sunscreens, stopping the diltiazem, and bleaching creams if needed. Other CCBs can be substituted without the reappearance of the hyperpigmentation.

Some chemotherapeutic agents have been reported to result in pigmentary changes of the skin, hair, and nails (see later discussion). Imatinib in particular has multiple reports of melasma-like hyperpigmentation particularly in darker skin types, and may also cause darkening in other sites, such as the palate. Multiple other agents can cause darkening of the hair, including antiviral drugs, valproate, retinoids, and CCBs; propofol has been reported to cause the hair to appear green in one case.

Periocular hyperpigmentation occurs in patients treated with prostaglandin analogs for glaucoma. These agents also cause pigmentation of the iris. Eyelash length increases. The periocular hyperpigmentation may gradually resolve when the medications are discontinued.

Vasculitis and Serum Sickness–Like Reactions

Leukocytoclastic vasculitis (LCV) is a rare reaction but can be induced by many medications. Propylthiouracil and hydralazine are frequent culprits (and can induce antineutrophil cytoplasmic antibody). Biologic agents (TNF inhibitors, rituximab, ustekinumab), cocaine (with or without levamisole), and even montelukast and statins have been reported as inciting agents for drug-induced vasculitis. Antibiotics (minocycline, nafcillin, ciprofloxacin, vancomycin, and others) are common culprits in the inpatient setting. Targeted chemotherapeutic agents, particularly immunotherapy/checkpoint inhibitors, have demonstrated multiple autoimmune-pattern eruptions, including vasculitis (see later discussion).

True serum sickness is caused by foreign proteins such as antithymocyte globulin, with resulting circulating immune complexes. In the patient with true serum sickness, purpuric lesions tend to be accentuated along the junction between palmoplantar and glabrous skin (Wallace line).

Serum sickness–like reactions refer to adverse reactions that have similar symptoms to serum sickness, but in which immune complexes are not found. This reaction was particularly common with cefaclor, occurring in 1%–2% of patients. Patients present with fever, an urticarial rash, and arthralgias 1–3 weeks after starting the medication, without the vasculitis, hypocomplementemia, or nephropathy of true serum sickness. Antibiotics are the most frequent culprits (especially β-lactams and minocycline), but other agents such as bupropion, influenza vaccination, NSAIDs, and rituximab have been reported to cause serum sickness–like reactions.

Lichenoid Reactions

Lichenoid reactions can be seen with many medications, including gold, hydrochlorothiazide, furosemide, NSAIDs, aspirin, antihypertensives (ACE inhibitors, β-blockers, CCBs), terazosin, quinidine, proton pump inhibitors, pravastatin, phenothiazines, anticonvulsants, antituberculous drugs, ketoconazole, sildenafil, imatinib, antivirals for hepatitis C, and antimalarials. Hepatitis B immunization may trigger a lichenoid eruption. Checkpoint inhibitors for cancer therapy are an emerging class of agents with high rates of lichenoid reactions (see later discussion). Lichenoid reactions may be photodistributed (lichenoid photoeruption) or generalized, and drugs causing lichenoid photoeruptions may also induce more generalized ones. In either case, the lesions may be plaques (occasionally with Wickham striae), small papules, or exfoliative erythema. Photolichenoid reactions favor the extensor extremities, including the dorsa of the hands. Oral involvement is less common in lichenoid drug reactions than in idiopathic lichen planus but can occur (and with imatinib may be severe). It appears as either plaques or erosions. The lower lip is frequently involved in photolichenoid reactions. The nails may also be affected and can be the only site of involvement. Lichenoid drug eruptions can occur within months to years of starting the offending medication and may take months to years to resolve once the medication has been stopped. Histologically, inflammation occurs along the DEJ, with necrosis of keratinocytes and a dermal infiltrate composed primarily of lymphocytes. Eosinophils are useful, if present, but are not common in photolichenoid reactions. The histology is often similar to idiopathic lichen planus, though eosinophils may be more prominent, and a clinical correlation is required to determine whether the lichenoid eruption is drug induced. If the drug is essential, the course of treatment may be tolerated with corticosteroid therapy.

Lichenoid reactions may be restricted to the oral mucosa, especially if induced by dental amalgam. In these patients, the lesions are topographically related to the dental fillings or to metal prostheses. Patients may be patch test positive to mercury, or less often gold, cobalt, or nickel, in up to two thirds of cases. Amalgam replacement will result in resolution of the oral lesions in these cases. Patients with cutaneous lesions of lichen planus and oral lesions do not improve with amalgam removal. An unusual form of eruption is the "drug-induced ulceration of the lower lip." Patients present with a persistent erosion of the lower lip that is tender but not indurated. It is induced by diuretics and resolves slowly once they are discontinued.

Adverse Reactions to Chemotherapeutic Agents

Patients undergoing treatment for cancer can develop skin manifestations due to their disease, paraneoplastic conditions, chemotherapeutic agents, immunosuppression-related conditions and

infections, and supportive medications. Patients who undergo bone marrow transplants can develop reactions due to engraftment syndrome, the eruption of lymphocyte recovery (nonspecific erythematous macules as lymphocyte count recovers), or GVHD (see Chapter 5) as well.

Chemotherapeutic agents can cause adverse reactions by multiple potential mechanisms. Adverse reactions may be related to toxicity either directly to the mucocutaneous surfaces (stomatitis, alopecia), or reflected in the skin, such as purpura resulting from thrombocytopenia. The use of localizing cooling devices to limit blood flow, and reduce chemotherapy delivery to sites of toxicity may help prevent or alleviate some side effects, such as nail damage or hair loss. Chemotherapeutic agents can also act as antigens inducing classic immunologic reactions, or as immunotherapy may stimulate autoimmune reactions through their intended mechanism of anticancer action. Chemotherapy reactions can be grouped by skin reaction pattern, or by drug class. Most reactions are assessed using the common terminology criteria for adverse events (CTCAE) grading scale to determine whether dose reduction, interval prolongation, or alternate agents are necessary. Xerosis (17%–20%), pruritus (17%–20%), and nonspecific erythematous papular eruptions are fairly common and managed with supportive care.

Dermatologists are rarely confronted with the acute hypersensitivity reactions seen during infusion of chemotherapeutic agents. These reactions resemble type I allergic reactions, with urticaria and hypotension, and can be prevented by premedication with systemic corticosteroids and antihistamines in most cases.

Toxic Erythema of Chemotherapy (Chemotherapy-Induced Acral Erythema, Palmoplantar Erythrodysesthesia Syndrome, Hand-Foot Syndrome, Intertriginous Eruptions)

The unifying term *toxic erythema of chemotherapy* was proposed by Bolognia in 2008. Many traditional chemotherapeutic agents can induce this relatively common reaction (taxanes, especially docetaxel, cytarabine, anthracyclines, 5-fluorouracil [5-FU] capecitabine, methotrexate, and others less commonly). In the case of pegylated liposomal doxorubicin, localization of the chemotherapeutic agent to the sweat glands has been demonstrated, and one report demonstrated a strikingly intertriginous/flexural erythema and peeling that spared only one axilla, which had been previously radiated and lacked adnexal structures. Cases of neutrophilic eccrine hidradenitis and syringometaplasia, all induced by the same agents, suggest that the eccrine glands are unique targets for adverse reactions to antineoplastic agents.

The initial manifestation is often dysesthesia or tingling of the palms and soles, usually 2–3 weeks after administration of chemotherapy. This is followed in a few days by painful, symmetric erythema and edema most pronounced over the distal pads of the digits. Painful erythema and skin peeling can occur and the skin becomes dusky, deep red-brown, and may blister and desquamate either superficially or involving most of the epidermis (Fig. 6.38). The desquamation is often the most prominent part of the syndrome. The eruption generally involves sites of contact, friction, rubbing, or high concentrations of eccrine ducts/sweat, presumably due to accumulation of toxic metabolites plus occlusion or mild trauma. A localized plaque of fixed erythrodysesthesia has been described proximal to the infusion site of docetaxel, and cytarabine can cause striking localized ear erythema.

The histopathology is nonspecific, with necrotic keratinocytes and vacuolar changes along the basal cell layer. Acute GVHD is in the differential diagnosis. Histologic evaluation may not be useful in the acute setting to distinguish these syndromes. The clinical distribution, timing, and presence or absence of extracutaneous involvement (gastrointestinal or liver findings of GVHD) are more helpful.

Fig. 6.38 Hand-foot syndrome.

Most patients require only local supportive care. Cold compresses and elevation are helpful, and cooling the hands during treatment may reduce the severity of the reaction. Modification of the dose schedule can be beneficial. Pyridoxine, 100–150 mg daily, decreased the pain of 5-FU–induced acral erythema in one study, but benefits are not proven. Cox-2 inhibitors have also been suggested. Local or systemic corticosteroids may be considered, depending on the severity. Lidocaine patches may help with pain. IVIG has been reported to be beneficial in a methotrexate-induced case of acral erythema. Cyclosporine has been reported to result in worsening of the condition.

Sorafenib and sunitinib are small, multikinase-inhibiting molecules with blocking activity for numerous tyrosine kinases, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGFRβ), and c-kit ligand (stem cell factor). Both agents induce a condition similar to acral erythema, also referred to as hand-foot skin reaction (HFSR). Patients also present with acral pain and dysesthesia, but usually less severe than with classic chemotherapeutic agents. In contrast to classic acral erythema, multikinase inhibitor–induced HFSR causes lesions over areas of friction, either blisters or patchy hyperkeratotic plaques. The HFSR is dose dependent, high grade in 9% of cases (with blisters, ulceration, and functional loss) and results in the sorafenib being stopped in about 1% of patients. The addition of another VEGF inhibitor, bevacizumab, leads to worse HFSR. Olmutinib was reported to induce a palmoplantar keratoderma in 3 patients. The development of hand-foot syndrome in patients receiving sorafenib for metastatic renal cell carcinoma is associated with better tumor response and improved progression-free survival.

Histologically, there are horizontal layers of necrotic keratinocytes within the epidermis (if biopsy is taken in first 30 days) or in the stratum corneum (later biopsies). Topical tazarotene, 40% urea, heparin ointment, and fluorouracil cream have been used to treat HFSR from multikinase inhibitors.

Neutrophilic eccrine hidradenitis is discussed in Chapter 33.

Chemotherapy-Induced Dyspigmentation

Many traditional chemotherapeutic agents (especially the antibiotics bleomycin, doxorubicin, and daunorubicin) and the alkylating

Fig. 6.39 Bleomycin-induced flagellate hyperpigmentation.

agents (cyclophosphamide and busulfan) cause various patterns of cutaneous hyperpigmentation; the risk of pigmentary changes with targeted chemotherapeutic agents is gaining recognition. Adriamycin (doxorubicin) causes marked hyperpigmentation of the nails, skin, and tongue. This is most common in black patients and appears in locations where constitutional hyperpigmentation is sometimes seen. Hydroxyurea can also cause this pattern of hyperpigmentation. Cyclophosphamide causes transverse banding of the nails or diffuse nail hyperpigmentation beginning proximally. Bleomycin and 5-FU cause similar transverse bands. Busulfan and 5-FU induce diffuse hyperpigmentation that may be photoaccentuated.

Bleomycin induces characteristic flagellate erythematous urticarial wheals associated with pruritus within hours or days of infusion (Fig. 6.39). Lesions continue to appear for days to weeks. Although investigators have not always been able to induce lesions, the pattern strongly suggests scratching is the cause. Bleomycin hyperpigmentation may be accentuated at areas of pressure, strongly supporting trauma as the cause of the peculiar pattern. Patients may present with linear erythematous wheals 1–2 days after eating raw or cooked shiitake mushrooms (Fig. 6.40). This so-called toxicodermia, or shiitake flagellate dermatitis, is thought to be caused by a toxic reaction to lentinan, a polysaccharide component of the mushrooms. It is self-limited and resolves within days to weeks of its appearance, but can be treated with topical corticosteroids to relieve the associated pruritus some patients experience. Other associations with flagellate eruptions include adult-onset Still disease, dermatomyositis, and docetaxel therapy.

5-FU, and less frequently other chemotherapeutic agents such as methotrexate, may produce a serpentine hyperpigmentation overlying the veins proximal to an infusion site (Fig. 6.41). This represents hyperpigmentation from a direct cytotoxic effect of the chemotherapeutic agent.

Targeted chemotherapeutic agents may also induce a variety of patterns of pigmentary changes, with one review showing 17% of patients with skin and 21% of patients with hair pigmentation sequelae. Most established is imatinib, which leads to dose-related generalized or localized hypopigmentation in 40% or more of pigmented persons (possibly due to inhibiting tyrosinase activity). Paradoxic hyperpigmentation of the skin, nails, and hair caused by imatinib has been reported. It starts an average of 4 weeks

Fig. 6.40 Shiitake mushroom–induced dermatitis. (Courtesy Don Adler, DO.)

Fig. 6.41 Methotrexate-induced vascular hyperpigmentation. (Courtesy Steven Binnick, MD.)

after treatment and progresses over time if treatment with imatinib is continued. Patients also complain of an inability to tan and "photosensitivity." Imatinib-induced pseudoporophyria has been reported. One patient with vitiligo had significant progression with imatinib therapy. Multikinase inhibitors (such as cabozantinib, pazopanib, sorafenib, and sunitinib) may inhibit *C-kit*, which is a regulator of melanogenesis, and may induce skin pigmentary changes through this mechanism, such as sunitinib-related depigmentation of the hair after 5–6 weeks of treatment. Sunitinib may lead to yellow pigmentation of the skin from the drug or its metabolites being deposited, though some mTOR inhibitors have also been reported to cause yellowing (temsirolimus). Eruptive melanocytic nevi and lentigines with an acral predisposition have been seen with sorafenib therapy. Ipilimumab, pembrolizumab, and nivolumab are immune-stimulating agents that likely induce vitiligo through autoimmune-activited CD8+ T cells targeting the melanocytes. EGF-receptor inhibitors, VEGF-receptor inhibitors, and other targeted agents have also been reported to cause both skin and hair hypopigmentation as well. Although in general targeted agents induce less alopecia (14% overall) than cytoxic chemotherapy, some (particularly vismodegib, at over 50%) have high rates.

Palifermin-Associated Papular Eruption

Palifermin is a recombinant human keratinocyte growth factor sometimes used to reduce the severity and duration of mucositis in patients undergoing hematopoietic stem cell transplantation. An intertriginous erythema accompanied by oral white confluent

plaques and small lichenoid papules developed in one patient receiving palifermin therapy. A direct hyperproliferative effect of the keratinocyte growth factor is the proposed mechanism.

Chemotherapy-Induced Pseudocellulitis

Gemcitabine has been reported to cause a bilateral bright red leg syndrome, which can mimic cellulitis. It has also been described as causing a lipodermatosclerosis-like eruption, possibly after the pseudocellulitis. Pemetrexed has also been noted to cause a similar eruption. Both of these reactions have been reported in sites of lymphedema or swelling, possibly through impaired lymphatic drainage leading to drug accumulation in the tissues. The bilaterality and symmetry may help distinguish from infection. Biopsy may demonstrate eosinophils within a mixed infiltrate.

Scleroderma-Like Reactions

Patients treated with the taxanes (docetaxel, paclitaxel) or pemetrexed have been reported to develop an acute, diffuse, infiltrated edema of the extremities and/or head. This occurs after one to several courses. The affected areas, specifically the lower extremities, evolve over months to become sclerotic and at times painful. Flexion contractures of the palm, digits, and large joints may occur. Biopsies of the initial lesion show lymphangiectasia and a diffuse infiltration with mononuclear cells in the superficial dermis. Late fibrotic lesions demonstrate marked dermal fibrosis. Discontinuation of the therapy leads to resolution in most cases.

Exudative Hyponychial Dermatitis

Repeated chemotherapeutic cycles can lead to patterned nail changes due to recurrent growth interruption (Beau lines). More severe nail toxicity is common (20%–44% in most studies, though some report as high as 89%) during chemotherapy for breast cancer, especially with taxanes (particularly docetaxel). Subungual hemorrhage, subungual abscesses, paronychia, subungual hyperkeratosis, and onychomadesis all occur, though onycholysis is most common, and can be severe. All these reactions probably represent various degrees of toxicity to the nail bed. Protective clear polish, clipping the nails back, using cotton gloves, and avoiding trauma are helpful; frozen gloves during chemotherapy may help prevent the reaction.

Cutaneous Side Effects of Epidermal Growth Factor Receptor Inhibitors

Epidermal growth factor receptor (EGFR) inhibitors are used for a variety of tumors, and include both monoclonal antibodies (cetuximab and panitumumab) and tyrosine kinase inhibitors. EGFR is expressed by basal keratinocytes, sebocytes, and the outer root sheath, explaining why up to 90% of patients treated with EGFR inhibitors may develop cutaneous side effects, including xerosis (19%), pruritus (24%), trichomegaly, hair curling, and signs of skin aging, and painful periungual or finger pulp fissures and paronychia (with or without periungual pyogenic granulomas) may develop in 15%–25% (Fig. 6.42).

The most common side effect is an acneiform rash, which is severe in up to 18% of cases. The severity of the reaction may indicate more drug metabolism and possibly better tumor response rates. When severe, however, the eruption can be dose limiting. The eruption begins 7–10 days after initiation of therapy, attaining maximum severity in the second week. The seborrheic areas of the scalp, central face, upper back, and retroauricular regions are mainly affected. The primary lesion is a follicular papule or pustule with few or no comedones. Crusting and confluence can occur. Cultures should be performed to rule out secondary infection in patients with severe disease. Radiation therapy during EGFR inhibitor therapy will enhance the skin toxicity, but previously radiated skin is often spared from inhibitor toxicity. Treatment is oral tetracycline antibiotics and corticosteroids. It is recommended that prophylactic sun protection and oral doxycycline be used in many cases. Effective topical therapies have included metronidazole, clindamycin, hydrocortisone, pimecrolimus, tretinoin, and possibly dapsone. In the most severe cases, isotretinoin or acitretin can be used. TNF-α and IL-1 are involved in the pathogenesis of EGFR inhibitor toxicity. Etanercept and anakinra, therefore, may also be therapeutically useful.

Fig. 6.42 Epidermal growth factor receptor (EGFR) inhibitor–induced paronychia.

Other Cutaneous Side Effects of Multikinase Inhibitors

In addition to the reactions previously listed, multikinase inhibitors may cause other skin reactions. Psoriasis exacerbation, acral psoriasiform hyperkeratosis, and pityriasis rosea-like eruptions have been described with imatinib. Both imatinib and sunitinib cause facial edema, with a periocular predilection. Increased vascular permeability caused by PDGFR inhibition has been the proposed mechanism. Dasatinib has caused a lobular panniculitis. Bevacizumab, a VEGF inhibitor, causes bleeding, painful distal subungual splinter hemorrhages, and wound healing complications. Extensive cutaneous surgery should probably be delayed for 60 days after bevacizumab therapy, and 28 days should elapse after surgery before initiation of bevacizumab therapy. Bevacizumab has also been associated with ulceration of striae distensae (Fig. 6.43). VEGF inhibitors in general can lead to mucosal bleeding (epistaxis).

BRAF-Inhibitor Reactions

BRAF mutations are common in melanoma and other malignancies. Targeted BRAF inhibitors (vemurafenib, dabrafenib) have been

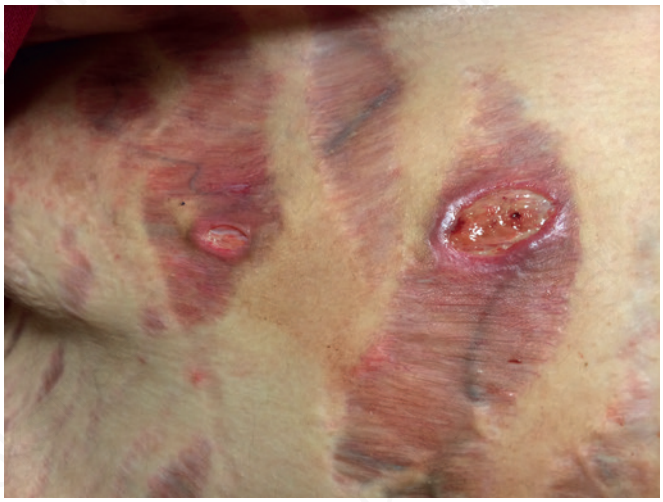

Fig. 6.43 Bevacizumab-induced ulceration of striae. (Courtesy Farber SA, Samimi S, Rosenbach M. Ulcerations within striae distensae associated with bevacizumab therapy. J Am Acad Dermatol 2015;72;1:e33-35.)

Fig. 6.44 Radiation recall induced by vemurafenib.

successfully used to treat metastatic melanoma, but may have a number of cutaneous adverse effects. Many patients exhibit pruritus and can develop a nonspecific eruption, and these agents are very photosensitizing. Verrucous keratoses resembling warts occur in more than 50% of patients. Patients may develop palmoplantar hyperkeratosis and curly hair. From 20%–30% of patients develop SCCs, including keratoacanthoma (KA)-type lesions, which may be eruptive early in treatment. BRAF-inhibitors can induce changes in existing nevi, and eruptive nevi. Radiation recall may be seen. A panniculitis has been reported in some patients. MEK inhibitors typically cause a papulopustular eruption, but have also been reported to cause a dusky erythema. When used in combination, patients on combined BRAF/MEK inhibitions have fewer of the BRAF-inhibitor–related side effects. Sorafenib is a multikinase inhibitor with BRAF-inhibitory activity, and has also been associated with the rapid development of multiple keratoacanthomas or SCCs, as well as eruptive melanocytic lesions. Bexarotene was reported as therapeutic in a patient with sorafenib-induced squamoproliferative lesions. Multiple monomorphous, follicular, keratotic skin-colored papules resembling keratosis pilaris can develop during sorafenib treatment. Histologically, these papules show hyperplasia of the follicular isthmus or follicular hyperkeratosis with plugging. Facial and scalp erythema and dysesthesia occur in about 60% of sorafenib-treated patients.

Checkpoint Inhibitors and Immunotherapy

Immunotherapy for cancer is a rapidly emerging area, with an explosion of indications for the novel class of anticancer agents, immune-checkpoint inhibitors. Ipilimumab is an anti CTLA-4 antibody used for metastatic melanoma, and can cause a maculopapular rash, alopecia, and fairly commonly vitiligo. Currently pembrolizumab and nivolimuab are approved PD-1 receptor inhibitors, with agents targeting the PD-1 ligand PD-L1 and other agents being rapidly developed. These drugs have many immune-mediated side effects, including cutaneous reactions. Nonspecific rash is common (15%–29%), as is pruritus (12%); vitiligo occurs in 7%–9% of patients (especially when the drugs are used to treat melanoma). Lichenoid reactions, both clinically and histologically, are also fairly common, including oral lichenoid mucositis. Patients who had skin reactions have been reported to have longer progression-free survival in small studies. Reports of rare reactions, such as vasculitis, granulomatous eruptions (sarcoidosis, granuloma annulare), panniculitis, lupus-like reactions, and SJS/TEN also exist. Alopecia may develop in these patients as well, an unlike traditional cytotoxic chemotherapy, may be alopecia areata or universalis pattern. Eruptive keratoacanthomas were reported in three patients. Interestingly, there are multiple reports of PD-1-inhibitor–induced autoimmune bullous eruptions resembling bullous pemphigoid with anti BP-180 antibodies. Most immune-mediated reactions are managed with topical or systemic corticosteroids.

Radiation Enhancement and Recall Reactions

Radiation dermatitis, in the form of intense erythema and vesiculation of the skin, may be observed in radiation ports. Administration of many chemotherapeutic agents, during or about the time of radiation therapy, may induce an enhanced radiation reaction. In some patients, however, months to years after radiation treatment, the administration of a chemotherapeutic agent may induce a reaction within the prior radiation port, with features of radiation dermatitis (Fig. 6.44). This phenomenon has been termed "radiation recall," reported with numerous chemotherapeutic agents (gemcitabine, small molecule inhibitors, tamoxifen, methotrexate, taxanes, and multiple other agents), high-dose IFN-α, and simvastatin. Besides the skin, internal structures such as the gut may also be affected. A similar reaction of reactivation of a sunburn after methotrexate therapy also occurs. Exanthems restricted to prior areas of sunburn are not true radiation recall, but may represent "locus minoris resistentiae," or a nonspecific eruption showing up at a site of prior damage.

Cutaneous Adverse Reactions to Traditional Immunosuppressants Used in Dermatology

Azathioprine is used as a steroid-sparing agent for dermatologic conditions and can cause a hypersensitivity syndrome. In addition, neutrophilic dermatoses resembling Sweet syndrome appear with azathioprine therapy and resolve with its discontinuation. Photosensitivity can also occur with azathioprine, despite its frequent use in severe photodermatoses.

Methotrexate can cause erosive skin lesions in two patterns. Ulceration or erosion of psoriatic plaques may be a sign that the patient is taking a midweek dose of methotrexate. This can be associated with severe methotrexate marrow toxicity. If renal failure is present or occurs during low-dose methotrexate therapy, a severe bullous eruption resembling TEN can occur. This apparently represents severe cutaneous toxicity from the prolonged blood and skin levels of methotrexate that result from reduced excretion because of coexistent renal disease and drug-drug interactions, and is more common in older patients, patients with renal disease, and higher dose without folic acid supplementation. If this scenario is recognized, leucovorin rescue should be prescribed.

Adverse Reactions to Cytokines

Cytokines, which are normal mediators of inflammation or cell growth, are increasingly used in the management of malignancies and to ameliorate the hematologic complications of disease or its treatment. Skin toxicity is a common complication of the use of these agents. Many cause local inflammation and ulceration at the injection site in a large number of the patients treated. More widespread papular eruptions are also frequently reported.

Granulocyte colony-stimulating factor (G-CSF) has been associated with the induction of several neutrophil-mediated disorders, most often Sweet syndrome or bullous pyoderma gangrenosum. These occur about 1 week after cytokine therapy is initiated and are present despite persistent neutropenia in peripheral blood. A rare complication of G-CSF is a thrombotic and necrotizing panniculitis. Both G-CSF and GM-CSF may exacerbate leukocytoclastic vasculitis. IFN-α, IFN-γ, and G-CSF have been associated with the exacerbation of psoriasis. Rarely, linear IgA disease can be induced by IFN-α. G-CSF can also cause granulomatous dermatitides. IFN therapy can induce granulomatous lesions, both systemic granulomatous processes and localized granulomatous reactions at injection sites. Anakinra and rarely erythropoietin can cause similar granulomatous skin reactions.

IL-2 frequently causes diffuse erythema, followed by desquamation, pruritus, mucositis (resembling aphthosis), glossitis, and flushing. Erythroderma with blistering or TEN-like reactions can occur and may be dose limiting. Administration of iodinated contrast material within 2 weeks of IL-2 therapy is associated with a hypersensitivity reaction in 30% of patients. Fever, chills, angioedema, urticaria, and hypotension may occur. Subcutaneous injections of IL-2 can lead to injection site nodules or necrosis. Histologically, a diffuse panniculitis with noninflammatory necrosis of the involved tissue is present.

Adverse Reactions to Biologic Agents

Tumor Necrosis Factor Inhibitors

The TNF inhibitors are associated with palmoplantar pustulosis, pustular folliculitis, new or worsening of psoriasis, interface dermatitis, neutrophilic eccrine hidradenitis, Sweet syndrome, lupus (systemic and subacute cutaneous), granulomatous reactions (sarcoidosis, granuloma annulare), and vasculitis. ISRs are common with etanercept therapy for rheumatologic disease, with 20%–40% of patients developing ISR. ISRs present as erythematous, mildly

Fig. 6.45 Plaque-type psoriasis.

swollen plaques, appearing 1–2 days after the injection. Pruritus occurs in 20% of patients. ISR is most common early in the treatment course (median number of injections, four) and stops appearing with continued treatment. Individual lesions resolve over 2–3 days. Recall ISR (reappearance of eruption at previous ISR site) occurs in 40% of patients. This adverse reaction appears to be mediated by CD8+ T cells. IL-1 (anakinra) therapy is associated with high rates of local ISRs (>50% in one study of 140 patients) and diffuse rash (25% of patients), which may be urticarial.

The paradoxic appearance of psoriasis or a psoriasiform dermatitis is now a well-recognized complication of TNF inhibitor therapy. It occurs with all of the TNF inhibitors. The psoriasis can appear from days to years after anti-TNF therapy. There is no age or gender predisposition. Several clinical patterns have been described. Palmoplantar pustulosis represents about 40% of cases. Generalized pustular disease may accompany the palmoplantar lesions. Plaque-type psoriasis occurs in about one third of TNF inhibitor–induced psoriasis (Fig. 6.45). New-onset guttate psoriasis occurs in 10% of cases. Stopping the TNF inhibitor led to improvement or resolution in the vast majority of patients. In some cases, therapy was continued and the eruption resolved. Experts disagree as to whether switching to a different anti-TNF agent may be tolerated in these patients. Many patients have been rechallenged with other TNF inhibitors. In severe cases, this is probably not prudent, but in milder or localized cases, this could be considered. The psoriasis caused by anti-TNF agents can be treated with topical corticosteroids, UV phototherapy, topical vitamin D analogs, methotrexate, acitretin, cyclosporine, or other antipsoriatic biologics. The proposed mechanism for the appearance with psoriasis with anti-TNF therapy is either overactivity of Th1 cells or increased IFN-α production by skin-resident plasmacytoid dendritic cells. Systemic IFN-α and topical imiquimod (an IFN inducer) have been reported to exacerbate psoriasis, supporting this hypothesis. Sarcoidosis induced by anti-TNF agents could also be related to increased IFN production.

Many patients on biologic therapy may develop new antinuclear antibodies (ANAs; 11% of etanercept patients for RA, similar rates with infliximab), though most of those do not have overt lupus. True drug-induced lupus (DIL) with features of SLE may occur. It begins on average after 41 weeks of treatment. Compared with DIL from other medications, the TNF inhibitors cause more skin disease with malar rash, discoid lesions, and photosensitivity. Many of the patients fulfill the American Rheumatology Association (ARA) criteria for SLE, and significant internal organ involvement can occur, including renal and central nervous system (CNS) involvement. Etanercept seems to cause skin lesions more frequently. Etanercept patients also developed vasculitis more often. The vast majority of patients improve about 10 months after therapy has been discontinued. Switching from one TNF inhibitor to another has been reported to be successful. Subacute cutaneous lupus erythematosus (SCLE) may also occur. This is important to keep in mind as the appearance may be psoriasiform, rather than the classic annular morphology, and can be mistaken for TNF-induced psoriasis. Dermatomyositis has also been caused by TNF inhibitor treatment.

Vasculitis is also a well-recognized complication of treatment with TNF inhibitors. Etanercept is the most common agent reported to induce vasculitis. The lesions of vasculitis may begin around the injection sites in some etanercept-induced vasculitis cases. More than 85% of patients present with skin lesions, usually a leukocytoclastic vasculitis. Ulcerations, nodules, digital lesions, chilblains, livedo, and other morphologies have also been described. Visceral vasculitis occurs in about one quarter of patients. They may be ANA positive or antineutrophil cytoplasmic antibody (ANCA) positive (usually p-ANCA) or may have cryoglobulins. Drug-induced antiphospholipid syndrome with TNF inhibitors can be associated with DIL or vasculitis and presents with thrombosis as well as cutaneous lesions. Some patients with TNF inhibitor–induced vasculitis have died. Stopping the TNF inhibitor leads to resolution of the vasculitis in more than 90% of cases. Rechallenge leads to new vasculitic lesions in 75% of cases. Other neutrophilic disorders induced by TNF inhibitors include Sweet syndrome–like reactions and neutrophilic eccrine hidradenitis. New onset vitiligo has also been reported with a variety of biologics, primarily the TNF inhibitors.

Lichenoid drug eruptions have been reported from anti-TNF agents. They are typically pruritic and affect areas typically involved by lichen planus: the flexor wrists. However, gluteal cleft lesions are also common. In some cases, the lichenoid eruption superimposes itself on psoriatic lesions, presenting as an exacerbation of the "psoriasis." Biopsies show features of both lichen planus and psoriasis, and stopping the anti-TNF therapy leads to improvement of the "psoriasis." Despite these agents' immunosuppressive properties, patients can still develop allergic contact dermatitis while taking them, and patch testing during anti-TNF treatment may identify relevant allergens. It appears that patients receiving anti-TNF agents are at slightly increased risk for development of nonmelanoma skin cancers, especially if they also have used methotrexate.

Other Biologic Agents

Recent years have seen the introduction of numerous other classes of biologic agents with specific targets, many of which can induce nonspecific rashes (eczematous, urticarial) and ISRs. Ustekinumab (IL-12/IL-23 inhibitor) has also been reported to induce psoriasis, sarcoidosis, small vessel vasculitis, bullous pemphigoid, and tumid lupus in scattered reports. The IL-17 inhibitors and new IL-23–specific inhibitors appear to be overall well tolerated, with no specific signal for cutaneous adverse events. Omalizumab (mAb against IgE receptor) is well tolerated, with rare anaphylactic reactions. Dupilumab (IL-4/IL-13 inhibitor), recently approved for atopic dermatitis, appears to be well tolerated, with trials demonstrating ISRs as the primary skin issue. Rituximab (anti-CD20 mAb) is generally well tolerated, but as a chimeric antibody patients can develop hypersensitivity reactions and serum sickness.

JAK Inhibitors

The janus-kinase signal transducer and activation of transcription (JAK-STAT) is involved in a broad set of interleukin and IFN signaling, and many inflammatory conditions involve this pathway. JAK inhibitors are being used for a growing list of skin conditions, including vitiligo, alopecia areata, atopic dermatitis, psoriasis, and small case reports of benefit in GVHD and dermatomyositis. JAK

inhibitors are generally well tolerated, with the notable exception being high rates of varicella-zoster virus reactivation.

Mercury

Mercury may induce multiple cutaneous syndromes. The classic syndrome is acrodynia, usually in infancy, also known as calomel disease, pink disease, and erythrodermic polyneuropathy. The skin changes are characteristic and almost pathognomonic: painful swelling of the hands and feet, sometimes associated with considerable itching of these parts. The hands and feet are also cold, clammy, and pink or dusky red. The erythema is usually blotchy but may be diffuse. Hemorrhagic puncta are frequently evident. Over the trunk, a blotchy macular or papular erythema is usually present. Stomatitis and loss of teeth may occur. Constitutional symptoms consist of moderate fever, irritability, marked photophobia, increased perspiration, and a tendency to cry most of the time. There is always moderate upper respiratory inflammation with throat soreness. The infant may have hypertension, hypotonia, muscle weakness, anorexia, and insomnia. Albuminuria and hematuria are usually present. The diagnosis is made by finding mercury in the urine.

An exanthem may occur from inhalation of mercury vapors or absorption by direct contact. A diffuse, symmetric, erythematous morbilliform eruption in the flexors and proximal extremities begins within a few days of exposure. Accentuation in the groin and medial thighs produces a "baboon syndrome" appearance. The eruption burns or itches, and small follicular pustules appear. Extensive desquamation occurs with resolution. Old broken thermometers or the application of mercury-containing skin-lightening creams and herbal medications are potential sources. In Haiti, elemental mercury is applied to surfaces for religious purposes and may result in contamination of those coming in contact.

Mercury is also a possible cause of foreign body granulomas and hyperpigmentation at sites of application. An eruption of 1–2 mm, minimally pruritic papules and papulovesicles on the palms (all patients) and soles, arms, and trunk has also been ascribed to levels of mercury in the blood at near the upper limits considered to be safe. Treatment with a seafood-free diet and chelation with succimer led to resolution of the eruption in some patients. Nummular dermatitis improved in two mercury patch test–positive patients when their dental amalgam was removed.

Halogenoderma

Bromoderma and Fluoroderma

Bromides and fluorides produce distinctive follicular eruptions: acneiform, papular, or pustular. Vegetative, exudative plaques studded with pustules may develop, resembling Sweet syndrome, pyoderma gangrenosum, or an orthopoxvirus infection. Any area of skin may be affected, but bromoderma and especially fluoroderma tend to affect the lower extremities more than iododerma. Histologically, the lesions show epidermal hyperplasia with intraepidermal and dermal neutrophilic abscesses. There is rapid involution of the lesions on cessation of bromide ingestion. Excessive cola or soft-drink consumption or ingestion of bromine-containing medications (ipratropium bromide, dextromethorphan hydrobromide, potassium bromide, pipobroman, Medecitral, sedatives) may be the cause of a bromoderma. Serum bromide level is elevated and confirms the diagnosis. Fluoroderma has been associated with intensive use of dental fluoride treatments.

Iododerma

Iodides may cause a wide variety of skin eruptions. The most common sources of exposure are oral and IV contrast materials and when iodides are used to treat thyroid disease. Application of povidone-iodine to the skin, mucosa, or as a tub soak has produced iododerma. The most common type is the acneiform eruption with numerous acutely inflamed follicular pustules, each surrounded by a ring of hyperemia (Fig. 6.46). Dermal bullous lesions are also common and may become ulcerated and crusted, resembling pyoderma gangrenosum or Sweet syndrome. The eruption may involve the face, upper extremities, trunk, and even the buccal mucosa. Acne vulgaris and rosacea are unfavorably affected by iodides. Acute iododerma may follow IV radiocontrast studies in patients with renal failure. The lesions may be associated with severe leukocytoclastic vasculitis, intraepidermal spongiform pustules, and suppurative folliculitis. The lesions respond to prednisone.

Drug-Induced Autoimmune Diseases

Lupus Erythematosus

Drug-induced SLE is rarely associated with skin lesions. It occurs in older patients and affects men as frequently as women. The symptoms are generally mild and include fever, myalgias/arthralgias, and serositis. This form of DIL is associated with a positive ANA, homogeneous pattern, and antihistone antibodies, but a negative anti-dsDNA antibody and normal complement levels. Procainamide, hydralazine, quinidine, captopril, isoniazid, minocycline, carbamazepine, propylthiouracil, sulfasalazine, and the statins are among the reported agents triggering this form of DIL. The TNF inhibitors, especially etanercept, may also cause an SLE-like syndrome but with prominent skin lesions. Women are favored, and nephropathy and CNS involvement can occur. Again, the affected patients are ANA positive, but also anti-dsDNA antibody positive, and more than half are hypocomplementemic. Methimazole has been implicated in bullous SLE.

Numerous medications have been reported to produce cutaneous lesions characteristic of SCLE. The eruption begins days to years after starting the medications. Hydrochlorothiazide, diltiazem (and other calcium channel blockers), and terbinafine have been traditionally the most common causative agents, but proton pump inhibitors (due to being widely available) and TNF inhibitors are rapidly rising toward the top of the list of causative agents. Other causes include ACE inhibitors, statins, anticonvulsants, NSAIDs, paclitaxel, doxycycline, and even agents used to treat lupus (e.g., hydroxychloroquine, leflunomide) can induce SCLE. Patients with SCLE may also be ANA positive, but in addition have positive anti-SSA antibodies; antihistone antibodies are less common than in DIL. Cutaneous lesions are photod, but not photodistributed, annular or papulosquamous thin plaques. Treatment is as for SCLE, with sun avoidance, and topical and systemic corticosteroids as required. Drug withdrawal results in resolution over weeks to months. The positive serologies may decrease as the eruption improves. The pathogenesis of drug-induced SCLE is unknown, but most causative agents also cause both photosensitive and lichenoid drug eruptions. Patients with SCLE are more likely to be HLA-B8 or DR3 haplotype.

Hydroxyurea Dermopathy

Chronic use of hydroxyurea for chronic myelogenous leukemia, thrombocythemia, or psoriasis may be associated with the development of cutaneous lesions characteristic of dermatomyositis. Scaly, linear erythema of the dorsal hands, accentuated over the knuckles, is noted. There may be marked acral atrophy and telangiectasia. Elbow and eyelid involvement characteristic of dermatomyositis may also be seen. Biopsy shows vacuolar degeneration of the basal cells and an interface lymphocytic infiltrate. The skin lesions tend to improve over months, although the atrophy may not improve. Muscle disease is less common. Patients with hydroxyurea can also develop ulcerations on the lateral ankles, occasionally with withdrawal of therapy.

Bullous Dermatoses

Linear IgA disease is frequently associated with medication exposure, especially vancomycin (but also other antibiotics, NSAIDs, lithium, infliximab, and other agents). Men and women are equally affected, and the eruption usually begins within 2 weeks of vancomycin therapy. Clinical morphology is variable and can include flaccid or tense bullae, vesicles, erythematous papules or plaques, exanthematous morbilliform eruptions typical of a drug exanthem, and targetoid papules. TEN or severe SJS may be simulated, but mucosal involvement is only 30%–45% and conjunctival involvement, 10%. Histology will show subepidermal blistering with neutrophils and eosinophils in biopsies taken from bullous lesions with linear IgA on DIF. In cases with morbilliform and TEN/SJS–like lesions, the DIF is essential to make the diagnosis, as histology may show only a vacuolar/lichenoid dermatitis with eosinophils. Treatment is to stop the offending drug, use systemic corticosteroids in severe cases, or dapsone at 100–200 mg daily.

Drug-induced pemphigoid and other blistering disorders are discussed in Chapter 21.

Leukotriene Receptor Antagonist–Associated Churg-Strauss Syndrome

Asthma patients being treated with leukotriene receptor antagonists may develop a syndrome resembling Churg-Strauss vasculitis. It occurs 2 days to 10 months after the leukotriene receptor antagonist has been started. Inhaled fluticasone has also been reported to produce this syndrome. Involvement may be limited to the skin. Features of the syndrome include peripheral eosinophilia, pulmonary infiltrates, and, less often, neuropathy, sinusitis, pericardial effusion, and cardiomyopathy. Skin lesions occur in about half the patients and are usually purpuric and favor the lower legs. Histologically, the skin lesions show LCV with significant tissue eosinophilia. Perinuclear ANCA (p-ANCA) may be positive. Withdrawal of leukotriene receptor antagonist therapy may lead to improvement, but systemic therapy may be required. The neuropathy may be permanent. The pathogenesis of this drug-induced syndrome is unknown. Unopposed leukotriene B4 activity, a potent chemoattractant for eosinophils and neutrophils, may explain the clinical findings.

Adverse Reactions to Corticosteroids

Cutaneous reactions may result from topical, intralesional, subcutaneous, or systemic delivery of corticosteroids.

Topical Application

The prolonged topical use of corticosteroid preparations may produce distinctive changes in the skin. The appearance of these side effects depends on four factors: strength of the steroid, area to which it is applied, amount of coexistent sun damage at the site of application, and patient's predisposition to certain side

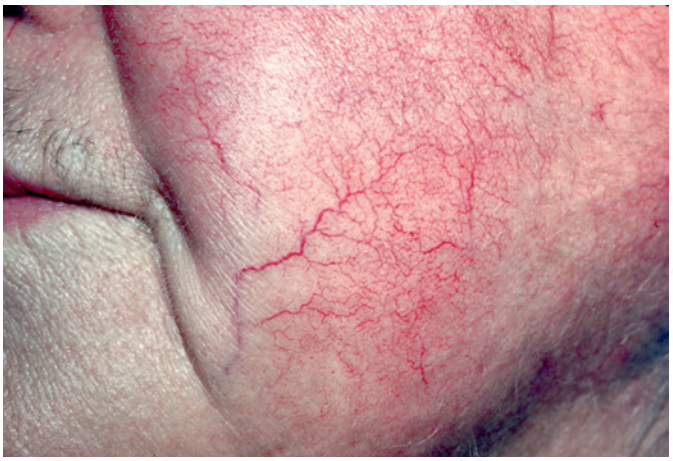

Fig. 6.47 Topical steroid-induced atrophy. (Courtesy Steven Binnick, MD.)

effects. Atrophy, striae, telangiectasia, skin fragility, and purpura are the changes most frequently seen. The most striking changes of telangiectasia are seen in fair-skinned individuals who use fluorinated corticosteroids on the face (Fig. 6.47). The changes in the skin are enhanced by occlusion. When these side effects occur, the strength of the steroid should be reduced or substituted with pimecrolimus or tacrolimus. Weekly pulse dosing of a potent topical corticosteroid can also reduce the incidence of side effects. Adjunctive measures to reduce steroid requirement could include addition of topical doxepin, pramoxine, or menthol and camphor to the regimen. Usually, the telangiectases disappear a few months after corticosteroid applications are stopped.

When corticosteroid preparations are applied to the face over weeks or months, persistent erythema with telangiectases, and often small pustules, may occur. Perioral dermatitis and rosacea may be caused by topical corticosteroids. Steroid rosacea has been reported from long-term use of 1% hydrocortisone cream. For this reason, the authors do not recommend chronic topical corticosteroid preparations of any strength in the adjunctive treatment of rosacea. A topical calcineurin inhibitor may be used instead as an antiinflammatory, although it can also induce a rosacea-like eruption. When a rosacea-like eruption appears in the setting of a topical antiinflammatory, a pustule should be opened and the contents examined for overgrowth of *Demodex* mites.

Repeated application of corticosteroids to the face, scrotum, or vulva may lead to marked atrophy of these tissues, including the red scrotum syndrome. The tissues become "addicted" to the topical steroid, so that withdrawing treatment results in severe itching or burning and intense erythema. Topical application of corticosteroids can produce epidermal atrophy with hypopigmentation. If used over large areas, sufficient topical steroids may be absorbed to suppress the hypothalamic-pituitary axis. This may affect the growth of children with atopic dermatitis and has led to addisonian steroid dependency and also Cushing syndrome. Atopic children with more than 50% BSA involvement have short stature. This may be related to their increased use of potent topical corticosteroids. In addition, bone mineral density is reduced in adults with chronic atopic dermatitis severe enough to require corticosteroid preparations stronger than hydrocortisone.

Injected Corticosteroids

Intralesional injection of corticosteroids is valuable in the management of many dermatoses. The injection of corticosteroids may produce subcutaneous atrophy at the site of injection. The injected corticosteroid may also migrate along lymphatic channels, causing not only local side effects but also linear, atrophic, hypopigmented hairless streaks. These may take years to resolve. These complications are best avoided by injecting directly into the lesion, not into the fat, and using only the minimal concentration and volume required. Triamcinolone acetonide, not hexacetonide, should be used for injecting cutaneous lesions.

Intramuscular steroid injections should always be given into the buttocks with a long needle (at least 1½ inches in adults). Injection of corticosteroids into the deltoid muscle sometimes causes subcutaneous atrophy. The patient becomes aware of the reaction by noticing depression and depigmentation at the site of injection. There is no pain, but it is bothersome cosmetically. The patient may be assured that this will fill in eventually but may take several years.

Systemic Corticosteroids

Prolonged use of corticosteroids may produce numerous changes of the skin. In addition, steroids have a profound effect on the metabolism of many tissues, leading to predictable, and sometimes preventable, complications. IM injections are not a safer delivery method than oral administration.

The skin may become thin and fragile. Spontaneous tearing may occur from trivial trauma. Purpura and ecchymoses are especially seen over the dorsal forearms in many patients over age 50, caused by aggravation of actinic purpura.

Cushingoid changes may occur, most commonly the alteration in fat distribution. Buffalo hump, facial and neck fullness, increased supraclavicular and suprasternal fat, gynecomastia, protuberant or pendulous abdomen, and flattening of the buttocks may occur. Aggressive dietary management with reduction in carbohydrate and caloric intake may ameliorate these changes.

Steroid-induced acne may develop as small, firm monomorphic follicular papules on the forehead, cheeks, and chest. Even inhaled corticosteroids for pulmonary disease can cause acne. Steroid acne can persist as long as the corticosteroids are continued. The management is similar to acne vulgaris with topical preparations and oral antibiotics.

Striae may be widely distributed, especially over the abdomen, buttocks, and thighs.

There may be generalized skin dryness (xerosis). The skin may become thin and fragile; keratosis pilaris may develop; persistent erythema of the skin in sun-exposed areas may occur, and erythromelanosis may rarely occur.

Hair loss occurs in about half of patients receiving long-term corticosteroids in large doses. There may be thinning and brittle fracturing along the hair shaft. Hair growth may be increased on the bearded area and on the arms and back with fine, vellus hairs.

Systemic complications may occur during prolonged systemic steroid therapy, including hypertension, peptic ulcer disease, diabetes, mood changes, cataracts, aseptic necrosis of the hip, and osteoporosis. Bone loss can occur early in the course of corticosteroid therapy, so it should be managed preemptively. Effective management can reduce steroid-induced osteoporosis. All patients with anticipated treatment courses longer than 1 month should be supplemented with calcium and vitamin D (1.0–1.5 g calcium and 400–800 U cholecalciferol daily). Smoking should be stopped and alcohol consumption minimized. Bone mineral density can be accurately measured at baseline with dual-energy x-ray absorptiometry (DEXA) scan and followed during corticosteroid therapy. Fracture risk assessment is essential, and most patients warrant up-front treatment with bisphosphonates (premenopausal women and younger men are a possible exception, depending on individual risks). Hypogonadism, which contributes to osteoporosis, can be treated in men and women with testosterone or estrogen, respectively. Implementation of bone loss prevention strategies by dermatologists is unacceptably low. Patients on concurrent aspirin or NSAIDs should consider proton pump inhibitor prophylaxis.

Patients are at risk for infection and should receive appropriate vaccination. Pneumocystis pneumonia (PCP) prophylaxis remains controversial and is not widely used.

7 Erythema and Urticaria

Bonus images for this chapter can be found online at expertconsult.inkling.com

FLUSHING

Flushing presents with transient erythema, usually localized to the face, neck, and upper trunk, and a sensation of warmth. Flushing may be physiologic or pathologic; though normally benign, causes range from emotions to hormones to medications and malignancy.

Menopausal flushing may be associated with perspiration, as is flushing induced by high ambient temperature, fever, or consumption of alcohol or hot or spicy foods and beverages. Flushing associated with medications, histamine, or serotonin is generally dry. Menopausal flushing may be age related, may be induced by oophorectomy or medication (tamoxifen, leuprolide acetate, treptorelin, clomiphene citrate, danazol), and may begin long before menses cease. Paraxetine, other antidepressants, or gabapentin may help. Men may also experience climacteric flushing after orchiectomy or antiandrogen therapy (flutamide).

Flushing may occur through thermoregulation. Blushing, or emotional flushing, may be either emotionally or physiologically induced. Simple facial redness may occur in individuals with translucent skin and is called anatomically predisposed blushing. Intense flushing may be associated with rosacea. In patients with rosacea, exercise, ambient heat or cold, spicy foods, alcohol, and hot beverages are common triggers for flushing. Topical cinnamic aldehyde can induce flushing. Drugs associated with flushing include niacin, hormonal agents, serotonin agonists, calcium channel blockers, cyclosporine, chemotherapeutic agents, antimicrobials (vancomycin, metronidazole, rifampin), disulfiram, bromocriptine, intravenous contrast material, vasodilators (nicotinic acid, nitroglycerine, sildenafil and related drugs), and glucocorticoids. Severe serotonin toxicity with flushing can be precipitated by the combination of a monoamine oxidase inhibitor and a selective serotonin reuptake inhibitor (SSRI). Reduced or absent methylnicotinate-induced flushing has been noted in patients with schizophrenia. This lack of flushing in response to methylnicotinate has been used for diagnostic psychiatric testing. Flushing after induction of general anesthesia with agents such as thiopental and muscle relaxants is more common in patients prone to blushing. It appears to be neuronally mediated rather than related to histamine release. Endogenous vasoactive substances are associated with flushing in carcinoid syndrome, mastocytosis, medullary thyroid carcinoma, and pheochromocytoma.

Some food additives, such as nitrites, sulfites, and spicy foods with capsaicin, can induce flushing; monosodium glutamate (MSG) has been reported to as well, but remains controversial. Nitrites are found in deli meats and cured meats, and sulfites are found in wine, dried fruit, prepared foods, and fresh grapes and potatoes. Scombroid fish poisoning from improperly refrigerated fish presents with flushing and systemic symptoms within 10–30 minutes of eating. Alcohol may produce flushing in patients using topical calcineurin inhibitors. Individuals who flush without an identifiable cause should be investigated for dietary triggers and subtle manifestations of rosacea.

Many cases of flushing remain idiopathic. Atypical causes or mimics include superior vena cava syndrome, thyroid disease, and malignancies (mastocytosis, pheochromocytoma, carcinoid syndrome, and others). Urinary catecholamines and serotonin and histamine metabolites should be measured if an endogenous cause is suspected.

The Women's Health Initiative studies concerning hormone replacement therapy (HRT) suggested that breast cancer risk is increased by combinations of estrogen and progestogen taken for longer than 5 years. Unopposed estrogen can increase the risk of endometrial carcinoma in premenopausal women. HRT does not appear to lower the risk of cardiac events, and the risks of long-term therapy often outweigh the benefits. Short-term HRT may still be very helpful in the management of perimenopausal flushing, because alternatives have generally been disappointing. Menopausal flushing may also respond to low-dose oral or transdermal estrogen. Flushing can be reduced by avoidance of alcohol, caffeine, and spicy foods. Niacin-induced flushing is mediated by prostaglandin D2 (PGD2). PGD2 shows some response to aspirin, as well as the PGD2 receptor-1 antagonist laropiprant.

ERYTHEMAS

The term *erythema* means blanchable redness (hyperemia) of the skin. A number of reactive skin conditions are referred to as erythema. These include toxic erythemas related to viral and bacterial infections, erythema multiforme, erythema nodosum, and the gyrate (figurate) erythemas.

Erythema Palmare

Erythema palmare, or persistent palmar erythema, is usually most marked on the hypothenar areas and is associated with an elevated level of circulating estrogen. Cirrhosis, hepatic metastases, and pregnancy are common causes. Hereditary palmar erythema (Lane disease) has been rarely reported.

Generalized Erythema

Generalized erythema may be caused by medications, bacterial toxins, or viral infection. It is often uneven in distribution, being most noticeable on the chest, proximal extremities, and face. In general, these reactions are self-limited and resolve when the offending medication is stopped or the associated infection is treated or resolves. Specific exanthems associated with bacterial or viral infections are discussed in Chapters 14 and 19.

Erythema Toxicum Neonatorum

Erythema toxicum neonatorum occurs in a quarter to under half of healthy full-term newborns, usually on the second or third day of life. Because it is so common, dermatologists are usually consulted only for the most florid or atypical cases. Characteristically, the broad erythematous flare is much more prominent than the small follicular papule or pustule it surrounds (Fig. 7.1). Lesions involve the face, trunk, and proximal extremities and appear rarely on the soles or palms. There may be confluent erythema on the face. Fever is absent, and the eruption generally disappears by the

Fig. 7.1 Erythema toxicum neonatorum.

Fig. 7.2 Erythema multiforme, target lesions.

10th day. Erythema toxicum must be distinguished from miliaria, bacterial folliculitis, neonatal herpes, and scabies. When the rash is atypical, smears of the pustules demonstrating eosinophils are adequate to confirm the diagnosis. Rarely, a biopsy is required and demonstrates folliculitis containing eosinophils and neutrophils.

Reginatto FP, et al: Prevalence and characterization of neonatal skin disorders in the first 72h of life. J Pediatr 2017; 93: 238.

Erythema Multiforme

In 1860 von Hebra first described erythema exudativum multiforme. The original disease described by von Hebra is now called erythema multiforme minor (minus) or herpes simplex–associated erythema multiforme. It is strongly associated with a preceding herpetic infection. When multiple mucous membranes are involved, the lesions are more intense, and fever or arthralgias accompany the eruption, erythema multiforme major (majus) is diagnosed. This is most often caused by *Mycoplasma* infection. In contrast, Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN) usually represent adverse reactions to medications (see Chapter 6). As treatment and prognosis are related in part to the inciting agent, it is useful to classify erythema multiforme (EM) as follows:

- Herpes simplex–associated EM (HAEM)
- Erythema multiforme major (most often caused by *Mycoplasma;* some suggest the term *mycoplasma pneumonia-induced rash and mucositis*)
- Chronic oral EM
- Contact dermatitis–induced EM (see Chapter 6)
- Radiation-induced EM (see Chapter 6)
- Idiopathic

Clinical Features

HAEM (erythema multiforme minor) is a recurrent self-limited disease, usually of young adults, occurring seasonally in the spring and fall, with each episode lasting 1–4 weeks. The individual clinical lesions begin as sharply marginated, erythematous macules, which become raised, edematous papules over 24–48 hours. The lesions may reach several centimeters in diameter. Typically, a ring of erythema forms around the periphery, and centrally the lesions become flatter, more purpuric, and dusky. This lesion is the classic "target" or "iris" lesion with three zones: central dusky purpura; an elevated, edematous, pale ring; and surrounding macular erythema (Figs. 7.2 and 7.3). The central area may be bullous.

Fig. 7.3 Erythema multiforme involving dorsal hands and penis.

Typical targets are best observed on the palms and soles. Lesions generally appear symmetrically and acrally, with initial involvement most frequently on the dorsal hands. The dorsal feet, extensor limbs, elbows, knees, palms, and soles typically become involved. In about 10% of patients, more widespread lesions occur on the trunk. The Koebner phenomenon or photoaccentuation may be observed. Mucosal involvement occurs in 25% of cases and is usually limited to the oral mucosa. Oral lesions may appear as indurated plaques, target lesions, or erosions (Fig. 7.4).

An atypical variant of HAEM has been described in women. It consists of outbreaks of unilateral or segmental papules and plaques that may be few in number or solitary. Lesions may be up to 20 cm in diameter. The plaques are erythematous and evolve to have a dusky center, which desquamates. Subcutaneous nodules resembling erythema nodosum may be simultaneously present. Histologic examination shows features of EM, and herpes simplex virus (HSV) DNA may be identified in the lesions by polymerase chain reaction (PCR). Acyclovir suppression prevents the lesions.

Erythema multiforme major is frequently accompanied by a febrile prodrome and sometimes arthralgias. It occurs in all ages, is centered on the extremities and face, but more often than EM minor may include truncal lesions, which are papular and erythematous to dusky in color. Mucous membrane disease is prominent and often severely involves the oral mucosa and lips with hemorrhagic sloughing; less commonly the genital and ocular mucosa may be involved as well (Fig. 7.5). SJS is distinguished morphologically by the presence of purpura or bullae in macular lesions of the trunk (Fig. 7.6). In children, polycyclic urticarial

Fig. 7.4 Mucosal lesions of erythema multiforme.

Fig. 7.5 Ocular erythema multiforme.

Fig. 7.6 Stevens-Johnson syndrome.

lesions often become dusky centrally and are frequently misdiagnosed as EM. This presentation of urticaria has been dubbed "urticaria multiforme." It represents urticaria, and histologic changes of EM are never present.

Etiologic Factors

Typical EM minor is usually associated with a preceding orolabial HSV infection. HAEM lesions appear 1–3 weeks (average 10 days) after the herpes outbreak. Episodes of EM minor may not follow every episode of herpes, and some EM outbreaks will not be preceded by a clinically recognizable herpetic lesion. Using PCR and in situ hybridization techniques, HSV DNA and antigens have been found in the lesions of EM minor. The majority of "idiopathic" cases of EM minor are associated with recurrent HSV infection, and patients may be successfully treated with suppressive antiviral regimens. Autoantibodies have been reported to a number of desmosomal adherence molecules, but whether these are pathogenic or incidental (due to epitope spreading from repeated exposure) is unclear. EM major is associated with *Mycoplasma* infections, although a minority may result from herpes simplex and a reaction to medications.

Histopathology

The histologic features are similar in HAEM and EM major and are not predictive of etiology. The extent of epidermal involvement depends on the duration of the lesion and where in the lesion the biopsy is taken. All lesions are characterized by cellular necrosis. Biopsies of EM demonstrate a normal basket-weave stratum corneum and a vacuolar interface reaction. Vacuoles and foci of individual cell necrosis are present and out of proportion to the number of lymphocytes. The dermal infiltrate is largely mononuclear and tends to be primarily around the upper dermal vessels and along the dermoepidermal junction. Activated T lymphocytes are present in lesions of EM, with cytotoxic or suppressor cells more prominent in the epidermis and helper T cells in the dermis. Leukocytoclastic vasculitis is not observed. Eosinophils may be present but are rarely prominent. The presence of eosinophils is not predictive of the etiology. Histologically, EM must be distinguished from the following:

- Fixed drug eruption, which often has a deeper infiltrate, eosinophils and neutrophils, papillary dermal fibrosis, and melanophages
- Graft-versus-host disease (GVHD), which typically has a more compact stratum corneum and involves the follicles
- Pityriasis lichenoides, which characteristically has a lymphocyte in every vacuole, erythrocyte extravasation, and neutrophil margination within dermal vessels
- Lupus erythematosus, which has compact hyperkeratosis, a deeper periadnexal infiltrate, dermal mucin, and basement membrane zone thickening

Differential Diagnosis

When characteristic target lesions are present, the diagnosis of EM is established clinically. When bullae are present, EM major must be distinguished from bullous arthropod reactions and autoimmune bullous diseases: pemphigus if mucous membrane involvement is prominent, and bullous pemphigoid if lesions are small and erythema is prominent at the periphery of the bulla. Paraneoplastic pemphigus may produce atypical target lesions, mucosal involvement, and a vacuolar interface dermatitis and may appear similar to *Mycoplasma*-induced EM major. Use of direct immunofluorescence may be necessary to exclude this possibility.

Treatment

Treatment of EM is determined by its cause and extent. EM minor is generally related to HSV, and prevention of herpetic outbreaks is central to control of the subsequent episodes of EM. A sunscreen lotion and sunscreen-containing lip balm should be used daily on the face and lips to prevent ultraviolet B (UVB)–induced outbreaks of HSV. If this does not prevent recurrence or if genital HSV is the cause, chronic suppressive doses of an oral antiviral drug (valacyclovir, 500 mg to 1 g/day, or famciclovir) may be used. If this dose is ineffective, it may be increased. This will prevent recurrences in up to 90% of HSV-related cases. Intermittent treatment with systemic antivirals or the use of topical antivirals is of minimal benefit in preventing HAEM. It should be noted that most cases of EM minor (HAEM) are self-limited, and symptomatic treatment may be all that is required. Symptoms related to oral lesions often respond to topical "swish and spit" mixtures containing lidocaine, diphenhydramine (Benadryl), and kaolin. In extensive cases of EM minor, intermittent steroids, or chronic dapsone, cyclosporine, azathioprine, or thalidomide may occasionally be helpful. Apremilast and rituximab have recently been reported for recalcitrant cases. If HSV infection is present, concurrent antivirals should be used. For patients with widespread EM unresponsive to the previous therapies, management is as for severe drug-induced SJS (see Chapter 6).

Oral Erythema Multiforme

A unique subset of EM is limited to or most prominent in the oral cavity. Clinically, patients are otherwise well; 60% are female, with a mean age of 43 years. The minority, about 25%, have recurrent, self-limited, cyclic disease. The oral cavity is the only site of involvement in 45%, in 30% there is oral and lip involvement, and in 25% the skin is also involved. All portions of the oral cavity may be involved, but the tongue, gingiva, and buccal mucosa are usually most severely affected. Lesions are almost universally eroded, with or without a pseudomembrane. There are no well-designed trials of treatment for oral EM, but the treatments previously listed for EM minor are typically used; topical corticosteroids may be helpful (fluocinonide gel 0.05%). "Swish and spit" mixtures containing lidocaine, diphenhydramine, and kaolin are helpful for symptomatic relief; patients should be warned the anesthetic effect may dampen their gag reflex.

Gyrate Erythemas (Figurate Erythemas)

The gyrate erythemas are characterized by clinical lesions that are round (circinate), ringlike (annular), polycyclic (figurate), or arcuate. The primary lesions are erythematous and slightly elevated. There may be a trailing scale, as in erythema annulare centrifugum. In some of these diseases, the lesions are transient and migratory, and in some they are fixed. Gyrate erythemas often represent the cutaneous manifestations of an infection, malignancy, or drug reaction. Certain diseases in this group have specific causes (erythema marginatum of rheumatic fever, carrier state of chronic granulomatous disease, erythema migrans of Lyme borreliosis) and are discussed in the relevant chapters.

Fig. 7.7 Erythema annulare centrifugum.

Erythema Annulare Centrifugum

Erythema annulare centrifugum (EAC) is the most common gyrate erythema. It is characterized by asymptomatic annular or polycyclic lesions that grow slowly (2–3 mm/day), rarely reaching more than 10 cm in diameter. Characteristically, there is a trailing scale at the inner border of the annular erythema (Fig. 7.7). The surface is typically devoid of crusts or vesicles, although atypical cases with telangiectasia and purpura have been described. Lesions usually occur on the trunk and proximal extremities. Mucosal lesions are absent.

Histologically, the epidermis will show mild focal spongiosis and parakeratosis. Within the superficial dermis and at times the deep dermis, lymphocytes are organized tightly around the blood vessels in a pattern described as a "coat sleeve" arrangement. The gyrate erythemas are divided into the superficial and deep types, but these histologic types do not correlate with etiology.

Waxing and waning in severity, EAC tends to be recurrent over months to years. Most cases eventually subside spontaneously. While active, the eruption is often responsive to topical steroids. Topical calcipotriol has also been reported to be successful.

The majority of EAC cases are idiopathic. Some cases are clearly associated with dermatophytosis or the ingestion of molds, such as those in blue cheese. Other foods, such as tomatoes, are sometimes implicated, and a dietary journal may be helpful. Medications are implicated in some cases, and internal cancer has been found (solid organ and hematologic). Annually recurrent EAC has been reported. Laboratory tests should be dictated by the physical examination and associated signs and symptoms. In one study of 66 patients, 48% had an associated cutaneous fungal infection such as tinea pedis, and 13% had internal malignancies.

The differential diagnosis of EAC includes conditions that can have annular configuration, including granuloma annulare, secondary syphilis, tinea, subacute cutaneous lupus erythematosus, sarcoidosis, Hansen disease, erythema marginatum, erythema migrans, annular urticaria, and mycosis fungoides. Histologic examination,

Fig. 7.8 Erythema gyratum repens. (Courtesy Donald Lookingbill, MD.)

clinical features, and basic laboratory examinations will usually allow these diseases to be excluded.

Erythema Gyratum Repens

Erythema gyratum repens (EGR) is a rare disease that is striking and unique in appearance. Lesions consist of undulating wavy bands of slightly elevated erythema with trailing scale over the entire body. Lesions migrate rapidly (up to 1 cm/day) and are characteristically concentric, giving the skin a "wood grain" appearance (Fig. 7.8).

Pruritus may be severe, and blood eosinophilia is often found. In more than 70% of patients, an underlying malignancy is found. Lung cancer is the most common associated malignancy, although a wide range of neoplasms has been described. The skin eruption precedes the detection of the malignancy by an average of 9 months. Given the high frequency of malignant disease, patients with EGR should have extensive evaluations to exclude internal malignancy. If the carcinoma is removed, the lesions clear. Otherwise, the eruption is generally resistant to treatment, although cetirizine and topical corticosteroids have been reported to improve individual cases. EGR may rarely occur due to other causes, including medications, infections (pulmonary tuberculosis, cryptogenic organizing pneumonia), or other systemic diseases (rheumatoid arthritis). These patients respond to discontinuation of the implicated medication or to treatment of the underlying condition.

Eosinophilic Annular Erythema

Adults or children may develop bilateral annular erythema, usually presenting on the trunk and often symmetric. Females are the favored sex. Histologically a dense perivascular and interstitial lymphocytic infiltrate with many eosinophils is seen but without flame figures. Spontaneous resolution may occur. Hydroxychloroquine and/or prednisone are favored treatments when needed, though phototherapy, nicotinamide, and other treatments have been used. Normally an isolated occurrence, there are reports in the setting of thymoma, prostate cancer, and autoimmune pancreatitis.

Fig. 7.9 Wells syndrome (eosinophilic cellulitis).

Samotij D, et al: Erythema gyratum repens associated with cryptogenic organizing pneumonia. Indian J Dermatol Venereol Leprol 2016; 82: 212.

EOSINOPHILIC CELLULITIS (WELLS SYNDROME)

In 1971 Wells described four patients with acute onset of plaques resembling cellulitis that persisted for many weeks (Fig. 7.9). Wells syndrome occurs at all ages, and pruritus is common. The condition is typically recurrent, and individual episodes may be prolonged. Degranulation of dermal eosinophils produces the flame figures seen in histologic sections. These consist of dermal collagen with adherent eosinophil granules. Eosinophilic panniculitis may also be present.

It is unclear whether Wells syndrome is a distinct disorder sui generis or a reaction pattern to many possible allergic stimuli. Many (perhaps most) cases represent arthropod reactions. It has also been associated with onchocerciasis, intestinal parasites, varicella, mumps, immunization, drug reactions that include interferon (IFN) and the anti–tumor necrosis factor (TNF)–α biologic agents, hypereosinophilic syndrome, myeloproliferative diseases, angioimmunoblastic lymphadenopathy, solid organ malignancies, atopic diathesis, inflammatory bowel disease (IBD), eosinophilic granulomatosis with polyangiitis (EGPA, Churg-Strauss syndrome), and fungal infection. Reports of Wells in association with chronic lymphocytic leukemia may represent another form of exuberant arthropod response in that disease. Most cases resolve without therapy; treatment may include topical and intralesional corticosteroids, oral antihistamines, or tacrolimus ointment. Systemic therapy for severe cases may include doxycycline, minocycline, phototherapy, antimalarials, dapsone, colchicine, sulfasalazine, low-dose prednisone, azathioprine, cyclosporine. Despite that some cases may be caused by exposure to TNF inhibitors, adalimumab has been used as well. Any underlying disease or triggering factor, including arthropod bites, should be eliminated.

REACTIVE NEUTROPHILIC DERMATOSES

As with the gyrate erythemas, the reactive neutrophilic dermatoses tend to follow certain stimuli, such as acute upper respiratory tract infections (URIs) or medications, or are associated with underlying diseases, such as IBD and hematologic malignancy. Some of the neutrophilic dermatoses share common triggers, and clinical features may overlap. Patients may exhibit the simultaneous or sequential appearance of two or more of the conditions. Most often is the combination of typical lesions of Sweet syndrome on the upper body and erythema nodosum (EN)–like lesions on the legs. In these patients, histology often enables the diagnosis of subcutaneous Sweet syndrome for the EN-type lesions, allowing one diagnosis to be made. In occasional cases, however, it may be difficult to establish the diagnosis firmly as one of the neutrophilic reactive dermatoses. For these reasons, it is clinically useful to think of these diseases as forming a spectrum of conditions expressed in certain individuals by a group of stimuli with various overlapping morphologies.

Erythema Nodosum

Erythema nodosum is discussed in Chapter 23.

Sweet Syndrome (Acute Febrile Neutrophilic Dermatosis)

Since its first description in 1964 by Dr. Robert Sweet, as a recurrent febrile dermatosis in women, the spectrum of this syndrome has expanded. Sweet syndrome primarily affects adults, and females outnumber males (reports vary with ranges from 3:1 up to 8:1 predominance, though some recent reports demonstrate near equivalent sex distribution). In younger adults, female predominance is marked, but in persons older than 50, the gender ratio is more equal, and cases associated with malignancy have a 1:1 ratio. In children, boys and girls are equally affected. In Europe, cases are more common in the spring and fall. Four main subtypes of Sweet syndrome have been described, based on their pathogenesis: the classic type (majority of cases), cases associated with neoplasia (3%–35% of cases), cases associated with inflammatory disease (3%–16%), and cases associated with pregnancy (1%–4%); drug-induced cases exist as well (1%–26%).

The clinical features of all four subtypes are similar, although dusky bullous lesions that overlap with pyoderma gangrenosum (PG) are more common in patients with associated leukemia. The primary skin lesion is a sharply marginated, rapidly extending, tender, erythematous or violaceous, painful, elevated plaque, 2–10 cm in diameter. Lesions may appear intensely edematous ("juicy"), or merely indurated (Fig. 7.10). They typically involve the face (Fig. 7.11), neck, upper trunk, and extremities. Lesions may burn but do not itch. The surface of the plaques may develop pseudovesiculation or pustulation as a result of an intense dermal inflammatory infiltrate and accompanying dermal edema. Pathergy or koebnerization may occur in 25%–30% of patients, from trauma, biopsies, peripheral IV lines, and rarely from phototherapy or radiation. Clinical morphologic variants more recently described include immunocompromised patients with deep necrosis simulating necrotizing fasciitis and patients whose lesions were extremely large and described as giant cellulitis–like in appearance.

Fig. 7.10 Sweet syndrome with acute myelogenous leukemia.

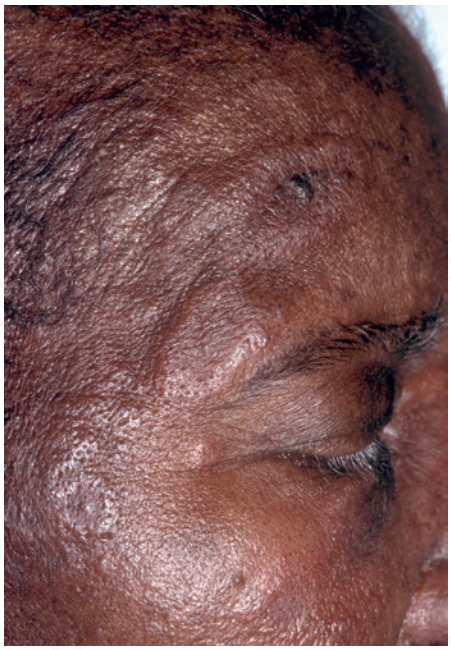

Fig. 7.11 Sweet syndrome.

More than three quarters of Sweet syndrome patients have systemic findings. The most common is fever, present in 50%–80% of patients. Arthritis, arthralgias, or myalgias occur in one third to two thirds of cases. About 30% of patients have conjunctivitis or episcleritis. Other ocular manifestations include periorbital inflammation, dacryoadenitis, limbal nodules, peripheral ulcerative keratitis, glaucoma, iritis, and choroiditis. Oral lesions resembling aphthae occur in 2% or 3% of classic cases, but in 10% or more of those associated with hematologic malignancy. Cough, dyspnea, and pleuritis may represent pulmonary involvement. Pulmonary infiltrates and effusions are often seen on chest radiographs of such patients. Rarely, there may be cardiac, renal, hepatic, intestinal,

and neurologic involvement. Multifocal sterile osteomyelitis may occur.

Laboratory findings include an elevated sedimentation rate (90%), neutrophilia (70%), leukocytosis (60%), and a left shift (increased bands; 50%). Patients with complete blood count (CBC) abnormalities may be more likely to have an underlying malignancy. Antineutrophilic cytoplasmic antibodies (ANCAs) have been rarely reported. In most cases, an attack lasts 3–6 weeks and then resolves. Recurrences may be seen with the same precipitating cause, such as URI. Persistent cases, with new lesions erupting before the old lesions resolve, may continue for many years.

The histologic hallmark of Sweet syndrome is a nodular and diffuse dermal infiltrate of neutrophils with karyorrhexis and massive papillary dermal edema. Leukocytoclastic vasculitis may be present focally, and this does not exclude a diagnosis of Sweet syndrome. Upper dermal edema may be so intense as to form subepidermal bullae. Leukemic cells may be present in the infiltrate, and clonal restriction of neutrophils has even been seen in Sweet syndrome not associated with malignancy.

Histologic variants described as histiocytic or lymphocytic Sweet syndrome have been reported. These entities are somewhat controversial, as Sweet syndrome is by definition a neutrophilic dermatosis. Occasionally, the main infiltrating cell resembles histiocytes, but in some studies with immunohistochemical stains, they are found to be immature myeloid cells, with positive myeloperoxidase stains. These can be mistaken for, and must be distinguished from, leukemia cutis. Patients with histiocytoid Sweets are more likely to have an underlying hematologic disorder or malignancy concurrent or shortly after the diagnosis is made.

The majority of cases of Sweet syndrome follow a URI or viral gastroenteritis and are therefore acute and self-limited. Other associated conditions include infections with *Yersinia*, toxoplasmosis, histoplasmosis, salmonellosis, tuberculosis, tonsillitis, vaccination, and vulvovaginal infections. Sweet syndrome has been reported in association with IBD and Behçet syndrome, and can develop in sites of lymphedema.

Hematologic malignancies or solid tumors are present in about 10% (3%–35% range) of reported cases. Sweet syndrome often presents early in the course of the cancer, but may present months to years before a diagnosis of malignancy is made. Sweet syndrome may occur with myelodysplastic syndromes or with hemoproliferative malignancies including leukemias (usually acute myelogenous) and lymphomas. One study reported an increased frequency of FLT3 mutations or del(5q) karyotype in AML patients with Sweets. Solid tumors are of any type but are most often genitourinary, breast (in women), or gastrointestinal (in men). Anemia is found in 93% of men and 71% of women with malignancy-associated Sweet syndrome. Thrombocytopenia is seen in half. Solitary, bullous, or ulcerative lesions are more frequently associated with malignancy, as is the histiocytoid histopathologic pattern.

Pregnancy-associated Sweet syndrome typically presents in the first or second trimester with lesions on the head, neck, trunk, and less often on the upper extremities. Lower-extremity lesions resembling EN may occur. The condition may resolve spontaneously or clear with topical or systemic corticosteroids. It may recur with subsequent pregnancies, but there seems to be no risk to the fetus.

Many drug therapies have been associated with Sweet-like reactions in the skin. The strongest association exists for granulocyte colony-stimulating factor (G-CSF). All-*trans*-retinoic acid (ATRA) and the new class of FLT3-inhibitors, which also have been reported to cause sweets, are, like G-CSF, often used in the treatment of diseases (such as leukemia) that themselves can be associated with Sweets, making causality assessments a challenge. Oral contraceptives, radiation therapy fields, radiocontrast dye, IFNs, interleukin-2 (IL-2), abatacept, TNF inhibitors, allopurinol, vaccines, multiple antineoplastic agents (bortezomib, gemcitabine, BRAF inhibitors, multikinase inhibitors, immunotherapy), anticonvulsants, antimicrobials (trimethoprim-sulfamethoxazole, minocycline, and many others), and azathioprine have been implicated. ATRA and FLT3 inhibitors cause terminal differentiation of some leukemic clones and are used to treat promyelocytic leukemia. After about 2 weeks of treatment, Sweet-like lesions may appear. Induction of the skin lesions appears to be related to the desired pharmacologic effect of the medication. ATRA has been reported to cause scrotal ulcers with neutrophils on histopathology; this is likely a site-specific manifestation of Sweet syndrome.

BOX 7.1 Revised Diagnostic Criteria for Diagnosis of Sweet Syndrome[a]

MAJOR CRITERIA

1. Abrupt onset of erythematous plaques or nodules, occasionally with vesicles, pustules, or bullae
2. Nodular and diffuse neutrophilic infiltration in the dermis with karyorrhexis and massive papillary dermal edema

MINOR CRITERIA

1. Preceded by a respiratory infection, gastrointestinal tract infection, or vaccination, or associated with the following:
   - Inflammatory disease or infection
   - Myeloproliferative disorders or other malignancy
   - Pregnancy
2. Malaise and fever (>38°C [100.4°F])
3. Abnormal laboratory findings ≥3 of the following:
   - Erythrocyte sedimentation rate >20 mm/hr
   - C-reactive protein elevated
   - Leukocytosis >8000/mm^3
   - Left shift with >70% neutrophils
4. Excellent response to treatment with systemic corticosteroids

[a]Both major criteria and two minor criteria are needed for diagnosis.

The two major criteria for the diagnosis of Sweet syndrome are the presence of red edematous plaques and a biopsy demonstrating neutrophils, karyorrhexis, and marked papillary dermal edema. Minor criteria include associated symptoms or conditions, laboratory findings, and response to therapy. Patients should have both major criteria and two of the four minor criteria for diagnosis (Box 7.1). Sweet syndrome is a diagnosis of exclusion, and often tissue culture is necessary to exclude infection. Bowel bypass syndrome has skin lesions that, on histologic examination, are identical to those of Sweet syndrome; fever and arthritis also accompany bowel bypass syndrome. Although it is easy to distinguish classic EN from Sweet syndrome, these two conditions share many features. Both occur most often in young adult women and frequently follow URIs. Both may be associated with pregnancy, underlying malignancy, and IBD. In both, fever and arthritis may occur, along with leukocytosis with neutrophilia. There are many reports of simultaneous or sequential EN and Sweet syndrome in the same patient. Leukemia-associated Sweet syndrome may overlap with pyoderma gangrenosum. A search for an underlying cause should be undertaken, especially in persons over age 50 and those with anemia, thrombocytopenia, histiocytoid pathology, or lesions that are bullous or necrotic. The standard treatment is systemic corticosteroids, with approximately 1–2 mg/kg/day of oral prednisone. This will result in resolution of fever and skin lesions within days. Topical or intralesional steroids may be tried for mild disease but are often ineffective. Dapsone, colchicine, potassium iodide (which may rarely cause paradoxic worsening similar to iododerma), sulfapyridine, doxycycline, clofazimine, and nonsteroidal antiinflammatory drugs (NSAIDs) may be helpful in chronic or refractory disease. Granulocyte adsorption apheresis,

Fig. 7.12 Neutrophilic dermatosis of the dorsal hands.

cyclosporine, intravenous immune globulin (IVIG), thalidomide/lenalidomide, methotrexate, rituximab, TNF inhibitors, and anakinra have been used for severe cases. Medication should be continued for several weeks to prevent relapse.

Neutrophilic Dermatosis of the Dorsal Hands

Neutrophilic dermatosis of the dorsal hands (NDDH) is a rare disease, which many consider a localized variant of Sweet syndrome, with similar age and sex distribution, presentation, and disease associations. Lesions of NDDHs present as edematous, pustular, or ulcerative nodules or plaques localized to the dorsal hands (Fig. 7.12); as palmar involvement has been described, some argue that the term NDDH is unnecessarily restrictive. Histologically, papillary dermal edema and a nodular and diffuse neutrophilic infiltrate with karyorrhexis are noted. Leukocytoclastic vasculitis may be present focally. Individual flares respond to prednisone and dapsone, but recurrences are common.

Neutrophilic Eccrine Hidradenitis

Neutrophilic eccrine hidradenitis is discussed in Chapter 33.

Marshall Syndrome

The rare Marshall syndrome is characterized by skin lesions resembling Sweet syndrome, which are followed by acquired cutis laxa. Cases occur primarily in children. Small red papules expand to urticarial, targetoid plaques with hypopigmented centers. Histologic evaluation of the skin lesions usually shows a neutrophilic dermatosis virtually identical to Sweet syndrome. Occasionally, an eosinophilic infiltrate will be found. The lesions resolve with destruction of the elastic tissue at the site, producing soft, wrinkled, skin-colored protuberant plaques that can be pushed into the dermis. Elastic tissue in other organs may also be affected, especially the heart and lungs. Some cases may be associated with α_1-antitrypsin deficiency.

Pyoderma Gangrenosum

Brunsting is credited with the initial clinical description of PG in 1930. PG is a rare disease that affects people of all ages, most commonly in the 40s to 60s, with a female predominance. Childhood cases are rare. Approximately 50% of patients with PG have an associated underlying medical condition or trigger, particularly inflammatory bowel disease, but also inflammatory arthritides and hematologic disorders (myelodysplastic syndrome, leukemia, immunoglobulin A [IgA] paraproteinemia, others); drug-induced cases exist but are rare. There are five clinical subtypes, with ulcerative the most common; others include bullous, vegetative, pustular, and peristomal.

Classic PG begins as an inflammatory pustule with a surrounding halo that enlarges and begins to ulcerate. A primary lesion may not always be seen as it can rapidly expand. Approximately 20%–30% of patients may exhibit pathergy, development of lesions from mild trauma. Satellite violaceous papules may appear just peripheral to the border of the ulcer and break down to fuse with the central ulcer, or multiple small erosions may develop concurrently and run together, resembling "cheese cloth" initially. Fully developed lesions are painful ulcers with undermined, purple to gray borders (Fig. 7.13). Lesions tend to be on the lower extremities and trunk. Lesions heal with characteristic thin, atrophic, crosslike "cribriform" scars.

Bullous PG is more superficial and less destructive than the ulcerative type. These red plaques become dusky and develop superficial erosions. These lesions have considerable overlap with "bullous Sweet syndrome" and are usually seen in patients with hematologic disorders (leukemia or myelodysplasia), and some argue whether these patients should not simply be diagnosed with Sweet syndrome.

Pustular PG consists of pustules that generally do not progress to ulcerative lesions. This forme fruste of PG is most often seen in IBD patients but can occur in other settings. Pyostomatitis vegetans and subcorneal pustular dermatosis are two other pustular neutrophilic diseases reported in association with PG, sometimes in patients with IgA gammopathy.

Vegetative PG is the least aggressive form of PG. Lesions present as chronic, superficial, cribriform ulcerations, usually of the trunk, that enlarge slowly and have elevated borders and clean

Fig. 7.13 Pyoderma gangrenosum.

bases. The lesions are rarely painful, generally respond to relatively conservative treatments, and are usually not associated with underlying systemic disease.

PG is rare in children. More than 40% of these patients have underlying IBD, and another 18% have leukemia. An association of childhood acquired immunodeficiency syndrome (AIDS) and PG has been documented. About one quarter of children with PG have no underlying disease. Genital and head/neck lesions can occur in children.

Overall, approximately 50% of patients with PG have an associated disease, most often IBD—both Crohn disease and ulcerative colitis. Between 1.5% and 5% of patients with IBD develop PG. The two diseases may flare together or run an independent course. Surgical removal of the diseased intestine may lead to complete remission of PG, or lesions may persist or first appear after removal of the affected bowel. If an ostomy is created, PG may present with peristomal erosions and ulcers, clinically similar to classic PG, but isolated to the abdomen near the stoma. Postoperative PG has also been reported following breast reconstructive surgery, and misdiagnoses of PG as necrotizing fasciitis leading to extensive debridement can be another dramatic presentation of postsurgical PG.

Many other associated conditions have been reported. Leukemia (chiefly acute or chronic myelogenous leukemia), myeloma, monoclonal gammopathy (chiefly IgA), polycythemia vera, myeloid metaplasia, chronic active hepatitis, hepatitis C, human immunodeficiency virus (HIV) infection, systemic lupus erythematosus, pregnancy, PAPA syndrome (see Autoinflammatory Syndromes next), and Takayasu arteritis are among the many diseases seen in conjunction with PG. Monoclonal gammopathy, usually IgA, is found in up to 10% of PG patients. Granulomatosis with polyangiitis (GPA; formerly Wegener) can present with "malignant pyoderma," cutaneous ulcerations that resemble PG but may in fact be cutaneous vasculitis. More than one third of PG patients have arthritis, usually an asymmetric, seronegative, monoarticular arthritis of the large joints. Children with congenital deficiency of leukocyte adhesion glycoproteins (LAD) develop PG-like lesions. There are increasing reports of PG occurring in hidradenitis suppurativa patients. Patients with PG may rarely develop extracutaneous organ inflammation, particularly sterile neutrophilic pulmonary infiltrates; the eyes, spleen, and musculoskeletal system may also be involved.

Early biopsies of PG show a suppurative folliculitis. The affected follicle is often ruptured. As the lesions evolve, they demonstrate suppurative inflammation in the dermis and subcutaneous fat. Massive dermal edema and epidermal neutrophilic abscesses are present at the violaceous, undermined border. These features are not diagnostic, and infectious causes must be excluded.

The clinical picture of PG, in the classic ulcerative form, is characteristic. Because no diagnostic serologic or histologic features exist, however, PG remains a diagnosis of exclusion. Clinical and pathologic correlation, coupled with extensive testing to exclude alternative etiologies, is essential. Many cases exist of PG being incorrectly diagnosed and patients treated with inappropriate immunosuppression. The initial workup of the patient includes studies necessary to ensure that the proper diagnosis is made, as well as to investigate possible associated diseases. Biopsy, tissue culture, evaluation for potential associated diseases such as IBD, hematologic disorders, inflammatory arthritis, and other entities is recommended. One large study of 356 cases of PG demonstrated that IBD is more common in patients younger than age 65 years, and malignancies and hematologic disorders are more common in patients over 65. Multiple infections, including mycobacteria, deep fungi, gummatous syphilis, synergistic gangrene, and amebiasis, must be excluded with cultures and special studies. Other disorders frequently misdiagnosed as PG include vascular occlusive or chronic venous disease, vasculitis, cancer, and exogenous tissue injury, including factitial disease. PG has been reported in association with levamisole-tainted cocaine.

The most difficult diagnosis to exclude is factitial disease. The clinical lesions may be strikingly similar, evolving from small papulopustules to form ulcerations that do not heal. Histologic evaluation will often simply show suppurative dermatitis, because the injected or applied caustic substance may not be identifiable (urine, disinfectants, drain cleaner). Even the most experienced clinician may misdiagnose factitial disease as PG.

Pyoderma gangrenosum may be misdiagnosed as a spider bite if there is only a solitary lesion on an extremity. Spider bites tend to evolve more rapidly and may be associated with other systemic symptoms or findings, such as disseminated intravascular coagulation.

Management of PG is challenging. Successful treatment requires both halting the inflammatory process and healing a large wound. Appropriate response to therapy is one of the minor diagnostic criteria, and if patients fail to respond, the diagnosis of PG should be questioned. If there is an underlying disease present, that should be identified and treated. The treatment is determined by the severity of disease and rate of progression. In rapidly progressive cases, aggressive early management may reduce morbidity.

Local treatment includes both proper wound care and medication to reduce inflammation; compresses or whirlpool baths are followed by the use of ointment or hydrophilic occlusive dressings. In solitary lesions or slowly progressive cases, application of potent topical corticosteroids, intralesional steroid injections, topical dapsone, or topical tacrolimus may be beneficial, although pathergy may be seen at sites of injection. The absorption of tacrolimus in large or multiple wounds may lead to systemic blood levels. Topical timolol has recently been described as beneficial in isolated reports. In general, the vegetative type will respond to topical or local measures.

For most cases, systemic treatment is indicated, with TNF inhibitors (infliximab in particular), systemic corticosteroids, and cyclosporine representing first-line treatments. Systemic corticosteroids can be extremely effective, with initial doses in the range of 1–2 mg/kg. If control is achieved, the dose may be rapidly tapered. If corticosteroid reduction is not possible, a steroid-sparing agent may be added. Severe patients may require pulse

methylprednisolone for 3–5 days, followed by prednisone tapering as the lesions heal. Initial doses of cyclosporine of approximately 4–5 mg/kg/day are effective in most cases, with the STOP GAP trial supporting efficacy at the 4-mg dose. The response is independent of any underlying cause. Infliximab has been shown to be effective in randomized trials, and is given in doses of about 5 mg/kg at weeks 0, 2, and 6 and then every 6–8 weeks.

Alternative treatment options or steroid-sparing agents for patients unable to taper include etanercept, adalimumab, alefacept, ustekinumab, mycophenolate mofetil (MMF), granulocyte apheresis IVIG, alkylating agents, and thalidomide. Anti–IL-1β agents such as canakinumab have been used in small studies with promising results. Systemic tacrolimus has been reported to help severe, recalcitrant cases. Sulfapyridine, sulfasalazine, salicylazosulfapyridine, dapsone, methotrexate, azathioprine, and minocycline generally are somewhat less effective but may be useful adjuncts or tried for patients with either mild disease, or contraindications/comorbidities that preclude more potent agents.

Patients typically show response within 1–2 weeks of initiation of therapy, with reduced pain, decreased exudate, and less erythema and edema. Systemic therapy should be tapered as the inflammation recedes. Often patients have a large wound, but the inflammation is under control—ongoing high-dose immunosuppression may not be necessary in these cases. Optimal wound care is essential, including compression if edema is present, though caution should be used to avoid compression-induced pathergy. Most wound care consists of keeping the wound clean and avoiding colonization, biofilm, or infection; Vaseline and impregnated nonstick gauze may help avoid trauma with dressing changes. Alginates or other absorptive dressings may be required for very exudative wounds. Epidermal allografts or autografts may be applied soon after PG is controlled. Pathergy is rarely noted at the donor site when patients are receiving adequate immunosuppressive therapy.

AUTOINFLAMMATORY SYNDROMES

The autoinflammatory syndromes are a group of disorders characterized by bouts of systemic inflammation related to dysregulation of the innate immune system. There are over 30 monogenic diseases described, many of which are related to excessive IFN and/or IL-1 signaling, sometimes referred to as inflammasomopathies or interferonopathies. These generally cause hereditary periodic fevers along with clinical and laboratory evidence of inflammation. These conditions present most often in children with episodes that often include fever and symptoms related to the skin, gastrointestinal (GI) tract, eyes, chest, musculoskeletal system, and central nervous system. Inflammatory skin lesions are often prominent manifestations, especially acne, PG, and erysipelas-like and urticaria-like lesions. Nonspecific elevations of erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are often seen.

Familial Mediterranean fever (FMF) is the most common monogenic inherited autoinflammatory syndrome and was the first recognized. FMF is an autosomal recessive disease caused by mutation in the *MEFV* gene, which produces pyrin, and affects IL-1b production downstream, but approximately 30% of patients with a similar phenotype lack a detectable gene defect. Clinically it is characterized by recurrent attacks of 12–72 hours of fever and a monoarthritis with overlying erysipelas-like erythema. Multiple diagnostic criteria have been proposed. Peritonitis, pleuritis, arthritis, and vasculitis, including Henoch-Schönlein purpura, may also occur in these patients, who usually present before the teenage years. Colchicine is the mainstay of treatment for FMF patients and can reduce the risk of associated amyloidosis. Anti–IL-1 treatment can be used in patients who fail to improve on colchicine.

The PAPA syndrome is an autosomal dominant disorder characterized by pyogenic sterile arthritis, PG, and acne and is caused by proline-serine-threonine-phosphatase–interacting protein 1 *(PSTPIP1)* or CD2-binding protein 1 *(CD2BP1)* gene mutations. PSTPIP1/CD2BP1, a tyrosine-phosphorylated protein involved in cytoskeletal organization, interacts with pyrin, the gene product important in the pathogenesis of FMF. Pyogenic arthritis, PG, acne, and suppurative hidradenitis (PA-PASH) syndrome has also been described, and PG, acne, and suppurative hidradenitis (PASH) syndrome has been reported with PSTPIP1 mutations as well.

The TNF-receptor–associated periodic syndrome (TRAPS) is similar to FMF but shows autosomal dominant inheritance, longer attacks, and a lack of response to colchicine. TRAPS is associated with mutations in the *TNFRSF1A* gene, resulting in decreased serum-soluble TNF receptor and excessive IL-1b secretion. TRAPS and deficiency of the IL-36 receptor antagonist (DITRA) are the most common autoinflammatory syndromes with onset in adulthood. Febrile episodes of 1–3 weeks are accompanied by periorbital edema, abdominal pain, myalgia, and a painful, distally migrating erythematous or urticarial-like plaques often overlying areas of myalgia. NSAIDs or prednisone can treat the acute episodes; anti–TNF-receptor antagonists or anakinra and other anti–IL-1 agents may prevent bouts.

An autosomal recessive DITRA is due to mutations in *IL36RN* leading to episodes of generalized pustular psoriasis, nail dystrophy, and geographic tongue. Treatment is as for pustular psoriasis. Deficiency of the IL-1 receptor antagonist (DIRA) also manifests as a pustular eruption, although onset is in the neonatal period.

Bone lesions, oral ulcers, and other findings are all reversed dramatically by anakinra, though steroids and traditional psoriasis treatments, including retinoids, have been used.

Deficiency of IL-1 receptor antagonist (DIRA) is a very rare autosomal recessive disease due to mutations in *IL1RN* that can present with neonatal sterile osteomyelitis, periostitis, and pustulosis. Deficiency of ADA2 (DADA2 syndrome) due to *CECR1* mutations has been described as early-onset stroke, intermittent fevers, and systemic vasculopathy, which can present with livedo racemosa, polyarteritis nodosa, or Raynaud phenomenon. TNF inhibitors are often used.

The recessively inherited hyper-IgD syndrome (HIDS), associated with mutations in the mevalonate kinase *(MVK)* gene, leading to MVK deficiency, also increases IL-1 and presents with hereditary periodic fever. Patients have fevers, lymphadenopathy, GI, musculoskeletal, and neurologic issues, in addition to mucocutaneous findings. Two thirds of patients manifest various morbilliform or urticarial eruptions and may develop aphthous stomatitis or genital ulcerations. NSAIDs, TNF inhibitors, or anti–IL-1 agents are generally used, though statins and colchicine have also been tried with limited success.

There are three autosomal dominant cryopyrin-associated periodic syndromes associated with mutations of *NLRP3*, which encodes cryopyrin and is involved in the IL-1 pathway. Familial cold autoinflammatory syndrome is characterized by fever, cold urticaria, conjunctivitis, and arthralgia elicited by generalized exposure to cold. Patients with Muckle-Wells syndrome manifest most often in adolescence with acute febrile inflammatory episodes comprising abdominal pain, arthritis, urticaria, hearing loss, and multiorgan amyloidosis. Neonatal-onset multisystem inflammatory disease is characterized by fever, chronic meningitis, uveitis, sensorineural hearing loss, urticarial rash, and a deforming arthritis. Patients may also have dysmorphic facial appearance, clubbing of the fingers, mild mental retardation, and papilledema. A second familial cold autoinflammatory syndrome is similar in its clinical findings but is related to mutations in the *NALP12* gene. Given the characteristic overproduction of IL-1, the mainstay of treatment is anti–IL-1 therapy with anakinra or canakinumab.

Blau syndrome is an autosomal dominant disease with arthritis, uveitis, granulomatous inflammation, and camptodactyly. It is associated with mutations in the *NOD2* gene, which also predisposes to Crohn disease and early-onset sarcoidosis. Another acquired syndrome, consisting of dermatitis, fever, arthritis, and serositis, without autoantibody formation and with the occurrence of a *NOD2* mutation, has been described in 22 patients. The dermatitis was polymorphic, but many patients had papules and plaques on the face, trunk, and extremities. Biopsies were also variable. The authors named it NOD2-associated autoinflammatory disease; the only effective therapy was prednisone or topical corticosteroids. Last, two patients with urticarial lesions that burned rather than itched had accompanying fever, or arthralgias, and/or laboratory markers of systemic inflammation, such as a high ESR or CRP. They did not respond to antihistamines but did respond to anakinra, suggesting their urticarial lesions were mediated by IL-1 and fit into this acquired autoinflammatory disease spectrum. This disease was dubbed "neutrophilic urticaria with systemic inflammation," which is differentiated from prior reports of neutrophilic urticaria.

Interferon-mediated diseases can cause autoinflammatory syndromes due to upregulated IFN signaling. These are very rare, but the list of identified gene mutations and syndromes is growing. Given signaling through the Janus kinases (JAKs), signal transducer and activator of transcription (STAT) pathway, experimental treatments with JAK inhibitors or IFN-targeting therapies are often employed. Aicardi-Goutières syndrome involves mutations in *TREX1* and involves neurologic disease, developmental delay, and a variety of skin rashes, including chilblain lesions. Stimulator of interferon genes-associated vasculopathy with onset in infancy (SAVI) patients present with erythematous or purpuric patches and plaques on cold-sensitive areas such as the cheeks, nose, ears, and acral sites. These may ulcerate and cause tissue loss. Chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) involves mutations in proteasome components, which leads to increased cell stress and proinflammatory cytokines. Patients present in the newborn period with fever; swollen purplish red eyelids; red and purplish papules and plaques of the trunk, neck, and extremities; and lipodystrophy of the face, along with other systemic findings. The skin biopsy reveals atypical cells of the myelocytic lineage in the dermis. It is caused by a mutation in the *PSMB8* gene.

URTICARIA (HIVES)

Urticaria is a vascular reaction of the skin characterized by the appearance of wheals (Fig. 7.14), generally surrounded by a red halo or flare and associated with severe itching, stinging, or pricking sensations. These wheals are caused by localized edema. Clearing of the central region may occur, and lesions may coalesce, producing an annular or polycyclic pattern. Subcutaneous swellings (angioedema) may or may not accompany the wheals. When angioedema is not present, and fever, malaise, and joint/bone pain coexist, an autoinflammatory or autoimmune condition should be considered.

Schnitzler syndrome is another diagnosis to consider. This rare acquired disorder is a combination of chronic nonpruritic urticaria, fever of unknown origin, disabling bone pain, hyperostosis, increased ESR, and monoclonal immunoglobulin M (IgM)

Fig. 7.14 Acute urticaria.

gammopathy. Pruritus is not generally a feature. The age of onset ranges from 29–77 years, without gender predilection. The skin biopsy most often reveals a predominant neutrophilic perivascular and interstitial infiltrate, although about one third of cases are mononuclear. In some patients, the IgM gammopathy progresses to neoplasia, especially Waldenström macroglobulinemia. Effective therapy for patients with Schnitzler syndrome has included anakinra, rituximab, tocilizumab, rilonacept, and canakinumab.

Classification

Acute urticaria evolves over days to weeks, producing evanescent wheals that, individually, rarely last more than 12 hours, with complete resolution of the urticaria within 6 weeks of onset. Daily episodes of urticaria and/or angioedema lasting more than 6 weeks are designated chronic urticaria. Chronic urticaria predominantly affects adults and is twice as common in women as in men.

More than 50% of cases of chronic urticaria are of unknown causation and are called chronic spontaneous urticaria. Physical stimuli may produce urticarial reactions and represent up to 35% of cases of chronic urticaria. The physical urticarias include dermatographic, cold, heat, cholinergic, aquagenic, solar, vibratory, galvanic, and exercise-induced cases. Physical urticaria usually coexists with chronic spontaneous urticaria.

Etiologic Factors

In general, infections, ingestants, inhalants, and injections should be considered as possible underlying causes of urticaria. In acute spontaneous cases, URIs and viral infections are the most common etiologies in children. Drugs (e.g., NSAIDs, antibiotics) and foods are other common causes in both adults and children. Clues suggesting physical urticaria as both a primary cause and as a coexistent second etiology should be sought historically.

In addition to streptococcal and viral URIs, the possibility of localized infection in the tonsils, a tooth, sinuses, gallbladder, prostate, bladder, or kidney should be considered. Treatment with antibiotics for *Helicobacter pylori* has led to resolution of the urticaria. Chronic viral infections, such as hepatitis B and C, may cause urticaria (Fig. 7.15). Acute infectious mononucleosis and psittacosis may also be triggering conditions. Helminths may cause urticaria and include *Ascaris*, *Ankylostoma*, *Strongyloides*, *Filaria*, *Echinococcus*, *Schistosoma*, *Trichinella*, *Toxocara*, and liver fluke.

Fig. 7.15 Urticaria secondary to hepatitis B.

The most allergenic foods are chocolate, shellfish, nuts, peanuts, tomatoes, strawberries, melons, pork, cheese, garlic, onions, eggs, milk, and spices. Food allergens that may cross-react with latex include chestnuts, bananas, passion fruit, avocado, and kiwi. Food additives and preservatives are also implicated in some cases. Natural food additives that may be implicated in urticaria include yeasts, salicylates, citric acid, egg, and fish albumin. Synthetic additives include azo dyes, benzoic acid derivatives, sulfite, and penicillin.

Inhalants that have caused urticaria include grass pollens, house dust mites, feathers, formaldehyde, acrolein (produced when frying with lard or by smoking cigarettes containing glycerin), castor bean or soybean dust, cooked lentils, cottonseed, animal dander, cosmetics, aerosols, pyrethrum, and molds.

Injections of both prescribed and recreational drugs, as well as vaccinations, should be considered in the historical data obtained.

Nonimmunologic mechanisms can produce mast cell degranulation. Common triggers include opiates, polymyxin B, tubocurarine, radiocontrast dye, aspirin, other NSAIDs, vancomycin, tartrazine, and benzoate.

Physical (Inducible) Urticarias

Specific physical stimuli cause up to 35% of all urticarias and occur most frequently in persons age 17–40. The most common form is dermatographism, followed by cholinergic urticaria and cold urticaria. Several forms of physical urticaria may occur in the same patient. Physical urticarias, particularly dermatographic, delayed pressure, cholinergic, and cold urticarias, are frequently found in patients with chronic idiopathic urticaria. Provocative testing off of all treatment at sites not recently affected by urticaria is a useful diagnostic maneuver, and repeated testing with treatment may help gauge therapeutic response. Treatment may be avoidance of the provocative stimulus and often antihistamines, as discussed later for chronic urticaria.

Dermatographism. Dermatographism is a sharply localized edema or wheal, with a surrounding erythematous flare occurring in seconds to minutes after the skin has been stroked (Fig. 7.16). It affects 2%–5% of the population. Dermatographism may arise spontaneously after drug-induced urticaria and persist for months. It has also been reported to be associated with the use of the H2 blocker famotidine. It may occur in hypothyroidism and hyperthyroidism, infectious diseases, diabetes mellitus, and during onset of menopause. It may be a cause of localized or generalized pruritus. Antihistamines suppress this reaction. The addition of an H2 antihistamine may be of benefit. Phototherapy has been used for severe cases.

Cholinergic Urticaria. Cholinergic urticaria, produced by the action of acetylcholine on the mast cell, is characterized by minute, highly pruritic, punctate wheals or papules 1–3 mm in diameter and surrounded by a distinct erythematous flare (Fig. 7.17). These lesions occur primarily on the trunk and face. The condition spares the palms and soles. Lesions persist for 30–90 minutes and are followed by a refractory period of up to 24 hours. Bronchospasm may occur. Familial cases have been reported.

The lesions may be induced in the susceptible patient by increasing the core body temperature with either exercise or a warm bath to raise core temperature by 0.7–1.0°C (1.2–1.8°F). In some cases, an attack may be aborted by rapid cooling of the body, as by taking a cold shower. Cholinergic dermatographism is noted in some patients.

Antihistamines suppress this reaction. The addition of an H2 antihistamine may be of benefit. Antihistamines have been combined with other agents, such as montelukast and propranolol. Attenuated

Fig. 7.16 Dermatographism.

Fig. 7.17 Cholinergic urticaria.

androgens, such as danazol, may be of benefit in patients with refractory cholinergic urticaria. Omalizumab has been used in a refractory case.

Adrenergic Urticaria. Adrenergic urticaria may occur alone or may coexist with cholinergic urticaria. Bouts of urticaria are mediated by norepinephrine. The eruption consists of small (1–5 mm) red macules and papules with a pale halo, appearing within 10–15 minutes of emotional upset, coffee, or chocolate. Serum catecholamines, norepinephrine, dopamine, and epinephrine may rise greatly during attacks, whereas histamine and serotonin levels remain normal. Propranolol, 10 mg four times daily, is effective; atenolol has been ineffective. Anxiolytic benzodiazepines have been used in a refractory case. A provocative test consists of intradermal administration of 3–10 ng of norepinephrine.

Cold Urticaria. Exposure to cold may result in edema and whealing on the exposed areas, usually the face and hands. The urticaria does not develop during chilling, but on rewarming. This heterogeneous group of disorders is classified into primary (essential), secondary, and familial cold urticaria.

Primary (essential) cold urticaria is not associated with underlying systemic diseases or cold-reactive proteins. Symptoms are usually localized to the areas of cold exposure, although respiratory and cardiovascular compromise may develop. Fatal shock may occur when these persons go swimming in cold water or take cold showers. This type of cold urticaria usually begins in adulthood. It usually yields a positive ice cube test result. Antihistamines suppress this reaction. The addition of an H2 antihistamine may be of benefit. Desensitization by repeated, increased exposures to cold has been effective in some cases. Anti–IL-5 therapy with reslizumab or omalizumab has been reported to help severe cases, with one randomized trial of 31 patients stopped early due to benefit from omalizumab at 150 mg or 300 mg doses. In many patients, cold urticaria will resolve after months, although about 50% of patients have symptomatic disease for years. As a provocative test, a plastic-wrapped ice cube is applied to the skin for 5–20 minutes. If no wheal develops, the area should be fanned for an additional 10 minutes. The use of a combination of cold and moving air is, in some cases, more effective in reproducing lesions than cold alone. The provocative test is not performed if secondary cold urticaria is being considered.

Secondary cold urticaria is associated with an underlying systemic disease, such as cryoglobulinemia. Other associations include cryofibrinogenemia, multiple myeloma, secondary syphilis, hepatitis, and infectious mononucleosis. Patients may have headache, hypotension, laryngeal edema, and syncope. An ice cube test is not recommended because it can precipitate vascular occlusion and tissue ischemia.

Familial cold autoinflammatory syndrome is grouped with the other autoinflammatory syndromes discussed earlier. The lesions produce a burning sensation rather than itching. They may have cyanotic centers and surrounding white halos and last for 24–48 hours. They may be accompanied by fever, chills, headache, arthralgia, myalgia, and abdominal pain. A prominent feature is leukocytosis, which is the first observable response to cold. Familial cold urticaria will yield a negative ice cube test result.

Heat Urticaria. Within 5 minutes of the skin being exposed to heat above 43°C (109.4°F), the exposed area begins to burn and sting, then becomes red, swollen, and indurated. This rare type of urticaria may also be generalized and is accompanied by cramps, weakness, flushing, salivation, and collapse. Heat desensitization may be effective. As a provocative test, apply a heated cylinder, 45°C (113°F), to a small area of skin on the upper body for 5 minutes.

Solar Urticaria. Solar urticaria appears soon after unshielded skin is exposed to sunlight. It is classified by the wavelengths of light that precipitate the reaction. Visible light can trigger solar urticaria, and sunscreens may not prevent it. Angioedema may occasionally occur. Solar urticaria may be a manifestation of porphyria, leukocytoclastic vasculitis, and EGPA (Churg-Strauss syndrome). Treatment is sun avoidance, sunscreens, antihistamines, or repetitive phototherapy; omalizumab has been recently used with success. (Solar urticaria is reviewed more extensively in Chapter 3.)

Pressure Urticaria (Delayed Pressure Urticaria). Pressure urticaria is characterized by the development of swelling with pain that usually occurs 3–12 hours after local pressure has been applied. It occurs most frequently on the feet after walking and on the buttocks after sitting. It is unique in that there may be a latent period of as long as 24 hours before lesions develop. Arthralgias, fever, chills, and leukocytosis can occur. The pain and swelling last for 8–24 hours. Pressure urticaria may be seen in combination with other physical urticarias. As a provocative test, a 15-lb weight is suspended from the shoulder by a 3-cm strap for 20 minutes and the area inspected after 4–8 hours (Fig. 7.18).

Fig. 7.18 Delated pressure urticaria.

Antihistamines may suppress this reaction. The addition of an H2 antihistamine or montelukast may be of benefit. Systemic corticosteroids are often therapeutic but are generally unsuitable for long-term use. Tranexamic acid, high-dose IVIG, TNF inhibitors, IL-1 inhibitors, and omalizumab have been used in refractory cases.

Exercise-Induced Urticaria. Although both cholinergic urticaria and exercise urticaria are precipitated by exercise, they are distinct entities. Raising the body temperature passively will not induce exercise urticaria, and the lesions of exercise urticaria are larger than the tiny wheals of cholinergic urticaria. Urticarial lesions appear 5–30 minutes after the start of exercise. Anaphylaxis may be associated. Atopy is common in these patients, and some have documented food allergy. Some patients only have such a reaction after eating celery before exercise. Avoiding these allergens may improve symptoms.

Antihistamines suppress the exercise-induced reaction. The addition of an H2 antihistamine may be of benefit. Self-injectable epinephrine kits are recommended for rare patients with episodes of anaphylaxis manifesting with respiratory symptoms. Exercise is a provocative test but may require priming with the identified food allergens.

Vibratory Angioedema. Vibratory angioedema, a form of physical urticaria, may be an inherited autosomal dominant trait or may be acquired after prolonged occupational vibration exposure. Dermatographism, pressure urticaria, and cholinergic urticaria may occur in affected patients. Plasma histamine levels are elevated during attacks. The appearance of the angioedema is usually not delayed. The treatment is antihistamines. As a provocative test, laboratory vortex vibration is applied to the forearm for 5 minutes.

Aquagenic Urticaria. The rare aquagenic urticaria is elicited by water or seawater at any temperature. Pruritic wheals develop immediately or within minutes at the sites of contact of the skin with water, irrespective of temperature or source, and clear within 30–60 minutes. Sweat, saliva, and even tears can precipitate a reaction. Aquagenic urticaria may be familial in some cases or associated with atopy or cholinergic urticaria. Systemic symptoms have been reported, including wheezing, dysphagia, and respiratory distress. The pathogenesis is unknown but may be associated with water-soluble antigens that diffuse into the dermis and cause histamine release from sensitized mast cells.

Whealing may be prevented by pretreatment of the skin with petrolatum. Antihistamines suppress this reaction. The addition of an H2 antihistamine may be of benefit. PUVA appears to prevent skin lesions but may not prevent the symptoms of pruritus. The provocative test is to apply water compresses, 35°C (95°F), to the skin of the upper body for 30 minutes.

Galvanic Urticaria. Galvanic urticaria has been described after exposure to a galvanic device for iontophoresis used to treat hyperhidrosis. The relationship of this condition to other forms of physical urticaria remains to be established.

Pathogenesis/Histopathology

Capillary permeability results from the increased release of histamine from the mast cells situated around the capillaries. The mast cell is the primary effector cell in urticarial reactions. Other mediators include IL-1 in the autoinflammatory conditions discussed earlier and bradykinin in angioedema associated with angiotensin-converting enzyme (ACE) inhibitors and in the hereditary and acquired angioedema syndromes discussed shortly.

About one third of patients with chronic idiopathic urticaria have circulating functional histamine-releasing IgG autoantibodies that bind to the high-affinity IgE receptor. Some patients have IgG that does not bind the IgE receptor, but rather causes mast cell degranulation. Thyroid autoantibodies are often present in women with chronic idiopathic urticaria, but clinically relevant thyroid disease is seldom present. Even in those with thyroid disease, treatment of the thyroid disorder generally does not affect the course of the urticaria.

The histopathologic changes in acute urticaria include mild dermal edema and margination of neutrophils within postcapillary venules. Later, neutrophils migrate through the vessel wall into the interstitium, and eosinophils and lymphocytes are also noted in the infiltrate. Karyorrhexis and fibrin deposition within vessel walls are absent, helping to differentiate urticaria from vasculitis.

A subset of patients have urticarial lesions with biopsies that show a preponderance of neutrophils; this has been called neutrophilic urticaria. Patients with such histology may present with acute urticaria, chronic urticaria, or physical urticaria. Because neutrophils are typically present in urticaria in general, it is likely that cases of neutrophilic urticaria simply represent urticaria with upregulation of some mast cell–derived cytokines. Some of these may be cases of urticarial vasculitis where the damaged vessels are not visualized. Dapsone may be an alternate therapy for neutrophil-predominant urticaria as well.

Diagnosis

Diagnosis of urticaria and angioedema is usually made on clinical grounds. Burning lesions in a fixed location for more than 24 hours or resolving with bruising suggest urticarial vasculitis, the urticarial phase of an immunobullous eruption, EM, granuloma annulare, sarcoidosis, or cutaneous T-cell lymphoma. If individual wheals last for longer than 24 hours, a skin biopsy should be performed.

Clinical Evaluation

Laboratory evaluation should be driven by associated signs and symptoms. Random tests in the absence of a suggestive history or physical findings are rarely cost-effective and are not recommended. A practical evaluation is limited to a detailed history and a thorough physical examination. Questions to ask include a history of the timing, duration, and frequency of wheals and any associated angioedema; possible association with foods, drugs, febrile illness, occupation, travel, or hobbies; and a family or personal history of atopy, or potential physical causes. A history of aspirin or NSAID ingestion should trigger their avoidance because these drugs may not only cause urticaria, but also aggravate preexisting disease.

If the urticaria is acute and recurrent, food allergy may be suggested by a food diary. Serum radioallergosorbent tests (RASTs) can be used to detect specific IgE, and elimination diets can occasionally be beneficial in some patients. If urticaria does not occur, suspected foods are added one by one and reactions observed.

Angioedema in the absence of urticaria may be related to hereditary angioedema (HAE) or an ACE inhibitor. C1 esterase deficiency does not cause hives, only angioedema, and measurement of C4 is indicated. If C4 is low, an evaluation of C1 esterase inhibitor is appropriate.

In patients with chronic spontaneous urticaria, a directed history and physical examination should elicit signs or symptoms of thyroid disease, connective tissue disease, changes in bowel or bladder habits, vaginal or urethral discharge, other localized infection, jaundice, or risk factors for hepatitis or Lyme disease. Positive findings should prompt appropriate screening tests. Although sinus x-ray films, a panoramic dental film, streptococcal throat culture, abdominal ultrasonography, and urinalysis with urine culture (with prostate massage in men) may reveal the most common occult infections triggering urticaria, positive cases are almost always associated with some signs or symptoms suggestive of the diagnosis. For example, if the patient has a history of sinus difficulties, particularly if there is palpable tenderness over the maxillary or ethmoid sinuses, radiologic sinus evaluation is recommended. Last, a routine CBC with differential, liver function testing, and ESR or CRP level may be done to help decide if infection may be a causal factor. In areas where parasitic disease is common, eosinophilia is an inexpensive screening test with a fair yield.

If the history suggests a physical urticaria, the appropriate challenge test should be used to confirm the diagnosis. Lesions that burn rather than itch, resolve with purpura, or last longer than 24 hours should prompt a biopsy to exclude urticarial vasculitis. If lesions burn rather than itch, and if patients have associated fever, arthralgias, or other evidence of systemic inflammation and antihistamines are not effective, an acquired autoinflammatory syndrome should be considered, and a trial of anakinra may be useful.

Treatment

Acute Urticaria

The mainstay of treatment of acute urticaria is administration of antihistamines. In adults, nonsedating antihistamines pose a lower risk of psychomotor impairment. If the cause of the acute episode can be identified, avoiding that trigger should be stressed. In patients with acute urticaria that does not respond to antihistamines, systemic corticosteroids are generally effective, but histamine-nonresponsive urticaria should prompt consideration for whether there is an underlying disease or continuing trigger present.

For severe reactions, including anaphylaxis, respiratory and cardiovascular support is essential. Patients should be monitored in the hospital. A 0.3-mL dose of a 1:1000 dilution of epinephrine is administered every 10–20 minutes as needed. In young children, a half-strength dilution is used. In rapidly progressive cases, intubation or tracheotomy may be required. Adjunctive therapy includes intramuscular antihistamines (25–50 mg hydroxyzine or diphenhydramine every 6 hours as needed) and systemic corticosteroids (250 mg hydrocortisone or 50 mg methylprednisolone intravenously every 6 hours for 2–4 doses).

Chronic Urticaria

In chronic spontaneous urticaria, the goal of therapy is to alleviate symptoms. The mainstay of treatment is administration of antihistamines. These should be taken on a daily basis; antihistamines should *not* be prescribed to be taken only as needed. Second-generation H1 antihistamines (cetirizine, desloratadine, fexofenadine, acrivastine, ebastine, mizolastine) are large, lipophilic molecules with charged side chains that bind extensively to proteins, preventing the drugs from crossing the blood-brain barrier; thus they produce less sedation in most patients than the third-generation antihistamine levocetirizine. Long-acting forms are available, and the long half-life of these antihistamines and reduced sedation result in improved compliance and efficacy. First-line treatment is the use of a second- or third-generation nonsedating antihistamine such as cetirizine, in standard dosage. If after 2 weeks the symptoms persist, the dosage should be increased up to 4 times the standard dosage, usually adding a second pill in the evening, then a third in the AM and a fourth in the AM to a maximum of 4 pills per day, two in the morning and two in the evening. If this is ineffective, another nonsedating antihistamine may be tried. Some experience indicates that fexofenadine is less likely to work at higher-than-standard dosages, so this is not escalated if there is no response at standard dosage. Cetirizine and some of the other second-generation antihistamines can cause drowsiness in some individuals, particularly in higher doses or when combined with other antihistamines.

Although some add an H2 blocker such as ranitidine as well, evidence is conflicting on whether this is an effective strategy. Ranitidine should not be used alone for treatment of urticaria because it may interfere with feedback inhibition of histamine release. Also, doxepin, a tricyclic antidepressant with potent H1 antihistaminic activity, may be useful, but evidence is weak. Doxepin is frequently dosed at bedtime, so much of the drowsiness and dry mouth are gone by morning. The same is true for first-generation antihistamines; if any is added to the previous second-generation strategy, it should only be used at night.

If it is necessary to consider other therapies, the following guidance is offered. Mycophenolate, cyclosporine, and prednisone are often effective, but the potential for side effects limits their clinical utility. At least 20% of patients, and up to 50% in some studies, will continue to have chronic spontaneous urticaria after 5 years, and chronic suppressive agents should be avoided if possible. Dapsone, colchicine, and sulfasalazine may be most useful if the biopsy shows a preponderance of neutrophils, and they may be added to antihistamine treatment if some response to the latter has been obtained. Hydroxychloroquine, leukotriene receptor antagonists such as montelukast, and even phototherapy may have some benefit in individual patients. Also, their more satisfactory safety profile makes these therapies worth considering as alternatives to medications such as MMF, omalizumab, and methotrexate, which show more evidence of efficacy. Omalizumab, a recombinant humanized monoclonal antibody that binds to free IgE, is effective in many patients with chronic spontaneous urticaria in doses of 150–300 mg every 4 weeks, with a good safety profile.

Topical corticosteroids, topical antihistamines, and topical anesthetics have no role in the management of chronic urticaria. For local treatment, tepid or cold tub baths or showers may be freely advocated if cold is not a trigger. Topical camphor and menthol can provide symptomatic relief. Sarna lotion contains menthol, phenol, and camphor.

In about one third of patients with chronic idiopathic urticaria, autoantibodies bind to high-affinity IgE receptors. Unfortunately, testing for this condition is not well standardized, has false-positive results, and is impractical. If chronic spontaneous urticaria is nonresponsive to the previous approach, patients may require more aggressive management, including chronic immunosuppressive therapy, plasmapheresis, or IVIG.

Angioedema

Angioedema is an acute, evanescent, circumscribed edema that usually affects the most distensible tissues, such as the eyelids, lips (Fig. 7.19), earlobes, and external genitalia, or the mucous membranes of the mouth, tongue, or larynx. The swelling occurs in

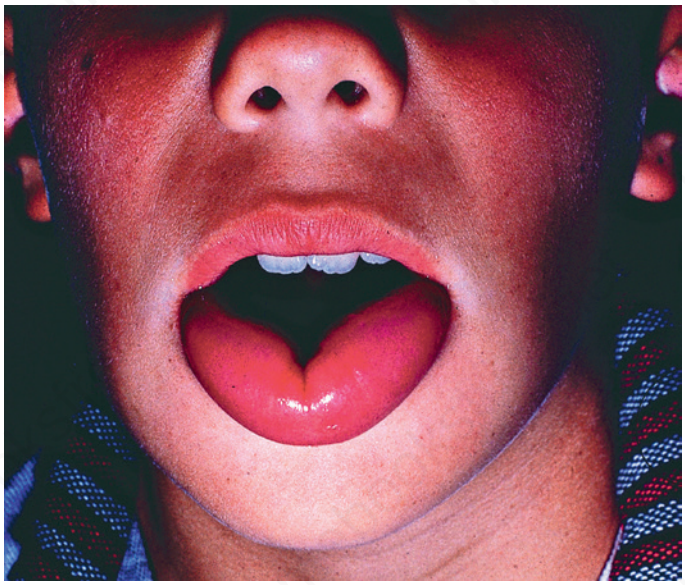

Fig. 7.19 Angioedema of the lips.

the deep dermis or in the subcutaneous tissues and as a rule is only slightly tender, with the overlying skin unaltered, edematous, or rarely ecchymotic. There may be a diffuse swelling on the hands, forearms, feet, and ankles. Frequently, the condition begins during the night and is found on awakening. Angioedema may target the GI and respiratory tracts, resulting in abdominal pain, coryza, asthma, and respiratory problems. Respiratory tract involvement can produce airway obstruction. Anaphylaxis and hypotension may also occur.

There are two distinct subsets of angioedema. The first is considered a deep form of urticaria and may be observed as solitary or multiple sites of angioedema alone or in combination with urticaria. The action of histamine creates vasomotor lability, and pruritus may be a significant feature. The second subgroup, angioedema associated with C1 esterase inhibitor deficiency, or that related to ACE inhibitors, is not associated with hives, or pruritus. Symptoms of pain predominate, and this deficiency is mediated by bradykinin.

Hereditary Angioedema

Also known as Quincke edema, HAE was originally described and named by Osler in 1888. HAE characteristically appears before age 20. Sudden attacks of angioedema occur as frequently as every 2 weeks throughout the patient's life, lasting for 2–5 days. Swelling is typically asymmetric, and urticaria or itching does not occur. The presentation may overlap with that of the autoinflammatory syndromes.

Patients may experience local swelling in subcutaneous tissues (face, hands, arms, legs, genitals, buttocks); abdominal organs (stomach, intestines, bladder), mimicking surgical emergencies; and the upper airway (larynx), which can be life threatening. There is minimal response to antihistamines, epinephrine, or corticosteroids. Mortality rate is high, often caused by laryngeal edema. GI edema is manifested by nausea, vomiting, and severe colic, and it may simulate appendicitis so closely that appendectomy is mistakenly performed. The factors that trigger attacks are minor trauma, surgery, sudden changes of temperature, or sudden emotional stress.

Inherited in an autosomal dominant fashion, HAE is estimated to occur in 1 in 50,000–150,000 persons. There are three phenotypic forms of the disease. Type I is characterized by low antigenic and functional plasma levels of a normal C1 esterase inhibitor protein (C1-EI). Type II is characterized by the presence of normal or elevated antigenic levels of a dysfunctional protein. Type III demonstrates normal C1-EI function and normal complement. The majority of patients are women. Criteria for type III include a long history of recurrent attacks of skin swelling, abdominal pain, or upper airway obstruction; absence of urticaria; familial occurrence; normal C1-EI and C4 concentrations; and failure of treatment with antihistamines, corticosteroids, and C1-EI concentrate.

The screening test of choice for types I and II is a C4 level. C4 will be low (<40% of normal) as a result of continuous activation and consumption. In addition to depressed C4 levels, patients with types I and II also have low C1, C1q, and C2 levels. If the clinical picture and screening tests are positive, a titer of C1-EI should be ordered. C1-EI is a labile protein, and sample decay is common. A low C1-EI in the presence of normal C4 levels should raise the suspicion of sample decay, rather than true HAE.

The treatment of choice for acute HAE types I and II is plasma-derived or recombinant C1 inhibitor or contact system modulators such as ecallantide or icatibant. Short-term prophylaxis (e.g., for patients undergoing dental care, endoscopy, or intubation for surgery) can be obtained from C1 inhibitor replacement therapy or danazol, an attenuated androgen. Lanadelumab, a monoclonal antibody inhibitor of plasma kallikrein, has been studied for prophylactic therapy. Estrogens in oral contraceptives, in contrast, may precipitate attacks. Attenuated androgens, C1 inhibitors, and in some cases antifibrinolytics are useful for long-term prophylaxis. Patients with type III do not respond to C1-EI replacement but may respond to danazol. Multiple agents are being evaluated to aid in the treatment of HAE, including C1 esterase inhibitor concentrates, recombinant C1INH, monoclonal antibodies against kallikrein, oral kallikrein inhibitors, and factor XIIa–blocking monoclonal antibodies.

Acquired C1 Esterase Inhibitor Deficiency

Some patients present with symptoms indistinguishable from HAE, but with onset after the fourth decade of life and lacking a family history. As in HAE, there is no associated pruritus or urticaria. This condition is subdivided into acquired angioedema I and II and an idiopathic form. Acquired angioedema I is a rare disorder associated with lymphoproliferative disease. These associations include lymphomas (usually B cell), chronic lymphocytic leukemia, monoclonal gammopathy, myeloma, myelofibrosis, Waldenström macroglobulinemia, and breast carcinoma. Some patients have detectable autoantibodies to C1-EI. Worsening of stable HAE has been the presenting sign of lymphoma. Part of the management of this condition is to treat the causative associated condition.

Acquired angioedema II is an extremely rare disease defined by the presence of autoantibodies to C1-EI. It is important to realize that autoantibodies directed against C1-EI may also be found in acquired angioedema I, particularly in patients with B-cell lymphomas, so the diagnosis of acquired angioedema II is made only when no such underlying condition exists.

The pathophysiology of acquired angioedema I is unknown but may be related to increased catabolism of C1-EI; many patients with the disorder have been shown to produce normal amounts of C1-EI. In acquired angioedema II, hepatocytes and monocytes are able to synthesize normal C1-EI; however, a subpopulation of B cells secretes autoantibodies to the functional region of the C1-EI molecule.

Management of acute attacks in acquired angioedema I is directed toward replacement of C1-EI with plasma-derived or recombinant C1 inhibitor. Some patients develop progressive resistance to the infusions. Antifibrinolytic agents, such as aminocaproic acid or tranexamic acid, may be beneficial and are more effective than antiandrogen therapy. Synthetic androgens, such as

danazol, may be helpful in angioedema I. However, androgens are ineffective in treating patients with acquired angioedema II, stressing the importance of identifying these patients. Immunosuppressive therapy has been shown to be effective in the treatment of acquired angioedema II by decreasing autoantibody production. Systemic corticosteroids may be temporarily effective.

Episodic Angioedema With Eosinophilia

Episodic angioedema or isolated facial edema may occur with fever, weight gain, eosinophilia, and elevated eosinophil major basic protein (Gleich syndrome). The disorder is not uncommon, and there is no underlying disease. Increased levels of IL-5 have been documented during periods of attack. Treatment options include administration of systemic steroidal medications, imatinib, antihistamines, and IVIG.

Anaphylaxis

Anaphylaxis is an acute and often life-threatening immunologic reaction, frequently heralded by scalp pruritus, diffuse erythema, urticaria, or angioedema. Bronchospasm, laryngeal edema, hyperperistalsis, hypotension, and cardiac arrhythmia may occur. Antibiotics (especially penicillins), other drugs, and radiographic contrast agents are the most common causes of serious anaphylactic reactions. Hymenoptera stings are the next most frequent cause, followed by ingestion of crustaceans and other food allergens. Atopic dermatitis is frequently associated with anaphylaxis, regardless of origin. Causative agents can be identified in up to two thirds of cases, and recurrent attacks are the rule. Exercise-induced anaphylaxis often depends on priming by prior ingestion of a specific food, or food in general, and aspirin may be an additional exacerbating factor.

8 Connective Tissue Diseases

Bonus images for this chapter can be found online at expertconsult.inkling.com

Lupus erythematosus (LE), dermatomyositis (DM), scleroderma, rheumatoid arthritis, Sjögren syndrome, eosinophilic fasciitis, relapsing polychondritis, and related disorders are classified as connective tissue diseases. Basic to all these is a complex array of autoimmune responses that target or affect collagen or ground substance.

LUPUS ERYTHEMATOSUS

Lupus may manifest as a systemic disease or in purely cutaneous forms. Cutaneous manifestations of LE are classified as in Box 8.1.

Chronic Cutaneous Lupus Erythematosus

Discoid Lupus Erythematosus

Discoid lupus erythematosus (DLE) generally occurs in young adults, with women outnumbering men 2:1. Lesions begin as dull-red macules or indurated plaques that develop an adherent scale, then evolve with atrophy, scarring, and pigment changes (Fig. 8.1). In darker-skinned individuals, lesions typically demonstrate areas of both hyperpigmentation and depigmentation. In lighter-skinned patients, the plaques may appear gray or have minimal pigment alteration. The hyperkeratosis characteristically extends into patulous follicles, producing carpet tacklike spines on the undersurface of the scale.

Localized Discoid Lupus Erythematosus. Discoid lesions are usually localized above the neck, particularly on sun-exposed sites such as the scalp, bridge of the nose, malar areas, lower lip, and ears (Fig. 8.2). The concha of the ear and external canal are frequently involved. Typical lesions are disk-shaped areas of erythema, with follicular plugging, which progress to develop atrophy, scarring, and pigment alteration. Some patients present with periorbital edema and erythema. On the scalp, most lesions begin as erythematous patches or plaques that evolve into white, often depressed, hairless patches. Perifollicular erythema and the presence of easily extractable anagen hairs are signs of active disease. Scarred areas may appear completely smooth or may demonstrate dilated follicular openings in the few remaining follicles. Itching and tenderness are common but rarely severe. On the lips, lesions may be gray or red and hyperkeratotic. They may be eroded and are usually surrounded by a narrow, red inflammatory zone (Fig. 8.3). In one study, 24% of DLE patients had mucosal involvement of the mouth, nose, eye, or vulva. Rarely, aggressive squamous cell carcinoma (SCC) may arise in long-standing lesions of DLE.

Patients with cutaneous lupus erythematosus (CLE) may develop systemic disease over time, sometimes with a lengthy delay (8–10 years), though overall only a small percentage (5%–23% reported, though more often the number is less than 15%) of patients with localized DLE will go on to meet criteria for systemic lupus erythematosus (SLE), usually due to cutaneous and mucosal criteria. Although progression from purely cutaneous DLE to SLE occurs infrequently, patients with SLE frequently have discoid lesions. These patients generally have systemic involvement early in the course of their disease, rather than evolving from chronic cutaneous LE to SLE. Fever and arthralgia are common in patients with SLE and discoid lesions. In patients with systemic symptoms, abnormal laboratory tests, such as elevation of antinuclear antibodies (ANAs), antibodies to double-stranded (ds) DNA and C1q, leukopenia, hematuria, and proteinuria, help to identify patients with SLE and suggest a prognosis.

Generalized Discoid Lupus Erythematosus. Generalized DLE is less common than localized DLE. All degrees of severity are encountered. Most often, the thorax and upper extremities are affected, as well as the head and neck (Fig. 8.4). The scalp may become quite bald with striking patterns of hyperpigmentation and depigmentation. Diffuse scarring may involve the face and upper extremities. Laboratory abnormalities, such as an elevated erythrocyte sedimentation rate (ESR), elevated ANAs, single-stranded (ss) DNA antibodies, and leukopenia, are more common with this form of LE than with localized DLE, and as such patients with generalized DLE are more likely to meet criteria for systemic lupus.

Childhood Discoid Lupus Erythematosus. Among children with DLE, a low frequency of photosensitivity and a higher rate of association with SLE have been noted, with one recent study showing 15% of patients with DLE had concurrent SLE, and 26% of the remaining patients eventually met SLE criteria. In most other respects, the clinical presentation and course are similar to those in adults.

Histology. The epidermis may demonstrate effacement of the rete ridge pattern or irregular acanthosis. Compact hyperkeratosis without parakeratosis is characteristic, and follicular plugging is typically prominent. Hydropic degeneration of the basal layer of the epidermis and follicular epithelium results in pigmentary incontinence. A patchy perivascular and periadnexal lymphoid inflammatory infiltrate occurs in the superficial and deep dermis. The infiltrate characteristically surrounds vessels, follicles, and the eccrine coil. Increased mucin is often present, though is not a reliable mechanism to distinguish lupus from mimickers. Thickening of the basement membrane zone (BMZ) may be prominent.

The histology varies with the stage of the lesion. Acute lesions show only patchy lymphoid inflammation and vacuolar interface dermatitis. Lesions established for several months begin to show hyperkeratosis, BMZ thickening, and dermal mucin. Chronic, inactive lesions show atrophy, with postinflammatory pigmentation and scarring throughout the dermis. At this stage, the inflammatory infiltrate is sparse to absent. Pilosebaceous units, except for "orphaned" arrector muscles, are destroyed. At this stage, the dermis appears fibrotic, but an elastic tissue stain can still distinguish the diffuse dermal scar of lupus from the focal, wedge-shaped, superficial scars of lichen planopilaris (LPP) or folliculitis decalvans. Direct immunofluorescence (DIF) testing of lesional skin is positive in more than 75% of cases, provided the lesions have been active for at least several months and usually demonstrate strong, continuous granular deposition of immunoglobulin and complement located at the dermoepidermal junction (DEJ).

Differential Diagnosis. Discoid LE must often be differentiated from seborrheic dermatitis, rosacea, lupus vulgaris, sarcoidosis, drug eruptions, actinic keratosis, Bowen disease, lichen planus (LP), tertiary syphilis, and polymorphous light eruption (PMLE).

BOX 8.1 Classification of Cutaneous Manifestations of Lupus Erythematosus

I. CHRONIC CUTANEOUS LE

A. Discoid LE
   1. Localized
   2. Disseminated
B. Verrucous (hypertrophic) LE (Behçet): usually acral and often lichenoid
C. Lupus erythematosus–lichen planus overlap
D. Chilblain LE
E. Tumid lupus
F. Lupus panniculitis (LE profundus)
   1. With no other involvement
   2. With overlying discoid LE
   3. With systemic LE

II. SUBACUTE CUTANEOUS LE

A. Papulosquamous
B. Annular
C. Syndromes commonly exhibiting similar morphology
   1. Neonatal LE
   2. Complement deficiency syndromes
   3. Drug induced

III. ACUTE CUTANEOUS LE: LOCALIZED OR GENERALIZED ERYTHEMA OR BULLAE, GENERALLY ASSOCIATED WITH SLE

LE, Lupus erythematosus; *SLE,* systemic lupus erythematosus.

Fig. 8.1 Extensive scarring from discoid lupus erythematosus.

Fig. 8.2 Discoid lupus erythematosus. (Courtesy Steven Binnick, MD.)

Fig. 8.3 Discoid lupus erythematosus.

Fig. 8.4 Generalized discoid lupus erythematosus.

Fig. 8.5 Hypertrophic lupus erythematosus. (Courtesy Steven Binnick, MD.)

Seborrheic dermatitis does not show atrophy, alopecia, or dilated follicles and has greasy, yellowish scale without follicular plugs. Acral, lip, and scalp lesions of chronic cutaneous LE may demonstrate lichenoid dermatitis histologically. In these cases, the presence of continuous granular immunoglobulin in addition to cytoid bodies is a helpful distinguishing feature.

In rosacea, atrophy does not occur, and pustules are almost always found. Apple-jelly nodules (granulomas) are seen with diascopy in lupus vulgaris. Sunlight-sensitizing agents, such as sulfonamides, may produce lesions similar to LE, because phototoxic reactions demonstrate vacuolar interface dermatitis. It may be necessary to differentiate syphilis and sarcoid by biopsy and serologic testing. PMLE is distinguished by the absence of scarring and the presence of intensely edematous plaques and papules. DIF is generally negative or nonspecific in PMLE.

Hypertrophic Lupus Erythematosus

Nonpruritic papulonodular lesions may occur on the arms and hands, resembling keratoacanthoma or hypertrophic LP (Fig. 8.5). The lips and scalp may also demonstrate lesions that resemble LP or LPP. Dermoscopy may help distinguish hypertrophic LE from SCC, but biopsy is often needed. Histologic sections of these lesions typically demonstrate lichenoid dermatitis, and a careful examination for other characteristic skin lesions of LE or LP, as well as DIF testing, may be critical in establishing a diagnosis. BMZ thickening, dermal mucin, eccrine coil involvement, and subcutaneous nodular lymphoid infiltrates are features of LE that are not found in LP. Recent reports suggesting the pattern and number of plasmacytoid dendritic cells may be helpful in distinguishing SCC from hypertrophic LE.

Lupus Erythematosus–Lichen Planus Overlap Syndrome

In addition to the cases of hypertrophic LE with lichenoid histology previously discussed, there are patients with a true overlap syndrome with features of both LE and LP. The lesions are usually large, atrophic, hypopigmented, red or pink patches and plaques. Pigment abnormalities become prominent over time, and fine telangiectasia and scaling are usually present. The extensor aspects of the extremities and midline back are typically affected. Prominent palmoplantar involvement is characteristic and tends to be the most troublesome feature for these patients. Nail dystrophy and anonychia may occur. Scarring alopecia and oral involvement have been noted in some patients. The histology of individual lesions has features of LP and/or LE. One study suggested that higher

Fig. 8.6 Tumid lupus.

CD3 and CD34 may favor LP over DLE, but this has not been widely examined. DIF may help differentiate the two, but they may share overlapping features. Response to treatment is poor, although potent topical corticosteroids, dapsone, thalidomide, or isotretinoin may be effective. Some patients require immunosuppressive therapy with agents such as mycophenolate mofetil (MMF) or azathioprine. It should also be noted that antimalarials can occasionally produce a lichenoid drug eruption. A rare variant of chronic CLE termed the *pigmented macular variant* has been described, with lichenoid to gray pigmentation in sun exposed areas; although these patients display interface reaction on biopsy and may have seropositivity, systemic disease is rare, and it is unclear if this represents a rare subtype of lupus or another lichenoid entity. Patients respond to topical steroids, sun protection, and hydroquinone.

Chilblain Lupus Erythematosus

Chilblain LE (Hutchinson) is a chronic, unremitting form of LE affecting the fingertips, rims of ears, calves, and heels, especially in women. It is usually preceded by DLE on the face. Systemic involvement is sometimes seen. Mimicry of sarcoidosis may be striking. Cryoglobulins and antiphospholipid antibody (APLA) should also be sought. Familial chilblain lupus has been linked to mutations in a number of genes, particularly *TREX-1*, and is considered part of the group of genetic diseases termed *interferonopathies*.

Tumid Lupus Erythematosus

Tumid LE is a rare but distinctive entity. Patients present with edematous erythematous plaques, usually on the trunk (Fig. 8.6). Histologically, the lesions demonstrate a patchy superficial and deep perivascular and periadnexal lymphoid infiltrate that frequently affects the eccrine coil. Dermal mucin deposition is typical and

Fig. 8.7 Lupus panniculitis with overlying discoid lupus erythematosus.

may be striking. The lesions generally respond readily to antimalarials. Tumid LE shares many features with reticular erythematous mucinosis, and some authorities consider them to be closely related entities.

Lupus Erythematosus Panniculitis (Lupus Erythematosus Profundus)

Patients with the panniculitis type of LE develop subcutaneous nodules that are usually firm, sharply defined, and nontender. The proximal extremities are typically involved. Usually, the overlying skin is normal, but overlying discoid or tumid lesions may occur (Fig. 8.7). Some cases are discovered incidentally when an unrelated lesion is biopsied. The lesions may progress to deep depressions, or "dells," from loss of the panniculus. LE panniculitis is characteristically chronic and occurs most often in women between ages 20 and 45. Many patients have DLE at other sites or less typically, in the overlying skin.

Histologic sections demonstrate lymphoid nodules in the subcutaneous septa, necrosis of the fat lobule, and fibrinoid or hyaline degeneration of the remaining lipocytes. Lipomembranous change, resembling frost on a windowpane, is more typical of stasis panniculitis (lipodermatosclerosis), but it may be noted focally in LE panniculitis. The overlying epidermis may show basal liquefaction and follicular plugging or may be normal. Dermal lymphoid nodules or vertical columns of lymphoid cells may be seen in fibrous tract remnants. Dermal mucin may be prominent, and dermal collagen hyalinization (resembling that seen in morphea) may be present. Continuous granular deposition of immunoglobulin and C3 may be seen at the DEJ. In active cases, abundant fibrin is usually noted in the panniculus.

The most important entity to consider in the differential diagnosis is subcutaneous panniculitis–like T-cell lymphoma (SPTCL). Important clues include the presence of lipocytes, rimmed by atypical lymphocytes with nuclear molding, and the presence of constitutional symptoms. Erythrophagocytosis may be present focally, and T-cell clonality can usually be demonstrated. The infiltrate may be CD8 dominant or may label strongly for CD56, as in natural killer cell lymphoma, or CD30, as in anaplastic lymphoma. CD5 and CD7 expression may be reduced (aberrant loss of pan-T markers). Unfortunately, T-cell clonality, erythrophagocytosis, CD8 predominance, and loss of CD5 or CD7 may also be seen in patients with LE panniculitis who respond to antimalarials or corticosteroids and do not progress to clinical lymphoma. Taken together, these data suggest that some cases of lymphoma may be virtually indistinguishable from LE panniculitis, or that some cases of LE panniculitis represent an abortive lymphoid dyscrasia. Patients diagnosed with lupus panniculitis should be monitored for progression.

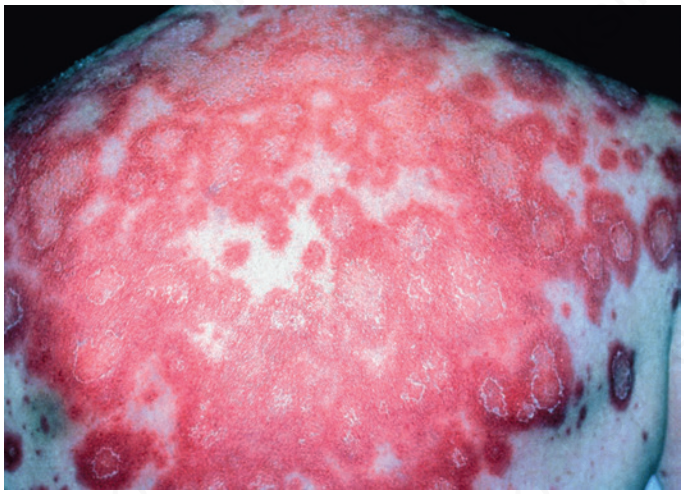

Fig. 8.8 Subacute cutaneous lupus erythematosus.

Subacute Cutaneous Lupus Erythematosus

In 1979 Sontheimer, Thomas, and Gilliam described a clinically distinct subset of cases of LE to which they gave the name subacute cutaneous lupus erythematosus (SCLE). Patients are most often white women age 15–40. SCLE patients make up approximately 10%–15% of the LE population. Lesions are scaly and evolve as polycyclic annular lesions (Fig. 8.8) or psoriasiform plaques, although rare widespread cases of erythrodermic SCLE or patients resembling SJS/TEN have been described. The lesions vary from red to pink with faint violet tones. The scale is thin and easily detached, and telangiectasia or dyspigmentation may be present. Follicles are not involved, the lesions tend to be transient or migratory, and there is no scarring. Lesions tend to occur on sun-exposed surfaces of the face and neck, the V portion of the chest and back, and the sun-exposed areas of the arms. Photosensitivity is prominent in about half of patients. Concomitant DLE is present in 20% of cases.

About three quarters of patients have arthralgia or arthritis, 20% have leukopenia, and 80% have a positive ANA test (usually in a particulate pattern). Between 20% and 50% of patients meet the American Rheumatology Association (ARA) criteria for a diagnosis of SLE. The majority of cases have antibodies to Ro/SSA antigen, and most are positive for human leukocyte antigen (HLA) DR3. La/SSB may also be present, and many patients have overlap features with Sjögren syndrome. The disease generally runs a mild course, and renal, central nervous system (CNS), or vascular complications are unusual. An association with autoimmune thyroid disease has been noted. Most patients respond to sun protection and antimalarial agents. From 12%–30% of cases may be drug induced. Medication-induced SCLE is traditionally most often related to hydrochlorothiazide due to its wide use, but proton pump inhibitors are increasingly recognized, perhaps due to over-the-counter availability. Drug-induced SCLE may also be seen with angiotensin-converting enzyme (ACE) inhibitors, calcium channel blockers (CCBs), interferons (IFNs), anticonvulsants,

griseofulvin, glyburide, piroxicam, penicillamine, spironolactone, terbinafine, statins, voriconazole, and chemotherapeutic agents. Chemotherapeutic agents implicated include fluorouracil, capecitabine, cemcitabine, docetaxel, paclitaxel, and doxorubicin, with emerging reports of nivolumab, other checkpoint inhibitors, and small molecule kinase inhibitors such as masitinib. TNF inhibitors are increasingly recognized as the triggering drug and are important to keep in mind due to the potential for psoriasiform SCLE to resemble psoriasis, which can lead to a misdiagnosis of TNF-induced psoriasis—photosensitivity is a clue to SCLE in these cases. Case reports describe both topical terbinafine and imiquimod inducing SCLE-like eruptions as well.

Histopathology

Vacuolar interface dermatitis is a universal finding in active SCLE lesions. Mild hyperkeratosis and parakeratosis may be present. Chronic changes of DLE, such as follicular plugging, BMZ thickening, and heavy lymphoid aggregates, are usually lacking. Dermal mucin is variable. DIF is positive in lesional skin in only about one third of cases. A dustlike particulate deposition of immunoglobulin G (IgG) in epidermal nuclei of Ro-positive patients may be present and is a helpful diagnostic finding.

Neonatal Lupus Erythematosus

Most infants with neonatal lupus are girls, born to mothers who carry the Ro/SSA antibody. These infants have no skin lesions at birth, but develop them during the first few weeks of life. Annular erythematous macules and plaques may appear on the head and extremities (Fig. 8.9). Periocular involvement (raccoon eyes) may be prominent. With time, the lesions fade and become atrophic. Telangiectasia or dermal mucinosis in an acral papular pattern may be the predominant findings in some cases. Telangiectatic macules or angiomatous papules may be found in sun-protected sites such as the diaper area, may occur independently of active lupus skin lesions, and may be persistent. The skin lesions usually resolve spontaneously by 6 months of age, and usually heal without significant scarring, although atrophy and telangiectatic mats may persist. Dyspigmentation and persistent telangiectasias may remain for months to years. Half the mothers are asymptomatic at delivery, although many will subsequently develop arthralgia, Sjögren syndrome, or other mild systemic findings.

Although the skin lesions are transient, half the patients have an associated isolated congenital heart block, usually third degree, which is permanent. Some infants have only this manifestation of LE, and for cardiac lesions alone, there is no female predominance. In children with cutaneous involvement, thrombocytopenia and hepatic disease may occur as frequently as cardiac disease. Close monitoring is recommended for at least the first 3 months of life, and by 9 months of life most cases resolve, with only 10% of infants with persistent antibodies at that time.

Fig. 8.9 Neonatal lupus erythematosus.

There is a strong association with Ro/SSA autoantibody. Almost all mothers, and thus almost all infants, are positive for this antibody, although some mothers are also positive for La/SSB, and some with only U1RNP antibodies have been described. Infants with only U1RNP antibodies have not developed heart block. There is linkage to HLA-DR3 in the mother. The risk that a second child will have neonatal LE is approximately 25%. Japanese infants apparently differ in that they may express anti-dsDNA antibodies, and 8% progress to SLE. In unselected women with anti-Ro antibodies, only 1%–2% will have an infant with neonatal LE.

Complement Deficiency Syndromes

Although deficiency of many complement components may be associated with LE-like conditions, deficiencies of the early components, especially C2 and C4, are most characteristic. Many such cases are found to have photosensitive annular SCLE lesions and Ro/SSA antibody formation. Patients with C4 deficiency often have hyperkeratosis of the palms and soles. Heterozygous deficiency of either complement component C4A or C4B has a frequency of approximately 20% in white populations. Homozygous deficiency of both is rare, and affected patients may present with SLE with mesangial glomerulonephritis, membranous nephropathy, and severe skin lesions. Although frequently asymptomatic, homozygous C2 deficiency can cause severe infections, SLE, and atherosclerosis.

Systemic Lupus Erythematosus

Young to middle-aged women are predominantly affected by SLE, manifesting a wide range of symptoms and signs. Skin involvement occurs in 80% of cases and is often helpful in arriving at a diagnosis. Its importance is suggested by the fact that 4 of the 11 American College of Rheumatology (ACR) criteria for the diagnosis of SLE are mucocutaneous findings. The diagnostic criteria are as follows:

1. Malar rash
2. Discoid rash
3. Photosensitivity
4. Oral ulcers (21%)
5. Arthritis
6. Proteinuria >0.5 g/day or casts
7. Neurologic disorders (seizures or psychosis in the absence of other known causes)
8. Pleuritis/pericarditis
9. Blood abnormalities (e.g., hemolytic anemia, leukopenia, thrombocytopenia)
10. Immunologic disorders, including anti-dsDNA antibody, anti-Sm, APLAs (based on IgG or IgM anticardiolipin antibodies, lupus anticoagulant [LA], or false-positive serologic test for syphilis known for at least 6 months)
11. Positive ANA blood test

For identification of patients in clinical studies, a patient may be said to have SLE if four or more of these criteria are satisfied, serially or simultaneously. It is important to note that many patients present with autoantibodies, arthralgia, and constitutional signs, but do not meet ACR criteria for SLE. With time, patients may evolve to meet all criteria. The Systemic Lupus International Collaborating Clinics (SLICC) group revision of the ACR criteria results in greater sensitivity with equal specificity. According to the SLICC rule, the patient must manifest at least four criteria (including at least one clinical criterion and one immunologic criterion) *or* must have biopsy-proven lupus nephritis in the presence of either ANAs or anti-dsDNA antibodies. Many patients with DLE or SCLE meet criteria for SLE due to mucocutaneous criteria.

Fig. 8.10 Bullous lupus erythematosus.

Fig. 8.11 Oral lupus erythematosus.

Cutaneous Manifestations

The characteristic butterfly facial erythema seen in patients with SLE is a common manifestation of acute cutaneous LE. The eruption usually begins on the malar area and the bridge of the nose. There may be associated edema. The nasolabial crease if often strikingly spared, unlike in DM. The ears and chest may also be the sites of early lesions. Biopsies at all sites show interface dermatitis and a scant perivascular lymphoid infiltrate. The eruption may last a day to several weeks and resolves without scarring. There may be more widespread erythema in some cases.

Bullous lesions of lupus erythematosus (BLE) occur as single or grouped vesicles or bullae, often widespread, with a predilection for sun-exposed areas (Fig. 8.10). Rarely, the lesions may itch. Most sets of published criteria require that patients with BLE meet ACR criteria for SLE, but some patients have identical bullous lesions and less than four ACR criteria. Histologically, neutrophils accumulate at the DEJ and within dermal papillae. In bullous lesions, there is a subepidermal bulla or superficial dermal edema containing neutrophils. Fluorescence with IgG, IgM, IgA, or C3 is typically present in a continuous, granular pattern at the BMZ on DIF testing. Neutrophils are found in or below the lamina densa on immunofluorescent electron microscopy. Most of these patients are HLA-DR2 positive. The recognition of this subset as distinct is made clear by its often dramatic therapeutic response to dapsone. Epidermolysis bullosa acquisita is histopathologically and immunopathologically identical, because both diseases are mediated by circulating antibodies against type VII collagen. Dapsone is usually ineffective in epidermolysis bullosa acquisita.

A variety of vascular lesions occur in 50% of SLE patients. Often, fingertips or toes show edema, erythema, or telangiectasia. Nailfold capillary loops in LE are more likely to show wandering glomeruloid loops, whereas DM and scleroderma capillary loops demonstrate symmetric dilation and dropout of vessels. Capillary loops in the Osler-Weber-Rendu syndrome demonstrate ectasia of half the capillary loop. Erythema multiforme (EM)–like lesions may predominate, termed Rowell syndrome. Rarely, lupus may present with TEN-like lesions due to intense interface inflammation leading to blistering.

In addition to periungual telangiectasia, red or spotted lunulae may be present in patients with SLE, as in RA. The palms, soles, elbows, knees, or buttocks may become persistently erythematous or purplish, sometimes with overlying scale. Diffuse, nonscarring hair loss is common. Short hairs in the frontal region are called "lupus hairs." These hairs result from a combination of chronic telogen effluvium and increased hair fragility.

Mucous membrane lesions are seen in 20%–30% of SLE patients. Conjunctivitis, episcleritis, and nasal and vaginal ulcerations may occur. Oral mucosal hemorrhages, erosions, shallow angular ulcerations with surrounding erythema, and gingivitis are common (Fig. 8.11). Erythema, petechiae, and ulcerations may occur on the hard palate.

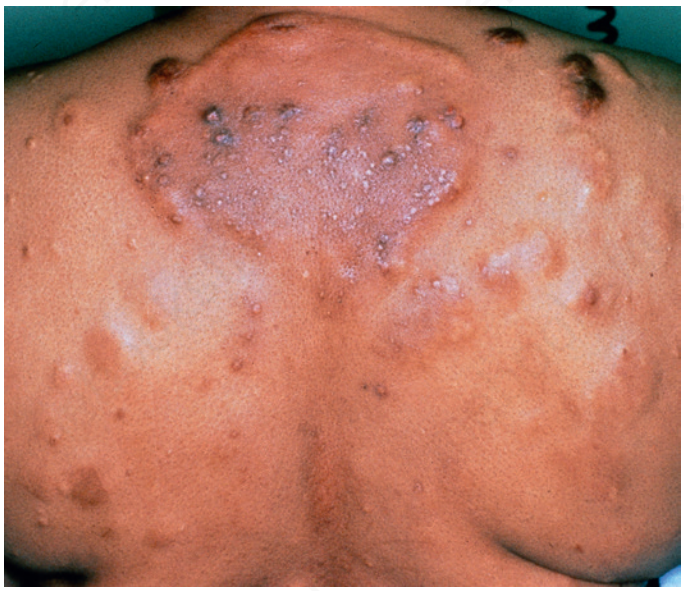

Fig. 8.12 Papulonodular mucinosis.

Multiple eruptive dermatofibromas have been described in SLE. Leg ulcers, typically deeply punched out and with very little inflammation, may be seen on the pretibial or malleolar areas. Many of these patients present with a livedoid pattern, and many have an antiphospholipid antibody. Sneddon syndrome is composed of livedo reticularis and strokes related to a hyalinizing vasculopathy.

Calcinosis cutis is uncommon but may be dramatic. Also seen infrequently are plaquelike or papulonodular depositions of mucin. These reddish purple to skin-colored lesions are often present on the trunk and arms or head and neck (Fig. 8.12). Last, a symmetric papular eruption of the extremities may occur. These skin-colored to erythematous lesions with a smooth, ulcerated or umbilicated surface may show vasculitis or, in older lesions, a palisaded granulomatous inflammation. These occur in patients with SLE, RA, or other immune complex–mediated disease. This eruption has been referred to as palisaded neutrophilic and granulomatous dermatitis of immune complex disease (Fig. 8.13).

Fig. 8.13 Palisaded neutrophilic granulomatous dermatitis.

Fig. 8.14 Cutaneous thrombosis in antiphospholipid antibody syndrome.

Systemic Manifestations

Most organs can be involved in SLE; the symptoms and findings are often caused by immune complex disease, especially vasculitis. The earliest changes noted may be transitory or migratory arthralgia, often with periarticular inflammation. Fever, weight loss, pleuritis, adenopathy, or acute abdominal pain may occur. Arthralgia is often the earliest abnormality and may remain the sole symptom for some time. About 95% of SLE patients will manifest this symptom. Arthralgia, deforming arthropathy, and acute migratory polyarthritis resembling RA may all occur as manifestations of SLE. Avascular necrosis of the femoral head has been observed. Although this is a known complication of systemic corticosteroid therapy, it has also occurred in patients with SLE who have never taken corticosteroids.

Patients with SLE have a higher rate of peripheral arterial disease compared with controls. Thrombosis in vessels of various sizes and thromboembolism may be a recurring event (Fig. 8.14). It may be attributed to a plasma constituent, paradoxically called "lupus anticoagulant" (LA) because it causes prolonged coagulation studies in vitro but thrombosis in vivo. The finding of an LA is usually associated with APLAs. These may be anticardiolipin antibodies, but other APLA types—antiphosphatidylserine, antiphosphatidylinositol, and antiphosphatidylethanolamine—may occur. APLAs and elevated homocysteine may each increase the risk of thrombosis. APLAs are associated with early-onset organ damage. SLE patients with APLAs have higher mortality. Many, but not all, patients have a false-positive blood test for syphilis. In one study, inflammatory lesions of SLE and infections were the most common causes of death during the initial 5 years of disease, whereas thromboses were the most common cause of death after the first 5 years.

Renal involvement is a predictor of poor prognosis. It may be of either nephritic or nephrotic type, leading in either case to chronic renal insufficiency with proteinuria and azotemia. Patients with lupus who are ANCA positive have higher rates of damage. Active nephritis is unlikely in the absence of anti-dsDNA. Both anti-dsDNA antibody and anti-C1q antibody are of relatively high specificity for active nephritis. Hypercholesterolemia and hypoalbuminemia may occur. Immunoglobulin and complement components have been found localized to the BMZ of glomeruli, where vasculitis produces the characteristic "wire-loop" lesion.

Myocarditis is indicated by cardiomegaly and gallop rhythm, but the electrocardiographic (ECG) changes are usually not specific. Pericarditis, the most frequent cardiac manifestation, and endocarditis also occur. Patients with SLE have accelerated atherosclerosis and elevated risk for cardiovascular morbidity and mortality. Raynaud phenomenon (RP) occurs in about 15% of patients, who have less renal disease and consequently lower mortality rates.

The CNS may be involved with vasculitis, manifested by hemiparesis, convulsions, epilepsy, diplopia, retinitis, and choroiditis. Livedo reticularis is a marker for patients at risk for CNS lesions (Sneddon syndrome; see earlier). Depression and anxiety are common in patients with SLE, and other psychiatric and personality have been reported as well.

Idiopathic thrombocytopenic purpura is occasionally the forerunner of SLE. Coombs-positive hemolytic anemia, neutropenia, and lymphopenia are other hematologic findings. The severity of thrombocytopenia may be a prognostic marker, but can also be followed as a biomarker for response to treatment. Gastrointestinal (GI) involvement may produce symptoms of nausea, vomiting, and diarrhea, and patients may develop intestinal pseudo obstruction. Frequently, the intestinal wall and the mesenteric vessels show vasculitis. Pulmonary involvement with pleural effusions, interstitial lung disease, pulmonary artery hypertension (PAH), and acute lupus pneumonitis may be present. Patients with SLE, pericardial effusions, and anti-RNP antibodies have higher rates of PAH. Sjögren syndrome (keratoconjunctivitis sicca) and Hashimoto thyroiditis are associated with SLE. Overlap with any of the connective tissue diseases may be seen, occurring in approximately 25% of patients. Muscular atrophy may accompany extreme weakness so that DM may be suspected. Myopathy of the vacuolar type may produce muscular weakness, myocardial disease, dysphagia, and achalasia of the esophagus. Steroid myopathy may also occur, and antimalarials may rarely induce myopathy.

The serum aldolase level may be elevated with a normal creatine phosphokinase.

A history of exposure to excessive sunlight before the onset of the disease or before an exacerbation is sometimes obtained. Some patients may have only mild constitutional symptoms for weeks or months, but immediately after exposure to strong sunlight, they may develop the facial eruption and severe disease complications.

Hydralazine, procainamide, sulfonamides, penicillin, anticonvulsants, minocycline, and isoniazid have been implicated as causes of drug-induced LE. Penicillamine induces (or unmasks) true SLE. HLA-DR4 individuals, who are slow acetylators, are predisposed to develop hydralazine-induced LE. Antibody to the histone complex H2A-H2B is closely associated with disease. Most drug-induced SLE is associated with a positive ANA, and antibodies directed against histones. Exceptions include penicillamine and etanercept, which may induce or unmask native disease with anti-dsDNA antibodies. L-Canavanine, an amino acid found in alfalfa sprouts and tablets, can also induce or worsen SLE. TNF-inhibitors can induce a variety of types of lupus, with infliximab surpassing etanercept as the most commonly reported culprit. Patients with anti–chimeric antibodies may be ANA positive, and patients with TNF-induced lupus frequently display a malar rash, photosensitivity, and meet ACR criteria for lupus.

Childhood Systemic Lupus Erythematosus

The onset of childhood SLE occurs between ages 3 and 15, with girls outnumbering boys 4:1. The skin manifestations may be the typical butterfly eruption on the face and photosensitivity. In addition, there may be morbilliform, bullous, purpuric, ulcerating, or nodose lesions. The oral mucosa is frequently involved. Skin eruptions may be associated with joint, renal, neurologic, and GI disease. Weight loss, fatigue, hepatosplenomegaly, lymphadenopathy, and fever are other manifestations. Pediatric patients with SLE and APLAs, specifically lupus anticoagulants, are at high risk of developing thromboembolic events.

Pregnancy and Female Hormones

Women with LE may have successful pregnancies, but they might have difficulty conceiving, and miscarriages occur with greater frequency, especially among those with APLAs. The course of pregnancy may be entirely normal, with remission of the LE, or the symptoms of LE may become worse. Risk of fetal death is increased in women with a previous history of fetal loss and anticardiolipin or anti-Ro antibodies. For the patient with these antibodies but without a history of previous fetal loss, the risk of fetal loss or neonatal lupus is low. In most cases, the pregnancy itself is well tolerated, although a flare of SLE may occur during the postpartum period. Although several studies failed to demonstrate a clinically significant association between oral contraceptive (OC) use and flares of SLE, recently a UK epidemiologic study found an increased risk of SLE with current use of OC, and the U.S. Nurses' Health Study suggested that OC and HRT were associated with SLE. There is a high incidence of thromboses in women with APLAs, and OCs containing second- or third-generation progestogens may induce a higher risk. One female-to-male transgender patient experienced significant improvement after testosterone therapy.

Etiology

Genetics plays an important role in LE, with over 100 loci identified in association with sLE. Many of these gene targets are involved in recognition of nucleic acid, type 1 IFN production, and immune signaling. Taken together, these data suggest polygenetic susceptibility to LE. A family history of connective tissue disease is a strong risk factor for all forms of LE. Monozygotic twins, however, display a low concordance rate, with lupus in approximately one fourth of cases. Some skin lesions of LE follow lines of Blaschko, suggesting postzygotic mutation or loss of heterozygosity for a genetic locus. Understanding of lupus genetics is rapidly evolving.

The C-reactive protein (CRP) response is defective in patients with flares of SLE, and the gene locus for CRP maps to 1q23.2 within an interval linked with SLE. Gene polymorphisms in *APRIL*, a member of the TNF family, have also been linked with SLE. Increased expression of TNF-α and IFN-inducible proteins are noted in cutaneous LE. Polymorphisms of the *C1qA* gene are associated with both systemic and cutaneous LE. HLA-DR3 confers risk for SLE, and C4 null alleles in Europeans is a specific genetic risk factor for SLE. Linkage varies in different ethnic groups and different clinical subsets of lupus.

Whole exome sequencing has helped identify rare monogenic variants of SLE and SLE-like diseases. *CYBB* mutations have an X-linked inheritance, and carriers have a higher risk of DLE and SLE. Mutations in *DNASE1L3* are associated with SLE with early onset and anti-dsDNA abs. *TREX1* mutations are associated with familial chilblain lupus.

Several aspects of the altered immune response are worth particular attention. T-suppressor cell function is reduced in patients with LE. Overproduction of γ-globulins by B cells and reduced clearance of immune complexes by the reticuloendothelial system may contribute to complement-mediated damage. Externalization of cellular antigens, such as Ro/SSA in response to sunlight, may lead to cell injury by way of antibody-dependent cellular cytotoxicity. Abnormal apoptosis or reduced clearance of apoptotic cells may lead to increased exposure of nucleosome antigens and antinucleosome antibodies.

Both ultraviolet (UV) B and UVA can upregulate antigen expression and cytokines, including IL-1, TNF-α, and LFA-1, causing release of sequestered antigens and free radical damage, with UV B felt to be the most pathologically relevant. All these mechanisms may contribute to photosensitivity and UV-induced flares of systemic disease. Air pollutants have been considered a potential trigger, due to increased concentrations of SLE in urban areas and a small Canadian study suggesting a possible link. Tobacco smoke is highly associated with cutaneous LE, but not with systemic LE, and may interfere with the efficacy of antimalarial therapy. Minimal credible data exist regarding other possible aggravating dietary factors, but some reports have implicated excess calories, excess protein, high fat (especially saturated and ω-6 polyunsaturated fatty acids), excess zinc, and excess iron.

Laboratory Findings

There may be hemolytic anemia, thrombocytopenia, lymphopenia, or leukopenia; ESR usually is greatly elevated during active disease but nonspecific. Coombs test may be positive, there is a biologic false-positive test for syphilis, and a rheumatoid factor (RF) may be present. IgG levels may be high, the albumin/globulin ratio is reversed, and serum globulin is increased, especially the γ-globulin or α2 fraction. Albumin, red blood cells, and casts are the most frequent findings in the urine.

Immunologic Findings

1. *ANA test.* This is positive in 95% of cases of SLE. Human substrates, such as Hep-2 or KB tumor cell lines, are far more sensitive than mouse substrates, and the historical entity "ANA-negative lupus" is quite rare now. ANA pattern has some correlation with clinical subsets, such as a shrunken peripheral pattern in SLE with renal disease, a fine particulate pattern in subacute cutaneous LE, and a homogeneous pattern with antihistone antibodies.
2. *Double-stranded DNA. Anti-dsDNA, anti–native DNA.* This is specific, but not very sensitive. It indicates a high risk of renal

disease, and correlates with a shrunken peripheral ANA pattern and positive DIF in sun-protected skin.

3. *Anti-Sm antibody.* Sensitivity is less than 10%, but specificity is very high.
4. *Antinuclear ribonucleic acid protein (anti-nRNP).* Very high titers are present in mixed connective tissue disease (MCTD). Lower titers may be seen in SLE.
5. *Anti-La antibodies.* These are common in SCLE and Sjögren syndrome, and occasionally found in SLE.
6. *Anti-Ro antibodies.* These are found in about 25% of SLE and 40% of Sjögren patients. They are more common in patients with SCLE (70%), neonatal LE (95%), C2- and C4-deficient LE (50%–75%), late-onset LE (75%), and Asian patients with LE (50%–60%). Photosensitivity may be striking, and externalization of the antigen is seen after UV exposure.
7. *Serum complement.* Low levels indicate active disease, often with renal involvement.
8. *Lupus band test. Direct cutaneous immunofluorescence.* Continuous granular deposits of immunoglobulins and complement along the DEJ occur in more than 75% of well-established lesions of DLE. In SLE, it usually is positive in sun-exposed skin. A positive test in normal, protected skin correlates with the presence of anti-dsDNA antibodies and renal disease. The lupus band test is seldom performed, because the same population of patients can be detected with anti-dsDNA antibodies.
9. *Anti-ssDNA antibody.* This test is sensitive but not specific. Many patients are photosensitive. An IgM isotope seen in DLE may identify a subset of patients at risk for developing systemic symptoms.
10. *Antiphospholipid antibodies.* Both the anticardiolipin antibody and the LA are subtypes of APLAs. These are associated with a syndrome that includes venous thrombosis, arterial thrombosis, spontaneous abortions, and thrombocytopenia. Livedo reticularis is a frequent skin finding, and nonfading acral microlivedo, with small, pink cyanotic lesions on the hands and feet, is a subtle clue to the presence of APLAs. These antibodies may occur in association with lupus and other connective tissue disease, or as a solitary event. In the latter case, it is referred to as the primary antiphospholipid syndrome.

Differential Diagnosis

Diagnostically, SLE must be differentiated from DM, EM, polyarteritis nodosa, acute rheumatic fever, RA, pellagra, pemphigus erythematosus (Senear-Usher syndrome), drug eruptions, hyperglobulinemic purpura, Sjögren syndrome, and myasthenia gravis. The SLE patient may have fever, arthralgia, weakness, lassitude, diagnostic skin lesions, increased ESR, cytopenias, proteinuria, immunoglobulin deposition at DEJ, and positive ANA test. Biopsies of skin lesions and involved kidney may also be diagnostic.

Treatment

Some general measures are important for all patients with LE. Exposure to sunlight must be avoided, and broad spectrum, high sun protection factor (SPF) sunscreen should be used daily. Photosensitivity is frequently present even if the patient denies it, and all patients must be educated about sun avoidance and sunscreen use. Smokers should be encouraged and assisted in quitting. The patient should also avoid exposure to excessive cold, to heat, and to localized trauma. Biopsies and scar revision will often provoke a flare of the disease. Women with SLE have an increased risk of osteoporosis, independent of corticosteroid use. Bone density should be monitored and calcium and vitamin D supplementation considered, especially with strict photoprotection. Vitamin D repletion was shown to improve response to some medications. Some women will benefit from bisphosphonate therapy, especially if corticosteroids are used. The most rapid bone loss with corticosteroid therapy occurs at the onset of treatment, so bisphosphonate therapy should not be delayed. Patients who will be treated with immunosuppressive agents should receive a tuberculin skin test, appropriate vaccinations, and thorough physical examination. Aggressive treatment is often necessary for discoid lesions and scarring alopecia. The slowly progressive nature of these lesions, and the lack of systemic involvement, may lead to inappropriate therapeutic complacency. The result is slow, progressive disfigurement.

Local Treatment. The application of potent or superpotent topical corticosteroids is beneficial in LE patients. Occlusion may be necessary and may be enhanced by customized vinyl appliances (especially for oral lesions) or surgical dressings. Tape containing corticosteroid (Cordran) is sometimes helpful. The single most effective local treatment is the injection of corticosteroids into the lesions. Triamcinolone acetonide, 2.5–10 mg/mL, is injected at intervals of 4–6 weeks. No more than 40 mg of triamcinolone should be used at one time. Steroid atrophy is a valid concern, but so are the atrophy and scar produced by the disease. The minimal intralesional dose needed to control the disease should be used; when the response is poor, however, it is generally better to err on the slightly more aggressive side of treatment than to undertreat. Topical calcineurin inhibitors may also be useful as second-line topical therapy. Topical retinoids have scattered reports of benefits, particularly for hypertrophic lesions. Cryosurgery has been used but may induce scarring, dyspigmentation, and flared. Although lupus is a photosensitive disorder, UVA-I therapy appears to be a useful adjuvant treatment modality in some patients; all light should be used with caution. Photodynamic therapy has been reported as effective. Lasers such as the PDL 585–595 nm laser have been used to treat individual lesions with improvement, but patients should be treated cautiously at low fluence if attempted.

Systemic Treatment. The safest class of systemic agent for LE is the antimalarials. Retinoids may be particularly helpful in treating hypertrophic LE. Systemic immunosuppressive agents are often required to manage recalcitrant cases or patients with systemic manifestations. Thalidomide can be effective, but its use is limited by the risk of teratogenicity and neuropathy. Methotrexate is often the next traditional systemic agent selected. Dapsone is the drug of choice for bullous systemic LE and may be effective in some cases of SCLE and DLE. Oral prednisone is generally reserved for acute flares of disease. Biologic agents and new targeted therapies are now used for refractory disease. One study of 73 antimalarial-refractory CLE patients showed that thalidomide was effective in 10 of 11, methotrexate in 10 of 19, dapsone in 8 of 18, belimumab in 6 of 16, MMF in 9 of 25, and azathioprine in 3 of 12.

Antimalarials. Hydroxychloroquine (Plaquenil), at a dose of 5 mg/kg/day or less, has an excellent safety profile and is generally used as first-line systemic therapy in most forms of cutaneous LE, with two thirds of patients responding. If no response occurs after 3 months, another agent should be considered. Chloroquine (Aralen) is effective at 250 mg/day for an average adult but is difficult to procure and has higher rates of ocular toxicity. Quinacrine (Atabrine), 100 mg/day, may be added to hydroxychloroquine because it adds no increased risk of retinal toxicity. Quinacrine is also difficult to procure and carries a higher risk of yellowish pigmentation than the other antimalarials. Systemic treatment can sometimes be reduced or stopped during the winter months. A Cochrane group review of randomized controlled trials (RCTs) concluded that hydroxychloroquine and acitretin appear to be of similar efficacy, although adverse effects are more severe and occur more often with acitretin.

Ocular toxicity is rare with doses of hydroxychloroquine of 5 mg/kg/day or less, and tends to occur in older patients, patients with liver or kidney disease, or after 5 years of therapy.

Ophthalmologic consultation should be obtained before, and approximately annually (depending on risk factors, this may not be necessary in the first few years of treatment). The finding of any visual field defect or pigmentary abnormality is an indication to stop antimalarial therapy.

Other reported side effects with antimalarials include hair loss, lichenoid eruptions, erythroderma, EM, purpura, urticaria, nervousness, tinnitus, abducens nerve paralysis, toxic psychoses, leukopenia, and thrombocytopenia. Antimalarials, except in very small doses, will exacerbate skin disease or cause hepatic necrosis in patients with porphyria cutanea tarda. They may also worsen or induce psoriasis. Quinacrine produces a yellow discoloration of the skin and conjunctivae. Antimalarials have also been known to produce blue-black pigmentation of the hard palate, nail beds, cartilage of the ears, alae nasi, and sclerae. Nausea, vomiting, anorexia, and diarrhea may develop. Aplastic anemia has rarely been noted in long-term therapy. A patient's brown or red hair may rarely turn light blond. Morbilliform eruptions are rare in patients with lupus, but occur in a quarter of patients with DM.

Corticosteroids. Systemic corticosteroids are highly effective for widespread or disfiguring lesions, but disease activity often rebounds quickly when the drug is discontinued. Because of long-term side effects, corticosteroid treatment should be limited to short courses to treat flares of disease or to obtain initial control while antimalarial therapy is being initiated. In patients with renal or neurologic involvement, corticosteroids should be administered in doses adequate to control the disease while treatment with a steroid-sparing regimen is initiated. Treatment with 1000 mg/day intravenous methylprednisolone for 3 days, followed by oral prednisone, 0.5–1 mg/kg/day, is effective in quickly reversing most clinical and serologic signs of activity of lupus nephritis. In general, the corticosteroid dose should be optimized to the lowest possible that controls symptoms and laboratory abnormalities.

Traditional Immunosuppressive Therapy. Aggressive treatment protocols with agents such as pulse cyclophosphamide (with hydration and mesna to prevent bladder toxicity) have greatly improved the outcome of renal LE. Other immunosuppressive agents (e.g., azathioprine, methotrexate, MMF), are often employed as steroid-sparing agents for refractory cutaneous disease. Methotrexate is often effective; patients with concomitant renal disease may be at higher risk of severe methotrexate toxicity, and all patients should receive folic acid concurrently. Some authorities have suggested that azathioprine is inferior to MMF in the treatment of cutaneous lesions.

Other Therapy. Isotretinoin therapy, 0.2–1 mg/kg/day, may be effective, especially in patients with hypertrophic or lichenoid lesions of LE. Rapid relapse may be noted when the drug is discontinued. Dapsone, clofazimine, acitretin, IFN alpha-2a, auranofin (oral gold), high-dose intravenous immune globulin (IVIG), and efalizumab have all been reported as effective in anecdotal use or limited trials. Thalidomide may be effective in antimalarial-refractory CLE, but is often limited by side effects including peripheral neuropathy. Lenalidomide may be more effective with lower rates of neurotoxicity and fewer side effects, and has increasingly been used to treat recalcitrant cases of CLE and SCLE, with response rates nearing 90%. Apremilast reduced disease activity in a pilot study of eight patients. Belimumab, a monoclonal antibody against B lymphocyte stimulator, was approved for SLE, but effects on cutaneous disease remain unclear. Anti-CD20 monoclonal antibody (rituximab) has been used successfully to treat life-threatening refractory SLE with renal and CNS involvement, as well as for hypocomplementemic urticarial vasculitis and refractory cutaneous lesions, though an RCT for SLE did not demonstrate success. Rituximab is also used for dapsone-resistant cases of BLE. Interleukin-6 (IL-6)–receptor inhibition with tocilizumab appears promising but may cause neutropenia. Sirukumab, another IL-6 antibody, was used in a study of 31 patients, with 91% experiencing adverse events and a nonsignificant decrease in disease activity.

Janus kinase (JAK) inhibitors are being explored for multiple interferonopathies and may have a role in treating lupus, and targeted anti-IFN antibodies are being evaluated as well. Ustekinumab has been reported as beneficial in a few cases of recalcitrant DLE.

DERMATOMYOSITIS

DM is typically characterized by inflammatory myositis and skin disease, although the hypomyopathic type (DM with subclinical) or amyopathic (with absent muscle disease) also occur. Muscle involvement without skin changes is called polymyositis (PM). With or without skin lesions, weakness of proximal muscle groups is characteristic.

Skin Findings

Usually the disease begins with erythema and edema of the face and eyelids. Eyelid involvement may be characterized by pruritic and scaly pink patches, edema, and pinkish violet (heliotrope) discoloration or bullae (Fig. 8.15). Edema and pinkish violet discoloration are often signs of inflammation in the underlying striated orbicularis oculi muscle, rather than the skin itself; the patient's eyelids may be tender to the touch.

Other skin changes include erythema, scaling, and swelling of the upper face, often with involvement of the eyebrows and scalp; scalp erythema alone may be the initial sign. Pruritus may be striking. Over time, some lesions may develop a reticulated pattern of white scarring. Extensor surfaces of the extremities are often pink, red, or violaceous with an atrophic appearance or overlying scale. The similarity to psoriasis can be striking, and patients may suffer severe flares of DM if they are inappropriately treated with phototherapy for presumed psoriasis. Photosensitivity to natural sunlight is common as well. Firm, slightly pitting edema may be seen over the shoulder girdle, arms, and neck (Fig. 8.16). Associated erythema and scale (with or without poikiloderma) over the shoulder regions is known as the "shawl sign." Similar changes on the hip are called the "holster sign." Pruritus may be severe, especially on the scalp, and is much more common in DM than in psoriasis or LE.

On the hands, telangiectatic vessels often become prominent in the proximal nailfolds. Enlarged capillaries of the nailfold appear as dilated, sausage-shaped loops with adjacent avascular regions, similar to those changes observed in scleroderma but without the associated sclerodactyly. There may be cuticular overgrowth with an irregular, frayed appearance (Fig. 8.17). A pink to reddish purple atrophic or scaling eruption often occurs over the knuckles, knees, and elbows (Gottron sign). Flat-topped, polygonal, violaceous papules over the knuckles (Gottron papules) are less common but highly characteristic of DM (Fig. 8.18). Hyperkeratosis, scaling, fissuring, and hyperpigmentation over the fingertips, sides of the thumb, and fingers, with occasional involvement of the palms, is referred to as "mechanic's hands" and has been reported in 70% of patients with antisynthetase antibodies (Fig. 8.19). Intermittent fever, malaise, anorexia, arthralgia, and marked weight loss are typically present at this stage.

Fig. 8.19 "Mechanic's hands" in dermatomyositis.

Rarely, large, persistent ulcerations in flexural areas or over pressure points may develop. Ulceration in the early stages of DM has been reported to be associated with a higher incidence of cancer and a poor prognosis, but the authors have seen many patients with ulcerative DM without associated cancer. In later stages, ulceration may merely be a manifestation of pressure or trauma to atrophic areas. Rare manifestations of DM include clinical findings of pityriasis rubra pilaris (Wong variant of DM) or generalized subcutaneous edema. Rarely, bullous DM may develop, which portends a poor prognosis, with associated severe inflammatory myopathy or lung disease. In approximately 5% of patients, a flagellate pattern mimicking bleomycin-induced linear edematous streaks or erythroderma may be seen.

Although the classic cutaneous manifestations of DM can be seen with patients with anti-Mi2 antibodies, recently other specific patterns of cutaneous findings that may correlate with certain disease-specific antibodies have been described. Dave Fiorentino has championed many of these subphenotyping efforts. Hypopigmented and telangiectatic ("red on white") patches, palmar hyperkeratotic papules, and psoriasis-like lesions may be associated with autoantibodies to TIF-1γ. Ovoid palatal violaceous erythema has also been reported. These patients have lower rates of ILD and arthritis, but this autoantibody appears to be associated with higher rates of malignancy (see later discussion). Patients with anti-MDA5 antibodies usually have clinically amyopathic DM, but display high rates of cutaneous ulcerations, digital tip ulcerations, swollen and puffy fingers, "inverse Gottron" lesions with papules on the flexural creases of the digits, which may ulcerate, and have high rates of vasculopathy and severe, rapidly progressive, often fatal interstitial lung disease. Patients with this phenotype may also have an elevated serum ferritin.

Calcium deposits in the skin and muscles occur in more than half of children with DM and are found infrequently in adults, although recently anti-NXP2 antibodies have been shown to be more associated with calcinosis cutis; in adults it is also a marker of an increased rate of malignancy. Calcification is related to duration of disease activity and its severity. Calcinosis of the dermis, subcutaneous tissue, and muscle occurs mostly on the upper half of the body around the shoulder girdle, elbows, and hands. Ulcerations and cellulitis are frequently associated with this debilitating and disabling complication of DM.

Muscle Changes

In patients with severe DM, early and extensive muscular weakness occurs, with acute swelling and pain. The muscle weakness is seen symmetrically, most frequently involving the shoulder girdle and sometimes the pelvic region, as well as the hands. The patients may notice difficulty in lifting even the lightest objects. They may be unable to raise their arms to comb their hair, and rising from a chair may be impossible without "pushing off" with the arms. Patients often complain of pain in the legs when standing barefoot or of being unable to climb stairs. Difficulty in swallowing, talking, and breathing, caused by weakness of the involved muscles, may be noted early in the disease, and as with cutaneous phenotypes, may turn out to be more common with certain disease-specific antibodies, as over 75% of patients with anti-SAE antibodies develop dysphagia. Some patients with severe diaphragmatic disease require mechanical ventilation. Cardiac failure may be present in the terminal phase of the disease.

Skin involvement frequently precedes muscle involvement, but some patients have typical skin findings of DM but never develop clinically apparent muscle involvement. These cases have been termed *amyopathic DM* or *DM sine myositis*. However, muscle inflammation often is present but not symptomatic, identified only via laboratory or radiographic testing, and the term *hypomyopathic* is preferred. Muscle enzymes (creatine kinase [CK] and aldolase), electromyography (EMG), and magnetic resonance imaging (MRI) may be required to detect subtle involvement.

Diagnostic Criteria

The following criteria are used to define DM/PM:

- Skin lesions
- Heliotrope rash (red-purple edematous erythema on upper palpebra)
- Gottron papules or sign (red-purple flat-topped papules, atrophy, or erythema on extensor surfaces and finger joints)
- Proximal muscle weakness (upper or lower extremity and trunk)
- Elevated serum CK or aldolase level
- Muscle pain on grasping or spontaneous pain
- Myogenic changes on EMG (short-duration, polyphasic motor unit potentials with spontaneous fibrillation potentials)
- Positive anti–Jo-1 (histadyl tRNA synthetase) antibody
- Nondestructive arthritis or arthralgias

- Systemic inflammatory signs (fever >37°C at axilla, elevated serum CRP level or accelerated ESR of >20 mm/hr by Westergren method)
- Pathologic findings compatible with inflammatory myositis

Patients with the first criterion, skin lesions, and four of the remaining criteria have DM. Patients lacking the first criterion but with at least four of the remaining criteria have PM. Some patients with DM have little evidence of myopathy, and drug eruptions may mimic the characteristic rash. In particular, hydroxyurea has been associated with a DM-like eruption. Antisynthetase antibody syndrome presents with variable systemic manifestations, mainly PM, interstitial lung disease, cutaneous lesions, and Raynaud phenomenon. These criteria may evolve as our understanding of the specific phenotypes correlating to subsets of DM-specific antibodies expands.

Fig. 8.20 Dermatomyositis, Gottron sign.

Associated Diseases

DM may overlap with other connective tissue diseases. Sclerodermatous changes are the most frequently observed; this is called sclerodermatomyositis. Antibodies such as anti-Ku and anti-PM/scl may be present in this subgroup. Mixed connective tissue disease associated with high anti-ribonucleoprotein (RNP), RA, LE, and Sjögren syndrome may occur concomitantly. DM may be associated with interstitial lung disease (ILD), which is frequently the cause of death, particularly in patients with anti-MDA5 DM who present with rapidly progressive ILD. The presence of anti–Jo-1 antibody, as well as other antisynthetase antibodies, such as anti–PL-7, anti–PL-12, anti-DJ, and anti-EJ, correlates well with the development of pulmonary disease. All patients with DM should routinely be screened for ILD.

Neoplasia With Dermatomyositis

In adults, malignancy is frequently associated with DM, with an overall relative risk 4–5 times the general population. The malignancy is discovered before, simultaneously, or after the DM at near-equal rates. The highest probability of finding an associated tumor occurs within 2 years of the diagnosis. Factors associated with malignancy include age, constitutional symptoms, rapid onset of DM, lack of Raynaud phenomenon, and a grossly elevated ESR or CK level. Anti–TIF1-γ and anti-NXP2 antibodies in adults may a marker for an even higher rate of malignancy. Malignancy is most frequently seen in patients in the fifth and sixth decades of life. Routine "age-appropriate screening" may be inadequate to uncover a significant number of malignancies, as some cancers, such as ovarian cancer and nasopharyngeal cancer, are strongly overrepresented in DM patients, and not captured on routine surveillance. In addition to history and physical examination, a stool guaiac test for occult blood (Hemoccult) or colonoscopy, mammography, pelvic examination and pap smear, chest radiography, and computed tomography (CT) scans of the abdominal, pelvic, and thoracic areas may be indicated. Transvaginal ultrasound or abdominal MRI may be necessary to evaluate the endometrium and ovaries. Tumor markers such as CA19-9 and CEA-125 should be considered. Some clinicians advocate for positron emission tomography imaging, as it may take patients a long time to obtain all of the individual screening tests; cost-benefit analyses are ongoing. Periodic rescreening may be of value, but the appropriate interval for screening has not been established, with most experts suggesting intense screening initially, within the first 3 years, followed by symptom-based and age-appropriate surveillance.

Childhood Dermatomyositis (Fig. 8.20)

Several features of childhood DM differ from the adult form. Two childhood variants exist. The more common Brunsting type has a slow course, progressive weakness, calcinosis, and steroid responsiveness. Calcinosis may involve intermuscular fascial planes or may be subcutaneous. The second type, the Banker type, is characterized by a vasculitis of the muscles and GI tract, rapid onset of severe weakness, steroid unresponsiveness, and high mortality rate. Internal malignancy is seldom seen in children with either type (even in children with the malignancy-associated antibodies), but insulin resistance may be present. Calcinosis cutis is more common in children with severe disease.

Etiology

Evidence indicates that muscle findings in DM are related to humoral immunity, a vasculopathy mediated by complement deposition, lysis of endomysial capillaries, and resulting muscle ischemia. In contrast, PM and inclusion-body myositis are related to clonally expanded CD8+ cytotoxic T cells invading muscle fibers and causing necrosis through the perforin pathway. The initial immune response in DM includes a type I IFN signature with an IFN-α/β–induced cascade with secondary stimulation of IFN-γ. Many autoantibodies may be present in DM, some of which are disease specific and can identify specific subgroups, indicating a possible role for B cells in the disease.

Both healthy individuals and children with juvenile DM may demonstrate persistence of maternal microchimerism, but the incidence is higher in children with juvenile DM. This has also been demonstrated in patients with other connective tissue diseases, such as scleroderma. The finding may be an epiphenomenon or may be part of a pathogenic alloimmune response. An inherited predisposition has been demonstrated, and studies of juvenile DM gene expression have shown DQA1*0501 in 85% of patients.

Viral or bacterial infections may produce an abnormal immune response, and human herpesvirus 6 reactivation has been reported. Fulminant disease may be related to an endotheliotropic viral infection. Epitopes of group A β-hemolytic streptococcal M protein have sequence homology with myosin and can elicit both cell-mediated cytotoxicity and TNF-α production when incubated with mononuclear cells from children with active juvenile DM. The TNF-α-308A allele is associated with increased TNF-α synthesis in juvenile DM patients and with increased thrombospondin 1 and small-vessel occlusion. Interestingly, as with LE, DM can be induced by anti-TNF biologic agents. In adults with PM and DM, endothelial damage occurs early. Pathogenic factors in adults include IL-1α, transforming growth factor–β (TGF-β), and myoblast production of IL-15. Cases associated with terbinafine may be related to apoptosis induced by the drug. DM is relatively rarely induced by medications, but atorvastatin has been reported, and the emerging reports of autoimmune

diseases in the setting of checkpoint inhibitor therapy include cases of DM.

Incidence

The disease is twice as prevalent in women as in men and 4 times as common in black as in white patients. There is a bimodal peak, the smaller one seen in children and the larger peak in adults age 40–65.

Histopathology

The histologic changes in DM are similar to those of LE. The two may be indistinguishable, although lesions of DM tend to become atrophic more often. Lesions typically demonstrate thinning of the epidermis, hydropic degeneration of the basal layer, BMZ thickening, papillary dermal edema, and a perivascular and periadnexal lymphocytic infiltrate in the superficial and deep dermis with increased dermal mucin. Scattered melanophages are present in the superficial dermis. Compared with LE, DM shows less eccrine coil involvement and fewer vertical columns of lymphocytes in fibrous tract remnants. Subcutaneous lymphoid nodules and panniculitis are rarely seen in DM. Certain subtypes and different lesion morphologies demonstrate different histopathologic findings, such as the dusky or ulcerated lesions in anti-MDA5 DM patients, which histologically often show vascular plugging and dermal necrosis. Characteristic changes are found in the muscles. The deltoid, trapezius, and quadriceps muscles seem to be almost always involved and are good biopsy sites. Muscle bundles demonstrate lymphoid inflammation and atrophy, which preferentially affects the periphery of the muscle bundle. Muscle biopsy is directed to those areas found to be most tender or in which EMG demonstrates myopathy. MRI is a useful aid in identifying active sites for muscle biopsy and may obviate the need for biopsy in some cases. The short T1 inversion recovery (STIR) magnetic resonance images are best and can be used to localize disease and longitudinally assess results of treatment.

Laboratory Findings

The serum CK levels are elevated in most patients. Aldolase, lactic dehydrogenase (LDH), and transaminases (AST in particularly, but also ALT) are other indicators of active muscle disease. There may be leukocytosis, anemia with low serum iron, and an increased ESR. Ferritin may be elevated. Positive ANA tests are seen in 60%–80% of patients; with the expanded profile of DM-specific antibodies being discovered, more than two thirds of DM patients may have identifiable myositis-specific antibodies.

Cutaneous DIF is positive in at least one third of cases, with a higher yield in well-established lesion (at least 3–6 months old). Cytoid bodies are often seen, although continuous granular staining with IgG, IgM, and IgA may be seen.

X-ray studies with barium swallow may show weak pharyngeal muscles. MRI of the muscles is an excellent way to assess activity of disease noninvasively.

The EMG studies for diagnosis show spontaneous fibrillation, polyphasic potential with voluntary contraction, short duration potential with decreased amplitude, and salvos of muscle stimulation.

Chest imaging and pulmonary function testing should be performed to evaluate for signs of interstitial lung disease.

Differential Diagnosis

DM must be differentiated from erysipelas, SLE, angioedema, drug eruptions, trichinosis, and EM. Aldosteronism, with adenoma of adrenal glands and hypokalemia, may also cause puffy heliotrope eyelids and face. Hydroxyurea may produce an eruption resembling DM.

Treatment

Prednisone is the mainstay of acute treatment for DM patients, at doses beginning with 1 mg/kg/day, until severity decreases and muscle enzymes are almost normal. The dosage is reduced with clinical response. The aspartate transaminase (AST, SGOT)/alanine transaminase (ALA/SGOT) and CK return to normal levels as remission occurs. Methotrexate and MMF are used as steroid-sparing agents and should be started early in the course of treatment to reduce steroid side effects. Because of the increased risk of ILD with methotrexate, some avoid this agent in patients with pulmonary disease or anti–Jo-1 antibodies, and many clinicians use MMF as the steroid-sparing drug of choice. This may be particularly helpful in patients with interstitial lung disease, due to possible antifibrotic effects. Azathioprine is less expensive than MMF, but skin disease may not respond as well. If patients do not respond adequately to methotrexate, MMF, or azathioprine, are often used. Rituximab may help muscle disease, but is less effective for skin disease. In severe cases tacrolimus in particular, but also cyclosporine or cyclophosphamide may be beneficial. Anti–TNF-α treatment with infliximab has proved a rapidly effective therapy for some patients with myositis. Etanercept has also been used, but some studies have found little improvement or flares of muscle disease. Because anti-TNF therapy has been shown to induce DM, patients should be monitored carefully. Leflunomide, an immunomodulatory drug used to treat RA, has been effective as adjuvant therapy.

In severe juvenile DM, pulse IV methylprednisone or oral prednisone are effective for acute management, but some data suggest that corticosteroids may not be necessary in many children treated with methotrexate or IVIG. Rituximab appears promising in the treatment of refractory disease. Onset of calcinosis is associated with delays in diagnosis and treatment, as well as longer disease duration. Calcinosis related to DM has been treated with aluminum hydroxide, alendronate, diphosphonates, diltiazem, probenecid, colchicine, low doses of warfarin, sodium thiosulfate, and surgery with variable, but usually poor, results. Autologous stem cell transplantation has been reported as successful.

The skin lesions may respond to systemic therapy; however, response is unpredictable, and skin disease may persist despite involution of the myositis. Because DM is photosensitive, sunscreens with high SPF (>30) should be used daily, and patients should be counseled about sun avoidance. Topical corticosteroids may be helpful in some patients. Antimalarials such as hydroxychloroquine at 200–400 mg/day (2–5 mg/kg/day in children) have been shown to be useful in abating the eruption of DM, although adverse cutaneous reactions occur in one fourth of patients, and up to one half of those who react to hydroxychloroquine will also react to chloroquine. Beyond the traditional immunosuppressant agents discussed previously, IVIG (0.5–1g/kg/d for 2 days each month) may be beneficial, particularly for skin disease. IVIG has been associated with thromboembolic events, including deep venous thrombosis, pulmonary embolism, myocardial infarction, and cerebrovascular accident (stroke), and this risk must be weighed against the benefits of the drug; some utilize concomitant aspirin. IVIG has been successfully used even in recalcitrant cases of severe anti-MDA5 pattern disease with rapidly progressive-ILD and vasculopathy. Case reports and series suggest dapsone can help cutaneous DM. Biologic agents have been utilized with increasing frequency in small reports, including anakinra, TNF inhibitors, tocilizumab, and abatacept. Recently the JAK inhibitor ruxolitinib has been reported to be dramatically beneficial for refractory cases of DM. Cannabinoids appear to reduce DM-associated inflammatory cytokines and are being actively studied. Other agents under investigation include sifalimumab and belimumab.

In pregnant patients who require treatment, evidence supports the use of topical corticosteroids and topical calcineurin inhibitors. Published evidence also suggests that systemic corticosteroids, hydroxychloroquine, and azathioprine may be used in pregnancy when necessary.

Prognosis

Major causes of death in DM patients are cancer, ischemic heart disease, and lung disease. Independent risk factors include failure to induce clinical remission, white blood cell count above 10,000/mm^3, temperature greater than 38°C (100.4°F) at diagnosis, older age, shorter disease history, and dysphagia. Early aggressive therapy in juvenile cases is associated with a lower incidence of disabling calcinosis cutis.

SCLERODERMA

Scleroderma disorders comprise a group of diseases characterized by thickening and sclerosis of the skin. This includes both localized, skin-only diseases, and systemic diseases. Localized scleroderma generally refers to morphea-spectrum disorders, including morphea (localized, generalized, profunda, atrophic, and pansclerotic types) or linear scleroderma (with or without melorheostosis or hemiatrophy). Systemic sclerosis includes limited systemic sclerosis (also known as CREST syndrome) and diffuse systemic sclerosis (at higher risk of significant internal organ disease). These disorders are characterized by the appearance of circumscribed or diffuse, hard, smooth, ivory-colored areas that are immobile and give the appearance of hidebound skin.

Cutaneous Types

Localized Morphea

The morphea form of scleroderma is twice as common in women as men and occurs in childhood as well as adult life. It presents most often as macules or plaques a few centimeters in diameter, but also may occur as bands or in guttate lesions or nodules. Rose or violaceous macules may appear first, followed by smooth, hard, somewhat depressed, yellowish white or ivory lesions. The lesions are most common on the trunk (Fig. 8.21) but also occur on the extremities.

The margins of the areas are generally surrounded by a lilac border or by telangiectases. Within the patch, skin elasticity is lost, and when it is picked up between the thumb and index finger,

Fig. 8.21 Morphea.

Fig. 8.22 Generalized morphea.

it feels rigid. The follicular orifices may be unusually prominent, leading to a condition that resembles pigskin.

In guttate morphea, multiple small, chalk-white, flat or slightly depressed macules occur over the chest, neck, shoulders, or upper back. The lesions are not very firm and may be difficult to separate clinically from guttate lichen sclerosus et atrophicus (LSA).

Morphea–Lichen Sclerosus Et Atrophicus Overlap

Some patients present with lesions of both morphea and LSA, typically women with widespread morphea who have LSA lesions separated from morphea or overlying morphea. When the changes are seen above dermal changes of morphea, the characteristic inflammatory lymphoid band of LSA is lacking, suggesting that the superficial homogenization is actually a manifestation of morphea rather than a separate disease process.

Generalized Morphea

Widespread involvement by indurated plaques with pigmentary change characterizes generalized morphea. Muscle atrophy may be present, but no visceral involvement (Fig. 8.22). These patients may have autoantibodies to topoisomerase, though antibody testing is not generally necessary, and diagnosis is made clinically. Patients may lose their wrinkles as a result of the firmness and contraction of skin. Spontaneous involution is less common with generalized morphea than with localized lesions. If very widespread, these patients can be mistaken as having systemic sclerosis; importantly, this type of morphea generally spares the hands and face and is not associated with Raynaud phenomenon.

Pansclerotic Morphea

Pansclerotic morphea manifests as sclerosis of the dermis, panniculus, fascia, muscle, and at times the bone. The patient has disabling limitation of joint motion. This devastating disorder can also be mistaken for systemic sclerosis, though again patients lack some of the internal involvement and vascular components of that disorder.

Morphea Profunda

Most types of morphea involve the dermis and little to none of the panniculus. Morphea profunda involves deep subcutaneous tissue, including fascia. There is clinical overlap with eosinophilic fasciitis, eosinophilia myalgia syndrome, and the Spanish toxic oil syndrome. The latter two conditions were related to contaminants found in batches of tryptophan or cooking oil. Unlike eosinophilic fasciitis, morphea profunda shows little response to corticosteroids and tends to run a more chronic debilitating course.

Fig. 8.23 Linear morphea. (Courtesy Debabrata Bandyopadhyay, MD.)

Linear Scleroderma/Linear Morphea

These linear lesions may extend the length of the arm or leg and may follow lines of Blaschko. Two thirds of cases are diagnosed in patients under 18, but adult cases do occur, and women are the majority of patients. Lesions may also occur parasagittally on the frontal scalp and extend partly down the forehead (en coup de sabre; Fig. 8.23). The Parry-Romberg syndrome, which manifests as progressive hemifacial atrophy, epilepsy, exophthalmos, and alopecia, may be a form of linear scleroderma. When the lower extremity is involved, there may be associated spina bifida, faulty limb development, hemiatrophy, or flexion contractures. Melorheostosis, seen on radiographs as a dense, linear cortical hyperostosis, may occur. At times, linear lesions of the trunk merge into more generalized involvement. Physical therapy of the involved limb is of paramount importance to prevent contractures and frozen joints. Patients may have additional associated autoimmune diseases.

Atrophoderma of Pasini and Pierini

In 1923 Pasini described a peculiar form of atrophoderma which some have considered within the spectrum of morphea. The disease consists of brownish gray, oval, round or irregular, smooth atrophic lesions depressed below the level of the skin, with a well-demarcated, sharply sloping "cliff-drop" border. Some of the appearance of depression is an optical illusion related to the color change. Atrophoderma occurs mainly on the trunk of young, predominantly female, patients (Fig. 8.24). The lesions are usually asymptomatic and may measure 20 cm or more in diameter. Linear atrophoderma of Moulin is a related condition that follows lines of Blaschko. Rarely congenital cases have been described.

Biopsies of atrophoderma demonstrate a reduction in the thickness of the dermal connective tissue, including alteration in elastic fibers (more so than collagen fiber changes characteristic of classic variants of morphea). Because the changes may be subtle, a biopsy should include normal-appearing skin so that a comparison may be made.

Fig. 8.24 Atrophoderma of Pasini and Pierini.

Fig. 8.25 Telangiectases in CREST syndrome.

Systemic Types

CREST Syndrome

This variant of systemic scleroderma has the most favorable prognosis because of the usually limited systemic involvement (limited systemic sclerosis [LcSSc]). Patients with CREST syndrome develop ***c***alcinosis cutis, ***R***aynaud phenomenon, ***e***sophageal dysmotility, ***s***clerodactyly, and ***t***elangiectasia (Fig. 8.25). Patients may present with sclerodactyly, severe heartburn, or telangiectatic mats. The mats tend to have a smooth outline, in contrast to the mats of the Osler-Weber-Rendu syndrome, which tend to exhibit an irregular outline with more radiating vessels. This

Fig. 8.26 Sclerodactyly.

form of scleroderma generally lacks serious renal or pulmonary involvement, though a subset may develop ILD or pulmonary hypertension. Patients typically have skin involvement limited to the hands, feet, face, and forearms. Anticentromere antibodies are highly specific for the CREST syndrome, being positive in 50%–90% of cases and only 2%–10% of patients with progressive sclerosis.

Progressive Systemic Sclerosis

Progressive systemic sclerosis (SSc) is a generalized disorder of connective tissue in which there is thickening of dermal collagen bundles, as well as fibrosis and vascular abnormalities in internal organs. RP is the first manifestation of SSc in more than half the cases. Other patients present with "woody edema" of the hands, which can precede the classic skin thickening. This form of scleroderma tends to involve the truncal skin as well. The heart, lungs, GI tract, kidney, and other organs are frequently involved. Women are affected 3 times more often than men, with peak age of onset between the third and fifth decades. Patients may have anti–Scl-70 antibodies (45%) and/or anti-RNA polymerase antibodies.

Classic criteria include either proximal sclerosis or two or all of the following:

1. Sclerodactyly (Fig. 8.26)
2. Digital pitting scars of the fingertips or loss of substance of the distal finger pad
3. Bilateral basilar pulmonary fibrosis

Localized forms of scleroderma must be excluded. These criteria have been shown to be 97% sensitive and 98% specific for the diagnosis. The ACR has proposed an expanded list of criteria for SSc, as follows:

1. *Skin changes:* tightness, thickening, and nonpitting induration, sclerodactyly, proximal scleroderma; changes proximal to the metacarpophalangeal or metatarsophalangeal joints and affecting other parts of the extremities, face, neck, or trunk (thorax or abdomen), digital pitting, loss of substance from the finger pad, bilateral firm but pitting finger or hand edema, abnormal skin pigmentation (often "pepper and salt"). The changes are usually bilateral and symmetric and almost always include sclerodactyly. The modified Rodnan skin score is typically used to measure skin involvement and estimate skin thickness using palpation.

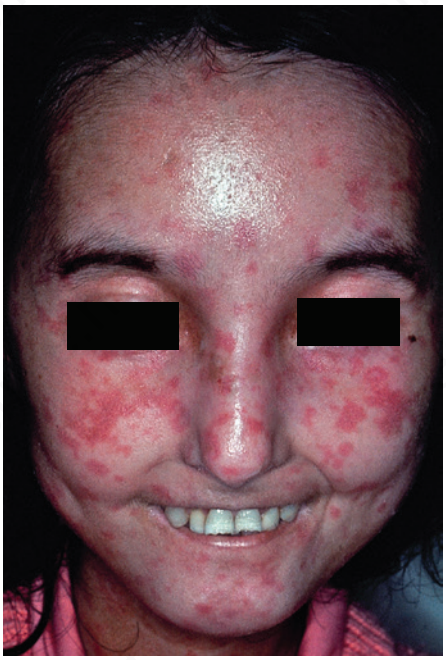

Fig. 8.27 Facial involvement in scleroderma.

2. *Raynaud phenomenon:* at least two-phase color change in fingers and often toes consisting of pallor, cyanosis, and reactive hyperemia.
3. *Visceral manifestations:* bibasilar pulmonary fibrosis not attributable to primary lung disease, lower (distal) esophageal dysphagia, lower (distal) esophageal dysmotility, colonic sacculations.

There exists a rare variant of scleroderma termed *systemic sclerosis sine scleroderma* in which patients only have internal organ involvement.

Skin Findings. In the earlier phases of scleroderma, affected areas are erythematous and swollen. Patients are frequently misdiagnosed as having carpal tunnel syndrome and may even have positive EMG results. RP is often present and suggests the correct diagnosis. Over time, sclerosis supervenes. The skin becomes smooth, yellowish, and firm and shrinks so that the underlying structures are bound down. The earliest changes often occur insidiously on the face and hands, and in more advanced stages these parts become "hidebound," so the face is expressionless, the mouth is constricted (Fig. 8.27), and the hands are clawlike. The facial skin appears drawn, stretched, and taut, with loss of lines of expression. The lips are thin, contracted, and radially furrowed; the nose appears sharp and pinched; and the chin may be puckered. The "neck sign" is described as a ridging and tightening of the neck on extension, occurring in 90% of patients with scleroderma.

The disease may remain localized to the hands and feet for long periods (acrosclerosis). The fingers become semiflexed, immobile, and useless, the overlying skin hard, inelastic, incompressible, and pallid. The terminal phalanges are boardlike and indurated. In the "round finger-pad sign," the fingers lose their normal peaked contour and appear as rounded hemispheres when viewed from the side. This process may lead to loss of pulp on the distal digit. Trophic ulcerations and gangrene may occur on the tips of the fingers and knuckles, which may be painful or insensitive. In pterygium inversum unguis, the distal part of the nail bed remains adherent to the ventral surface of the nail plate; it may be seen in scleroderma and LE or may be idiopathic. Dilated nailfold capillary loops are present in 75% of systemic scleroderma patients. Symmetrically dilated capillaries are seen adjacent to avascular areas. Nailfold capillary hemorrhage in two or more fingers is highly specific for scleroderma and correlates with the anticentromere antibody.

Keloid-like nodules may develop on the extremities or the chest, either as an extremely rare isolated skin phenomenon (nodular scleroderma), or within other areas of sclerosis. There may be a widespread diffuse calcification of the skin, as shown by radiographs. A diffuse involvement of the chest may lead to a cuirass-like restraint of respiration. Late in the course of the disorder, hyperpigmented or depigmented spots or a diffuse bronzing may be present. The most characteristic pigmentary change is a loss of pigment in a large patch with perifollicular pigment retention within it. Perifollicular pigmentation may appear in response to UV light exposure. Pigment may also be retained over superficial blood vessels. The affected areas become hairless, and atrophy is often associated with telangiectasia. Bullae and ulcerations may develop, especially on the distal parts of the extremities.

Rarely patients may have true overlap of morphea and systemic sclerosis. In one review of 370 patients with SSc, 12 (3.2%) of patients had coexistent morphea, generally in patients with limited cutaneous SSc.

Internal Involvement. Sclerosis may involve most of the internal organs. Esophageal involvement is seen in more than 90% of SSc patients; the distal two thirds of the esophagus is affected, leading to dysphagia and reflux esophagitis. Small intestinal atonia may lead to constipation, malabsorption, or diarrhea. Pulmonary fibrosis with arterial hypoxia, dyspnea, and productive cough may be present. Progressive nonspecific interstitial fibrosis, with bronchiectasis and cyst formation, is the most frequent pathologic change. Pulmonary hypertension and right-sided heart failure are ominous signs, occurring in 5%–10% of patients. The cardiac involvement produces dyspnea and other symptoms of congestive heart failure. Sclerosis of the myocardium also produces conduction changes and may result in arrhythmia. Pericarditis, hypertension, and retinopathy may be present.

The skeletal manifestations include articular pain, swelling, and inflammation. Polyarthritis may be the first symptom in SSc. There is limitation of motion as a result of skin tautness, followed by ankylosis and severe contractual deformities. The hand joints are involved most frequently. There may be resorption and shortening of the phalanges and narrowing of the joint spaces. Osteoporosis and sclerosis of the bones of the hands and feet may occur, as well as decalcification of the vault of the skull.

Childhood SSc has identical cutaneous manifestations. RP occurs less often, whereas cardiac wall involvement is more common and is responsible for half of deaths. Renal disease is unusual. Familial scleroderma rarely occurs.

Prognosis. The course of SSc is variable. Renal disease accounts for some early mortality, but pulmonary disease remains the major cause of death. The patient's age at disease onset is a significant risk factor for pulmonary arterial hypertension. Cardiac disease also correlates with a poor prognosis, whereas GI involvement contributes mainly to morbidity. ANA patterns predict different subsets of disease with varying prognosis. Anticentromere antibodies correlate with CREST syndrome and a good prognosis, whereas Scl-70 and ANA correlate with a poorer prognosis. Malignancy may be associated with SSc in up to 10% of patients, with lung and breast cancer the most frequent associated malignancies. The presence of many telangiectases is strongly associated with the presence of pulmonary vascular disease.

Laboratory Findings. In SSc, ANA testing is positive in more than 90% of patients. As noted, several of these antibodies identify specific clinical subsets of patients. The antinucleolar pattern is considered most specific for systemic sclerosis and when present as the only pattern, it is highly specific for systemic sclerosis.

When antibodies to such nucleolar antigens as RNA polymerase t and fibrillarin are present, diffuse sclerosis, generalized telangiectasia, and internal organ involvement are often seen. The homogeneous ANA pattern is seen in patients with PM-Scl antibodies, the marker for PM-SSc overlap. The true speckled or anticentromere pattern is sensitive and specific for the CREST variant. Patients with antibodies to Scl-70 tend to have diffuse truncal involvement, pulmonary fibrosis, and digital pitted scars, but a lower incidence of renal disease. Antibodies to nuclear RNP are found in patients with Raynaud phenomenon, polyarthralgia, arthritis, and swollen hands. Very high RNP titers define MCTD. These patients are fairly homogeneous and the term is not synonymous with connective tissue overlap. Anti-ssDNA antibodies are common in linear scleroderma. Anti-Rpp25 chemiluminescence and anti-Th/To by immunoprecipitation correlate with limited cutaneous and internal involvement. Anti-U11 RNP, Scl-70, Th/To, and TRIM/Ro52 have been related to ILD and poor survival. RNA pol III is associated with diffuse disease, but low risk of ILD. Cryoglobulins are only found in about 3% of patients with SSc, but the presence of cryoglobulinemic vasculitis is associated with a poor prognosis. Monoclonal gammopathy has rarely been reported in association with morphea, particularly morphea profunda.

Radiographic Findings. The GI tract is almost always involved. Esophagography, esophageal manometry, and a 24-hour pH study may be helpful. In early esophageal involvement, a barium swallow in the usual upright position may be reported as normal, but if the patient is supine, barium will often be pool in the flaccid esophagus. The stomach may atonic resulting in delayed emptying time, and involvement of the intestine may cause producing a characteristic radiographic picture of persistently dilated intestinal loops long after the barium has passed through. CT scan of the chest may reveal interstitial lung disease. Echocardiography may detect both direct cardiac involvement and pulmonary hypertension. Cardiac MRI may be preferred to identify heart fibrosis. Cutaneous calcinosis may be visualized on plain radiography, though that is rarely required.

Histology

Systemic and localized forms of scleroderma show similar histologic changes, although lymphoid infiltrates tend to be heavier in the acute phase of morphea. In the acute phase, there is a perivascular lymphocytic infiltrate with plasma cells that is heaviest at the junction of the dermis and subcutaneous fat. Collagen bundles become hyalinized, and the space between adjacent bundles is lost. Loss of CD34+ dermal dendritic cells is an early finding.

Dermal sclerosis typically results in a rectangular punch biopsy specimen. As the dermis replaces the subcutaneous tissue, eccrine glands appear to be in the midportion of the thickened dermis. The subcutaneous fat is quantitatively reduced, and adventitial fat (fat that normally surrounds adnexal structures on trunk) is lost. Collagen abuts directly on the adnexal structures. Elastic fibers in the reticular dermis may be prominent and stain bright red, and the papillary dermis may appear pale and edematous. In advanced lesions, the inflammatory infiltrate may be minimal. Pilosebaceous units are absent, and eccrine glands and ducts are compressed by surrounding collagen.

On DIF testing of skin, the nucleolus may be stained in the keratinocytes if antinucleolar circulating antibodies are present. A "pepper-dot" epidermal nuclear reaction pattern may be seen in CREST patients who have anticentromere antibodies in their serum.

Differential Diagnosis

Myxedema is softer and associated with other signs of hypothyroidism. Diabetic scleredema tends to be erythematous and affects the central back in a pebbly pattern. Scleromyxedema begins with discrete papules but may assume an appearance similar to SSc. A paraprotein is typically present. Sclerodactyly may be confused with digital changes of Hansen disease and syringomyelia. Eosinophilic fasciitis (EF) lacks RP and is more treatment responsive. The skin is thickened, edematous, and erythematous and has a coarse, peau d'orange appearance, unlike its sclerotic, taut appearance in scleroderma. The hands and face are usually spared in EF, and when the arms are involved, the blood vessels draw inward when the arms are raised, producing a "dry riverbed" appearance. EF of the forearms may cause finger contraction and can be mistaken for SSc.

In vitiligo, the depigmentation is the sole change in the skin, and sclerosis is absent. Scleroderma in the atrophic stage may closely resemble acrodermatitis chronica atrophicans (ACA), but ACA shows more attenuation of collagen fibers and a diffuse lymphohistiocytic infiltrate. Lyme titers may be positive.

Dermal fibrosis is a major feature of chronic, sclerodermoid graft-versus-host disease (GVHD), porphyria cutanea tarda, phenylketonuria, carcinoid syndrome, juvenile-onset diabetes, progeria, and the Werner, Huriez, and Crow-Fukase (POEMS) syndromes. Occupational exposure to silica, epoxy resins, polyvinyl chloride (PVC), and vibratory stimuli (jackhammer or chainsaw) may produce sclerodermoid conditions. Chemicals (e.g., PVC), bleomycin, isoniazid, pentazocine, valproate sodium, epoxy resin vapor, vitamin K (after injection), contaminated Spanish rapeseed oil (toxic oil syndrome), contaminated tryptophan (eosinophilia-myalgia syndrome), nitrofurantoin, and hydantoin may also induce various patterns of fibrosis. Gadolinium-containing contrast agents may rarely induce nephrogenic systemic fibrosis (NSF) in patients with kidney dysfunction, which can closely resemble SSc. The "stiff skin syndrome," also known as congenital fascial dystrophy, is characterized by stony-hard induration of the skin and deeper tissues of the buttocks, thighs, and legs, with joint limitation and limb contractures. The disease begins in infancy. Scleroderma-like symptoms may be the presenting features of multiple myeloma and amyloidosis. IgG4-related disease presents with soft tissue sclerosis, elevated serum IgG4, and increased IgG4-positive plasma cells in a variety of tissues.

Pathogenesis

The pathogenesis of systemic sclerosis and morphea involves vasculopathy, fibrosis, and inflammation, and may result from a combination of environmental exposures and genetic risk factors resulting in epigenetic changes, including DNA methylation and histone modification, leading to the observed phenotype. It has been suggested that the autoimmune mechanisms may be due to microchimerism resulting in alloimmune graft-versus-host reactions. Both anticardiolipin and anti–β2-glycoprotein I antibodies appear to play roles in pathogenesis. The plasma D-dimer concentration correlates with macrovascular complications. *Borrelia afzelii* and *Borrelia garinii* are related to the development of morphea-like lesions in some cases. Other environmental agents may be involved. Epidemiologic studies support the role of organic solvents and certain chemicals. In women, there is an association with teaching and working in the textile industry. Genetically *HLA DRB1*, *DQB1*, *DQA1*, *DPB1* genes, and variants in *STAT4*, *IRF5*, and *CD247* have been reported in association with SSc, with one study also suggesting GSDMA and PRDM1 gene loci as conferring risk. *HLA-DRB1* and B37 may be risk alleles for morphea. One case control study identified occupational exposure to heavy metals including antimony, cadmium, lead, mercury, molybdenum, palladium, and zinc as potential risk factors for SSc. Morphea has been reported following trauma, subcutaneous medication injections, and there are multiple radiation-induced cases.

The immune mechanisms involved are complex. Certain chemokines and cytokines that have been identified as potentially

involved include NFKB, STAT4, IFN-γ, and interleukins. CXCL9 appears to be an important chemokine and has been proposed as a possible biomarker of disease activity in morphea. Upregulated proteins and messenger RNAs include monocyte chemoattractant protein 1 (MCP-1), pulmonary and activation-regulated chemokine, macrophage inflammatory protein 1 (MIP-1), IL-4, IL-6, IL-8, CRP, platelet-derived growth factor receptor–β (PDGFR-β), and possibly TGF-β. These factors may stimulate extracellular matrix production, TGF-β production and activation, and chemoattraction of T cells. Various target antigens have been proposed, including a protein termed *protein highly expressed in testis* (PHET), which is ectopically overexpressed in scleroderma dermal fibroblasts. Serum antibodies to a recombinant PHET fragment have been detected in 9 (8.4%) of 107 scleroderma patients, but in none of 50 SLE patients or 77 healthy controls.

The macrophage receptor protein CD163 is upregulated in scleroderma, and increased levels of soluble CD163 correlate with disease progression. Expression of CD40 is increased on fibroblasts in lesional skin, and ligation of CD40 by recombinant human CD154 results in increased production of IL-6, IL-8, and MCP-1 in a dose-dependent manner. These phenomena are not shown in normal fibroblasts with the addition of CD154. Lesion skin of early-stage scleroderma contains T cells preferentially producing high levels of IL-4. CD4+ T-helper 2 (Th2)–like cells can inhibit collagen production by normal fibroblasts and the inhibition is mediated by TNF-α. The inhibition is dominant over the enhancement induced by IL-4 and TGF-β. To be inhibitory, Th2 cells require activation by CD3 ligation. Th2 cells are less potent than T-helper 1 (Th1) cells in inhibiting collagen production by normal fibroblasts, and fibroblasts from involved skin are resistant to inhibition. Because Th2 cells reduce type I collagen synthesis through the effect of TNF-α, TNF-α blockade by new biologics should be approached with caution. Drug-induced morphea has been related to the cathepsin K inhibitor balicatib, used for osteoporosis. Capecitabine, an oral prodrug of 5-fluorouracil used in the treatment of metastatic colon and breast carcinoma, has been associated with a hand-foot syndrome with sclerodactyly. Onset of systemic sclerosis with digital ulcers has been reported during IFN-β therapy for multiple sclerosis.

Treatment

Although effective treatment is available for many of the visceral complications of SSc, treatment for the skin disease remains unsatisfactory. Spontaneous improvement may be seen in some children and in some cases of localized scleroderma. Physical therapy emphasizing range of motion for all joints as well as the mouth is important. Exposure to cold is to be avoided, and smoking is forbidden. Among patients with scleroderma, smokers are 3 to 4 times more likely than never-smokers to incur digital vascular complications. Although early treatment may be beneficial, end-stage fibrosis or inactive morphea may not respond to even high-dose suppression. The future lies with early aggressive intervention before the development of fibrosis and organ damage. Monitoring treatment response is important. The Rodnan score can be used to measure skin disease. Objective measures of improvement of skin sclerosis can be obtained by means of durometer measurements and high-resolution ultrasound. The course of microangiopathic changes can be evaluated with serial nailfold videocapillaroscopy.

RP is managed with vasodilating drugs—CCBs, angiotensin II receptor antagonists, topical nitrates, and prostanoids—as the mainstay of medical therapy. CCBs such as nifedipine (Procardia XL), 30–60 mg/day, are often used as first-line therapy. Some patients who experience worsening of esophageal reflux with nifedipine do better with diltiazem (Cardizem CD), 120–180 mg/day. Phosphodiesterase-5 (PDE-5) inhibitors can reduce the frequency and severity of RP attacks. Antioxidants such as vitamin C have been used, but data are mixed. Both sildenafil (Viagra) and IV or inhaled iloprost are useful in the treatment of both pulmonary hypertension and RP. Ginkgo biloba has been shown to have some efficacy in a double-blind trial. Oral L-arginine has reversed digital necrosis in some patients with RP and improved symptoms in others. Fluoxetine has been reported to improve RP in one small study. Botulinum toxin, topical nitroglycerin, and warming—both maintaining a warm core, and direct hand warming—on a regular basis may also be effective. Bosentan, an oral, dual endothelin receptor antagonist, has been effective in preventing and treating scleroderma-related ulcers, and oral treprostinil diethanolamine has been shown to improve skin perfusion in an open label trial. Digital ulcers may benefit from IV iloprost, bosentan, and/or PDE-5 inhibitors.

Systemic sclerosis should be managed in conjunction with an experienced rheumatologist and other organ-specific experts, and managed based on their disease subset, pattern of organ involvement, and comorbidities. Diffuse SSc should be treated with immunosuppression, generally methotrexate, mycophenolate mofetil, or cyclophosphamide as first-line treatment. Azathioprine or mycofenolate are often used after cyclophosphamide for maintenance. Systemic corticosteroids have been used, but evidence of benefit is limited and patients must be monitored closely for scleroderma renal crisis. TNF blockade has shown some benefit in reducing fibrosis, but has also triggered onset of disease. Rituximab has resulted in resolution of limited disease associated with anti-TNF therapy. Extracorporeal phototherapy has been used in the past. IVIG was helpful for internal involvement in one retrospective study in France. Abatacept has been reported as beneficial in a small randomized trial. Tyrosine kinase inhibitors are being actively studied due to their activity on pathways involved in fibrosis, including imatinib and nilotinib. Similarly, anti-IFN therapy, agents that target TGF-β1 signaling, and inhibitors of histone deacetylase are being actively explored. Although there is strong evidence that the ACE inhibitors are disease modifying for scleroderma renal crisis, better RCTs are still needed. Epoprostenol is used to treat pulmonary hypertension in scleroderma, based largely on evidence that it can be lifesaving in the treatment of primary pulmonary hypertension. Other promising drugs for visceral involvement include bosentan (for pulmonary hypertension and ischemic ulcers), cyclophosphamide (for alveolitis), IFN-γ (for interstitial pulmonary fibrosis), IV prostaglandins (for vascular disease), and sildenafil (for pulmonary hypertension and Raynaud phenomenon). Bone marrow and nonmyeloablative allogeneic hematopoietic stem cell transplantation has shown dramatic and sustained benefits in some patients.

For localized scleroderma/morphea, management depends on the type of disease. If there is no inflammation, and simply bound down tissue, it is doubtful whether active antiinflammatory or suppressive therapy is helpful. If there is active inflammation, topical therapy with corticosteroids tacrolimus, or calcipotriene may be helpful for plaque disease. Topical imiquimod 5% was helpful in one small study. Deeper disease or recalcitrant plaque disease can be treated with phototherapy with NB-UVB and photochemotherapy, especially with UVA I. Generalized morphea or linear morphea may be treated with methotrexate, with or without corticosteroids, generally as first-line treatment. Mycophenolate is second line after methotrexate. Severe or recalcitrant cases may be treated with agents similar to SSc. Cyclosporine has been shown to be effective in a retrospective study of 12 patients with morphea. Widespread morphea has been treated with hydroxychloroquine, TNF inhibitors, oral calcitriol, retinoic acid, penicillamine, colchicine, and oral tacrolimus as well. Halofuginone, an inhibitor of collagen type I synthesis, can decrease collagen synthesis in the tight-skin mouse and murine GVHD, and application of halofuginone caused a reduction in skin scores in a pilot study with scleroderma patients.

Calcinosis tends to be challenging to treat. Surgical removal, CCBs, bisphosphonates, colchicine, minocycline, and other agents have been employed with limited success. Carbon dioxide (CO_2) laser vaporization has produced remission of symptoms in cutaneous calcinosis of CREST syndrome. Emerging reports of sodium thiosulfate, both systemically and locally, show mixed results.

EOSINOPHILIC FASCIITIS

In 1974 Lawrence Shulman described a disorder that he called diffuse eosinophilic fasciitis. Classically, patients had engaged in strenuous muscular activity for a few days or weeks before the acute onset of weakness, fatigability, and pain and swelling of the extremities. The prodrome was followed by severe induration of the skin and subcutaneous tissues of the forearms and legs. A favorable response to corticosteroids was noted. Since the initial description, environmental exposures have been rarely reported as possible triggers for the syndrome, including L-tryptophan contaminated with 1,1′-ethylidenebis, *Borrelia*, and exposure to trichloroethylene. Some consider this disease to be a variant of scleroderma, though it lacks the vascular and internal manifestations. Polycythemia vera, metastatic colorectal carcinoma, and multiple myeloma have been associated in a limited number of patients, suggesting that some cases may represent a paraneoplastic phenomenon.

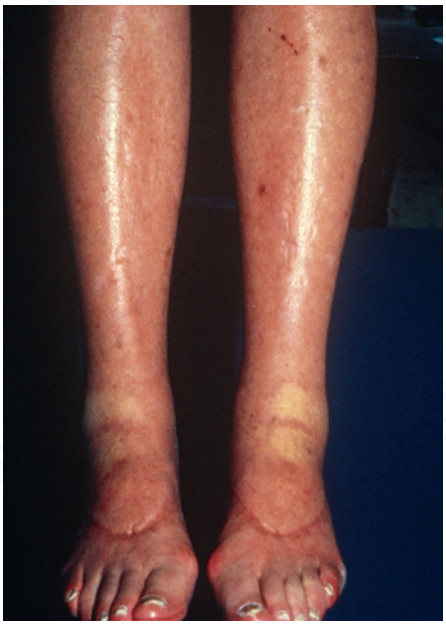

Fig. 8.28 Eosinophilic fasciitis.

The skin is usually edematous and erythematous, with a coarse peau d'orange appearance, and a "pseudocellulite" appearance most noticeable inside the upper arms, thighs, or flanks. The hands and face are usually spared. When the patient holds the arms laterally or vertically, linear depressions occur within the thickened skin. This "groove sign" or "dry riverbed sign" follows the course of underlying vessels (Fig. 8.28). This contrasts with scleroderma, in which the skin remains smooth and taut. Limitation of flexion and extension of the limbs and contracture may develop in 50% of patients, and patients may be unable to stand fully erect. Physical therapy is important. In contrast to scleroderma, RP is absent. Tightening of the forearm may retract the fingers, and it is important to distinguish EF from SSc. Associated systemic abnormalities have included carpal tunnel syndrome, peripheral neuropathy, seizures, posterior ischemic optic neuropathy, pleuropericardial effusion, pancytopenia, anemia, antibody-mediated hemolytic anemia, thrombocytopenia, Sjögren syndrome, lymphadenopathy, pernicious anemia, and IgA nephropathy. Patients with EF are frequently misdiagnosed initially. Detected cytokine abnormalities are similar to those in atopic patients, but with a striking elevation of TGF-β1. Th17-mediated inflammation may be involved. ESR is generally increased, and hypergammaglobulinemia is common. Many patients (10%–40%) exhibit a peripheral eosinophilia. Increased production of IL-5 and clonal populations of circulating T cells have been reported.

Biopsy shows a patchy lymphohistiocytic and plasma cell infiltrate in the fascia and subfascial muscle, with massive thickening of the fascia and deep subcutaneous septa. Eosinophils may or may not be present in the affected fascia. The inflammatory infiltrate is mainly composed of macrophages and lymphocytes, often with a CD8+ T lymphocyte predominance. CT and MRI have both been used to demonstrate fascial thickening and may obviate the need for biopsy in some cases.

Early treatment is ideal, but sometimes delayed due to failure to recognize EF. Patients are often treated with initially high-dose steroids, and then weekly methotrexate, and may do better with

combination therapy than corticosteroids alone. The response to systemic corticosteroids is generally excellent. In responders, complete recovery is usual within 1–3 years. Some patients have also demonstrated a response to histamine blockers, including hydroxyzine and cimetidine. Patients with a prolonged course unresponsive to systemic corticosteroids are sometimes diagnosed as overlap cases with morphea profunda. In refractory cases, hydroxychloroquine, cyclosporineazathioprine, psoralen plus UVA (PUVA), bath PUVA, extracorporeal photochemotherapy, IVIG, rituximab, mycophenolate, sirolimus, and other immunosuppressive regimens have been used with variable success. Recently high-dose IV pulse methotrexate was reported as helpful. Both infliximab and IV cyclophosphamide used with moderate- to high-dose prednisolone have been reported as effective in refractory cases.

MIXED CONNECTIVE TISSUE DISEASE

Patients with a constellation of overlapping clinical and serologic features of other connective tissue diseases, including SSc, myositis, rheumatoid arthritis, and lupus, may be diagnosed with MCTD. It is unclear whether MCTD is a final diagnosis or whether it represents an overlap syndrome and that overtime patients with MCTD may end up better characterized as a specific autoimmune disease, often SSc or SLE. MCTD is defined by the presence of Raynaud phenomenon, arthralgias, swollen joints, esophageal dysfunction, muscle weakness, and sausage-like appearance of the fingers (Fig. 8.29), together with the presence of high titer anti-RNP antibodies in the absence of anti-Sm antibodies. The term is not synonymous with "overlap syndrome," a combination of diseases in which each disease complies with the diagnostic criteria for that disorder. MCTD is not synonymous with undifferentiated connective tissue disease (UCTD)—patients with connective tissue disease who have not yet developed a defined disease. Only about 4% of patients with UCTD go on to develop MCTD.

The ANA test typically demonstrates a particulate pattern in MCTD, reflecting the high titers of nuclear RNP antibodies (anti-RNP antibodies). In addition, particulate epidermal nuclear IgG deposition on DIF study of skin is a distinctive finding in MCTD. Anti–TS1-RNA antibodies appear to define a subpopulation with predominance of lupus-like clinical features. Patients with a younger age of onset and those with pulmonary hypertension, Raynaud phenomenon, and livedo reticularis have a higher risk of mortality. Causes of death include pulmonary fibrosis and pulmonary arterial hypertension, cardiovascular events, renal disease, CNS disease, thrombotic thrombocytopenic purpura, and infection.

Fig. 8.29 Mixed connective tissue disease. (Courtesy Steven Binnick, MD.)

For acute treatment, corticosteroids such as prednisone (1 mg/kg/day) are effective for inflammatory features such as arthritis and myositis. As with LE, MCTD may be associated with an independent risk of osteoporosis, and the long-term morbidity associated with corticosteroid treatment can be significant. Bisphosphonate therapy and therapy with a steroid-sparing agent should be considered early. In general, the LE features of MCTD are the most likely to improve with therapy, and the scleroderma features are the least likely to improve. Generally, the prognosis is better than that of scleroderma, largely related to the lower incidence of renal disease. Life-threatening complications refractory to other treatment often respond to rituximab. In the setting of thrombocytopenia, the response rate is 80%.

NEPHROGENIC SYSTEMIC FIBROSIS

NSF is a fibrosing skin condition that resembles scleromyxedema histologically. It usually develops in patients with renal insufficiency on hemodialysis, although it has been noted in patients with acute renal failure who had never undergone dialysis. Gadolinium-containing MRI contrast agents are considered the trigger, and incidence of NSF has decreased since their use has been limited in patients with renal failure. Cases typically develop weeks to months after gadolinium, but may develop many years (3–10) after exposure. Concurrent infection, increased serum phosphate and calcium concentrations, iron, and acidosis may play important roles in pathogenesis. Clinical findings of NSF include thickened sclerotic or edematous papules and plaques involving the extremities and trunk. Yellow scleral plaques and scleral telangiectasia resembling conjunctivitis have been described. Gadolinium within cutaneous sclerotic bodies, termed *gadolinium-associated plaques*, has been reported. Soft tissue calcification is rare but may be extensive when it occurs. Clinically, NSF differs from scleromyxedema by the lack of involvement of the face, absence of plasma cells, and lack of paraproteinemia. Deep tissue or systemic involvement is generally absent but may occur.

Histologic sections demonstrate plump bipolar CD34+ spindle cells with dendrites extending along both sides of elastic fibers (tram track sign), many new collagen bundles, and increased mucin. With time, thickened collagen bundles become prominent in the reticular dermis. Ossification with trapped elastic fibers appears to be fairly specific for gadolinium exposure. Myofibroblasts have been noted in lesional skin. Immunohistochemical staining for CD34 and procollagen I in the spindle cells of NFD suggests that many of the dermal cells of NFD may represent circulating fibrocytes recruited to the dermis. The CD34 positivity in NFD contrasts with the loss of CD34+ cells in morphea.

Effective therapy remains elusive. Improved renal function appears to improve NSF, including renal transplantation, which may be significantly helpful. Topical retinoids, steroids, and vitamin D analogs are not effective. Immunosuppressive therapy appears

to be of little benefit. In three cases evolving after liver transplantation, treatment with basiliximab, MMF, calcineurin inhibitor, and prednisone did not stop the development of "woody" skin induration of the distal extremities, erythematous papules, and contractures. Some data support a beneficial effect from phototherapy, extracorporeal photopheresis, or IV sodium thiosulfate, tyrosine kinase inhibitors, and rapamycin. All patients should be referred for physical therapy.

SJÖGREN SYNDROME (SICCA SYNDROME)

Sjögren syndrome is a chronic autoimmune disorder characterized by lymphocytic infiltration of the exocrine glands, particularly the salivary and lacrimal glands. One third of patients present with extraglandular manifestations, such as vasculitis. Most patients are age 50 or older, and more than 90% are women. Genes associated with Sjögren syndrome generally fall in the NF-kB, IFN signaling, lymphocyte signaling, and antigen presentation pathways. *IRF5*, a gene in IFN signaling and B-cell differentiation, may confer risk. Secondary Sjögren syndrome is defined as xerostomia and keratoconjunctivitis sicca in patients with other connective tissue diseases. The presence of arthritis, leukopenia, proteinuria, or low complement levels suggests secondary Sjögren syndrome. These patients have lower incidences of xerostomia and ILD compared with patients who have primary Sjögren syndrome.

Xerostomia may produce difficulty in speech and eating, increased tooth decay, thrush, and decreased taste (hypogeusia). Patients frequently suck on sour candies to stimulate what little salivary secretions remain, and those unfamiliar with the condition may blame the habit of sucking lemon drops for the ensuing tooth decay. Sjögren syndrome alters the composition of saliva, producing a decrease in salivary amylase and carbonic anhydrase, along with an increase in lactoferrin, β2-microglobulin, cystatin C, sodium, and lysozyme C.

Rhinitis sicca (dryness of nasal mucous membranes) may induce nasal crusting and decreased olfactory acuity (hyposmia). Vaginal dryness and dyspareunia may develop. Dry eyes are painful, feel gritty or scratchy, and produce discharge and blurry vision. Fatigue is a prominent symptom. In addition, there may be laryngitis, gastric achlorhydria, thyroid enlargement resembling Hashimoto thyroiditis, malignant lymphoma, thrombotic thrombocytopenic purpura, painful distal sensory axonal neuropathy, and splenomegaly.

Skin manifestations of Sjögren syndrome include vasculitis, xerosis, pruritus, and annular erythema. Decreased sweating occurs. Asian patients have been described who develop erythematous, indurated, annular dermal plaques, primarily on the face. This is different from the annular lesions of SCLE, which show epidermal change and histologic changes of lupus. Patients may also present with an overlap of Sjögren syndrome and LE. A common finding in these patients is Ro/SSA antibody positivity. These patients are also at risk of neonatal lupus. SCLE patients with Sjögren syndrome have a worse prognosis than patients with SCLE not associated with Sjögren syndrome. Patients may have low levels of vitamin D, and some data suggest that it may play a role in disease pathogenesis.

Patients with Sjögren syndrome and cutaneous vasculitis also have a significant incidence of peripheral, renal, or CNS vasculitis. Cutaneous vasculitis may present as purpura of the legs, which may be palpable or nonpalpable. Sjögren vasculitis accounts for most patients with Waldenström benign hypergammaglobulinemic purpura; about 30% of these patients will have or will develop Sjögren syndrome, and a high percentage have SSA and SSB antibodies. Other cutaneous vascular manifestations are urticarial vasculitis, digital ulcers, and petechiae. Histologically, a leukocytoclastic vasculitis is found at the level of the postcapillary venule, with expansion of the vascular wall, fibrin deposition, and karyorrhexis, but no necrosis of the endothelium.

Labial salivary gland biopsy from inside the lower lip is usually regarded as the most definitive test for Sjögren syndrome. Typically, there is a dense lymphocytic infiltrate with many plasma cells and fewer histiocytes in aggregates within minor salivary glands. More than one focus of 50 or more lymphocytes is typically present per 4 mm^2 of the tissue biopsy. Lymphoepithelial islands predominate early, whereas glandular atrophy predominates in the late stages. At this stage, few lymphoid aggregates are present. Xerostomia is diagnosed by the Schirmer test and reflects diminished glandular secretion from the lacrimal glands. Imaging studies are also helpful.

Classically, the diagnosis is made when there is objective evidence for two of three major criteria: (1) xerophthalmia, (2) xerostomia, and (3) an associated autoimmune, rheumatic, or lymphoproliferative disorder. These criteria may be too restrictive, however, because patients are increasingly being identified with predominantly extraglandular disease. The lack of sicca symptoms or anti-SSA or anti-SSB antibodies does not exclude Sjögren syndrome. Numerous serologic abnormalities are associated with Sjögren syndrome or its associated conditions. Antibodies to fodrin, a major component of the membrane cytoskeleton of most eukaryotic cells, are present in some populations with primary and secondary Sjögren syndrome. IgA and IgG antibodies against α-fodrin are detected in 88% and 64%, respectively, in some studies. In other populations, fodrin antibodies are less helpful. About 80% of patients have anti-Ro/SSA antibodies; half as many have anti-La/SSB antibodies. The RF is usually positive, and elevated ESR, serum globulin, and CRP and high titers of IgG, IgA, and IgM are common. Cryoglobulins may be demonstrated. Dendritic cells are increased in tissue during the early phases of the disease.

The aquaporin family of water channels (proteins freely permeated by water but not protons) appears to be an important target in the pathogenesis of Sjögren syndrome. Both duct and secretory cells are targets for the activation of CD4+ T cells. IL-12 and IFN-γ are upregulated. It appears that Th1 cytokines mediate the functional interactions between antigen-presenting cells (APCs) and CD4+ T cells in early lesions.

Patients with Sjögren syndrome are predisposed to the development of lymphoreticular malignancies, especially non-Hodgkin B-cell lymphoma. Both malignant and nonmalignant extraglandular lymphoproliferative processes occur. Cases of pseudolymphoma have the potential for regression or for progression to overt B-cell lymphoma. Patients with palpable purpura, low C4, and mixed monoclonal cryoglobulinemia are at higher risk for lymphoma.

The differential diagnosis of Sjögren syndrome includes sarcoidosis, lymphoma, amyloidosis, and human immunodeficiency virus (HIV) disease. HIV produces diffuse infiltrative lymphocytosis syndrome (DILS), which is characterized by massive parotid enlargement; prominent renal, lung, and GI manifestations; and a low frequency of autoantibodies.

Treatment for Sjögren syndrome has largely been symptomatic, but disease-modifying therapy is also becoming a reality. Artificial lubricants are helpful for eye symptoms as well as oral, nasal, and vaginal dryness. Topical lubricants are useful for xerosis. In hot climates, patients with impaired sweating must be counseled to

avoid heatstroke. Secretagogs such as pilocarpine and cevimeline, along with topical fluoride, are used for dry mouth. In all trials, mechanical stimulation by the lozenge may play a significant role in improvement of symptoms, as reflected in a high placebo response. Acid maltose lozenges are less expensive and remain useful for symptomatic relief. Secretagogs may also have a role in the treatment of dry eyes. Topical cyclosporine is often employed as well. Pilocarpine has been shown to have a beneficial effect on subjective eye symptoms, as well as improvement of rose bengal staining. For patients with systemic disease, there is a lack of high-quality evidence to guide therapy. Hydroxychloroquine is often used, and depending on severity and type of symptoms, immunosuppressive agents are frequently used. Severe disease may require high-dose steroids, and cryoglobulinemia may require plasma exchange or rituximab. TNF inhibitors show some promise.

Reactive Palisading Granulomatous Dermatitis

Rheumatoid arthritis (RA) is a fairly common inflammatory arthritis that can occur at any age, and occurs in women 2–3 times more than in men. HLA-DRB1 contributes to disease risk, and more specific alleles have been identified in different populations and with varying clinical significance. Polymorphisms in STAT-4 and IL-10 genes confer risk. Beyond genetic factors, environmental exposures and epigenetics appears to play a role, particularly cigarette smoke. The most common skin finding is the development of rheumatoid nodules (RNs), which occur in 20% of patients, particularly those with high titers of RF. There may be annular erythemas, purpura, bullae, shallow ulcers, and gangrene of the extremities. Many diseases have been reported to occur in association with RA, such as erythema elevatum diutinum, pyoderma gangrenosum, Felty syndrome, IgA vasculitis, linear IgA disease, Sjögren syndrome, bullous pemphigoid, and yellow nail syndrome. Treatment of RA with disease-modifying drugs has reduced the burden of destructive disease for patients, and treatment paradigms are rapidly evolving.

Methotrexate remains a mainstay of treatment, with corticosteroids serving as temporary bridging agents primarily. Other disease-modifying antirheumatic drugs (DMARDs) include sulfasalazine and hydroxychloroquine. Biologic agents are being used with increasing frequency, including TNF inhibitors, IL-6 antagonists, abatacept, and rituximab, along with the JAK inhibitors. Methotrexate-treated RA patients have an increased incidence of melanoma. Of interest to dermatologists, extracts from the *Rhus* family of plants have shown some benefit in limited studies.

Rheumatoid Nodules

Subcutaneous nodules are seen in 20%–30% of patients (Fig. 8.30). They may arise anywhere on the body but most frequently are found over the bony prominences, especially on the extensor surface of the forearm just below the elbow and the dorsal hands. The lesions are nontender, firm, skin-colored, round nodules, which may or may not be attached to the underlying tissue. Frequently, they are attached to the fibrous portions of the periarticular capsule, or they may be free in the subcutaneous tissue. RNs can easily be mistaken for xanthomas because of a yellow color (pseudoxanthomatous variant). They are seen most commonly when there is a high RF. RNs may also occur in 5%–7% of patients with SLE, especially around small joints of the hands, with variable RF positivity. Accelerated RN may occur with the appearance of multiple RNs, typically following initiation of a treatment for RA, most commonly methotrexate (but may also occur in the setting of TNF or hydroxychloroquine therapy). Histologic examination of the RN shows intensely staining eosinophilic necrobiosis surrounded by histiocytes in palisade arrangement. There is scant to absent mucin staining, distinguishing from subcutaneous granuloma annulare.

Fig. 8.30 Rheumatoid nodules.

RNs are differentiated from Heberden nodes, which are tender, hard, bony exostoses on the dorsolateral aspects of the distal interphalangeal joints of patients with degenerative joint disease. Nodules or tophi of gout are characterized by masses of feathery urate crystals surrounded by a chronic inflammatory infiltrate often containing foreign body giant cells.

Rarely, RA patients present with multiple ulcerated nodules and high RF, but no active joint disease. This variant of rheumatoid disease without destructive joint disease is designated "rheumatoid nodulosis." These patients may instead have subcutaneous granuloma annulare (GA) rather than RA.

Rheumatoid Vasculitis

This is a rare complication with declining incidence, typically seen in late-stage, severe RA. Peripheral vascular lesions appear as localized purpura, nailfold infarcts, cutaneous ulceration, and digital ischemia and gangrene of the distal parts of the extremities. Additionally, papular lesions located primarily on the hands have been described as rheumatoid papules. These show a combination of vasculitis and palisading granuloma formation. An RF is typically present. Peripheral neuropathy is frequently associated with the vasculitis. The presence of RNs may help to distinguish these lesions of vasculitis from SLE, polyarteritis nodosa, eosinophilic granulomatosis with polyangiitis (Churg-Strauss), Buerger disease (thromboangiitis obliterans), and the dysproteinemias. Prednisone and cytotoxic agents are frequently used, as in other forms of vasculitis. Hydroxychloroquine and aspirin may be protective. Rituximab has also been used successfully.

Rheumatoid Neutrophilic Dermatosis

Chronic urticaria–like plaques characterized histologically by a dense neutrophilic infiltrate have been described in patients with debilitating RA (Fig. 8.31). The differential diagnosis includes erythema elevatum diutinum and Sweet syndrome. Patients have been treated with steroids, dapsone, or other RA-targeting therapies.

Fig. 8.31 Rheumatoid neutrophilic dermatosis presents with urticarial plaques.

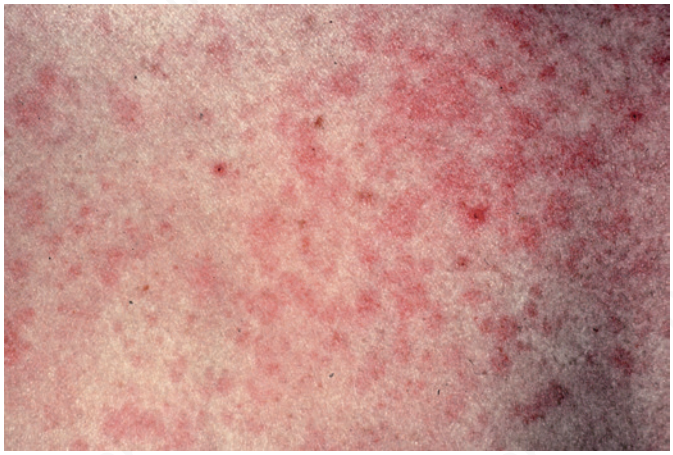

Fig. 8.32 Still disease.

Reactive Palisading Granulomatous Dermatitis

Reactive granulomatous dermatitis may be seen in patients with RA, such as interstitial granulomatous dermatitis (IGD) with arthritis, which shares significant overlap with palisaded neutrophilic and granulomatous dermatitis. IGD can present with round to oval erythematous or violaceous plaques on the flanks, axillae, inner thighs, and lower abdomen. Linear, slightly red or skin-colored cords extending from the upper back to the axilla called the "rope sign" have been described. When the lesions resolve, they may leave behind hyperpigmentation and a slightly wrinkled appearance. Arthritis may occur before, during, or after the eruption and tends to affect multiple joints of the upper extremities. IGD and related disorders can also occur with other autoimmune diseases, including SLE, and with hematologic disorders. Medication-induced cases have been rarely described, particularly with CCBs.

Histologically, a moderate to dense inflammatory infiltrate is seen through the reticular dermis, composed mostly of histiocytes distributed interstitially around discrete bundles of sclerotic collagen, which may demonstrate a "floating sign" as the inflammatory collection peels away from the normal collagen. Variable numbers of neutrophils and eosinophils are seen. Mucin, necrobiosis, vasculitis, and vacuolar change are usually absent or mild. The eruption is typically asymptomatic and may spontaneously involute after many months or years. If therapy is required, intralesional corticosteroids, methotrexate, hydroxychloroquine, dapsone, etanercept, ustekinumab, tocilizumab, and cyclosporine have been used, though most treatment is directed at the underlying disease.

Palisaded neutrophilic and granulomatous dermatitis represents another reactive granulomatous disorder and usually associated with a well-defined connective tissue disease, most commonly SLE, or RA. It often presents with eroded or ulcerated, symmetrically distributed umbilicated papules or nodules on the elbows, knuckles, and knees. The biopsy may reveal interstitial neutrophils and leukocytoclastic debris, with leukocytoclastic vasculitis in 30% of cases, accompanied by varying degrees of collagen degeneration. Palisaded granulomatous infiltrates with dermatofibrosis and scant neutrophilic debris are seen in older lesions. Mucin is absent, helping differentiate from interstitial GA.

Juvenile Rheumatoid Arthritis (Juvenile Idiopathic Arthritis)

Juvenile rheumatoid arthritis (JRA) is not a single disease but a group of disorders characterized by arthritis and young age of onset. The subset called Still disease accounts for only 20% of the patients. It shows skin manifestations in about 40% of young patients age 7–25 years. An eruption consisting of evanescent, nonpruritic, salmon-pink, macular, or papular lesions on the trunk and extremities may precede the onset of joint manifestations by many months (Fig. 8.32). Patients generally have extremely high serum ferritin levels. Neutrophilic panniculitis has been described. The systemic symptoms of fever and serositis usually recur over weeks each afternoon. Most patients remit permanently by adulthood. TNF-α IL-1, IL-6, IL-18, and IFN-γ are implicated in the pathogenesis of JRA, as are phagocyte-specific S100-proteins, such as S100A8, S100A9, and S100A12. Steroid-sparing agents are useful to decrease steroid-associated toxicity. The dose-response curve for methotrexate plateaus with parenteral administration of 15 mg/m^2/week. Refractory disease has been treated with biologic agents as described, pulse methylprednisolone, and cyclophosphamide.

Anakinra and canakinumab have been employed and may be helpful.

Fibroblastic Rheumatism

Fibroblastic rheumatism is a rare condition characterized by bilateral distal polyarthritis, flexion contractures, cutaneous nodules, sclerodactylitis, thickened palmar fascia, and Raynaud phenomenon. Biopsy demonstrates a fibroblastic proliferation with a collagenous stroma varying from smooth muscle actin–positive cellular fascicles to paucicellular areas with randomly arranged spindle or stellate cells. Elastic fibers are typically absent. Standard therapy includes immunosuppressive agents, typically methotrexate and oral corticosteroids, although some patients have responded to physical therapy without immunosuppressive treatment. Interferon has also been used. One patient has been reported with elevated lead levels, of unclear significance.

Zou XW, et al: Fibroblastic rheumatism. Clin Exp Dermatol 2015; 40: 309.

Paraneoplastic Rheumatism

Paraneoplastic syndromes resembling adult Still disease have been associated with a variety of neoplasms, including gastric carcinoma, lung carcinoma, and lymphoma. Patients with new onset of rheumatologic disease should be screened for signs and symptoms suggesting neoplasm.

Symmetric Synovitis

Symmetric seronegative synovitis is an idiopathic form of arthritis sometimes associated with idiopathic edema. Symmetric synovitis may also be a manifestation of Blau syndrome, an early-onset granulomatous disease with symmetric arthritis and recurrent uveitis, related to the caspase recruitment domain gene *CARD15/NOD2* and considered by some to be a form of early-onset sarcoidosis.

RELAPSING POLYCHONDRITIS

Relapsing polychondritis is characterized by intermittent episodes of inflammation of the articular and nonarticular cartilage resulting in chondrolysis and collapse of the involved cartilage. The course of the disease is chronic and variable, with episodic flares. Both genders are equally affected, with age between the third to sixth decade, most commonly around age 50, though pediatric and elderly cases may occur. Dissolution of the cartilage involves the ears, nose, and respiratory tract. The eye, joints, inner ear, and heart may rarely be involved. During bouts of inflammation, the bright-red involvement of the ears is confined to the cartilaginous portion while the earlobes remain conspicuously normal (Fig. 8.33). The affected areas are swollen and tender. There may be conductive deafness as a result of the obstruction produced by the swollen cartilage. The nasal septal cartilage is similarly involved to produce rhinitis, with crusting and bleeding and eventually saddle nose. Involvement of the bronchi, larynx, and epiglottis produces hoarseness, coughing, and dyspnea. Endobronchial ultrasonography has been used to facilitate the diagnosis of relapsing polychondritis. Migratory arthralgia and atypical chest pain are often present. Patients evaluated for chest pain are often released without treatment and with a diagnosis of costochondritis. Ocular disease most often presents as conjunctivitis, scleritis, or iritis. Perforation of the globe may occur. Complete heart block has been reported as a presenting sign. Michet criteria include auricular, nasal, or laryngotracheal chondritis as major criteria, and ocular inflammation, hearing loss/vestibular dysfunction, or seronegative arthritis as minor criteria, requiring two major or one major and two minor criteria. The MAGIC syndrome is a combination of Behçet disease and relapsing polychondritis (mouth and genital ulcers with inflamed cartilage).

Fig. 8.33 Relapsing polychondritis characteristically involves cartilaginous portions of the ear but spares the lobe.

Cell-mediated immunity and antibodies against cartilage and collagen (primarily IgG anti–type II collagen antibodies, though reports of other types exist), in titers corresponding with disease activity. Elevations in ESR, CRP levels, and urinary type II collagen neoepitope levels correlate with disease activity. A second connective tissue disease or other autoimmune disease is present in about one third of patients with relapsing polychondritis, and some cases appear to be paraneoplastic, occurring in association with hematopoietic malignancies. Limited data suggest that serum levels of Th1 cytokines (IFN-γ, IL-12, IL-2) may correlate better with disease activity than those of Th2 cytokines (IL-4, IL-5, IL-6, IL-10). Monocyte chemoattractant protein 1 levels, macrophage inflammatory protein, and IL-8 are increased during disease flares.

Histologically, a predominantly neutrophilic infiltrate is noted in the perichondrium. Varying degrees of chondrolysis may be present. DIF often demonstrates a lupus-like, continuous granular band of immunoglobulin and complement in the perichondrium.

NSAIDs, corticosteroids, or traditional immunosuppressants have been used. Biologics are increasingly being evaluated for this disorder. Dapsone, colchicine, hydroxychloroquine, leflunomide, and IVIG may be varyingly effective. Dapsone may reduce frequency of flares but is usually inadequate for the disease. Systemic corticosteroids should be used to treat acute flares, but most patients require a steroid-sparing immunosuppressive drug. Methotrexate, azathioprine, MMF, cyclosporine, TNF-α inhibitors, abatacept, anakinra, tocilizumab, and rituximab have been used, but only about half of the patients experienced a good response. Sustained response to etanercept has been reported, even after failure to respond to infliximab. Cyclophosphamide may be used for extremely severe disease.

9 Mucinoses

Bonus images for this chapter can be found online at expertconsult.inkling.com

Within the dermis is a fibrillar matrix, termed *ground substance*, composed of proteoglycans and glycosaminoglycans. These acid mucopolysaccharides, produced by fibroblasts, are highly hygroscopic, binding about 1000 times their own volume in water. They are critical in holding water in the dermis and are responsible for dermal volume and texture. Normally, the sulfated acid mucopolysaccharide chondroitin sulfate and heparin are the primary dermal mucins. In certain diseases, fibroblasts produce abnormally large amounts of acid mucopolysaccharides, usually hyaluronic acid. These acid mucopolysaccharides (mucin) accumulate in large amounts in the dermis and may be visible histopathologically as pale-blue, granular or amorphous material between collagen bundles. They are often not visualized with hematoxylin and eosin stains because the water they bind is removed in processing, so the presence of increased mucin is suspected by the presence of large, empty spaces between the collagen bundles. Acid mucopolysaccharides can be detected by special stains, such as colloidal iron, alcian blue, and toluidine blue. Incubation of the tissue with hyaluronidase eliminates the staining, confirming the presence of hyaluronic acid.

Increased dermal mucin may result from many diseases and is a normal component of wound healing. The mucinoses are diseases in which production of increased amounts of mucin is the primary process. Mucin may also accumulate in the skin as a secondary phenomenon in lupus erythematosus, dermatomyositis, Degos disease, granuloma annulare, and cutaneous tumors, or after therapies such as psoralen plus ultraviolet A (PUVA) or retinoids. The genetic diseases in which mucin accumulates as a result of inherited metabolic abnormalities are termed the *mucopolysaccharidoses* (see Chapter 26). Myxedema and pretibial myxedema are reviewed in Chapter 24.

LICHEN MYXEDEMATOSUS

The terminology used to describe disorders in the lichen myxedematosus group has varied widely over the years; the 2001 classification of Rongioletti and Rebora is used here. A generalized form, scleromyxedema, is usually accompanied by a monoclonal gammopathy (lambda more commonly than kappa) and may have systemic organ involvement. Five localized forms are recognized, characterized by a lack of a monoclonal antibody and systemic disease. Also, patients may have disease that does not fit into these subsets, and their condition is termed atypical or intermediate in type. Mucin deposition secondary to thyroid disease is excluded from the classification.

Generalized Lichen Myxedematosus

Scleromyxedema affects both men and women and generally appears between ages 30 and 80. It is chronic and progressive. The primary lesions are multiple, waxy, 2–4 mm, dome-shaped or flat-topped papules (Fig. 9.1). They may coalesce into plaques (Fig. 9.2) or may be arranged in linear arrays. Less often, urticarial, nodular, or even annular lesions are seen. The dorsal hands, face, elbows, and extensor extremities are most frequently affected (Fig. 9.3). Mucosal lesions are absent.

A diffuse infiltration develops, leading to "woody" sclerosis of the skin. A reduced range of motion of the mouth, hands, and extremities may follow (Fig. 9.4). On the glabella and forehead, coalescence of lesions leads to the prominent furrowing of a "leonine facies." At the proximal interphalangeal joint, induration surrounding a centrally depressed area has been called the "doughnut sign." Pruritus may occur.

Scleromyxedema is often associated with visceral disease. Gastrointestinal findings are most common. Dysphagia from esophageal involvement often occurs, and the stomach or intestine may also be affected. Pulmonary complications with dyspnea caused by restrictive or obstructive disease are also common. Proximal muscle weakness with an inflammatory myopathy or a nonspecific vacuolar change may occur. Carpal tunnel syndrome occurs in 10% of patients. Arthralgia or inflammatory arthritis frequently develop. Disease-specific adenopathy and renal impairment may be present.

The most serious systemic findings are cardiac, hematologic, and neurologic manifestations. Peripheral neuropathies and central nervous system disturbances can occur, including confusion, dizziness, dysarthria, ascending paralysis, seizures, syncope, and coma. The latter conditions have been called "dermato-neuro syndrome" and may be due to disruption in perfusion by the excessive immunoglobulins leading to an encephalopathy. Middle-aged men are most frequently affected, and one third of these patients demonstrate recurrent symptoms. Plasmapheresis and intravenous immune globulin (IVIG) may result in dramatic recovery from this life-threatening emergency. Visceral disease can be fatal.

Criteria for inclusion in the scleromyxedema category include mucin deposition, fibroblast proliferation and fibrosis, normal thyroid function tests, and presence of a monoclonal gammopathy. Approximately 10% of patients do not have a gammopathy on initial evaluation. Association with hepatitis C, diabetes mellitus, and multiple sclerosis has also been reported. The gammopathy is usually an immunoglobulin G–λ (IgG-λ) type, suggesting an underlying plasma cell dyscrasia. Bone marrow examination may be normal or may reveal increased numbers of plasma cells or frank multiple myeloma.

Clinical and histologic features are usually diagnostic. Skin biopsies of early papular lesions demonstrate a proliferation of fibroblasts with mucin and many small collagen fibers. The papules generally appear more fibrotic than mucinous. Over time, fibroblast nuclei become less numerous, and collagen fibers become thickened.

Many clinical findings in scleromyxedema are also found in systemic scleroderma, including cutaneous sclerosis, Raynaud phenomenon, dysphagia, and carpal tunnel syndrome. This distinction in some cases may be difficult without a biopsy. Other infiltrative disorders, such as amyloidosis, must be excluded. Nephrogenic systemic fibrosis presents with skin thickening in the setting of renal failure and gadolinium exposure (see Chapter 8). In its earliest form, it includes mucin along with collagen deposition with a proliferation of CD34+ cells in the dermis. The histologic findings are identical to those of scleromyxedema, and a first report referred to a scleromyxedema-like disease associated with renal failure. The clinical findings are dominated by fibrosis (see Chapter 8).

Treatment of scleromyxedema is difficult and usually undertaken in concert with an oncologist. Therapy is targeted to treat the gammopathy (if present). Typical therapies may include immunosuppressive agents, especially melphalan, bortezomib, or cyclophosphamide, with or without plasma exchange and high-dose prednisone. IVIG has also been used with success. Thalidomide and the newer thalidomide analog lenalinomide have shown benefit

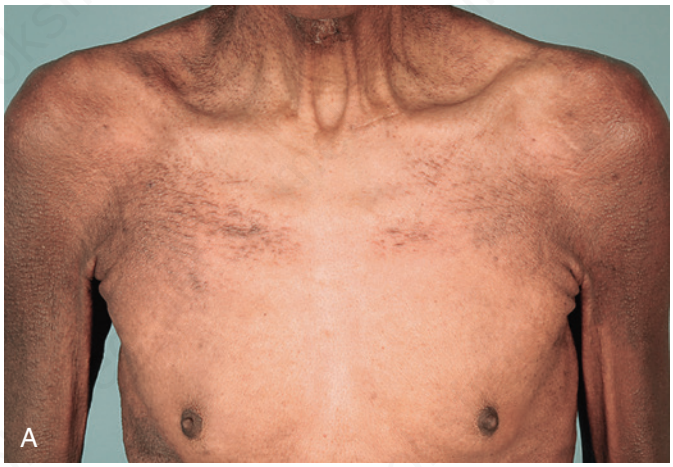

Fig. 9.1 Scleromyxedema. (Courtesy Douglas Pugliese, MD.)

Fig. 9.2 Scleromyxedema. (Courtesy Douglas Pugliese, MD.)

Fig. 9.4 Scleromyxedema. (Courtesy Rui Tavares Bello, MD.)

in patients with or without a paraproteinemia and may provide a long-term maintenance option. Temporary remission of progressive visceral disease may occur. These short-term benefits must be weighed against the increase in malignancies and sepsis complicating such therapy. Chances of remission are enhanced by the use of autologous stem cell transplantation with high-dose melphalan.

Skin-directed therapy may also be used. Physical therapy is indicated. Retinoids, plasmapheresis, extracorporeal photochemotherapy, grenz ray and electron beam therapy, PUVA, thalidomide, interferon-α (IFN-α), cyclosporine, topical dimethyl sulfoxide, and topical and intralesional hyaluronidase and corticosteroids have all produced improvement in the skin of select patients. Many others, however, have not benefited, and visceral disease is usually not affected. Ultraviolet B (UVB) light and IFN-α have exacerbated scleromyxedema.

Occasional patients are reported who spontaneously remit even after many years of disease; however, scleromyxedema remains a therapeutic challenge, and the overall prognosis is poor.

Localized Lichen Myxedematosus

The localized variants of lichen myxedematosus lack visceral involvement or an associated gammopathy. As a group, they are benign but often persistent. No therapy is reliably effective in any of the localized forms of lichen myxedematosus. Because there is no gammopathy, visceral involvement, or associated thyroid disease in any of the variants, often no treatment is needed. Shave excision or carbon dioxide (CO_2) ablation are other options for individual lesions. Spontaneous resolution may occur in all varieties.

Discrete Papular Lichen Myxedematosus

Discrete papular lichen myxedematosus is characterized by the occurrence of waxy, 2–5 mm, firm, flesh-colored papules, usually confined to the limbs or trunk. The papules may have an erythematous or yellowish hue, may coalesce into nodules or plaques, and may number into the hundreds. Nodules may occasionally be the predominant lesion present, with few or absent papules. The underlying skin is not indurated, and there is no associated gammopathy or internal involvement. Biopsy reveals the presence of mucin in the upper and middle dermis. Fibroblast proliferation is variable, but collagen deposition is minimal. The slow accumulation of papules is the usual course, without the development of a gammopathy or internal manifestations. Occasional cases may spontaneously involute.

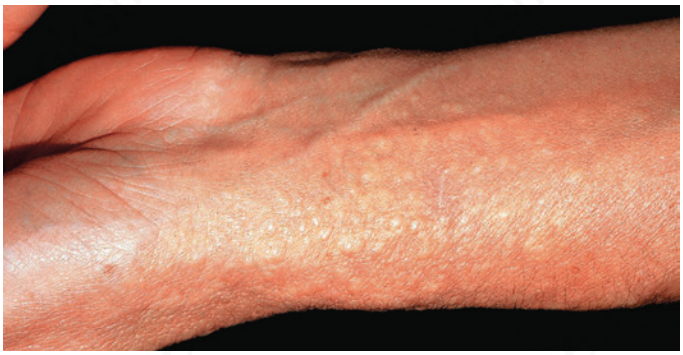

Fig. 9.5 Acral persistent papular mucinosis.

Fig. 9.6 Self-healing papular mucinosis.

Patients with advanced human immunodeficiency virus (HIV) disease have been reported to develop mucinous papules, usually widespread, unassociated with a paraprotein. It is usually seen in patients diagnosed with acquired immunodeficiency syndrome (AIDS), in patients with multiple infectious complications. These lesions may occur in association with an eczematous dermatitis or on normal skin. If associated with an eczematous dermatitis, the lesions often clear if the eczema is controlled. Lesions on normal skin may respond to systemic retinoid therapy. Intralesional hyaluronidase has been used for lesions of papular mucinosis. At times, spontaneous remission occurs. The authors have also seen a patient with AIDS and true scleromyxedema with visceral involvement, and two patients have been reported with acral persistent papular mucinosis.

Acral Persistent Papular Mucinosis

Patients with acral persistent papular mucinosis have a few to more than 100 bilaterally symmetric, 2–5 mm, flesh-colored papules localized to the hands and wrists (Fig. 9.5). The knees, calves, or elbows may also be involved in a minority of patients. The face and trunk are spared. Women outnumber men by 5 : 1. The course is one of persistence and slow progression. Two involved sisters have been reported. Histologically, there is a collection of upper dermal mucin with minimal or no increase in fibroblasts. Electrocoagulation of these lesions was reported to result in no recurrence in 6 months and topical tacrolimus was also reported to have some benefit.

Self-Healing Papular Mucinosis

Self-healing papular mucinosis occurs in a juvenile and an adult form. The juvenile variant, also called self-healing juvenile cutaneous mucinosis, is a rare but distinct disorder characterized by the sudden onset of skin lesions and polyarthritis. Children, usually between ages 5 and 15, are affected. Familial cases are reported. Skin lesions are ivory-white papules of the head, neck, trunk, and typically the periarticular regions; deep nodules on the face and periarticular sites; and hard edema of the periorbital area and face. An acute arthritis affects the knees, elbows, and hand joints. In the adult form, papular lesions occur, usually without the associated joint symptoms (Fig. 9.6). Histology of the skin lesions reveals dermal mucin with minimal fibroblastic proliferation or collagen deposition. Although the initial presentation is worrisome, the prognosis is excellent. Spontaneous resolution without sequelae occurs over several months.

Papular Mucinosis of Infancy

Also referred to as cutaneous mucinosis of infancy, this rare syndrome occurs at birth or within the first few months of life. Skin-colored, yellow, pink or translucent, grouped or discrete, 2–8 mm papules develop on the trunk or upper extremities, especially the back of the hands. A case of familial cutaneous mucinosis of infancy has been reported. Patients with Carney complex can also have widespread myxomas, which can look similar. Biopsies of papular mucinosis show very superficial upper dermal mucin without proliferation of fibroblasts. Existing lesions remain static; new lesions continue to accumulate gradually. Similar lesions may sometimes be noted in association with neonatal lupus erythematosus.

Nodular Lichen Myxedematosus

Patients may have multiple nodules on the trunk or extremities.

Atypical or Intermediate Lichen Myxedematosus

The cutaneous mucinoses are all relatively uncommon. In a literature dominated by case reports, individual patients have been found who do not fit well into the previously described scheme. For example, some patients with acral persistent papular mucinosis have a paraprotein, with localized papular mucinosis and immunoglobulin A (IgA) nephropathy, whereas others with apparently classic scleromyxedema with visceral lesions may not have a detectable circulating paraprotein.

SCLEREDEMA

Scleredema is a skin disease characterized by a stiffening and hardening of the subcutaneous tissues, as if infiltrated with paraffin. It occurs in two forms: with and without diabetes mellitus. In the more generalized, nondiabetic condition, a sudden onset after an infection, typically streptococcal, may occur. This reactive variant may also present as a drug eruption. In other cases, onset is insidious and chronic and has no preceding infection. In the more common diabetes-associated disease, a long-lasting induration of the upper back is characteristic.

In cases not associated with diabetes, females outnumber males by 2:1. The onset can be from childhood through adulthood. Skin tightness and induration begin on the neck and/or face, spreading symmetrically to involve the arms, shoulders, back, and chest. The distal extremities are spared. The patient may have difficulty opening the mouth or eyes and a masklike expression as a result of the infiltration. The involved skin, which is waxy and of woodlike consistency, gradually transitions into normal skin with no clear demarcation. Associated findings occur in variable numbers of patients and can include dysphagia caused by tongue and upper esophageal involvement, cardiac arrhythmias, and an associated paraproteinemia, usually an IgG type. Myeloma may be present. There may be pleural, pericardial, or peritoneal effusion.

In about half the patients in whom scleredema follows an infection, spontaneous resolution will occur in months to a few years. In one patient whose disease had a sudden onset after beginning infliximab treatment for rheumatoid arthritis, the condition resolved quickly after discontinuation of the medicine and did not recur after etanercept was initiated. The remaining patients with nondiabetic scleredema have a prolonged course. Therapy is generally of no benefit, but patients may live with the disease for many years. Cyclosporine, UVA I, pulsed dexamethasone, tamoxifen, IVIG, and extracorporeal photopheresis have reportedly been beneficial in individual patients. Bortezomib induced remission in one patient with myeloma-associated scleredema.

In the second group, which in most dermatologists' experience is the more common type, there is an association with late-onset, insulin-dependent diabetes. Men outnumber women by 10:1.

Fig. 9.7 Scleredema.

Affected men tend to be obese. The lesions are of insidious onset and long duration, presenting as woody induration and thickening of the skin of the middle-upper back, neck, and shoulders (Fig. 9.7). There is a sharp step-off from the involved to the normal skin. Persistent erythema and folliculitis may involve the affected areas. The associated diabetes is of long duration and is difficult to control. Further, patients often have complications of their diabetes, such as nephropathy, atherosclerotic disease, retinopathy, and neuropathy. Control of the diabetes does not affect the course of the scleredema. No paraprotein is detected, and no visceral involvement is seen. Lesions are persistent and usually unresponsive to treatment. Intravenous penicillin, electron beam alone or in combination with photon irradiation, narrow-band UVB, and both bath and systemic PUVA, in one case combined with colchicine, and frequency-modulated electromagnetic neural stimulation have each been effective in individual patients. Although low-dose methotrexate was successful in one patient, it was ineffective in a case series of seven patients.

The histology of both forms is identical. The skin is dramatically thickened, with the dermis often expanded twofold to threefold. There is no hyalinization, such as that seen in scleroderma, but rather the thick, dermal collagen bundles are separated by clear spaces that may contain visible mucin (hyaluronic acid). The amount of mucin is variable and usually only prominent in early lesions. In late lesions, slightly widened spaces between thick collagen bundles are the sole finding, because the amount of mucin is scant.

RETICULAR ERYTHEMATOUS MUCINOSIS (REM SYNDROME, PLAQUELIKE CUTANEOUS MUCINOSIS)

Reticular erythematous mucinosis (REM) favors women in the third and fourth decades of life. The eruption frequently appears after intense sun exposure. Clinical lesions are erythematous plaques or reticulated patches that are several centimeters in diameter and usually in the midline of the chest and back (Fig. 9.8). Evolution is gradual, photosensitivity may be present, and lesions may be induced with UVB. Onset or exacerbation with oral contraceptives, menses, and pregnancy is another feature. Serologic tests for lupus erythematosus (LE) are negative.

Histologically, there are varying degrees of lymphocytic infiltration around dermal vessels, with deposits of mucin in the dermis. Direct immunofluorescence is negative, but focal vacuolar interface dermatitis is sometimes seen. Treatment with antimalarials is successful in most cases. The pulsed dye laser has led to resolution in two patients.

Lesions of REM have also been reported to occur on the face, arms, abdomen, and groin. When evaluating patients with mucinous smooth-surfaced erythematous lesions it is important to consider the possibility of connective tissue disease. Plaquelike or papulonodular lesions in sites away from the central chest and back may infrequently herald the development of systemic LE, discoid LE, dermatomyositis, or scleroderma.

Tumid LE is a subset of chronic cutaneous lupus characterized by erythematous papules, nodules, and plaques that most often involve the face, extensor aspects of the arms, shoulders, V of the neck, and upper back. Histology more often has a deep perivascular and panfollicular location and commonly reveals direct immunofluorescence activity than REM. REM also tends to have more superficial mucin and lymphocytes with fewer plasmocytoid dendritic cells. Tumid LE is photoinducible and responsive to antimalarials. Although serologic abnormalities occur in a small percentage of patients, this is usually a skin-limited condition.

FOLLICULAR MUCINOSIS (ALOPECIA MUCINOSA)

Alopecia mucinosa is characterized by inflammatory plaques with alopecia that demonstrate mucinous deposits in the outer root sheath of the hair follicle on histopathology. The plaques may be simply hypopigmented or erythematous and scaly, eczematous, or composed of flesh-colored, follicular papules (Fig. 9.9). There may be only one lesion, especially on the head and neck, or multiple sites may be present. The plaques are firm and coarsely rough to the palpating finger. They are distributed mostly on the face, neck, and scalp but may appear on any part of the body. Itching may or may not be present. Alopecia occurs regularly in lesions on the scalp and frequently in lesions located elsewhere. Some papules show a comedo-like black central dot that corresponds to a broken hair or the mucin itself and in children can simulate a nevus comedonicus. The follicular involvement may cause the surface of a patch to resemble keratosis pilaris. Sensory dissociation, with hot-cold perception alterations or anesthesia to light touch, has been reported in some lesions, with a resultant misdiagnosis of leprosy.

The term *alopecia mucinosa* may be used to describe the disease process, and *follicular mucinosis* to describe the histologic features. The disease may be limited to skin and benign (primary follicular mucinosis) or may be associated with follicular mycosis fungoides (Fig. 9.10). When lesions are solitary or few in number and cluster on the head and neck of individuals younger than 40, the condition usually follows a benign, chronic course, even when the infiltrate is found to be clonal in nature. Widespread lesions in an older patient, however, will usually be found to be cutaneous T-cell lymphoma (CTCL) at initial presentation or will progress to lymphoma within 5 years. These two subsets are not exclusive,

Fig. 9.8 Reticulated erythematous mucinosis.

Fig. 9.10 Follicular mucinosis associated with mycosis fungoides. (Courtesy Ellen Kim, MD.)

however, and no clinical or histologic criteria absolutely distinguish them in the absence of diagnostic findings of CTCL.

Histologically, follicular mucinosis demonstrates large collections of mucin within the sebaceous gland and outer root sheath. The mucin typically stains as hyaluronic acid. A mixed dermal infiltrate is present. When the condition occurs in association with CTCL, the perifollicular infiltrate is atypical but not generally epidermotropic, and considerable admixture of eosinophils and plasma cells is present. The additional finding of the presence of syringolymphoid hyperplasia should raise concern that lymphoma is or will become evident. T-cell receptor gene rearrangement studies that indicate clonality are also supportive but do not alone predict an aggressive course.

Spontaneous involution of primary follicular mucinosis may occur, especially in young children. Topical corticosteroids produce improvement and are favored for localized disease, especially in children. Hydroxychloroquine is an excellent first-line systemic therapy. Dapsone, PUVA, radiation therapy, IFN alpha-2b, minocycline, isotretinoin, photodynamic therapy, imiquimod, and indomethacin have been effective in individual cases. Follicular mycosis fungoides, with or without associated mucin, is more refractory to treatment and has a worse prognosis than classic CTCL. All patients should be followed for progression of disease.

CUTANEOUS FOCAL MUCINOSIS

Focal mucinosis is characterized by a solitary nodule or papule. Lesions are asymptomatic and usually occur on the face, neck, trunk, or extremities. They appear in adulthood. Histologically, the lesion is characterized by a loose dermal stroma containing large quantities of mucin together with numerous dendritic-shaped fibroblasts. The clinical appearance is not distinctive and at times may suggest a cyst, basal cell carcinoma, or neurofibroma. Treatment is surgical excision.

MYXOID CYSTS

Myxoid cysts, also called synovial and digital mucous cysts, occur most frequently on the dorsal or lateral terminal digits of the hands but may also occur on the toes. These lesions present as solitary, 5–7 mm, opalescent or skin-colored cysts. They may occur as asymptomatic swellings of the proximal nailfold, as subungual growths, or over the distal interphalangeal joint. Women are more frequently affected, and osteoarthritis is often present in the adjacent distal interphalangeal joint. Myxoid cysts that can be reduced with pressure communicate directly with the joint space.

Multiple myxoid cysts are associated with connective tissue disease. Young children, even infants, may present with multiple digital mucous cysts as the initial manifestation of juvenile rheumatoid arthritis.

When a synovial cyst is present beneath the proximal nailfold, a characteristic groove may be formed in the nail plate by pressure of the lesion on the nail matrix (Fig. 9.11). Those located beneath the nail cause a transverse nail curvature and a red or blue discoloration of the lunula. Nail integrity typically is compromised, leading to distal or longitudinal splitting or onycholysis. The diagnosis can be confirmed by magnetic resonance imaging or surgical exploration. Myxoid cysts contain a clear, viscous, sticky fluid that may spontaneously drain. These cysts do not have an epithelial lining, but rather a compacted fibrous wall.

Treatment depends on the site of the myxoid cyst. The repeated puncture technique for cysts located beneath the proximal nailfold may achieve a cure rate of up to 70%, but multiple punctures

(>40) may be required. This technique may be complicated by local tissue or joint infection. Steroids may be injected into the tissue after draining the cyst. Intralesional injection of sodium tetradecyl sulfate has an 80% response rate. Destruction by cryotherapy, CO_2 laser ablation, curettage, and fulguration are alternatives with similar cure rates, but these therapies result in scarring.

Surgical approaches that reflect the skin overlying the cyst and either excise or tie off the communication to the joint, which may be visualized by injecting the myxoid cyst with methylene blue, have a cure rate greater than 90%.

10 Seborrheic Dermatitis, Psoriasis, Recalcitrant Palmoplantar Eruptions, Pustular Dermatitis, and Erythroderma

Bonus images for this chapter can be found online at expertconsult.inkling.com

SEBORRHEIC DERMATITIS

Clinical Features

Seborrheic dermatitis is common, occurring in 2%–5% of the population. It is a chronic, superficial, inflammatory disease with a predilection for the scalp, eyebrows, eyelids, nasolabial creases, lips, ears (Fig. 10.1), sternal area, axillae, submammary folds, umbilicus, groins, and gluteal crease. The disease is characterized by scaling on an erythematous base. The scale often has a yellow, greasy appearance. Itching may be severe. Dandruff (pityriasis sicca) represents a mild form of seborrheic dermatitis. An oily type, pityriasis steatoides, is accompanied by erythema and an accumulation of thick crusts.

Other types of seborrheic dermatitis on the scalp include arcuate, polycyclic, or petaloid patches and psoriasiform, exudative, or crusted plaques. The disease frequently spreads beyond the hairy scalp to the forehead, ears, postauricular regions, and neck. On these areas, the patches have convex borders and are reddish yellow or yellowish. In dark-skinned individuals, arcuate and petaloid lesions typically involve the hairline. In extreme cases, the entire scalp is covered by a greasy, dirty crust with an offensive odor. In infants, yellow or brown scaling lesions on the scalp, with accumulated adherent epithelial debris, are called "cradle cap."

Erythema and scaling are often seen in the eyebrows. The lids may show fine, yellowish white scales and faint erythema. The edges of the lids may be erythematous and granular (marginal blepharitis), and the conjunctivae may be injected. If the glabella is involved, fissures in the wrinkles at the inner end of the eyebrow may accompany the fine scaling. In the nasolabial creases and on the alae nasi, there may be yellowish or reddish yellow scaling macules, sometimes with fissures. In men, folliculitis of the beard area is common.

In the ears, seborrheic dermatitis may be mistaken for an infectious otitis externa. There is scaling in the aural canals, around the auditory meatus, usually with marked pruritus. The postauricular region and skin under the lobe may be involved. In these areas, the skin often becomes red, fissured, and swollen. In the axillae, the eruption begins in the apices, bilaterally, and later progresses to neighboring skin. This pattern resembles that of allergic contact dermatitis to deodorant, but differs from that of clothing dermatitis (which involves periphery of axillae but spares the vault). The involvement may vary from simple erythema and scaling to more pronounced petaloid patches with fissures. The inframammary folds and the umbilicus may be involved. The presternal area is a favored site on the trunk.

Seborrheic dermatitis is common in the groin and gluteal crease, where its appearance may closely simulate tinea cruris or candidiasis. In these areas, the appearance often overlaps with that of inverse psoriasis. In fact, many of these patients have an overlap of the two conditions (sebopsoriasis or seborrhiasis) in the groin, as well as the scalp. The lesions may also become generalized and progress to an exfoliative erythroderma (erythroderma desquamativum), especially in infants. A minority of these infants will have evidence of immunosuppression. In adults, generalized eruptions may be accompanied by adenopathy and may simulate mycosis fungoides or psoriatic erythroderma.

Seborrheic dermatitis may be associated with several internal diseases. Parkinson disease is often accompanied by severe refractory seborrheic dermatitis involving the scalp and face, with waxy, profuse scaling. A unilateral injury to the innervation of the face, or a stroke, may lead to unilateral localized seborrheic dermatitis. Patients with acquired immunodeficiency syndrome (AIDS) have an increased incidence of seborrheic dermatitis. An increased incidence has also been noted in patients who are seropositive for human immunodeficiency virus (HIV) but have not developed other signs of clinical disease. Diabetes mellitus (especially in obese persons), sprue, malabsorption disorders, epilepsy, neuroleptic drugs (e.g., haloperidol), and reactions to arsenic and gold have all produced seborrheic dermatitis–like eruptions.

Etiology and Pathogenesis

The etiology of this common disorder is complex but may be related to the presence of the lipophilic yeast *Malassezia ovalis (Pityrosporum ovale)*, which produces bioactive indoles, oleic acid, malssezin, and indole-3-carbaldehyde. The density of yeast has been correlated with the severity of the disease, and reduction of the yeast occurs with response to therapy. *M. ovalis* may also be abundant on the scalps of patients who have no clinical signs of the disease, and the yeast may only be pathogenic in predisposed individuals. Heavy colonization with *Staphylococcus epidermidis* has also been noted.

Patients with seborrheic dermatitis may show upregulation of interferon (IFN)–γ, expressed interleukin-6 (IL-6), expressed IL-1β, and IL-4. Expression of cytotoxicity-activating ligands and recruitment of natural killer (NK) cells have also been noted.

Histology

The epidermis demonstrates regular acanthosis with some thinning of the suprapapillary plates. Varying degrees of spongiosis and lymphocyte exocytosis are noted. A characteristic finding is the presence of a focal scale crust adjacent to the follicular ostia.

Differential Diagnosis

Some cases of seborrheic dermatitis bear a close clinical resemblance to psoriasis, and the two conditions may overlap. Patients with psoriasis tend to have more pronounced erythema and heavier silvery scales that peel in layers. Removal of scales in psoriasis may disclose bleeding points (Auspitz sign). This sign is common but lacks great specificity. Severe itching favors seborrheic dermatitis. Characteristic psoriasis elsewhere (nail pitting, balanitis) may resolve the question. Impetigo of the scalp, especially when associated with pediculosis, may cause difficulty in differentiation. Scalp impetigo can be an indolent crusted dermatosis associated with failure to thrive. Langerhans cell histiocytosis may also resemble seborrheic dermatitis, but typically demonstrates

Fig. 10.1 Seborrheic dermatitis.

yellow-brown perifollicular papules and groin fissuring. Crusted scabies of the scalp can also be confused with seborrheic dermatitis, and *Trichophyton tonsurans* often produces a subtle seborrheic scale. In subtle cases of tinea, a moist gauze pad rubbed vigorously on the scalp will typically dislodge short, broken potassium hydroxide (KOH)–positive hairs. This can be the fastest way to make the diagnosis.

Treatment

Agents suitable for use on glabrous skin include corticosteroid creams, gels, sprays, and foams. Corticosteroids tend to produce a rapid effect with high clearance rates, but on the face, even medium-potency corticosteroids can produce steroid rosacea. For this reason, antifungal agents and topical calcineurin inhibitors (CNIs) are often used. Ketoconazole, ciclopirox, sertaconazole, tacrolimus, pimecrolimus, zinc pyrithione, and *Quassia amara* extract preparations are all effective alone and in combination. The antifungals are now available in a wide range of vehicles, including foams, gels, and liquids. Surfactant-based pronosomal formulations can improve drug delivery. Proniosomes are particles coated with a nonionic surfactant. Bifonazole shampoo has been effective in treating infants and small children. Topical CNIs may be associated with a burning sensation, especially on moist skin, and may produce flushing if patients consume alcohol. Patients generally tolerate these agents better after initial treatment with a corticosteroid. An open, randomized, prospective, comparative study of topical pimecrolimus 1% cream versus topical ketoconazole 2% cream found the two to be equally effective, but side effects were somewhat more common with pimecrolimus. Preliminary studies suggest oral itraconazole and oral terbinafine may show some efficacy. Oral fluconazole showed marginal benefit. Study results with topical metronidazole have been mixed.

When secondary bacterial infection is present, a topical or oral antibiotic may be required. In patients infected with HIV, lithium succinate ointment has been used for facial disease. Lithium gluconate 8% ointment has compared favorably with ketoconazole 2% emulsion in healthy adults and was more effective in terms of control of scaling and symptoms. Sodium sulfacetamide products, with or without sulfur, are effective in some refractory patients.

For scalp disease, selenium sulfide, ketoconazole, tar, zinc pyrithione, fluocinolone, and resorcin shampoos are effective. In many patients, these agents may be used two to three times a week, with a regular shampoo used in between as required. White patients often prefer antifungal foams and gels, as well as corticosteroid solutions, foams, gels, and sprays, whereas some black patients prefer ointment or oil preparations.

Itching of the external ear canal usually responds to a topical corticosteroid, CNIs, or antifungals (e.g., ketoconazole, ciclopirox). Some patients require the use of a class 1 corticosteroid on weekends to control refractory pruritus. Cortisporin otic suspension (neomycin, polymyxin B, hydrocortisone) can bring about prompt clearing, but contact dermatitis to neomycin may complicate the use of some Cortisporin products. Desonide otic lotion (0.05% desonide, 2% acetic acid) is also effective and may be better tolerated than Domeboro otic solution (aluminum acetate).

Sodium sulfacetamide drops or ointment may be effective for seborrheic blepharitis. Oral tetracyclines can also be effective and have been shown to decrease the density of microorganisms in the affected follicles. Steroid preparations are suitable for short-term use but may induce glaucoma and cataracts. Daily gentle cleansing with a cotton-tipped applicator and baby shampoo in water can reduce symptoms. In severe cases, oral antibiotics or oral antifungals may be combined with topical agents. Low-dose isotretinoin has also been shown to be effective in refractory disease.

PSORIASIS

Clinical Features

Psoriasis is a common, chronic, and recurrent inflammatory disease of the skin characterized by circumscribed, erythematous, dry, scaling plaques of various sizes, usually covered by silvery white lamellar scales. The lesions are usually symmetrically distributed and have a predilection for the scalp, nails, extensor surfaces of the limbs, umbilical region, and sacrum. It usually develops slowly but may be exanthematous, with the sudden onset of numerous guttate (droplike) lesions (Fig. 10.2). Subjective symptoms, such as itching or burning, may be present and may cause extreme discomfort.

The early lesions are small, erythematous macules covered with dry, silvery scales from the onset. The lesions increase in size by peripheral extension and coalescence. The scales are micaceous, meaning they peel in layers, and are looser toward the periphery and adherent centrally. When removed, bleeding points appear (Auspitz sign). Although plaques typically predominate, lesions may be annular or polycyclic. Old patches may be thick and covered with tough lamellar scales like the outside of an oyster shell (psoriasis ostracea). Descriptive terms applied to the diverse appearance of the lesions include psoriasis *guttata*, in which the lesions are the size of water drops; psoriasis *follicularis*, in which tiny, scaly lesions are located at the orifices of hair follicles; psoriasis *figurata*, *annulata*, or *gyrata*, in which curved linear patterns are produced by central involution; psoriasis *discoidea*, in which central involution does not occur and solid patches persist; and psoriasis *rupioides*, in which crusted lesions occur, resembling syphilitic rupia. The term *chronic plaque psoriasis* is often applied to stable lesions of the trunk and extremities. Inverse psoriasis predominates in intertriginous areas (Fig. 10.3). Pustular variants of psoriasis may be chronic on the palms and soles (Fig. 10.4),

Fig. 10.2 Guttate psoriasis.

Fig. 10.4 Pustular psoriasis of the hand.

Fig. 10.3 Psoriasis.

Fig. 10.5 Nail with oil spot of psoriasis.

or these may be eruptive and accompanied by severe toxicity and hypocalcemia.

Involved nails can demonstrate distal onycholysis, random pitting caused by parakeratosis from the proximal matrix (Fig. 10.5), oil spots (yellow areas of subungual parakeratosis from the distal matrix; Fig. 10.6), or salmon patches (nail bed psoriasis). Thick, subungual hyperkeratosis may resemble onychomycosis.

Types

Seborrheic-Like Psoriasis

Some cases of psoriasis overlap with seborrheic dermatitis. Seborrheic lesions may predominate on the face, under the breasts, and in the scalp, flexures, and axillae. Lesions in these areas are moist and erythematous, with yellow, greasy, soft scales, rather than dry and micaceous scales. Terms such as sebopsoriasis and seborrhiasis may be used to describe the condition of such patients.

Fig. 10.8 Psoriatic arthritis.

Inverse Psoriasis

Inverse psoriasis selectively and often exclusively involves folds, recesses, and flexor surfaces, such as the ears, axillae, groin, inframammary folds (Fig. 10.7), navel, intergluteal crease, penis, lips, and web spaces. Other areas, such as the scalp and nails, may be involved.

"Napkin" Psoriasis

Napkin psoriasis, or psoriasis in the diaper area, is characteristically seen in infants between 2 and 8 months of age. Lesions appear as brightly erythematous, sharply demarcated patches of skin involving much of the diaper area. The lesions typically clear with topical therapy, but psoriasis may reappear in adulthood.

Psoriatic Arthritis

Five clinical patterns of psoriatic arthritis occur, as follows:

1. Asymmetric distal interphalangeal joint involvement with nail damage (16%)
2. Arthritis mutilans with osteolysis of phalanges and metacarpals (5%) (Fig. 10.8)
3. Symmetric polyarthritis-like rheumatoid arthritis (RA), with clawhand (15%)
4. Oligoarthritis with swelling and tenosynovitis of one or a few hand joints (70%)
5. Ankylosing spondylitis alone or with peripheral arthritis (5%)

Most radiographic findings resemble those in RA, but certain findings are highly suggestive of psoriasis. These include erosion of terminal phalangeal tufts (acrosteolysis), tapering or "whittling" of phalanges or metacarpals with "cupping" of proximal ends of phalanges ("pencil in a cup deformity"), bony ankylosis, osteolysis of metatarsals, predilection for distal interphalangeal and proximal interphalangeal joints, relative sparing of metacarpophalangeal and metatarsophalangeal joints, paravertebral ossification, asymmetric sacroiliitis, and rarity of "bamboo spine" when the spine is involved. Almost half the patients with psoriatic arthritis have type human leukocyte antigen (HLA)–B27.

Rest, splinting, passive motion, and nonsteroidal antiinflammatory drugs (NSAIDs) may provide symptomatic relief but do not prevent deformity. Methotrexate, cyclosporine, tacrolimus, anti-TNF, anti-IL-17 and anti-IL-12/23 agents are disease-modifying drugs that prevent deformity.

Guttate Psoriasis

In the distinctive guttate form of psoriasis, typical lesions are the size of water drops, 2–5 mm in diameter. Lesions typically occur as an abrupt eruption after acute infection, such as a streptococcal pharyngitis. Guttate psoriasis occurs mostly in patients under age 30. This type of psoriasis usually responds rapidly to broad-band ultraviolet B (UVB) at erythemogenic doses. Suberythemogenic doses often have little impact on the lesions. This is one of the few forms of psoriasis where broad-band UVB may have an advantage over narrow-band (NB) UVB. Minimal erythemogenic (erythema) dose (MED) testing is recommended to allow for appropriately aggressive treatment. Recurrent episodes may be related to pharyngeal carriage of the responsible streptococcus by the patient or a close contact. A course of a semisynthetic penicillin (e.g., dicloxacillin, 250 mg four times daily for 10 days) with rifampin (600 mg/day for adults) may be required to clear chronic streptococcal carriage.

Generalized Pustular Psoriasis (von Zumbusch Psoriasis)

Typical patients with generalized pustular psoriasis have plaque psoriasis and often psoriatic arthritis. The onset is sudden, with formation of lakes of pus periungually, on the palms, and at the edge of psoriatic plaques. Erythema occurs in the flexures before the generalized eruption appears. This is followed by a generalized erythema and more pustules (Fig. 10.9). Pruritus and intense burning are often present. Mucous membrane lesions are common. The lips may be red and scaly, and superficial ulcerations of the tongue and mouth occur. Geographic or fissured tongue frequently occurs (Fig. 10.10).

The patient is frequently ill with fever, erythroderma, hypocalcemia, and cachexia. A number of cases of acute respiratory distress syndrome associated with pustular and erythrodermic psoriasis have been reported. Other systemic complications include pneumonia, congestive heart failure, and hepatitis.

Episodes are often provoked by withdrawal of systemic corticosteroids. The authors have also observed generalized pustular psoriasis as the presenting sign of Cushing disease. Other implicated drugs include iodides, coal tar, terbinafine, minocycline, hydroxychloroquine, acetazolamide, and salicylates. There is usually a strong familial history of psoriasis. Generalized pustular psoriasis may occur in infants and children with no implicated drug. It may also occur as an episodic event punctuating the course of localized acral pustular psoriasis.

Acitretin is the drug of choice in this severe disease. The response is generally rapid. Isotretinoin is also effective. Cyclosporine,

Fig. 10.9 Pustular psoriasis.

Fig. 10.10 Fissured and geographic tongue in patient with generalized pustular psoriasis.

methotrexate, and biologic agents are alternatives. In some cases, dapsone is effective in doses of 50–100 mg/day.

Acrodermatitis Continua (of Hallopeau)

Typical patients develop acral erythematous plaques studded with pustules. The nail beds are heavily involved, and the fingernails float away on lakes of pus, resulting in anonychia. Hyperkeratosis often ensues, and the fingertips become increasingly painful, tapering to long, keratotic points. Occasionally, patients may develop generalized pustular flares. Acrodermatitis continua is discussed in more detail later (see Dermatitis Repens under Recalcitrant Palmoplantar Eruptions, later in this chapter).

Fig. 10.11 Erythrodermic psoriasis.

Impetigo Herpetiformis

The term *impetigo herpetiformis* has been applied to pustular psoriasis of pregnancy. Flexural erythema, studded with pustules, often occurs initially, followed by a generalized pustular flare and increasing toxicity. These patients are pregnant, so systemic retinoids are not appropriate. Many patients only respond to delivery, and early delivery should be strongly considered as soon as it is safe for the infant. Alternatively, patients may respond to prednisone, 1 mg/kg/day. The corticosteroid can also contribute to neonatal lung maturity.

Keratoderma Blennorrhagicum (Reiter Syndrome)

Keratoderma blennorrhagicum resembles psoriasis both histologically and clinically, except for its tendency for thicker keratotic lesions. Patients are often positive for HLA-B27 and develop reactive arthritis and skin disease after a bout of urethritis or enteritis.

Erythrodermic Psoriasis

Patients with psoriasis may develop a generalized erythroderma (Fig. 10.11). Erythrodermic psoriasis is covered in greater detail in Chapter 11 under Exfoliative Dermatitis.

Course

The course of psoriasis is unpredictable. It usually begins on the scalp or elbows and may remain localized in the original region for years. Chronic disease may also be almost entirely limited to the fingernails. Involvement over the sacrum may easily be confused with candidiasis or tinea. Onset may also be sudden and widespread.

Two of the chief features of psoriasis are its tendency to recur and its persistence. The isomorphic response (Koebner phenomenon) is the appearance of typical lesions of psoriasis at sites of even trivial injury (Fig. 10.12). Lesions may occur at sites of

Fig. 10.12 Koebner phenomenon in psoriasis.

scratches, incisions, and burns. Lesions may first appear after viral exanthema or pityriasis rosea. The isomorphic response may occur if psoriatic lesions are severely burned during phototherapy. With a reduction in light dosage, the erythema and burning resolve, and the plaques begin to clear. Woronoff ring is concentric blanching of the erythematous skin at or near the periphery of a healing psoriatic plaque. It is often the first sign that the patient's psoriasis is responding to phototherapy.

The palms and soles are sometimes exclusively affected, showing discrete, dry, erythematous scaling patches, circumscribed verrucous thickenings, or pustules on an erythematous base. The patches usually begin in the midportion of the palms or on the soles and gradually expand. Psoriasis of the palms and soles is typically chronic and extremely resistant to treatment.

Many studies report an association between hepatitis C and psoriasis, and hepatitis C virus (HCV) has also been implicated in psoriatic arthritis. If treatment of psoriasis is to include a potentially hepatotoxic drug, such as methotrexate, a full hepatitis panel should be obtained. Also, IFN treatment of the hepatitis can further exacerbate or induce psoriasis. Anti–tumor necrosis factor (TNF)–α therapy shows promise in the treatment of psoriasis, even in the setting of chronic HCV infection.

Inheritance

In a large study of psoriasis in monozygotic twins, heritability was high and environmental influence low. Patients with psoriasis often have relatives with the disease, and the incidence typically increases in successive generations. Multifactorial inheritance is likely. Analysis of population-specific HLA haplotypes has provided evidence that susceptibility to psoriasis is linked to major histocompatibility complex (MHC) classes I and II on human chromosome 6. A number of genetic loci are linked to psoriasis, including *PSORS1* on chromosome 6 and within the MHC, and *PSORS2* on chromosome 17q. Also, there are two subsets that differ in age of onset and frequency of HLA associations. Early onset is type I psoriasis and is associated mostly with Cw6, B57, and DR7. Late onset is type II and predominantly features Cw2. *PSORS9* has also been confirmed as a susceptibility locus for psoriasis.

A variety of other HLA associations have been reported. It is believed that any individual who has B13 or B17 carries a fivefold risk of developing psoriasis. In pustular psoriasis, HLA-B27 may be seen, whereas B13 and B17 are increased in guttate and erythrodermic psoriasis. In palmoplantar pustulosis, there is an association with HLA-B8, Bw35, Cw7, and DR3. HLA typing is a research tool for population-based studies, but of limited value in assessing an individual patient.

Epidemiology

Psoriasis occurs with equal frequency in men and women. Between 1% and 2% of the U.S. population has psoriasis. It occurs less frequently in the tropics. It is less common in North American and West African black persons. Native (Indian) Americans and native Fijians rarely have psoriasis. The onset of psoriasis is at a mean age of 27 years, but the range is wide, from the neonatal period to the seventies. Severe emotional stress tends to aggravate psoriasis in almost half of those studied.

In pregnancy, there is a distinct tendency for improvement or even temporary disappearance of lesions in the majority of women studied. After childbirth, there is a tendency for exacerbation of lesions. Paradoxically, pregnancy is also the milieu for impetigo herpetiformis, and psoriasis may behave differently from one pregnancy to another in the same patient.

A high prevalence of celiac disease has been noted in patients with psoriasis. Lymphoma also has an increased incidence in these patients, and psoriasis has been linked to the metabolic syndrome and a higher risk of cardiovascular disease, although early age of onset does not appear to correlate with greater risk. Patients should be screened for comorbidities.

Pathogenesis

Psoriasis is a hyperproliferative disorder, but the proliferation is driven by a complex cascade of inflammatory mediators. Psoriasis appears to represent a mixed T-helper 1 (Th1) and Th17 inflammatory disease. Th17 cells appear to be more proximal in the inflammatory cascade. T cells and cytokines play pivotal roles in the pathophysiology of psoriasis. Overexpression of type 1 cytokines, such as IL-2, IL-6, IL-8, IL-12, IFN-γ, and TNF-α, has been demonstrated, and overexpression of IL-8 leads to the accumulation of neutrophils. The main signal for Th1 development is IL-12, which promotes intracellular IFN-γ production. In animal models, shifting from Th1 to Th2 responses improves psoriasis. IL-4 is capable of inducing Th2 responses and improving psoriasis. Reduced expression of the antiinflammatory cytokines IL-1RA and IL-10 has been found, and polymorphisms for IL-10 genes correlate with psoriasis. IL-10 is a type 2 cytokine with major influence on immunoregulation, inhibiting type 1 proinflammatory cytokine production. Patients receiving established traditional therapies show rising levels of IL-10 messenger RNA expression, suggesting that IL-10 may have antipsoriatic capacity.

IL-15 triggers inflammatory cell recruitment, angiogenesis, and production of inflammatory cytokines, including IFN-γ, TNF-α, and IL-17, all of which are upregulated in psoriatic lesions. The interplay is complex, but IL-17 appears to be proinflammatory, and IL-22 may serve to retard keratinocyte differentiation. IL-23 stimulates survival, as well as proliferation of Th17 cells. Circulating NK cells are reduced in psoriasis.

Streptococci

Streptococci play a role in some patients. Patients with psoriasis report sore throat more often than controls. β-Hemolytic streptococci of Lancefield groups A, C, and G can cause exacerbation of chronic plaque psoriasis. Th1 cells recognize cell wall extract

isolated from group A streptococci. HLA variation has a significant effect on the immune response to group A streptococci.

Stress

Various studies have shown a positive correlation between stress and severity of disease. In almost half of patients studied, stress appears to play a significant role.

Drug-Induced Psoriasis

Psoriasis may be induced by β-blockers, lithium, antimalarials, terbinafine, calcium channel blockers, captopril, glyburide, granulocyte colony-stimulating factor, interleukins, interferons, and lipid-lowering drugs. Systemic steroids may cause rebound or pustular flares. Antimalarials are associated with erythrodermic flares, but patients traveling to malaria-endemic regions should take appropriate prophylaxis. Often, drugs such as doxycycline or mefloquine are appropriate for the geographic area, but when a quinine derivative offers the best protection, it is generally better to take the prophylactic doses of a quinine derivative than to risk disease and full-dose treatment.

Pathology

Histologically, all psoriasis is pustular. The microscopic pustules include spongiform intraepidermal pustules, and Munro microabscesses within the stratum corneum. In early guttate lesions, focal parakeratosis is noted within the stratum corneum. The parakeratotic focus typically has an outline resembling a seagull. Neutrophils are generally noted immediately above the focus of parakeratosis, but in some sections the neutrophils will not be visible as a result of sampling error. In plaque psoriasis, neutrophilic foci are so numerous that they are rarely missed. Neutrophilic microabscesses are generally present at multiple levels in the stratum corneum, usually on top of small foci of parakeratosis. These foci generally alternate with areas of orthokeratotic stratum corneum, suggesting that the underlying spongiform pustules arise in a rhythmic fashion. The granular layer is absent focally, corresponding to areas producing foci of parakeratosis. In well-developed plaques, there is regular epidermal acanthosis with long, bulbous rete ridges, thinning over the dermal papillae, and dilated capillaries within the dermal papillae. The last two findings correlate with the Auspitz sign. The stratum corneum may be entirely parakeratotic but still shows multiple small, neutrophilic microabscesses at varying levels. Spongiosis is typically scant, except in the area immediately surrounding collections of neutrophils.

In pustular psoriasis, geographic tongue, and Reiter syndrome, intraepidermal spongiform pustules tend to be much larger. Grossly pustular lesions often have little associated acanthosis. In Reiter syndrome, the stratum corneum is often massively thickened, with prominent foci of neutrophils above parakeratosis, alternating with orthokeratosis.

Acral lesions often demonstrate nondiagnostic features histologically. Spongiosis is typically prominent in these lesions and often leads to a differential diagnosis of psoriasis or chronic psoriasiform spongiotic dermatitis. Foci of neutrophils often contain serum and may be interpreted as impetiginized crusting.

On direct immunofluorescence testing, the stratum corneum demonstrates intense fluorescence with all antibodies, complement, and fibrin. This fluorescence is independent of the fluorescent label, as it has been noted in hematoxylin and eosin–stained sections and frozen unstained sections. The same phenomenon of stratum corneum autofluorescence has been noted in some cases of candidiasis that demonstrate a psoriasiform histology.

Psoriasis can generally be distinguished from dermatitis by the paucity of edema, relative absence of spongiosis, tortuosity of the capillary loops, and presence of neutrophils above foci of parakeratosis. Neutrophils in the stratum corneum are often seen in tinea, impetigo, candidiasis, and syphilis, but they rarely are found atop parakeratosis alternating with orthokeratosis rhythmically. In psoriasiform syphilis, the rete ridges are typically long and slender; a vacuolar interface dermatitis is usually present; dermal blood vessels appear to have no lumen because of endothelial swelling; and plasma cells are present in the dermal infiltrate. About one third of biopsies of syphilis lack plasma cells, but the remaining characteristics still suggest the correct diagnosis. Psoriasiform lesions of mycosis fungoides exhibit epidermotropism of large lymphocytes with little spongiosis. The lymphocytes are typically larger, darker, and more angulated than the lymphocytes in the dermis. There is associated papillary dermal fibrosis, and the superficial perivascular infiltrate is asymmetrically distributed around the postcapillary venules, favoring the epidermal side ("bare underbelly sign").

Clinical Differential Diagnosis

Psoriasis must be differentiated from dermatomyositis (DM), lupus erythematosus (LE), seborrheic dermatitis, pityriasis rosea, lichen planus, eczema, and psoriasiform syphilid. The distribution in psoriasis is on the extensor surfaces, especially of the elbows and knees, and on the scalp; DM shares this distribution, whereas LE generally lacks involvement of the extensor surfaces. Patients with DM may exhibit a heliotrope sign, atrophy, poikiloderma, and nailfold changes. Advanced lesions of discoid LE often demonstrate follicular hyperkeratosis (carpet tack sign). Seborrheic dermatitis has a predilection for the eyebrows, nasolabial angle, ears, sternal region, and flexures. The scales in psoriasis are dry, white, and shiny, whereas those in seborrheic dermatitis are greasy and yellowish. On removal of the scales in psoriasis, blood oozes from the capillaries (Auspitz sign), whereas this does not occur in seborrheic dermatitis.

In pityriasis rosea, the eruption is located on the upper arms, trunk, and thighs, and the duration is over weeks. Lesions are typically oval and follow skin tension lines. Individual lesions show a crinkling of the epidermis and collarette scaling. A herald patch is frequently noted. Lichen planus chiefly affects the flexor surfaces of the wrists and ankles. Often the violaceous color is pronounced. In darker-skinned individuals, the lesions have a tendency to pronounced hyperpigmentation. The nails are not pitted as in psoriasis, but longitudinally ridged, rough, and thickened. Pterygium formation is characteristic of lichen planus.

Hand eczema may resemble psoriasis. In general, psoriatic lesions tend to be more sharply marginated, but at times the lesions are indistinguishable. Psoriasiform syphilid has infiltrated copper-colored papules, often arranged in a figurate pattern. Serologic tests for syphilis are generally positive, but prozone reactions may occur, and the serum may have to be diluted to obtain a positive test. Generalized lymphadenopathy and mucous patches may be present.

Treatment

Topical therapy, intralesional triamcinolone, excimer laser, light emitting diode (LED), and other forms of focused light may be suitable for limited plaques. Phototherapy remains highly cost-effective for widespread psoriasis. Cyclosporine has a rapid onset of action but is generally not suitable for sustained therapy. Methotrexate remains the systemic agent against which others are compared. Biologic agents can produce dramatic responses at dramatic expense.

Topical Treatment

Corticosteroids. Topical application of corticosteroids in creams, ointments, lotions, foams, and sprays is the most frequently

prescribed therapy for localized psoriasis. Class I steroids are suitable for 2-week courses of therapy on most body areas. Therapy can be continued with pulse applications on weekends to reduce the incidence of local adverse effects. On the scalp, corticosteroids in propylene glycol, gel, foam, and spray bases are preferred by most white patients. Black patients may find them drying and may prefer oil and ointment preparations. Low- to medium-strength creams are preferred in the intertriginous areas and on the face. To augment effectiveness of topical corticosteroids in areas with thick keratotic scale, the area should be hydrated before application and covered with an occlusive dressing of polyethylene film (plastic wrap) or a sauna suit. Side effects include epidermal atrophy, steroid acne, miliaria, and pyoderma.

Intralesional injections of triamcinolone are helpful for refractory plaques. Triamcinolone acetonide (Kenalog) suspension, 10 mg/mL, may be diluted with sterile saline to make a concentration of 2.5–5 mg/mL. Good results are also obtained in the treatment of psoriatic nails by injecting triamcinolone into the region of the matrix and the lateral nailfold. A digital block can be performed before injection to provide anesthesia. Injections are given once a month until the desired effect is achieved.

Tars. Crude coal tar and tar extracts such as liquor carbonis detergens (LCD) can be compounded into agents for topical use. Tar bath oils and shampoos are readily available. Oil of cade (pine tar) or birch tar in concentrations of 5%–10% may also be incorporated into ointments. The odor of all tars may be offensive, and relapse is more rapid than with topical agents such as calcipotriene.

Anthralin. Anthralin is effective but is irritating and stains skin, clothing, and bedding. To avoid these drawbacks, short-contact anthralin treatment (SCAT) can be helpful, with anthralin washed off after 15–30 minutes. Anthralin exerts a direct effect on keratinocytes and leukocytes by suppressing neutrophil superoxide generation and inhibiting monocyte-derived IL-6, IL-8, and TNF-α.

Tazarotene. Tazarotene is a nonisomerizable retinoic acid receptor–specific retinoid. It appears to treat psoriasis by modulating keratinocyte differentiation and hyperproliferation, as well as by suppressing inflammation. Combining its use with a topical corticosteroid and weekend pulse therapy can decrease irritation.

Calcipotriene. Vitamin D_3 affects keratinocyte differentiation partly through its regulation of epidermal responsiveness to calcium. Treatment with the vitamin D analog calcipotriene (Dovonex) in ointment, cream, or solution form has been effective in the treatment of plaque-type and scalp psoriasis. Combination therapy with calcipotriene and high-potency steroids may provide greater response rates, fewer side effects, and steroid sparing. Calcipotriene is unstable in the presence of many other topical agents and degrades in the presence of UV light. Monitoring of serum calcium levels in adults is not required. Calcipotriene plus betamethasone dipropionate is more effective than either agent alone.

Macrolactams (Calcineurin Inhibitors). Topical macrolactams such as tacrolimus and pimecrolimus are especially helpful for thin lesions in areas prone to atrophy or steroid acne. The burning associated with these agents can be problematic but may be avoided by prior corticosteroid treatment and application to dry skin rather than after bathing.

Salicylic Acid. Salicylic acid is used as a keratolytic agent in shampoos, creams, and gels. It can promote the absorption of other topical agents. Widespread application may lead to salicylate toxicity, manifesting with tinnitus, acute confusion, and refractory hypoglycemia, especially in patients with diabetes and those with compromised renal function.

Ultraviolet Light. Phototherapy is a cost-effective and underused modality for psoriasis. In most cases, sunlight improves psoriasis. However, severe burning of the skin may cause the Koebner phenomenon and an exacerbation. Artificial UVB light is produced by fluorescent bulbs in broad-band or NB spectrum. Maximal effect is usually achieved at MEDs. Although suberythemogenic doses can be effective, the response is slower than with erythemogenic regimens. With treatment, a tanning response occurs, and the dose must be increased to maintain efficacy. Maintenance UVB phototherapy after clearing contributes to the duration of remission and is justified for many patients.

Using a monochromator, it has been shown that wavelengths of 254, 280, and 290 nm are ineffective; at 296, 300, 304, and 313 nm, however, there is clearing. NB UVB (peak emission about 311 nm) is now widely available.

Goeckerman Technique. Goeckerman therapy remains an effective and cost-effective method of treatment even in patients with poor responses to biologic agents. In its modern form, a 2%–5% tar preparation is applied to the skin, and a tar bath is taken at least once a day. The excess tar is removed with mineral or vegetable oil, and UV light is given. In psoriasis day care centers, patients clear in an average of 18 days, and 75% remain free of disease for extended periods. The addition of a topical corticosteroid to the Goeckerman regimen shortens the time required for remission. Phototoxic reactions (tar smarts) may result from UVA generated by the predominantly UVB bulbs.

Ingram Technique. Ingram therapy consists of a daily coal tar bath in a solution such as 120 mL LCD to 80 L of warm water. This is followed by daily exposure to UV light for increasing periods. An anthralin paste is then applied to each psoriatic plaque. Talcum powder is sprinkled over the lesions, and stockinette dressings are applied. Modern versions of the technique employ SCAT.

PUVA Therapy. High-intensity longwave UV radiation (UVA) given 2 hours after ingestion of 8-methoxypsoralen (Oxsoralen-Ultra), twice a week, is highly effective, even in severe psoriasis. Most patients clear in 20–25 treatments, but maintenance treatment is needed.

Although PUVA therapy is highly effective, in patients with less than 50% of the skin surface affected, UVB may be as effective. Polyethylene sheet bath PUVA is another therapeutic alternative to oral psoralen–UVA. The patient is immersed in a psoralen solution contained in plastic sheeting that conforms to the patient's body.

Oral psoralen can produce cataracts, and protective eyewear must be used. PUVA therapy is a risk factor for skin cancer, including squamous cell carcinoma (SCC) and melanoma. Arsenic exposure is a more significant cofactor than prior exposure to methotrexate, UVB, or concomitant use of topical tar. Men treated without genital protection are at an increased risk of developing SCC of the penis and scrotum. Although the risk of cancer is dose related, there is no definitive threshold dose of cumulative PUVA exposure above which carcinogenicity can be predicted.

Surgical Treatment

In patients with pharyngeal colonization by streptococci, an excellent response has been reported after tonsillectomy. More effective antibiotic regimens, such as a 10-day course of dicloxacillin combined with rifampin (600 mg/day for adult), have largely replaced tonsillectomy.

Hyperthermia

Local hyperthermia can clear psoriatic plaques, but relapse is usually rapid. Microwave hyperthermia may produce significant

complications, such as pain over bony prominences and tissue destruction.

Occlusive Treatment

Occlusion with surgical tape or dressings can be effective as monotherapy or when combined with topical drugs.

Systemic Treatment

Corticosteroids. The hazards of the injudicious use of systemic corticosteroids must be emphasized. There is great risk of "rebound" or induction of pustular psoriasis when therapy is stopped. Corticosteroid use is generally restricted to unique circumstances, such as impetigo herpetiformis when expeditious delivery is not possible.

Methotrexate. This folic acid antagonist remains the standard against which other systemic treatments are measured. Methotrexate has a greater affinity for dihydrofolic acid reductase than does folic acid. The indications for methotrexate include psoriatic erythroderma, psoriatic arthritis, acute pustular psoriasis (von Zumbusch type), or widespread body surface area (BSA) involvement. Localized pustular psoriasis or palmoplantar psoriasis that impairs normal function and employment may also require systemic treatment.

It is important to ensure the patient has no history of liver or kidney disease. Methotrexate can be toxic to the liver, and decreased renal clearance can enhance toxicity. Other important factors to consider are alcohol abuse, cryptogenic cirrhosis, severe illness, debility, pregnancy, leukopenia, thrombocytopenia, active infectious disease, immunodeficiency, anemia, colitis, and ability to comply with directions. Hepatic enzymes, bilirubin, serum albumin, creatinine, alkaline phosphatase, complete blood count, platelet count, hepatitis serology (B and C), HIV antibody, a test for tuberculosis, and urinalysis should all be evaluated before starting treatment. Patients with hypoalbuminemia have a higher risk of developing pulmonary complications.

The need for liver biopsy remains controversial. Biopsy is not without risks and is not usually performed in the setting of methotrexate therapy for rheumatic disease. However, patients with psoriasis have a greater risk of liver disease than other patient populations. Weekly blood counts and monthly liver enzyme assessment are recommended at the onset of therapy or when the dosage is changed, but hepatitis fibrosis can occur without elevations in liver enzymes. Monitoring of aminoterminal procollagen III peptide may reduce or eliminate the need for liver biopsy.

Numerous treatment schedules have evolved, and the liquid for injection may be dosed orally in orange juice as a less expensive alternative to pills. The authors recommend either three divided oral doses (12 hours apart) weekly, weekly single doses orally, or single weekly subcutaneous injections. The weekly dose varies from 5 mg to more than 50 mg, with most patients requiring 15–30 mg a week. Once a single dose exceeds 25 mg, oral absorption is unpredictable, and subcutaneous injections are recommended. Midweek doses can result in severe toxicity and must be avoided. Oral or cutaneous ulceration may be a sign that the patient has taken a midweek dose. Oral folic acid has been reported to decrease side effects, especially nausea, and doses of 1–4 mg/day are used. Oral folic acid is not adequate for the treatment of overdosage, and leukovorin must be used in such cases.

Cyclosporine. The therapeutic benefit of cyclosporine in psoriatic disease may be related to downmodulation of proinflammatory epidermal cytokines. The microemulsion formulation Neoral has greater bioavailability and is now standard. Doses of 2–5 mg/kg/day generally produce rapid clearing of psoriasis, with both efficacy and risk being dose related. Unfortunately, the lesions recur rapidly as well, and transition to another form of therapy is required. Treatment durations of up to 6 months are associated with a low incidence of renal complications, but blood pressure and serum creatinine must be monitored and doses adjusted accordingly. Usually, the dose is reduced if the baseline creatinine increases by one third. Some data support the feasibility of pulse dosing for a few days each week for both the induction and the maintenance of response in psoriasis patients.

Diet. The antiinflammatory effects of fish oils rich in n-3 polyunsaturated fatty acids (PUFAs) have been demonstrated in RA, inflammatory bowel disease, psoriasis, and asthma. The n-3 and n-6 PUFAs affect a variety of cytokines, including IL-1, IL-6, and TNF. Herbal remedies have also been used with variable effects. Many of these products are unpalatable, and their efficacy does not compare favorably to pharmacologic agents.

Oral Antimicrobial Therapy. The association of streptococcal pharyngitis with guttate psoriasis is well established. *Staphylococcus aureus* and streptococci secrete exotoxins that act as superantigens, producing massive T-cell activation, and pharyngeal colonization should be addressed as previously noted. Oral bile acid supplementation has been shown to improve psoriasis, presumably by affecting the microflora and endotoxins in the gut. Oral ketoconazole, itraconazole, and other antibiotics have shown efficacy in a limited number of patients with psoriasis.

Retinoids. Oral treatment with the aromatic retinoid ethylester etretinate has been effective in many patients with psoriasis, especially in pustular disease. Because of its long half-life, etretinate has been replaced by acitretin. Alcohol ingestion can convert acitretin to etretinate and is discouraged. 13-*Cis*-retinoic acid can also produce good results in some patients with pustular psoriasis. All these drugs are potent teratogens, and elevated triglyceride levels may complicate therapy. Combinations of retinoic acids with photochemotherapy can be effective in chronic plaque psoriasis, resulting in lowered cumulative doses of light.

Dapsone. Dapsone use is limited largely to palmoplantar pustulosis or other variants of pustular psoriasis. Even in this setting, it is a second- or third-line agent with limited efficacy.

Biologic Agents

A number of biologic agents are available that can produce dramatic responses in some patients with psoriasis; all are expensive. Retrospective analysis using BSA multiplied by physician's global assessment as an endpoint suggests that outcomes with biologic agents are superior to those with other systemic agents, despite the patients taking biologics having a higher baseline severity and a greater number of previous treatments.

Several agents block TNF-α. Infliximab is a chimeric monoclonal antibody (mAb) to TNF-α and requires intravenous infusion; etanercept is a fusion protein of human TNF type II receptor and the Fc region of immunoglobulin (Ig)G1; and adalimumab is a recombinant, fully human IgG1 mAb to TNF-α. Alefacept is a fusion protein of the external domain of LFA-3 and the Fc region of IgG1; it blocks T-cell activation and triggers apoptosis of pathogenic T cells, but was withdrawn from the market in the United States. Golimumab is an anti-TNF agent with less frequent dosing used in patients with psoriatic arthritis, and certolizumab has also demonstrated efficacy. Ustekinumab, a human mAb against IL-12 and IL-23, blocks the inflammatory pathway at a more proximal point than anti-TNF agents. Guselkumab is an IL-23 receptor monoclonal antibody. Ixekizumab and secukinumab are IL-17A antagonists. Brodalumab is a human, anti–IL-17RA monoclonal antibody.

Percentage of Patients Clearing With Each Drug. Published data allow for some comparisons of biologic agents, but the endpoints of some trials differ. Newer anti–IL-17 and anti-IL-23 agents can achieve PASI 100 in some patients, a dramatic improvement over previous biologic agents. The anti–IL-17 agents include secukinumab, ixekizumab, and brodalumab. A meta-analysis of published trials of the older biologics suggested that of the agents studied at the end of the induction phase (week 24), ustekinumab had the greatest probability of achieving at least 75% improvement from baseline in the psoriasis area and severity index (PASI 75), followed by infliximab, adalimumab, and etanercept. The percentage of patients reaching PASI 75 at week 10 is about 70% with infliximab at 3 mg/kg and 90% at 5 mg/kg, compared with 6% for placebo. About 35% of patients receiving etanercept, 25 mg subcutaneously twice weekly, achieve PASI 75 at 12 weeks and 45% at 24 weeks. With the 50-mg induction dose administered twice a week, about 46% of patients achieve PASI 75 at 12 weeks and 50% at 24 weeks. The data available suggest that about 53% of patients taking 40 mg of adalimumab every other week achieve PASI 75 by week 12, and about 80% of those taking 40 mg a week achieve PASI 75.

Risks. Anti-TNF agents are contraindicated with demyelinating disease and anti-IL-17 agents are contraindicated with inflammatory bowel disease. The anti-TNF agents may induce flares of psoriasis through upregulation of plasmacytoid dendritic cells. This may be a class effect. The biologic agents all suppress the normal immune response. Infliximab has been associated with reactivation of tuberculosis, demyelinating disease, and serious systemic opportunistic infection. Infliximab may also lose its effect because of neutralizing antibodies. Methotrexate or azathioprine may be needed as concomitant therapy to reduce the incidence of neutralizing antibodies and infusion reactions. Even though adalimumab is a fully human antibody, it may also induce an antibody response. Serious infections have been reported in RA patients treated with this agent. Etanercept has been associated with infection, onset, or exacerbation of multiple sclerosis, vasculitis, and LE-like manifestations. All these effects are rare and may not be statistically increased from the general population. Many of the reported complications, such as lymphoma, demyelinating disease, progressive multifocal leukoencephalopathy and infection, are not unique to any one immunosuppressive agent.

The National Psoriasis Foundation has endorsed a recommendation that all patients be screened for latent tuberculosis infection before any immunologic therapy. The Foundation recommends delaying immunologic therapy until prophylaxis for latent tuberculosis infection is completed, although noting that patients with severe disease may be treated after 1–2 months of prophylaxis. IFN-γ assays have greater specificity than tuberculin skin tests and are being used along with imaging studies to confirm tuberculosis in patients with positive skin tests.

Phosphodiesterase Inhibitors

Apremilast, a small molecule specific inhibitor of phosphodiesterase 4, has demonstrated efficacy in recalcitrant plaque psoriasis. It is also indicated for psoriatic arthritis. Diarrhea is the most common adverse effect. Other adverse reactions include nausea, depression, upper respiratory tract infection, and headache.

Janus Kinase Inhibitors

Janus kinase (JAK) inhibitors such as tofacitinib have demonstrated efficacy in the treatment of psoriasis, including nail psoriasis. The side-effect profile of tofacitinib includes dose-dependent decreases in red blood cell counts, along with transient or reversible dose-dependent decreases in neutrophil counts. Tofacitinib has also demonstrated transient increases in lymphocyte counts, primarily attributable to increases in B-cell counts.

Combination Therapy

In more severe forms of psoriasis, a combination of treatment modalities may be employed. In treating patients with methotrexate, for example, concomitant topical agents may be used to minimize the dose. Methotrexate has been combined with infliximab to reduce the incidence of neutralizing antibodies, and also has been used with acitretin in managing patients with severe, generalized pustular psoriasis. Recent evidence suggests that neutralizing antibodies correlated with loss of response to biologics other than infliximab, suggesting a broader role for combination therapy. The use of PUVA and retinoids is called Re-PUVA and has been studied extensively. Acitretin has been combined with biologic agents to treat refractory psoriasis. Combination systemic therapy has the potential to reduce overall toxicity if the toxicities of each agent are different. However, new regimens should be used with caution because of the potential for cumulative toxicity or drug interaction.

Evolving Therapies

Alternative therapies for psoriasis include mycophenolate mofetil, sulfasalazine, paclitaxel, azathioprine, fumaric acid esters, climatotherapy, and grenz ray therapy. A3 adenosine receptor agonists are also being developed. Nail disease can respond to systemic agents, topical retinoids, local triamcinolone injections, and topical 5-fluorouracil. The latter agent can cause onycholysis if applied to the free edge of the nail.

REACTIVE ARTHRITIS WITH CONJUNCTIVITIS/ URETHRITIS/DIARRHEA (REITER SYNDROME)

The syndrome includes a characteristic clinical triad of urethritis, conjunctivitis, and arthritis. The disease occurs chiefly in young men of HLA-B27 genotype, generally following a bout of urethritis or diarrheal illness. Systemic involvement can include the gastrointestinal tract, kidneys, central nervous system, and cardiovascular system. Because few patients present with the classic triad, the American College of Rheumatology recognizes criteria for limited manifestations of the syndrome, including peripheral arthritis of more than 1-month duration in association with urethritis, cervicitis, or bilateral conjunctivitis.

Hans Reiter was a Nazi war criminal, involved with or having knowledge of involuntary sterilization as well as a study of an experimental typhus vaccine that resulted in hundreds of deaths of concentration camp internees. Some believe that he should no longer be afforded the name recognition to designate the syndrome.

Clinical Features

Any part of the triad may occur first, often accompanied by fever, weakness, and weight loss. Although the inciting urethritis may be bacterial, later manifestations include a nonbacterial urethritis with painful urination and pyuria. Cystitis, prostatitis, and seminal vesiculitis may be accompaniments. Vulvar ulceration has been reported. About one third of patients develop conjunctivitis, which may be bulbar, tarsal, or angular. Keratitis is usually superficial and extremely painful. Iritis is common, especially in recurrent cases. Infrequently, optic neuritis may occur. Uveitis correlates with axial joint disease and HLA-B27 positivity. An asymmetric arthritis may affect peripheral joints, especially weight-bearing joints. Its onset is usually sudden. Pain in one or both heels is a frequent symptom. Sacroiliitis may develop in up to two thirds of patients, most of whom are of HLA-B27 type.

The skin involvement usually begins with small, guttate, hyperkeratotic, crusted or pustular lesions of the genitals (Fig. 10.13), palms, or soles. Involvement of the glans penis (balanitis circinata) occurs in 25% of patients. Lesions on the soles and trunk often become thickly crusted or hyperkeratotic. The eruption on the soles is known as keratoderma blennorrhagicum and occurs in 10% of patients (Fig. 10.14). The buccal, palatal, and lingual mucosa may show painless, shallow, red erosions. The nails become thick and brittle, with heavy subungual keratosis. Children are much more likely to have the postdysenteric form, often with conjunctivitis and arthritis as the most prominent complaints.

The syndrome generally follows an infectious urethritis or diarrheal illness. Implicated organisms include *Chlamydia*, *Shigella*, *Salmonella*, *Yersinia*, *Campylobacter*, *Ureaplasma*, *Borrelia*, *Cryptosporidium*, gonococci, and bacille Calmette-Guérin (BCG). *Chlamydia trachomatis* and *Ureaplasma urealyticum* have been isolated from the synovial fluid of affected joints, and some patients respond to antibiotic therapy. Chlamydial antigens demonstrate high homology with human sequences containing the binding motif of HLA-B27. Reiter syndrome has also been observed in HIV disease but may not be directly related to the virus, because it frequently occurs during treatment as the immune response improves. The disease has also been triggered by adalimumab and leflunomide in the setting of ankylosing spondyloarthropathy and Crohn disease.

Peripheral leukocytosis of 10,000–20,000/mm^3 and elevated erythrocyte sedimentation rate are the most consistent findings.

Fig. 10.13 Genital involvement in reactive arthritis.

Fig. 10.14 Keratoderma blennorrhagicum.

There is no specific test for Reiter syndrome. The differential diagnosis includes RA, ankylosing spondylitis, gout, psoriatic arthritis, gonococcal arthritis, acute rheumatic fever, chronic mucocutaneous candidiasis, and serum sickness. The presence of associated mucocutaneous lesions establishes the diagnosis. Some cases of Lyme disease overlap with Reiter syndrome. Individual skin lesions may be indistinguishable from those in psoriasis. Hyperkeratotic lesions generally have a thicker scale crust than most psoriatic plaques, but are otherwise identical.

Mucocutaneous lesions are generally self-limited and clear with topical corticosteroids. Joint disease is managed with rest and NSAIDs.

Antibiotic therapy has been effective in *Chlamydia*-triggered arthritis, but the role of antibiotics in arthritis triggered by enteric pathogens is less clear, with some studies suggesting a higher incidence in patients treated with antibiotics. Immunosuppressive agents, such as methotrexate, are used for refractory joint disease. TNF-α biologics, acitretin, and cyclosporine have been used in severe disease.

SUBCORNEAL PUSTULAR DERMATOSIS (SNEDDON-WILKINSON DISEASE)

In 1956 Sneddon and Wilkinson described a chronic pustular disease that occurred chiefly in middle-aged women. The pustules are superficial and arranged in annular and serpiginous patterns, especially on the abdomen, axillae, and groins. Cultures from the pustules are sterile. Oral lesions are rare. The condition is chronic, with remissions of variable duration. Some cases have followed administration of drugs including sorafenib.

Histologically, the pustules form below the stratum corneum, as in impetigo. Acantholysis is absent, but spongiform pustules may be noted in the upper epidermis. The histologic differential diagnosis includes pustular psoriasis and superficial fungal and bacterial infections.

IgA pemphigus shows significant overlap with subcorneal pustular dermatosis. Presentations of IgA pemphigus include subcorneal pustular dermatosis and intraepidermal neutrophilic IgA dermatosis types. Immunoblotting techniques have shown that human desmocollin 1 is an autoantigen for the subcorneal pustular dermatosis type of IgA pemphigus.

Localized cases may respond well to topical corticosteroids. Dapsone, 50–200 mg/day (adult), is effective for most of the remaining cases. Some patients have responded better to sulfapyridine therapy. Acitretin, NB UVB phototherapy, colchicine, azithromycin, biologic agents, and tetracycline with niacinamide may also be effective in subcorneal pustular dermatosis. Paraprotein-associated disease has resolved after treatment of the associated myeloma.

EOSINOPHILIC PUSTULAR FOLLICULITIS

Eosinophilic pustular folliculitis (EPF) was first described in 1970 by Ofuji, although it is also referred to as sterile eosinophilic pustulosis. It occurs more often in males and is mostly reported in Asia. The mean age of onset is 35. It is characterized by pruritic, follicular papulopustules that measure 1–2 mm. The lesions tend to be grouped, and plaques usually form. New lesions may form at the edges of the plaques, leading to peripheral extension, while central clearing takes place. The most frequent site is the face, particularly over the cheeks. The trunk and upper extremities frequently are affected, and 20% have palmoplantar pustules. The distribution is usually asymmetric, and the typical course is one of spontaneous remissions and exacerbations lasting several years. The condition must be distinguished from eosinophilic folliculitis in infancy, HIV infection, and posttransplantation. A similar condition has occurred in association with HCV infection, with allopurinol, and during pregnancy.

Histologically, there is spongiosis and vesiculation of the follicular infundibulum and heavy infiltration with eosinophils. Follicular mucinosis may be present. There is a peripheral eosinophilia in half the cases, and pulmonary eosinophilia has been described. The cause is unknown; but numerous studies have implicated chemotactic substances, intercellular adhesion molecule 1 (ICAM-1), and cyclooxygenase-generated metabolites. Tryptase-positive and chymase-negative mast cells have also been implicated.

Indomethacin is effective in the vast majority of patients with eosinophilic pustular folliculitis. Topical and intralesional corticosteroids, clofazimine, minocycline, isotretinoin, UVB therapy, dapsone, colchicine, cyclosporine, topical tacrolimus, nicotine patches, infliximab, and cetirizine have also been reported as effective.

Childhood cases have been described. This subset differs from the typical cases in Asian males. Pediatric patients develop sterile pustules and papules preferentially over the scalp, although scattered clusters of pustules may occur over the trunk and extremities. Leukocytosis and eosinophilia are often present. Recurrent exacerbations and remissions usually occur, with eventual spontaneous resolution. High-potency topical steroids are the treatment of choice in pediatric patients.

RECALCITRANT PALMOPLANTAR ERUPTIONS

Dermatitis Repens

Dermatitis repens, also known as acrodermatitis continua (see earlier) and acrodermatitis perstans, is a chronic inflammatory disease of the hands and feet. It usually remains stable on the extremities, but in rare cases, generalized pustular flares may occur. The disease usually begins distally on a digit, either as a pustule in the nail bed or as a paronychia. Extension takes place by eruption of fresh pustules with subsequent hyperkeratosis and crusting. The disease is usually unilateral at first and asymmetric throughout its entire course. As the disease progresses, one or more of the nails may become dystrophic or float away on pus. Anonychia is common in chronic cases. Some have used the term *dermatitis repens* to refer to more indolent involvement of the distal fingers.

Involvement of the mucous membranes may occur, even when the eruption of the skin is localized. Painful, circular, white plaques surrounded by inflammatory areolae are found on the tongue and may form a fibrinous membrane. Fissured or geographic tongue may occur.

Histologically, intraepithelial spongiform pustules identical to those of psoriasis are seen in the acute stage. Later stages show hyperkeratosis with parakeratosis or atrophy.

Numerous treatment options have been used, including topical corticosteroids, calcipotriene, dapsone, sulfapyridine, methotrexate, PUVA, acitretin, cyclosporine, topical mechlorethamine, anti-TNF agents, and anakinra. The choice of agent to use should consider the severity of disease and the patient's age and functional impairment. It should be noted that anti-TNF agents have triggered similar eruptions.

Palmoplantar Pustulosis (Pustular Psoriasis of Extremities)

Chronic palmoplantar pustulosis is essentially a bilateral and symmetric dermatosis (Fig. 10.15). The favorite locations are the thenar or hypothenar eminences or the central portion of the palms and soles. The patches begin as erythematous areas in which minute intraepidermal pustules form. At the beginning, these are pinhead sized; then they may enlarge and coalesce to form small lakes of pus. As the lesions resolve, denuded areas, crusts, or hyperkeratosis may persist. Palmoplantar pustulosis is strongly associated with thyroid disorders and cigarette smoking. Medications such as lithium, which aggravate psoriasis, have also been reported to induce palmoplantar pustular psoriasis.

In 1968 Kato described the first case of bilateral clavicular osteomyelitis with palmar and plantar pustulosis. In 1974 Sonozaki described persistent palmoplantar pustulosis and sternoclavicular hyperostosis. These conditions belong to the spectrum of skin and joint involvement designated by Kahn as the SAPHO syndrome (synovitis, acne, pustulosis, hyperostosis, and osteitis). Common features include palmoplantar pustulosis, acneiform eruption, and pain and swelling of a sternoclavicular joint or at sternomanubrial or costochondral junctions. There is shoulder, neck, and back pain, and limitation of motion of the shoulders and neck is common. Brachial plexus neuropathy and subclavian vein occlusion may occur. The lumbar spine and sacroiliac joints are usually spared. Chronic multifocal osteomyelitis in children may be a pediatric variant. Others have described an association between palmoplantar pustulosis and arthritis or osteitis. SAPHO syndrome may coexist with features of Behçet disease. The knees, spine, and ankles may be involved. Ivory vertebrae have been described.

The disease typically is resistant to treatment. Topical corticosteroids, retinoids, calcipotriene, and macrolactams are of some benefit. Acitretin is generally extremely effective at 1 mg/kg/day, although rebound occurs more quickly than with etretinate. Apremilast, dapsone, colchicine, tofacitanib, cyclosporine, allitretinoin, cefcapene pivoxil hydrochloride (a third-generation cephalosporin), leflunomide, and mycophenolate mofetil may be effective. Oral 8-methoxypsoralen and high-intensity UVA irradiation or soak PUVA can both be helpful, and grenz ray therapy can induce prolonged remissions in some patients. Chronic osteomyelitis in SAPHO syndrome has been reported to respond to bisphosphonates.

Fig. 10.15 (A) Plantar pustulosis. (B) Pustules and hyperkeratosis are typical.

Pustular Bacterid

Pustular bacterid was first described by George Andrews. It is characterized by a symmetric, grouped, vesicular, or pustular eruption on the palms and soles, marked by exacerbations and remissions over long periods. Andrews regarded the discovery of a remote focus of infection, and cure on its elimination, as crucial to the diagnosis.

The primary lesions are pustules. Tiny hemorrhagic puncta intermingled with the pustules are frequently seen. When lesions are so numerous as to coalesce, they form a honeycomb-like structure in the epidermis. The disease usually begins on the midportions of the palms or soles, from which it spreads outwardly until it may eventually cover the entire flexor aspects of the hands and feet. There is no involvement of the webs of the fingers or toes, as in tinea pedis.

When the eruption is fully developed, both palms and soles are completely covered, and the symmetry is pronounced. During fresh outbreaks, the white blood count may show a leukocytosis that ranges from 12,000 to 19,000 cells/mm^3 with 65%–80% neutrophils. As a rule, scaling is present in fully evolved lesions, and the scales are adherent, tough, and dry. During exacerbations, crops of pustules or vesicles make their appearance, and there is often severe itching of the areas. Tenderness may be present. Many regard this condition as a variant of psoriasis, triggered by infection.

Infantile Acropustulosis

Infantile acropustulosis is an intensely itchy vesicopustular eruption of the hands and feet (Fig. 10.16). Most cases are postscabetic, and active scabies can produce similar lesions. Lesions often predominate at the edges of the palms and soles. Individual crops of lesions clear in a few weeks, but recurrences may continue for months or years.

Histologically, a subcorneal pustule with neutrophils is noted. Eosinophils may be numerous. The lesions are easily punctured to produce smears of the inflammatory cells, so biopsies are seldom employed.

Lesions often respond to topical corticosteroids. Refractory lesions may respond to dapsone at doses of 1–2 mg/kg/day.

11 Pityriasis Rosea, Pityriasis Rubra Pilaris, and Other Papulosquamous and Hyperkeratotic Diseases

Bonus images for this chapter can be found online at expertconsult.inkling.com

PITYRIASIS ROSEA

Clinical Features

Pityriasis rosea is a mild inflammatory exanthem characterized by salmon-colored thin papules and plaques that are at first discrete but may become confluent (Fig. 11.1). The individual patches are oval or circinate and covered with finely crinkled, dry epidermis, which often desquamates, leaving a collarette of scaling in the center. When stretched across the long axis, the scales tend to fold across the lines of stretch, the so-called hanging curtain sign or Christmas tree sign. The disease most frequently begins with a single herald or mother patch (Fig. 11.2), usually larger than succeeding lesions, which may persist 1 week or longer before others appear. This is often confused for tinea corporis because it is an isolated patch with central colarette of scale mistaken for being annular. By the time involution of the herald patch has begun, new lesions arise rapidly (Fig. 11.3). The total course is typically 3–8 weeks, and then the lesions spontaneously resolve. Relapses and recurrences are observed infrequently. The incidence is highest between ages 15 and 40, and the disease is most prevalent in the spring and autumn. Women are more frequently affected than men.

The fully developed eruption has a striking appearance because of the distribution and definite characteristics of the individual lesions. These are arranged so that the long axis of the macules runs parallel to the lines of cleavage. The eruption is usually generalized, affecting chiefly the trunk and sparing sun-exposed surfaces. Less common presentations are localized (involving neck, thighs, groins, or axillae), distribution (sparing covered areas), unilateral, papular, and segmental pattern. Children with darker skin pigmentation are particularly predisposed to the papular variant and are also more prone to facial and scalp involvement. In darker-skinned patients, the lesions often resolve with hypopigmentation. A vesicular variant has also been described, and erythema multiforme–like lesions may occur. Purpuric pityriasis rosea may manifest with petechiae and ecchymoses along Langer lines of the neck, trunk, and proximal extremities, and may rarely be a sign of an underlying leukemia. Pityriasis rosea occurring during pregnancy may be associated with premature delivery, neonatal hypotonia, and fetal loss, especially if the eruption occurs within the first 15 weeks of gestation.

When the eruption localized, it can be difficult to distinguish from unilateral laterothoracic exanthema (asymmetric periflexural exanthema of childhood). Confluent circinate patches with gyrate borders may form and may resemble tinea corporis. Rarely, the eyelids, palms and soles, scalp, or penis may be involved, and syphilis should be ruled out, especially with palm and sole involvement. Oral lesions are relatively uncommon; they are asymptomatic, erythematous macules with raised borders and clearing centers or aphthous ulcer–like lesions. They involute simultaneously with the skin lesions. Moderate pruritus may be present, particularly during the outbreak, and mild constitutional symptoms may occur before the onset.

Etiology

Pityriasis rosea is most likely a response to a virus. The most commonly implicated viruses are herpes viridae such as human herpesvirus (HHV)–6 and HHV-7. Watanabe et al. (2002) demonstrated active replication of HHV-6 or HHV-7 in mononuclear cells of lesional skin, as well as identifying the viruses in serum samples of patients including women who experienced miscarriage in association with pityriasis rosea. Although these viruses are almost universally acquired in early childhood and remain in a latent phase as mononuclear cells, the eruption is likely secondary to reactivation leading to viremia. HHV-2 and hepatitis C virus (HCV) have also been implicated in individual cases.

A pityriasis rosea–like eruption may occur as a reaction to medications such as captopril, imatinib mesylate, interferon, ketotifen, arsenicals, gold, bismuth, clonidine, methoxypromazine, tripelennamine hydrochloride, ergotamine, lisinopril, acyclovir, lithium, adalimumab, nortriptyline, lamotrigine, rituximab, imatinib, asenapine, barbiturates, or bacille Calmette-Guérin (BCG) vaccine.

Histology

The histologic features of pityriasis rosea include mild acanthosis, focal parakeratosis, and extravasation of erythrocytes into the epidermis. Spongiosis may be present in acute cases. A mild perivascular infiltrate of lymphocytes is found in the dermis. Histologic evaluation is especially helpful in excluding the conditions with which pityriasis rosea may be confused.

Differential Diagnosis

Pityriasis rosea may closely mimic seborrheic dermatitis, tinea corporis, secondary syphilis (macular syphilid), drug eruption, other viral exanthems, and psoriasis. In seborrheic dermatitis, the scalp and eyebrows are usually scaly; there is a predilection for the sternal and interscapular regions, as well as the flexor surfaces of the articulations, where the patches are covered with greasy scales. Tinea corporis is rarely so widespread. Tinea versicolor may also closely simulate pityriasis rosea but the individual lesions tend to be flatter and smaller. A positive potassium hydroxide (KOH) examination serves well to differentiate these last two. In macular syphilid, the lesions are of a uniform size and assume a brownish tint. Scaling and itching are absent or slight, and there is typically generalized adenopathy with mucous membrane lesions, palmoplantar lesions, positive nontreponemal and treponemal tests, and often the remains of a chancre. Because syphilis can so closely mimic pityriasis rosea and syphilis incidence is rising again, strong consideration for syphilis testing should be considered in patients with pityriasis rosea. Scabies and lichen planus may be confused with the papular type.

Treatment

Most patients with pityriasis rosea require no therapy because they are asymptomatic; however, the duration of the eruption may be notably reduced by several interventions. A Cochrane review cited inadequate evidence for efficacy for most published treatments;

Fig. 11.1 Pityriasis rosea.

Fig. 11.2 Herald patch of pityriasis rosea.

however, lack of evidence does not equate to lack of efficacy. The most data exists for the use of acyclovir with multiple trials showing decrease the eruption and itching. In pregnant patients, given the small risk of harm to the fetus early in pregnancy, acyclovir could be considered along with input from an obstetrician to help weigh the risks and benefits. Erythromicin has demonstrated benefit in small studies. The gastrointestinal side effects of erythromycin may limit its use. Use of ultraviolet B (UVB) light in erythema exposures may expedite the involution of the lesions after the acute inflammatory stage has passed. The erythema produced by ultraviolet (UV) treatment is followed by superficial exfoliation. Narrow Band UVB therapy may help improve individual lesions but may not shorten the course or alleviate pruritis. Corticosteroid lotions or creams provide some relief from itching. For dryness and irritation, simple emollients are recommended.

PITYRIASIS RUBRA PILARIS

Clinical Features

Pityriasis rubra pilaris (PRP) is a chronic skin disease characterized by small follicular papules that coalesce into salmon colored pink scaling patches, and often, solid confluent yellow-orange palmoplantar hyperkeratosis. The papules are the most important diagnostic feature, being more or less acuminate (pointy), salmon colored to reddish brown, about pinhead sized, and topped by a central horny plug (Fig. 11.4). A hair, or part of one, may be embedded in the horny center. There are two peaks of during the first 5 years of life or in the fifties. Some cases of PRP are caused by genetic mutations, thus explaining their chronic recalcitrant nature.

PRP is generally symmetric and diffuse, with characteristic small islands of normal skin within the affected areas (Fig. 11.5). There is a hyperkeratosis of the palms and soles (Fig. 11.6), with a tendency to fissures. The classic disease generally manifests first by scaliness and erythema of the scalp. The eruption is limited in the beginning, having a predilection for the sides of the neck and

Fig. 11.4 Pityriasis rubra pilaris.

Fig. 11.5 Islands of sparing in pityriasis rubra pilaris.

trunk and the extensor surfaces of the extremities, especially the backs of the first and second phalanges. Then, as new lesions occur, extensive areas are converted into sharply marginated patches of various sizes, which look like exaggerated gooseflesh and feel like a nutmeg grater. Any part or the entire skin surface may be affected. On the soles especially, the hyperkeratosis typically extends up the sides, in the distribution of a sandal. The nails may be dull, rough, thickened, brittle, and striated, and are apt to crack and break. They are rarely, if ever, pitted. The exfoliation may become generalized and the follicular lesions less noticeable, finally disappearing and leaving a widespread dry, scaly erythroderma. The skin becomes dull red, glazed, atrophic, sensitive to slight changes in temperature, and over the bony prominences, subject to ulcerations. In the classic juvenile type, limited plaques occur on extensor surfaces, with adjacent "nutmeg-grater" papules.

The skin may be itchy or asymptomatic. The Koebner phenomenon may be present. The general health of most patients is not affected. Occasionally arthritis may accompany the eruption and rarely a protein-losing enteropathy may occur if there is very widespread involvement. A number of cases of associated malignancy

Fig. 11.6 Childhood pityriasis rubra pilaris.

have recently been reported. It remains to be established whether these are true associations or chance findings. Both hypothyroidism and hypoparathyroidism have been reported, as has the combination of sacroiliitis and autoimmune thyroiditis.

PRP may be classified according to familial (typically autosomal dominant) or acquired types and to the onset of disease in childhood or adulthood. Griffith's classification is useful in this regard. Type I, the classic adult type, is seen most often and carries a good prognosis, with 80% involuting over a 3-year period. Most patients with the classic juvenile type (type III) have clearing of the disease in 1 year, although it may recur, even into adulthood. The atypical adult (type II) and circumscribed juvenile (type IV) form account for a minority of cases and carry a poorer prognosis for spontaneous recovery. Type V appears in infancy or early childhood and has a more chronic course that has been associated with a CARD14 mutation, likely explaining the chronic nature. CARD14 mutations have also been demonstrated in pustular psoriasis. A type VI has been proposed that is seen in patients infected with human immunodeficiency virus (HIV) and is associated with acne conglobata, hidradenitis suppurativa, or lichen spinulosus.

Etiology

Although CARD14 has been found in chronic early-onset forms, the etiology of spontaneous PRP is unknown. Either gender may be affected, with equal frequency. Both clinically and histologically, the disease has many features that suggest it is a vitamin deficiency disorder, particularly of vitamin A. Some reports of patients with low serum levels of retinol-binding protein have appeared, but this is not a reproducible finding. Streptococcal infections have rarely been implicated in children. A similar eruption has been described secondary to imatinib, sorafenib, and telaprevir.

Histology

There is hyperkeratosis, follicular plugging, and focal parakeratosis at the follicular orifice. Parakeratosis may alternate both vertically and horizontally, producing a checkerboard pattern. Acantholysis may be present, especially within adnexal structures. The inflammatory infiltrate in the dermis is composed of mononuclear cells and is generally mild. Although making an unequivocal histologic diagnosis of PRP may be difficult, the findings of psoriasis, which is the most common clinical entity in the differential diagnosis, are not present.

Diagnosis

Once fully manifested, the diagnosis of fully developed PRP is rarely difficult because of its distinctive features, such as the peculiar orange or salmon-yellow color of the follicular papules, containing a horny center, on the backs of the fingers, sides of the neck, and extensor surfaces of the limbs; the thickened, rough, and slightly or moderately scaly, harsh skin; the sandal-like palmoplantar hyperkeratosis; and the islands of normal skin in the midst of the eruption. It is distinguished from psoriasis by the scales, which in the latter are silvery and light, and overlap like shingles, and by the papules, which extend peripherally to form patches. Phrynoderma (follicular hyperkeratosis) caused by vitamin A deficiency gives a somewhat similar appearance to the skin, as may eczematous eruptions caused by vitamin B deficiency. Rheumatologic disorders, such as subacute cutaneous lupus erythematosus and dermatomyositis, may present with similar cutaneous findings.

Treatment

The management of PRP is generally with systemic retinoids, although topical tazarotene has also been reported to be of benefit. Isotretinoin, may induce prolonged remissions or cures. It may take 6–9 months for full involution to occur, and tapering of the drug may prevent recurrence. Acitretin and methotrexate have also been shown to improve PRP. Ustekinumab has shown efficacy including in patients with familial PRP from CARD14 mutations. Resolution by way of an erythema gyratum repens–like pattern has been described during methotrexate therapy. UV light may flare some patients, but in others, psoralen plus ultraviolet A (PUVA), UVA I, or narrow-band (NB) UVB, alone or in combination with retinoids, may be effective. Phototesting before initiating light therapy is recommended. Extracorporeal photochemotherapy, cyclosporine, anti–tumor necrosis factor (TNF) agents, and azathioprine have also been reported to be effective in resistant and severe cases.

Topical applications of calcineurin inhibitors, lactic acid, or urea-containing preparations may be helpful. Responses to topical corticosteroids are not very effective as a rule. Systemic corticosteroids are beneficial only for acute, short-term management, but are not recommended for chronic use. In HIV-related disease, multiagent antiviral therapy may be useful alone or in combination with retinoids.

SMALL PLAQUE PARAPSORIASIS

Small plaque parapsoriasis (SPP) is characterized by hyperpigmented or yellowish red scaling patches, round to oval in configuration, with sharply defined, regular borders. Most lesions occur on the trunk, and all are 1–5 cm in diameter. In the digitate variant, yellowish tan, elongated, fingerprint-like lesions are oriented along the cleavage lines, predominantly on the flank (Fig. 11.7). These lesions may at times be longer than 5 cm. There is an absence of the induration, the large, erythematous to purplish red lesions, and poikiloderma that characterize small patches of cutaneous T-cell lymphoma in its early stages. Histology can help differentiate from pityriasis lichenoides. The eruption may be mildly itchy or asymptomatic and has a male preponderance. Typical SPP rarely progresses to mycosis fungoides, although the histologic changes can overlap, and clonality may be demonstrated in SPP. Debate continues on this issue. A hypopigmented variant may have a somewhat higher rate of progression to hypopigmented mycosis fungoides. SPP has been reported in the setting of liposarcoma, with resolution of the eruption after resection of the tumor.

The histologic findings of SPP are characterized by an infiltrate in the superficial dermis composed predominantly of lymphocytes. The overlying epidermis demonstrates mild acanthosis, spongiosis, and focal overlying parakeratosis. SPP is considered to be a type of chronic spongiotic dermatitis. Lesional skin also demonstrates an increase in CD1a(+), Langerhans cells, CD1a-positive dermal dendritic cells, and CD68(+) macrophages.

Although SPP may be refractory to topical steroids alone, patients usually respond to phototherapy. Treatment with UVB, NB UVB, or natural sunlight, alone or in combination with a low-strength topical corticosteroid or simple lubricant, will usually

Fig. 11.7 Digitate parapsoriasis. (Courtesy Thomas Nicotori, MD.)

clear SPP. Without treatment, the patches of SPP may persist for years to decades but rarely progress to lymphoma.

CONFLUENT AND RETICULATED PAPILLOMATOSIS (GOUGEROT AND CARTEAUD)

The eruption of confluent and reticulated papillomatosis (CARP) typically begins on the inframammary and upper lateral trunk as slightly scaly macules that may slowly spread to involve the remainder of the trunk (Fig. 11.8). There is a nummular version that simulates tinea versicolor or erythema dychromicum perstans. In light-skinned people, the lesions vary from skin colored or faintly erythematous to hyperpigmented; in more darkly pigmented people, lesions usually show hyperpigmentation, although a nonpigmenting form with fine, white scale has been described. There may be severe itching, or the lesions may be entirely asymptomatic. Familial cases have been reported. The pathophysiology is unknown, but the consistent response to minocycline and doxycycline suggests an infectious or inflammatory etiology. An actinomycete, dubbed *Dietzia papillomatosis*, has been isolated from lesional skin, although it is unknown if this is causative. Isolated cases have been associated with hypothyroidism and 15q tetrasomy syndrome.

Histologically, hyperkeratosis, acanthosis, and papillomatosis are generally seen and *Pityrosporum (Malassezia)* yeast are frequently present. The histologic changes resemble those seen in acanthosis nigricans, and the two conditions may occur together.

A variety of antibiotics have been successful in treating this papillomatosis. Minocycline or doxycycline, for 4–8 weeks, is used most often. Successful treatment has also been reported with oral fusidic acid, clarithromycin, amoxicillin, erythromycin, azithromycin, and topical mupirocin. Topical and oral retinoids have also been used successfully, either alone or in combination with topical lactic acid, urea, or alcohol. CARP associated with polycystic ovarian syndrome has responded to contraceptive therapy. One case of CARP resolved with delivery of a baby.

Pseudo–atrophoderma colli may be a related condition that occurs on the neck. It manifests as papillomatosis, pigmented, and atrophic glossy lesions with delicate wrinkling, which tend to have a vertical orientation and may respond to minocycline.

PALMOPLANTAR KERATODERMA

The term *keratoderma* is frequently used synonymously with the terms *keratosis palmaris et plantaris* (KPP), *palmoplantar keratoderma* (PPK), and *tylosis*. This group of conditions is characterized by excessive formation of keratin on the palms and soles. There are hereditary and acquired PPKs. PPK nomenclature has improved over time as genetic testing has improved and the etiology of many of the PPKs has been elucidated, but there are still many historical names used. Hereditary PPK can be divided into diffuse and focal PPK, as well as PPK with and without associated features. The diffuse forms can be subdivided based on presence or absence of transgrediens (involvement onto the dorsal aspect sides of the hand/foot), and the focal forms can be further divided into punctate and striate forms. Those PPKs that are part of a syndrome such as pachyonychia congenita, Huriez syndrome, tyrosinemia II (Richner-Hanhart), Darier disease, Clouston (hidrotic ectodermal dysplasia), Naxos syndrome (keratoderma, wooly hair, and cardiomyopathy), various ichthyoses, and dyskeratosis congenita are discussed in other chapters.

Acquired types include keratoderma climactericum, arsenical keratoses, corns, calluses, porokeratosis plantaris discreta, glucan-induced keratoderma in acquired immunodeficiency syndrome (AIDS), and many skin disorders associated with palmoplantar keratoderma, such as psoriasis, paraneoplastic syndromes, PRP, lichen planus, and syphilis. Palmoplantar keratoderma has been described with multikinase inhibitors such as sorafenib. Treatment of these PPKs is aimed toward treating the primary disease or withdrawing the offending agent. Arsenical keratoses can occur from tainted water supplies, intentional poisoning, and medications containing arsenic. Arsenical keratoses have been treated with a combination of keratolytics and low-dose acitretin.

FOCAL PALMOPLANTAR KERATODERMAS

Keratosis Punctata of the Palmar Creases

Keratosis punctata of the palmar creases has also been referred to as keratotic pits of the palmar creases, punctate keratosis of the palmar creases, keratosis punctata, keratodermia punctata, hyperkeratosis penetrans, lenticular atrophia of the palmar creases, and hyperkeratosis punctata of the palmar creases. This common disorder occurs most often in patients of African descent. The

Fig. 11.9 Keratosis punctata of the palmar creases.

Fig. 11.10 Striate keratoderma.

primary lesion is a 1–5 mm depression filled with a comedo-like keratinous plug. The lesions localize to the creases of the palms or fingers (Fig. 11.9). The soles may be involved.

Keratosis punctata of the palmar creases has been associated with atopic dermatitis, Dupuytren contractures, pterygium inversum unguis, dermatitis herpetiformis, knuckle pads, striate keratoderma, and psoriasis, although some of these may just be disorders with a similar clinical phenotype and not truly associated. Keratolytic agents and topical retinoids have provided temporary relief. Extremely painful lesions respond to punch excision.

Striate Keratodermas

The striate keratodermas are a group of autosomal dominant palmoplantar keratodermas with streaking hyperkeratosis involving the fingers and extending onto the palm (Fig. 11.10). In some patients, mutation in desmoglein 1 (DSG-1) or desmoplakin and keratin 1 (KRT-1) have been described. In other patients, desmosome numbers are normal, but their inner plaques are attenuated. Brunauer-Fohs-Siemens syndrome is one form with diminished desmosomes, clumping of keratin filaments, and enlarged keratohyalin granules. Striate keratoderma has also been reported in association with Rubinstein-Taybi syndrome.

Punctate Palmoplantar Keratoderma

Punctate keratoses of the palms and soles has also been referred to as punctate keratoderma, keratodermia punctata, keratosis punctata palmaris et plantaris, keratoma hereditarium dissipatum palmare et plantare, keratoderma disseminatum palmaris et plantaris, palmar keratoses, and palmar and plantar seed dermatoses. *AAGAB* as well as *COL14A1* mutations have been implicated. Spiny keratoderma of the palms and soles, known as "music box spines," is a distinct variant (Fig. 11.11).

Fig. 11.11 "Music box" spiny keratoderma.

There may be from 1 to over 40 papules, with an average in one series of 8.3. The main symptom is pruritus. The onset is between ages 15 and 68. Individuals of African descent predominate, and it more frequently affects men. The histology may show pyknotic, vacuolated epithelium, basal layer spongiosis, and dilated, occluded sweat ducts, blood vessels, and lymph vessels. Mechanical debridement may help.

Circumscribed palmar hypokeratosis is a delayed manifestation of friction and repetitive-use trauma that presents as a sharply circumscribed, erythematous patch on the palm. Histologically, thickness of the stratum corneum decreases abruptly.

Acrokeratoelastoidosis

Acrokeratoelastoidosis presents with translucent to erythematous papules at the margins of the palms. Both sporadic and autosomal dominant forms have been reported. Small, round, firm papules occur over the dorsal hands, knuckles, and lateral margins of the palms and soles. The lesions appear in early childhood or adolescence in the inherited form and progress slowly. They are most often asymptomatic. The characteristic histologic feature is dermal elastorrhexis.

The differential diagnosis includes focal acral hyperkeratosis, which occurs as a familial trait in African American patients. The lesions are marginal hyperkeratotic papules, often with a central dell and usually on both the hands and the fingers. No alteration of the collagen or elastin is present on biopsy.

Porokeratosis Plantaris Discreta

Porokeratosis plantaris discreta occurs in adults, with a 4:1 female preponderance. It is characterized by a sharply marginated, rubbery, wide-based papule that on blunt dissection reveals an opaque plug without bleeding on removal. Lesions are multiple, painful, and usually 7–10 mm in diameter. They are usually confined to the weight-bearing area of the sole, beneath the metatarsal heads. Treatment may begin with fitted foot pads to redistribute the weight. Surgical excision, blunt dissection, and cryotherapy have been successful.

Focal Acral Hyperkeratosis

Focal acral hyperkeratosis occurs in autosomal dominant and sporadic forms. Clinically, it is characterized by crateriform keratotic papules and plaques along the borders of the hands and feet. It differs from acrokeratoelastoidosis and collagenous and elastotic marginal bands by the lack of underlying dermal changes.

DIFFUSE PALMOPLANTAR KERATODERMAS

Most diffuse palmoplantar keratoderms are genetic, but they can be acquired. The most helpful clinical differentiator is the presence or absence of transgrediens. Diffuse palmoplantar keratodermas are poorly responsive to therapy; 5% salicylic acid, 12% ammonium lactate, and 40% urea have been used. Fifty percent propylene glycol in water under occlusion may help soak off the hyperkeratosis. Systemic retinoid therapy is impractical because of bone toxicity with long-term use, and topical retinoids are generally not effective.

Diffuse Palmoplantar Keratodermas without Transgrediens

Vorner and Unna-Thost PPK are caused by KRT1 and KRT9 mutations. Vorner is epidermolytic and Unna-Thost is nonepidermolytic, although there is significant overlap. Variants without epidermolytic hyperkeratosis (EHK) may have more waxy appearance. They are dominantly inherited, have marked congenital thickening of the epidermal horny layer of the palms and soles, are usually symmetric, and affect all parts equally (Fig. 11.12). There is thick yellow keratin and the arches of the feet are generally spared. The uniform thickening forms a rigid plate, which ends with characteristic abruptness at the periphery of the palm. Diffuse PPK can also be caused by DSG-1 mutations. Patients with this variant can have thickened yellow nails, and on histopathology there is acantholysis especially in the superficial epidermal layers. Bothnian type PPK is a nonepidermolytic palmoplantar keratoderma due to the aquaporin 5 (AQP5), water-channel protein.

Diffuse Palmoplantar Keratodermas with Transgrediens

Mal de Meleda type PPK is a rare, autosomal recessive form of palmoplantar keratoderma seen in individuals from the island of Meleda. The hyperkeratosis does not remain confined to the palms, and the extensor surfaces of the arms are frequently affected. Mutations in the gene encoding secreted lymphocyte antigen-6/urokinase-type plasminogen activator receptor–related protein 1 *(SLURP-1)* are causative.

Nagashima-type PPK is a nonprogressive, autosomal recessive form caused by mutations in SERPINB7 that resembles a mild form of mal de Meleda and is more common in Japan. There is a higher rate of melanoma in these patients possibly due to a lack of circulating Langerhans cells. PPK of Sybert shows autosomal dominant inheritance and a lack of associated systemic features and can also involve the groin, elbows, knees, and forearms.

Fig. 11.12 Diffuse hyperkeratosis of the palms, Unna-Thost.

OTHER PALMOPLANTAR KERATODERMAS

Palmoplantar Keratodermas and Malignancy

Howell-Evans reported a diffuse, waxy keratoderma of the palms and soles occurring as an autosomal dominant trait associated with esophageal carcinoma. Other related features are oral leukoplakia, esophageal strictures, squamous cell carcinoma of tylotic skin, and carcinoma of the larynx and stomach. The tylosis esophageal cancer gene has been localized to chromosome 17q25. Acquired forms of palmoplantar keratoderma have also been associated with cancers of the esophagus, lung, breast, urinary bladder, and stomach.

Buschke-Fisher-Brauer is a focal PPK caused by mutations in the *AAGAB* gene. It is characterized by painful hyperkeratosis on the palms and soles that can begins most commonly in childhood and is associated with colon, breast, prostate, and lung cancer in addition to psoriasis and neurologic abnormalities.

Mutilating Keratoderma of Vohwinkel

Vohwinkel described honeycomb palmoplantar hyperkeratosis associated with starfish-like or honeycomb keratoses on the backs of the hands and feet, linear keratoses of the elbows and knees, and annular constriction (pseudo-ainhum) of the digits (Fig. 11.13), which may progress to autoamputation. Inheritance is mostly autosomal dominant, although a recessive type exists. The disease is more common in women and in Caucasians, with onset in infancy or early childhood. Reported associations include deafness, deaf-mutism, high-tone acoustic impairment, congenital alopecia universalis, pseudopelade-type alopecia, acanthosis nigricans, ichthyosiform dermatoses, spastic paraplegia, myopathy, nail changes, mental retardation, and bullous lesions on the soles. Vohwinkel keratoderma without deafness is due to a mutation loricrin and Vohwinkel with deafness is due to mutation in GJB2 (connexin 26). Other disorders caused by mutations in connexin 26 include keratisis ichthyosis deafness syndrome (KID) and is hystrix-like ichthyosis-deafnesss (HID) syndromes, as well as Bart-Pumphrey syndrome, which may also lead to deafness. There have been some reports of a response to acitretin (or etretinate) therapy helping patients with Vohwinkel.

Fig. 11.13 Mutilating keratoderma of Vohwinkel.

Fig. 11.14 Olmsted syndrome.

Other forms of mutilating keratoderma also occur. They lack the constricting bands, honeycomb palmoplantar hyperkeratosis, and starfish-like keratoses of Vohwinkel syndrome. The affected digits are often shortened, narrow, rigid, and tapered.

Olmsted Syndrome

Olmsted syndrome is characterized by mutilating palmoplantar keratoderma and periorificial keratotic plaques caused by mutations in TRPV3. The distinctive features of this syndrome include a congenital, sharply marginated, palmoplantar keratoderma (Fig. 11.14); constriction of the digits; linear keratotic streaks on the flexural aspects of the wrists; onychodystrophy; and periorificial keratoses. Constriction of digits may result in spontaneous amputations. Extensive grafting has sometimes been necessary. Most cases of Olmsted syndrome are sporadic. Associated abnormalities have included hyperhidrosis of the palms and soles and congenital deafness. Histologically, there is acanthosis, papillomatosis, and orthokeratotic hyperkeratosis. The finding of Ki-67 staining of suprabasal keratinocytes suggests that Olmsted syndrome is a hyperproliferative disorder of the epidermis.

Papillon-Lefèvre Syndrome

The Papillon-Lefèvre syndrome is inherited in an autosomal recessive fashion and presents with palmoplantar keratoderma and destructive periodontitis, usually beginning in young childhood. Well-demarcated, erythematous, hyperkeratotic lesions on the palms and soles may extend to the dorsal hands and feet. Hyperkeratosis may also be present on the elbows, knees, and Achilles tendon areas. Transverse grooves of the fingernails may occur. Severe gingival inflammation with loss of alveolar bone is typical. Histology reveals a psoriasiform pattern. Mutations in the gene for cathepsin C are causative in most cases. The condition usually has an early age of onset, although a late-onset variant has been reported. Some patients with late-onset disease have not shown mutations in the cathepsin C gene.

The early onset of periodontal disease has been attributed to alterations in polymorphonuclear leukocyte function caused by *Actinomyces actinomycetemcomitans*, although a variety of other bacteria have also been implicated. Acro-osteolysis and pyogenic liver abscesses may occur. There are asymptomatic ectopic calcifications in the choroid plexus and tentorium. Some patients have responded to acitretin, etretinate, or isotretinoin.

The stocking-glove distribution of the hyperkeratosis is similar to that seen in mal de Meleda. Haim-Munk syndrome is autosomal recessive with periodontal disease, keratoderma, and onychogryphosis, linked to cathepsin C gene mutations.

Keratoderma Climactericum

Keratoderma climactericum is characterized by hyperkeratosis of the palms and soles (especially the heels) beginning at about the time of menopause. The discrete, thickened, hyperkeratotic patches are most pronounced at sites of pressure such as around the rim of the sole. Fissuring of the thickened patches may be present. There is a striking resemblance to plantar psoriasis, and indeed, keratoderma climactericum may represent a form of psoriasis. Therapy consists of keratolytics such as 10% salicylic acid ointment, lactic acid creams, or 20%–30% urea mixtures. The response to topical corticosteroids is often disappointing. Acitretin is more effective than isotretinoin.

OTHER PALMOPLANTAR DERMATOSES

Collagenous and Elastotic Marginal Plaques of the Hands

Collagenous and elastotic marginal plaques of the hands are slowly progressive lesions at the margins of the palms that demonstrate thickened collagen bundles admixed with elastic fibers and amorphous basophilic elastotic material.

Keratolysis Exfoliativa (Lamellar Dyshidrosis, Recurrent Palmar Peeling)

Keratolysis exfoliativa is a superficial exfoliative dermatosis of the palms and sometimes soles. Clinically inflammation is minimal to absent, and the areas of cleaved epidermis appear as asymptomatic white spots that expand and then peel leaving a colarette of scale (Fig. 11.15). The eruption is often exacerbated by environmental factors. Many patients have an atopic background, and some have lesions of dyshidrotic eczema. Although some suggest it is a cohesion disorder of the stratum corneum, keratolysis exfoliativa more likely represents subclinical eczema. The differential diagnosis includes mild epidermolysis bullosa simplex and acral peeling skin syndrome, both of which should manifest earlier in life. The condition must also be differentiated from dermatophytosis, and a KOH examination or culture is recommended.

Because keratolysis exfoliativa is generally asymptomatic, no treatment may be necessary. In some patients, spontaneous involution occurs in a few weeks. For patients who require treatment, avoidance of wetness and friction when possible and emollients, corticosteroid preparations, tar, urea, and lactic acid or ammonium lactate may be effective.

Fig. 11.15 Keratolysis exfoliativa.

Fig. 11.16 Transient reactive papulotranslucent acrokeratoderma.

Acquired Aquagenic Syringeal Acrokeratoderma (Aquagenic Wrinkling of the Palms)

Patients with papulotranslucent acrokeratoderma, sometimes referred to as aquagenic wrinkling, develop white papules on the palms after water exposure. The skin quickly takes on a waterlogged appearance similar to what normally happens after long exposures to water in normal hosts. The lesions are sharply demarcated from the surrounding skin and appear white. There may be a central prominent pore within each white lesion (Fig. 11.16). In affected individuals the lesions appear 3–5 minutes after exposure to water and resolve within a short time of drying. Sometimes the white skin can be peeled off. The majority of patients with cystic fibrosis and approximately 10% of carriers will have aquagenic wrinkling of the palms, although there is no genotype phenotype correlation. Excess salinity of the sweat creates an osmotic gradient pulling water into the skin. It has also been reported in patients taking aspirin or rofecoxib. Autosomal dominant inheritance has been suggested in some cases, and abnormally active AQP5 has been described in sweat glands.

EXFOLIATIVE DERMATITIS (ERYTHRODERMA)

Exfoliative dermatitis is also known as dermatitis exfoliativa, pityriasis rubra (Hebra), and erythroderma (Wilson-Brocq). Exfoliative erythroderma is not a diagnosis but a clinical phenotype that can result from various diseases including atopic dermatitis, psoriasis, PRP, medication reactions, and cutaneous T-cell lymphoma (CTCL). Patients present with extensive erythema and scaling (Fig. 11.17). Ultimately, the entire body surface is dull scarlet and covered by small, laminated scales that exfoliate profusely. An extensive telogen effluvium may be noted. In both PRP and mycosis fungoides, distinctly spared islands of skin are frequently noted. Patients with PRP also have thickened, orange palms and "nutmeg grater" follicular papules on the dorsa of the fingers (see earlier), although a palmoplantar keratoderma can be seen in CTCL as well.

Itching of the erythrodermic skin may be severe, and the onset is often accompanied by symptoms of general toxicity, including fever and chills. Transepidermal water loss is high, and secondary infections by *Staphylococcus aureus* and streptococcal infections often complicate the disease course in the absence of treatment. Severe complications include sepsis, high-output cardiac failure, acute respiratory distress syndrome, and capillary leak syndrome. The mortality rate attributable to the erythroderma approaches 7% in some series.

Etiology

Erythroderma is usually caused by exacerbation of a pre-existing dermatosis such as atopic dermatitis or psoriasis. Erythroderma can also be from severe drug reactions, idiopathic and less commonly CTCL. In children, espoecially infants, immunodeficiency, netherton syndrome, ichthyosis, metabolic syndrome, and infection

Fig. 11.17 Erythroderma.

should be considered. Atopic dermatitis presenting as erythroderma is usually observed later, after the neonatal period.

In a comparison of patients with and without HIV infection, erythroderma in the HIV-positive group was most often related to drug reactions. HIV-positive patients did not have an overall increase in the number of episodes of erythroderma.

Mycosis fungoides can be erythrodermic without meeting the criteria for the Sézary syndrome. Sézary syndrome consists of generalized exfoliative dermatitis with intense pruritus, leonine facies, alopecia, palmoplantar hyperkeratosis, and onychodystrophy. The criteria for a diagnosis of Sézary syndrome include an absolute Sézary cell count of at least 1000 cells/mm^3; a CD4/CD8 ratio of 10 or higher by flow cytometry, caused by an increase in circulating T cells or loss of expression of pan–T-cell markers; increased lymphocyte counts with evidence of a T-cell clone by Southern blot or polymerase chain reaction; or a chromosomally abnormal T-cell clone. Prognosis is poor and similar to that of patients with nodal involvement.

Hodgkin disease may show generalized exfoliative dermatitis. Fever, lymphadenopathy, splenomegaly, and hepatomegaly are frequently present. The erythrocyte sedimentation rate is elevated in most of these patients.

Histopathology

Exfoliative dermatitis may retain the histologic features of the original disease process. This is particularly true in patients with psoriasis and mycosis fungoides. Often, however, the histology is nonspecific, with hyperkeratosis, mild acanthosis, and focal parakeratosis.

Treatment

Treatment of the erythroderma should target the primary cause the treatments are covered in greater depth in the individual sectiosn that discuss those diseases. Application of a medium-strength corticosteroid after soaking and occlusion under a sauna suit are often helpful, regardless of the cause of the erythroderma. Moist pajamas can be added under the sauna suit. Acitretin, cyclosporine, and methotrexate are useful in psoriatic erythroderma. Isotretinoin, acitretin, and methotrexate are useful in erythroderma caused by PRP. TNF-α agents should be avoided if the diagnosis is in question as they can lead to significant worsening of CTCL.

12 Lichen Planus and Related Conditions

Bonus images for this chapter can be found online at expertconsult.inkling.com

LICHEN PLANUS

Lichen planus (LP) is a common, pruritic, inflammatory disease of the skin, mucous membranes, and hair follicles. It occurs throughout the world, in all races. Cutaneous LP affects 0.3% of men and 0.1% of women. Oral LP affects 1.5% of men and 2.3% of women. It may be familial in rare cases. The pattern of LP detected and the age distribution vary among various genetic and geographic groups; certain human leukocyte antigen (HLA) alleles (HLA-DR/DQ, HLA-A3), gene mutations (MTHFR), and single-nucleotide polymorphisms (tumor necrosis factor–α [TNF-α], NRP2, IGFBP4) have been reported to confer risk in select populations and subgroups. In persons of European descent, LP appears primarily after age 20 and peaks between 40 and 70. Very few cases appear after age 80. Childhood LP typically accounts for 5% or less of LP cases, although in some regions, including the Indian subcontinent, Arab countries, and Mexico, it represents 10%–20%. Race appears to be the critical factor; in the United States, LP occurs more commonly in African American children, and in the United Kingdom, for example, Indians account for 80% of childhood LP. Pathophysiologically LP is a T-cell disorder with increased Th1 cytokine expression and T-cell activity at the basement membrane zone.

The primary lesions of LP are characteristic, almost pathognomonic: small, flat-topped, polygonal papules (Fig. 12.1). The color of the lesions initially is erythematous. Well-developed lesions are violaceous, and resolving lesions are often hyperpigmented, especially in patients with darker skin. The surface is glistening and dry, with scant, adherent scales. On the surface, gray or white puncta or streaks (Wickham striae) cross the lesions—a feature seen more easily with dermoscopy. Lesions begin as pinpoint papules and expand to 0.5–1.5 cm plaques. Infrequently, larger lesions are seen. There is a predilection for the flexor wrists, trunk, medial thighs, shins, dorsal hands, and glans penis (Fig. 12.2). The face is only rarely involved, with lesions usually confined to the eyelids and lips. The palms and soles may be affected with small papules or hyperkeratotic plaques (Fig. 12.3). Certain morphologic patterns favor certain locations (e.g., annular lesions favoring penis; keratotic lesions favoring anterior shins). Lesions are often bilateral and relatively symmetric. The Koebner phenomenon occurs in LP (Fig. 12.4). Oral mucosal involvement is common.

Pruritus is often prominent in LP. The pruritus may precede the appearance of the skin lesions, and the intensity of the itch may seem out of proportion to the amount of skin disease. Most patients react to the itching of LP by rubbing rather than scratching, and thus scratch marks are usually not present, though linear papules of LP can indicate prior scratching and koebnerization.

The natural history of LP is highly variable and dependent on the site of involvement and the clinical pattern. Two thirds of patients with skin lesions will have LP for less than 1 year, and many patients spontaneously clear in the second year. Hypertrophic and mucosal disease tends to be more chronic. Recurrences are common. In older patients, and those with comorbidities such as hyperlipidemia and diabetes, LP may persist for longer duration.

Nail changes are present in approximately 5%–10% of patients (Fig. 12.5), with fingernails more often affected than toenails. Involvement of the nail can occur as an initial manifestation, especially in children. Longitudinal ridging and splitting are most common, seen in 90% of patients with nail involvement. Onycholysis and subungual debris may be present, indicating involvement of the nail bed. The lunulae are red in 30% of patients with nail LP. Involvement of the entire matrix may lead to obliteration of the whole nail plate (anonychia). Pterygium formation is characteristic of LP of the nails, but seen in only about 20% of patients. The nail matrix is destroyed by the inflammation and replaced by fibrosis. The proximal nailfold fuses with the proximal portion of the nail bed. Dermoscopy can show pitting of the nail matrix, tachyonychia, chromonychia, onycholysis, or splinter hemorrhages. LP may be a cause of some cases of 20-nail dystrophy of childhood. In the absence of periungual lesions or pterygium formation, 20-nail dystrophy usually resolves spontaneously, and frequently in these children, no other stigmata of cutaneous or mucosal LP are found.

Involvement of the genitalia, with or without lesions at other sites, is common. On the glans or shaft of the penis, the lesions may consist of flat, polygonal papules, or these may be annular. Erosive LP can occur on the glans. Simultaneous involvement of the gingival and penile mucosa may occur. On the labia and anus, similar lesions are observed, which may be whitish because of maceration. Half of women with oral LP also have vulvovaginal LP, but in only half of these patients is the genital LP symptomatic. Vulval LP occurs in three main forms. The *classic* type presents with polygonal papules resembling cutaneous LP and affects the clitoral hood and labia minora. Pruritus is the usual symptom. Although only about 20% of women with vulval LP have *erosive* or *ulcerative* LP, this type represents the vast majority of patients seen for vulval LP, because it is usually very symptomatic. Soreness, pain, and dyspareunia are frequent complaints. Vaginal involvement with a bloody discharge can occur. Involvement is symmetric from the fourchette to the anterior vestibule. The erosions have a lacy white periphery, a good area to biopsy to confirm the diagnosis of vulval LP. Vulvovaginal-gingival syndrome is characterized by involvement at these three sites, with significant long-term sequelae due to scaring; patients may also have scarring at other mucosal sites, including the esophagus and eye. The third, and least common, form of vulval LP is the *hypertrophic* type. It involves the perineum and perianal skin (but not the vagina) with warty plaques with a violaceous edge. Pruritus is severe. Vulval splitting, vaginal stenosis, and sealing of the clitoral hood may be caused by LP. It is important to distinguish vulvovaginal LP from lichen sclerosus et atrophicus.

Conjunctival involvement is a rarely recognized complication of LP but was seen in 0.5% of patients with vulval LP in one series. It most frequently occurs in patients with involvement of other mucosal surfaces. Cicatrization, lacrimal canalicular duct scarring, and keratitis can occur. It may closely simulate mucous membrane pemphigoid. Routine histology and direct immunofluorescence (DIF) may be required to confirm the diagnosis.

Otic involvement by LP is rarely reported. It affects primarily females (80% of patients) and is associated with oral and vulval LP in more than 50% of cases, and cutaneous LP in 5 of 19 (26%). Hearing loss and external auditory canal stenosis are the most common otic complaints and complications. Four of 19 (21%) patients with otic LP also had esophageal involvement.

Fig. 12.5 Lichen planus of the nail.

LP of the esophagus is uncommon but increasingly being recognized, and the diagnosis is frequently delayed. One study involving endoscopy in 32 consecutive patients with LP identified 10 with probable and 10 with definitive esophageal disease. Dysphagia, odynophagia, and weight loss are typical manifestations. The proximal esophagus is more frequently affected. Most patients have coexistent oral disease. Esophageal involvement is much more common in women. One paper in the gastrointestinal literature noted that stricture formation occurs in 80% of esophageal LP and may require frequent dilations; the observed rate in dermatologic practice is much lower. Esophageal squamous cell carcinoma (SCC) may complicate esophageal LP, suggesting that, once this diagnosis is made, routine gastrointestinal evaluation is required.

Whether the many clinical variants of LP represent separate diseases or part of the LP spectrum is unknown. They all demonstrate typical LP histologically. The variants are described separately because their clinical features are distinct from classic LP. Some patients with these clinical variants may have typical cutaneous, follicular, or mucosal LP. The more common or well-known variants are described here.

Fig. 12.6 Annular lichen planus. (Courtesy Steven Binnick, MD.)

Linear Lichen Planus

Small, linear lesions caused by the Koebner phenomenon often occur in classic LP. Limitation of LP to one band or streak has also been described in fewer than 1% of patients of European descent. In Japan, however, up to 10% of cases are linear, and in India, 7% of childhood cases of LP are linear. Although originally described as following dermatomes (zosteriform), the lesions actually follow lines of Blaschko. It is more common in children but also occurs in adults. Papules with varying degrees of overlying hyperkeratosis or simple hyperpigmentation may be the presenting manifestations. There are often "skip areas" of normal skin between the individual lesions. Ipsilateral mucosal disease may be seen.

Annular and Annular Atrophic Lichen Planus

Annular LP occurs in 3%–7% of patients with LP, and is more common in men (90% of cases). Lesions with this configuration favor the axilla, penis/scrotum (Fig. 12.6), and groin. LP lesions of the mucosa, scalp, and nails are rare in patients with annular LP. Patients usually have fewer than 10 lesions. Most patients with annular LP are asymptomatic. The ringed lesions are composed of small papules and measure about 1 cm in diameter. Central hyperpigmentation may be the dominant feature. They may coalesce to form polycyclic figures. Annular lesions may also result from central involution of flat papules or plaques, forming lesions with violaceous, elevated borders and central hyperpigmented macules. A rare type of annular lichenoid dermatitis which may resemble morphea, inflammatory vitiligo, or mycosis fungoides has been described in pediatric patients termed annular lichenoid dermatitis of youth; one report from a region with endemic borrelia suggested a possible etiologic link, which has not been proven.

Hypertrophic Lichen Planus

Hypertrophic LP usually occurs on the shins but may occur anywhere. The anterior lower leg below the knee is the sole area of involvement in most patients. The typical lesions are verrucous plaques with variable amounts of scale (Fig. 12.7). At the edges of the plaques, small, flat-topped, polygonal papules may at times be discovered. Superficial inspection of the lesion often suggests psoriasis or a keratinocytic neoplasm rather than LP, but the typical appearance resembling rapidly cooled igneous rock (igneous rock sign) may be useful in suggesting LP over keratinocytic neoplasms. The lesions are of variable size but are frequently several centimeters in diameter and larger than the lesions of classic LP. Dermoscopy of hypertrophic LP may demonstrate pearly white

Fig. 12.7 Hypertrophic lichen planus. (Courtesy Debabrata Bandyopadhyay, MD.)

areas and peripheral striations, which can help distinguish it from mimickers in some cases; however, clinical diagnosis may be difficult, and biopsy is often required. Histologically, the pseudoepitheliomatous keratinocyte hyperplasia may be marked, leading to the erroneous diagnosis of SCC. Eosinophils are much more often present in the dermal infiltrate of hypertrophic LP than classic LP. True SCC may also evolve from long-standing hypertrophic LP, over long as 11–12 years. In addition, keratoacanthoma-like proliferations may occur in lesions of hypertrophic LP. This has also been called "hypertrophic lichen planus–like reactions combined with infundibulocystic hyperplasia." Hypertrophic LP is chronic and often refractory to topical therapy. Hypertrophic lupus erythematosus (LE) resembles hypertrophic LP both clinically and histologically. Hypertrophic LE tends to affect the distal extremities, face, and scalp. The finding of continuous granular immunoglobulin on DIF strongly suggests a diagnosis of hypertrophic LE rather than LP.

Erosive/Ulcerative/Mucosal Lichen Planus

Erosive LP has significant impact on quality of life, and patients with erosive LP have high levels of depression, anxiety, and stress. Ulcerative LP is rare on the skin but common on the mucous membranes. A rare ulcerative variant of cutaneous LP, or LE/LP overlap syndrome, affects the feet and toes, causing bullae, ulcerations, and permanent loss of the toenails. These chronic ulcerations on the feet are painful and disabling. Cicatricial alopecia may be present on the scalp, and the buccal mucosa may also be affected. These cases are a therapeutic challenge, and aggressive oral retinoid or immunomodulatory treatment is indicated if there is a poor response to standard topical and systemic agents. Skin grafting of the soles has produced successful results.

Oral mucosal LP is the most common form of mucosal LP, and it is usually chronic. Between 10% and 15% of patients with oral LP will also have skin lesions. Women represent 50%–75%

Fig. 12.8 Lichen planus, reticulate white lesions of the buccal mucosa.

Fig. 12.9 Desquamative gingivitis in the vulvovaginal syndrome.

of patients with oral LP. Oral LP in women begins 10 years later than in men (age 57 vs. 47). Oral lesions may be reticulate (reticular), the oral version of Wickham striae (Fig. 12.8), erythematous (atrophic), or ulcerative (erosive) (Fig. 12.9); lesions are often bilateral and symmetric. The most common pattern in oral LP is the ulcerative form (40% of patients). Usually, reticulate and erythematous lesions are found adjacent to the ulcerative areas. The erythematous pattern is the predominant pattern in 37% of patients, but almost always, reticulate lesions are also seen in these patients. In oral LP, the "classic" reticulate lesions are most prominent in 23% of patients. Rarely patients may have a white plaque mimicking leukoplakia, bullous, or papular lesions. Symptoms are least common in patients with reticulate lesions; 23% are symptomatic, and then only when the tongue is involved. All patients with erosive lesions are symptomatic, usually with burning or pain. Patients may simultaneously have several patterns, so patients are characterized by the primary form they exhibit. Lesions appear on any portion of the mouth, and multisite involvement is common. The buccal mucosa is involved in 90%, the gingiva in more than 50%, and the tongue in about 40%.

On the gingiva, LP may produce desquamative gingivitis (see Fig. 12.9). Gingival involvement is particularly difficult to diagnose and often requires biopsy for both histology and DIF to confirm the diagnosis and exclude other autoimmune causes of desquamative gingivitis. Gingival involvement is associated with accelerated gingival recession. Mechanical injury from dental procedures and poorly fitting appliances may trigger or exacerbate gingival LP. On the tongue and palate, lesions are often mistaken for leukoplakia. The lower lip is involved in 15% of oral LP patients, but the upper lip in only 2%. Lower lip LP is frequently mistaken for actinic cheilitis. Imiquimod treatment can lead to exacerbation of the labial LP, with extensive erosion and crusting. Oral LP is stable but chronic, with fewer than 3% of patients having a spontaneous remission in an average 5-year follow-up. Periodontitis appears to exacerbate oral LP, especially gingival disease. Plaque control either by the patient after training or by a dental professional improves the clinical appearance and pain.

Oral lichenoid lesion (OLL), or oral lichenoid reaction (OLR), refers to an oral lesion histologically identical to oral LP (OLP) but from a different cause, such as graft-versus-host disease (GVHD), medications (antihypertensives, dapsone, nonsteroidal antiinflammatory drugs [NSAIDs], penicillamine, phenothiazines, antimalarials, oral hypoglycemics, and more), and local or systemic exposures. Gold, cobalt, indium, manganese, chrome, nickel, palladium, cinnamate, and spearmint sensitivity may induce OLLs. The most common causes, however, are the metals in dental amalgams, including mercury, copper, zinc, and tin. If the lesions in the oral mucosa are physically close to the amalgam, removal of the amalgam will lead to resolution of the OLL in 36%. In patients patch test positive to a metal in the amalgam, 44% and 47% of OLLs healed with removal of the amalgam in two studies. In patients with the OLL in strict contact with the amalgam, and there is a relevant positive patch test to a component of the amalgam, 80% to 90% or more of OLLs will heal. Patch testing, however, may not identify all patients whose OLLs improve with removal of the oral metal. Rarely, patients with metal sensitivity will also have skin and nail lesions that improve with removal of the oral metal. In one study, 6 of 10 patients with nail LP who were patch test positive to a metal in their amalgam improved with removal of the dental material or with oral disodium chromoglycate treatment.

Involvement of the vulva and vagina with LP, along with the gingiva, has been called the vulvovaginal-gingival (VVG) syndrome. Although all three of these mucous membranes may be involved, only one or two sites may be involved at any one time. The prevalence of erosive vulvar LP had been underappreciated simply because many women with oral LP did not volunteer their vulvovaginal complaints and were not asked about them. The vaginal lesions of VVG are erythematous, friable erosions that are very painful. Untreated scarring is severe and can lead to adhesions, vestibular bands, and even vaginal stenosis. In one third of patients, typical reticulate buccal LP is seen, and in up to 80% the oral mucosa is also involved. Cutaneous lesions occur in 20%–40% of VVG patients. The course of the VVG syndrome is protracted, and patients frequently have sequelae, including chronic pain, dyspareunia, and even scarring of the conjunctiva, urethra, and oral, laryngeal, pharyngeal, and esophageal mucosae. Nails are involved in about 15% of patients with VVG, compared with only 2% of patients with oral LP. The VVG syndrome is now considered to be a separate subgroup of mucosal LP that is particularly disabling, scarring, and refractory to therapy.

Bullous Lichen Planus

Two forms of LP may be accompanied by bullae. In bullous LP (BLP), individual lesions, usually on the lower extremities, will vesiculate centrally, with bullae confined to preexisting LP lesions. Histology reveals the bullae are due to a large Max-Joseph space within the extensive lichenoid inflammatory infiltrate. These lesions often spontaneously resolve. There are familiar forms of bullous

lichen planus, with earlier onset and more chronic course. Recently checkpoint inhibitors such as PD-1 inhibitors (pembrolizumab) have been shown to cause bullous LP-like reactions, LP pemphigoides, and bullous pemphigoid.

LP pemphigoides describes a rare subset of patients who usually have typical LP, then, an average of 8 months later, develop blistering on their LP lesions and on normal skin. Less often, the blister and the LP lesions occur simultaneously. Clinically, these patients appear to be a combination of LP and bullous pemphigoid. Oral disease may occur and resemble either LP or mucous membrane pemphigoid. LP pemphigoides can be triggered by medications, especially angiotensin-converting enzyme (ACE) inhibitors, as well as interferon (IFN), hepatitis B virus (HBV), and psoralen plus ultraviolet A (PUVA). Pruritus may be severe, and lesions may evolve to resemble pemphigoid nodularis. Bullous pemphigoid affects an older age-group than LP pemphigoides; typical onset for LP pemphigoides is 30–50. Histologically, the LP lesions show LP, and the bullous lesions show the features of bullous pemphigoid. DIF is positive in a linear pattern, with immunoglobulin G (IgG) and C3 along the basement membrane zone (BMZ), at the roof of saline split skin. The antigen targeted by the autoantibody in LP pemphigoides is located in the same region as the bullous pemphigoid antigen, at the basal hemidesmosome. Antibodies from patients with LP pemphigoides typically bind the 180-kD bullous pemphigoid antigen, but in a different region from bullous pemphigoid sera. One case of clinical and histologic bullous LP was reported with autoantibodies to BP180, with authors suggesting chronic inflammation and damage to the BMZ may expose antigens and lead to development of overt LPP over time. LP pemphigoides tends to follow a benign and chronic course, even compared with bullous pemphigoid. Treatment of LP pemphigoides is similar to bullous pemphigoid, with potent topical steroids, systemic steroids, tetracycline, nicotinamide, intravenous immune globulin (IVIG), and immunosuppressives all being variably effective.

Hepatitis-Associated Lichen Planus

Three liver conditions have been associated with LP: hepatitis C virus (HCV), hepatitis B immunization, and primary biliary cirrhosis. HCV infection has been found in proportionately more patients with LP than in controls in numerous studies. The prevalence of HCV infection in patients with LP varies from 1.6% to 20%. There is an association with the HLA-DR6 allele. A systematic review and meta-analysis of 1807 cases of oral LP and 2519 controls revealed an odds ratio was 6.07, with OLP patients having a sixfold higher risk for HCV infection than controls. Despite multiple systematic reviews suggesting a connection, the association of HCV infection and LP has been questioned, perhaps due to geographic differences in disease prevalences. In a large series of patients with oral LP from the United States, none of the 195 patients was infected with HCV, whereas 29% of patients with oral LP from Italy had HCV. In Scotland, 20% of patients infected with HCV had oral LP, compared with 1% of seronegative patients. Although the data are conflicting, screening for HCV appears appropriate in persons from a geographic region where or a population in whom HCV infection is frequently associated with LP. The clinical features of LP in patients with hepatitis C are identical to classic LP, but LP patients with HCV infection are reported as being more likely to have erosive mucous membrane disease, and higher rates of malignancy. The HCV genome is not found in lesions of LP associated with HCV infection. The existence of underlying hepatitis cannot be predicted by clinical pattern or the results of liver function tests. Treatment of hepatitis C with IFN-α may be associated with the initial appearance of LP or exacerbation of preexisting LP. LP may occur at IFN injection sites, and skin testing may reproduce LP-like lesions. LP may improve or may not change with IFN and ribavirin treatment for hepatitis C. Improvement is usually seen toward the end of the treatment course. Most patients do not completely clear their LP. Treatment with newer antivirals for HCV, including ledipasvir-sofosbuvir, have shown conflicting results, with some responders clearing their coexistent LP, and one case of LP developing after HCV clearance.

Although less robust data support an association, HBV immunization may be associated with the appearance of LP in both children and adults. Lesions are typical of LP, and the oral mucosa may be affected. Typically, the first lesions of LP appear about 1 month after the second dose of vaccine. Lesions usually resolve after some time.

Primary biliary cirrhosis and LP may coexist. Patients with this liver abnormality also have a marked propensity to develop a lichenoid eruption while receiving D-penicillamine therapy. Xanthomas in patients with primary biliary cirrhosis may appear initially in lesions of LP, and the infiltrate, although lichenoid, may contain xanthomatous cells. Primary sclerosing cholangitis has been associated with oral LP.

Cancer Risk and Lichen Planus

The risk of malignant transformation in LP varies by morphologic type, with mucosal disease having higher rates. Rare cases of SCC of the skin occurring on the lower leg in lesions of hypertrophic LP have been reported. Cutaneous LP alone is not considered to be a condition with increased cancer risk. Oral LP and vulvovaginal LP, however, do appear to increase the risk of developing SCC. In a study of 13,100 women in Finland, LP was associated with an increased risk of cancers of the lip, tongue, oral cavity, esophagus, larynx, and vulva. About 1% of patients with oral LP will develop oral SCC. A higher risk is seen in smokers, alcoholics, and patients with HCV infection. SCC occurs in patients with erythematous or ulcerative LP, not in those with only the reticulate pattern. Of the oral LP patients who develop oral SCC, only about 45% have one cancer. The majority develop multiple cancers, and close vigilance is recommended in these patients. LP patients with erosive penile and vaginal disease also have developed SCC. The number of penile cases is too low to determine the frequency, but in patients with vulvar LP, development of SCC may be as high as 3%. Clinicians should have a low threshold to biopsy fixed erosive or leukokeratotic lesions in patients with mucosal LP. The use of oral and topical calcineurin inhibitors (CNIs) for LP has been associated with the appearance of SCC on the genitalia. There is no evidence that the medications caused the neoplasia, but if these agents are used, regular follow-up and careful examination are required.

Pathogenesis and Histology

LP is characterized by a Th1 immunologic reaction mediated by CD8+ T cells. These cells induce keratinocytes to undergo apoptosis. Although this inflammatory reaction is thought to be autoimmune, the antigen targeted by these effector T lymphocytes is unknown. The prevalence of autoimmune phenomena is not increased in patients with classic cutaneous LP, however, patient with erosive LP of the vulva (and lichen sclerosus) may have an autoimmune basis. A personal and family history of autoimmune disorders (usually thyroid disease) is present in up to 30% of patients with vulvar LP, and up to 40% have circulating autoantibodies. Patients with oral LP may also have elevated rates of thyroid disease. Patients with LP and OLP have a high rate of dyslipidemia, with elevated triglycerides, elevated low-density lipoprotein (LDL) cholesterol and reduced high-density lipoprotein (HDL) cholesterol. Inflammatory markers also are elevated in the blood of LP patients, potentially contributing to this dyslipidemia. In addition, both insulin resistance and frank type 2 diabetes mellitus are increased in patients with LP compared with controls. Both insulin resistance and dyslipidemia are cardiovascular risk

factors. Adult LP patients should be evaluated appropriately. Drug induced lichenoid eruptions are common with a long list of potential triggering agents (including but not limited to checkpoint inhibitors, NSAIDs, allopurinol, oral hypoglycemic agents, anticonvulsants, cardiovascular/blood pressure medications, biologics, antimicrobials, antimalarials, antipsychotic drugs, and more, with some causing specifically photo-accentuated lichenoid eruptions, including antiviral agents such as lepidasvir/sofosbuvir).

LP pemphigoides is hypothesized to result from exposure to the immune system of epitopes in the BP180 antigen as keratinocytes are destroyed by the lichenoid inflammation. Epitope spreading can occur, and LP pemphigoides patients may also develop autoantibodies to the same epitopes as bullous pemphigoid patients.

The histologic features of LP are distinctive and vary with the stage of the lesion. In early lesions, there is an interface dermatitis along the dermoepidermal junction. As the lesion evolves, the epidermis takes on a characteristic appearance. There is destruction of the basal layer with a "sawtooth" pattern of epidermal hyperplasia, orthokeratosis, and beaded hypergranulosis. The basal cells are lost, so the basal layer is described as "squamatized." In the superficial dermis, there is a dense, bandlike infiltrate composed of lymphocytes and melanophages. "Civatte bodies" (cytoid bodies, colloid bodies) represent necrotic keratinocytes in the superficial dermis. Hypertrophic LP shows marked epidermal hyperplasia (pseudoepitheliomatous hyperplasia). Old lesions of LP show effacement of the rete ridge pattern, melanophages in the upper dermis, and occasional Civatte bodies. LP rarely demonstrates parakeratosis or eosinophils (except in hypertrophic LP, where these are characteristic). The presence of either of these suggests a different cause of lichenoid tissue reaction, such as lichenoid drug eruption. Lichen planopilaris, frontal fibrosing alopecia (FFA), and Graham-Little-Piccardi-Lasseur syndrome show the findings of LP, centered on the superficial follicular epithelium.

Lesions of LP of the skin or mucosae can demonstrate clumps of IgM on DIF, and less frequently IgA, IgG, and C3, subepidermally, corresponding to the colloid bodies. Dense, shaggy staining for fibrinogen along the BMZ is characteristic of LP. A lichenoid drug eruption may be difficult to differentiate from LP. The presence of eosinophils or parakeratosis supports the diagnosis of lichenoid drug eruption. GVHD tends to have a sparser infiltrate than LP, and the infiltrate may involve hair follicles if present. Hypertrophic LE may be histologically identical to LP, and the diagnosis is best made by clinical correlation, serologies, and DIF. In most other forms of LE, there is a greater tendency for epidermal atrophy with parakeratosis, dermal mucin is found, and follicular plugging is more prominent. The infiltrate in lupus tends to surround and involve deep portions of the appendageal structures, such as the follicular isthmus and eccrine coil. Deep, nodular, perivascular lymphoplasmacytic infiltrates and necrosis of the fat lobule with fibrin or hyalin rings are also findings characteristic of LE.

Differential Diagnosis

Classic LP (Fig. 12.10) displays lesions that are so characteristic that clinical examination is often adequate to lead to suspicion of the diagnosis. Lichenoid drug eruptions may be difficult to distinguish. A lichenoid drug reaction should be suspected if the eruption is photodistributed, scaly but not hypertrophic, and confluent or widespread—clinical features that are unusual for idiopathic LP. The presence of oral mucosa involvement may prompt suspicion of LP, but oral lesions may occasionally occur in lichenoid drug eruptions as well. Pityriasis rosea, guttate psoriasis, the small papular or lichenoid syphilid, and pityriasis lichenoides et varioliformis acuta are dermatoses that may resemble generalized LP. Mucous membrane lesions may be confused with leukoplakia, LE, mucous patches of syphilis, candidiasis, cancer, and oral lesions of autoimmune bullous diseases, such as pemphigus or cicatricial pemphigoid. On the scalp, the atrophic lesions may be mistaken for other cicatricial alopecias, such as LE, folliculitis decalvans, and pseudopelade of Brocq. Hypertrophic LP type may simulate psoriasis, LE, SCC, and keratoacanthomas. Isolated patches of LP may resemble lichen simplex chronicus.

Fig. 12.10 Generalized lichen planus.

Treatment

There is virtually no high-quality evidence for treatment of LP of the skin, scalp, or mucosae. Limited lesions may be treated with superpotent topical corticosteroids or intralesional steroid injections. Topical tacrolimus or pimecrolimus can be effective, particularly for erosive disease. Topical vitamin D derivatives have also been reported to help in small studies. In patients with widespread disease, these treatments are usually unsatisfactory. Widespread lesions respond well to systemic corticosteroids but tend to relapse as the dose is reduced. Monthly pulse dosing has been championed by dermatologists in India. Phototherapy may be effective for cutaneous LP, including narrow-band (NB) ultraviolet B (UVB), UVA I, and PUVA (topical or oral). NB UVB was superior to systemic corticosteroids in one study. A variety of lasers have been reported as helpful in isolated case reports for different morphologic and anatomic forms of LP. Photodynamic therapy with topical 5-aminolevulinic acid can be effective in genital LP. The oral retinoids—isotretinoin, alitretinoin, and acitretin, in doses similar to or slightly lower than those used for other skin conditions—may also be useful and avoid the long-term complications of systemic steroids. They are especially beneficial in patients with hypertrophic LP and palmoplantar LP. Retinoid therapy may be combined with phototherapy in refractory cases. Hydroxychloroquine in standard doses can be effective for cutaneous, oral, genital and follicular LP. Adding quinacrine, 100 mg daily, may be considered in patients with only a partial response to hydroxychloroquine. Thalidomide, 50–150 mg daily, can improve refractory oral and cutaneous LP. Griseofulvin can improve cutaneous LP. Sulfasalazine led to a partial response in 11 of 26 patients. Low-molecular-weight heparin (enoxaparin), injected subcutaneously once a week, led to remission of cutaneous and reticulate oral LP

in 61% of patients and improvement in 11%. Enoxaparin is less effective than systemic steroids. Dapsone and metronidazole in small studies failed to outperform topical or phototherapy, though one small series did show 40% of patients responding to metronidazole 250 mg every 8 hours. Apremilast, a phosphodiesterase type IV inhibitor, at a dose of 20 mg twice daily, showed modest efficacy in pooled data, but pruritus was dramatically decreased.

In the most severe cases, immunosuppressive agents may be indicated. Cyclosporine, methotrexate, and mycophenolate mofetil are all options and can induce remission in severe cases of cutaneous and oral LP. The TNF inhibitors have been effective in anecdotal cases. Similarly, extracorporeal photophoresis (ECP), anakinra, rituximab, systemic tacrolimus, and IVIG have been successful in extremely refractory cases.

For oral lesions, superpotent steroids in Orabase or gel form are useful. Vinyl dental trays may be used to apply steroid ointments to the gingiva. Begin with 30-minute applications three times a day and reduce to maintenance of 20 minutes every evening. Addition of nystatin to clobetasol in Orabase may be especially effective. Overall, more than 70% of patients with vulvar LP have relief of symptoms with topical clobetasol. Intralesional injections may be used for focal unresponsive lesions. Topical tacrolimus 0.1% ointment has become standard treatment in erosive LP of the oral and genital mucosa. Burning may occur initially but can be reduced by concomitant use of topical steroids or initial use of a lower strength of tacrolimus ointment. Higher concentrations, up to 0.3%, also may be used. Most patients have a partial but significant response, with increased ability to eat with much less pain. Blood levels can be detected, independent of area of involvement, but tend to decrease over time as the oral erosions heal. Pimecrolimus can be used successfully in patients intolerant of topical tacrolimus. Sustained remissions are rare, and chronic use is usually required to maintain remission. Topical cyclosporine is comparable to topical steroids and should not be used first-line, but may be tried in recalcitrant cases. Topical retinoids may be used but are generally less desirable than topical steroids. Aloe vera gel has been used and in one study was equivalent to steroids. PUVA, photodynamic therapy, and 308-nm excimer laser have been effective in oral LP. The systemic agents recommended earlier to treat cutaneous LP may also improve mucosal disease. For VVG syndrome, corticosteroids topically and systemically are beneficial. Topical therapy with corticosteroids may be enhanced by mixing the steroid in vaginal bioadhesive moisturizer (Replens). Iontophoresis may improve delivery.

Adnexal Lichen Planus: Follicular Lichen Planus (Lichen Planopilaris) and Acrosyringeal Lichen Planus

Lichen planopilaris (LPP) is lichen planus involving the follicular apparatus. Most cases involve the scalp, and LPP is an important cause of cicatricial alopecia (Fig. 12.11; see Chapter 33). From 70%–90% or more of affected patients are women, usually about age 50. The oral mucosa may be involved in 7%–27% of patients, and 20%–40% of patients have cutaneous involvement. Patients often demonstrate perifollicular erythema and scale with progressive scarring; dermoscopy may reveal subtle signs of the folliculocentric inflammation. As with classic LP, there are reports of trauma inducing LPP. Patients may have lesions scattered throughout the scalp, clustered centrally, or on the margins; one study of 80 patients showed the FFA variant in 31% of patients with LPP. FFA is considered a variant of LPP markedly more common in postmenopausal women, with rare skin-colored papules on the upper face often lateral to the eyes, frequent loss of eyebrows, and occasionally loss of axillary and/or pubic hair. One study demonstrated an androgen excess in LPP and an androgen deficiency in patients with FFA. Graham-Little-Piccardi-Lasseur syndrome is a rare variant of LPP of the scalp with coexistent keratosis pilaris–like LPP lesions on the skin. Patients may rarely present with localized linear LPP. The rarest variant of LPP is lichen planus follicularis tumidus, formerly called agminate lichen follicularis with cysts and comedones. This presents in the retroauricular area and on the cheeks of middle-age women, where the lesions appear as tumid, red-violet plaques covered with numerous small, white-yellow cysts and comedones. The lesions resemble the plaques seen in Favre-Racouchot syndrome and phymatous cystic rosacea. The ears, chin, and scalp can be similarly involved. Other areas of LP of the skin and nails can occur in the same patient, and these may appear at about the same time. Histologically, a dense lichenoid

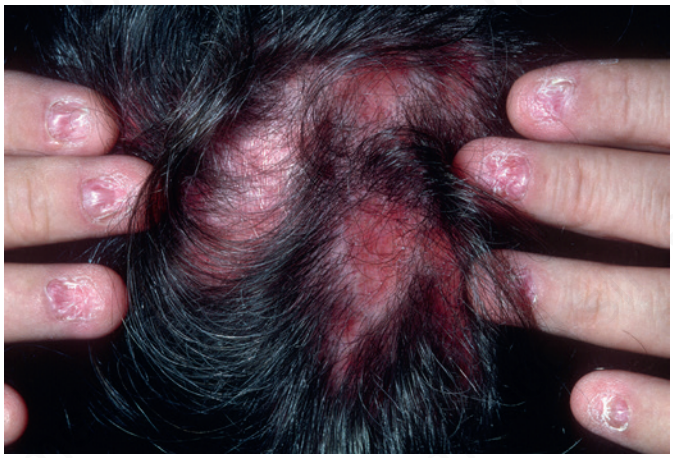

Fig. 12.11 Lichen planopilaris.

infiltrate surrounds the follicles and cysts of the affected skin. The cysts are considered secondary to the lichenoid inflammation. Favre-Racouchot syndrome, follicular mucinosis, and LE must be distinguished histologically from LPP. LPP treatment often involves potent topical corticosteroids and/or intralesional injections, with systemic options including hydroxychloroquine, tetracycline-class antibiotics, retinoids, pioglitazones, and sometimes suppressive agents such as cyclosporine, mycophenolate, methotrexate, or systemic steroids. FFA has been treated with 5-α reductase inhibitors as well. Hair transplantation may be an option once the inflammation is controlled.

LP can involve the soles and at times the palms. Lesions are typically scaly plaques that look very hyperkeratotic or psoriasiform and are usually only diagnosed by the coexistence of typical LP elsewhere or by biopsy. Less often, the lesions of LP of the palms and soles may present as petechial-like lesions, or diffuse keratoderma. When palmoplantar LP affects primarily the acrosyringium, the lesions appear as umbilicated papules or punctate keratoses. A biopsy is usually required to confirm the diagnosis, unless typical LP is present elsewhere. Palmoplantar LP can respond well to oral retinoids.

Lichen Planus Pigmentosus/Actinicus

LP pigmentosus is seen primarily in Central America, the Indian subcontinent, the Middle East, and Japan. It appears to be a form of LP restricted to certain racial groups. The persons from these genetic groups can develop the condition when they move to North America and Europe, but Caucasians from Europe and North America do not develop LP pigmentosus when they move to tropical areas where the disease is common. LP pigmentosus patients are young, usually 20–45, and men and women are equally affected. Men present a decade earlier (mean age 26 vs. 34). One study suggested a possible association with thyroid disease, usually hypothyroidism. The face and neck are primarily involved (Fig. 12.12), but the axilla, inframammary region, and groin may also be affected; ocular involvement has been reported but is extremely rare. Lesions may be unilateral. The condition is usually mild (<10% body surface area), and although patients may have associated pruritus, it is usually much milder than in patients with classic LP. Sometimes, other types of LP may coexist or classic LP papules may occur at the periphery of the lesions. In the United States persons of color may demonstrate this pattern of LP. Individual lesions are typically several millimeters to several centimeters in size, are oval in shape, and may follow lines of Blaschko.

Some patients with LP pigmentosus may have lesions predominantly in sun-exposed areas, and the diagnosis LP actinicus can be used in these cases. LP actinicus is reported most frequently in Africa, the Middle East, and the Indian subcontinent and represents a substantial proportion of LP diagnosed in these geographic areas (36% of all LP patients in an Egyptian series).

Fig. 12.12 Lichen planus pigmentosa. (Courtesy Debabrata Bandyopadhyay, MD.)

Most cases reported as LP actinicus occur in childhood through young adulthood, with 20–30 the primary decade of presentation. The disease presents in the spring or summer and is frequently quiescent in winter. Lesions favor the sun-exposed parts of the body, especially the face, which is almost always the most severely affected site. Most lesions occur on the forehead, cheeks, eyelids, and lips. Outside the face, the V area of the chest, the neck, the backs of the hands, and the lower extensor forearms are involved. Associated pruritus, the hallmark of LP, is usually described as mild or absent. Lesions are usually annular but may be reticulate or diffuse. Individual lesions are often macular but may be plaques with peripheral violaceous papules. Characteristically, lesions are hyperpigmented, sometimes with the blue-gray tinge of dermal melanin. They may resemble melasma. It is important to exclude alternate explanations for photo-distributed lichenoid eruptions, such as connective tissue diseases or chronic HIV photodermatitis, when rendering this diagnosis.

Because cases of LP pigmentosus and LP actinicus overlap, it is best to think of these conditions as a single disorder that may or may not be photoexacerbated. It is important to recognize the LP actinicus variant of LP pigmentosus because the actinicus patients do respond to sun protection, with gradual fading of their hyperpigmentation. Mucous membrane disease is significantly less common in patients with LP pigmentosus/actinicus. Histologically, any papular element will usually show features of LP. Even macular areas may show subtle evidence of an interface dermatitis, with prominent dermal melanophages.

LP pigmentosus-inversus is a unique, separate, and uncommon disorder. Lesions can be seen in patients with classic LP pigmentosus; however, this inverse pattern has a different racial distribution and has been reported in Caucasian patients as well as Asians and Hispanics. The axillae are the primary region of involvement in most patients (90%), although other skin folds such as the groin, inframammary, neck, retroauricular, and flexural areas can also be involved. As with other types of LP pigmentosus, pruritus is uncommon in the inversus type, and oral, nail, and hair involvement usually does not occur. The etiology is unknown, although a temporal association to occupational exposure to heavy metals was reported in one case, and others have suggested koebnerization from tight-fitting clothing.

The treatment of LP pigmentosus of all types is similar to other forms of LP. Topical corticosteroids and CNIs, antimalarials, retinoids, and even immunomodulators can be used. The lesions may fade slowly because they are primarily caused by melanin incontinence, and even if the active agent has stopped the interface reaction, the pigment will persist. Chemical peels and retinoids have been reported to improve the discoloration.

Erythema Dyschromicum Perstans

Erythema dyschromicum perstans is also known as "ashy dermatosis" or dermatosis cenicienta. The age of onset is virtually always before 40, but it is a chronic disease, so patients of all ages have been described, with a slight female predominance. Prepubertal children have been reported. Lesions are typically several centimeters in size and affect primarily the trunk, along with the neck and upper extremities. A characteristic very fine (several millimeters), erythematous, palpable, nonscaling border is seen at the periphery of the lesions. This is described as feeling like a small cord. Unfortunately, this leading edge (and diagnostic feature) of the disorder is only present early in the disease course (a few months). Pruritus is not reported, and typical lichenoid papules are said not to occur. Nail and mucosal involvement is not found. An association with HLA-DR4 has been suggested for Mexican patients, and rare drug-induced cases have been reported (recently with fluoxetine, omeprazole, and other agents). Unfortunately, erythema dyschromicum perstans became a catchall term for the panoply of dermatologic disorders that heal with prominent postinflammatory change in pigmented persons. It is now believed that most cases previously called erythema dyschromicum perstans are actually cases of LP pigmentosus. Childhood cases may represent idiopathic eruptive macular pigmentation. True erythema dyschromicum perstans, if it exists, is quite rare and largely restricted to certain geographic regions.

At the active border, the characteristic histologic features of erythema dyschromicum perstans are those of a lichenoid dermatitis. In the centers of the lesions, the histologic changes are those of postinflammatory pigmentation. Therapeutic agents used for LP may benefit the acute inflammatory stage but have limited effect on the pigmented lesions. Isolated reports mention some improvement of dyspigmentation in patients with NB-UVB phototherapy, retinoids, and topical tacrolimus. Some lasers have been reported to improve the appearance, occasionally in conjunction with topical tacrolimus. Spontaneous improvement has occurred, leading some to suggest that no treatment is reasonable.

Idiopathic Eruptive Macular Pigmentation

Although rarely reported, idiopathic eruptive macular pigmentation (IEMP) is not rare. Young persons (mean age 11 years in one study) presented with asymptomatic widespread brown to gray macules of up to several centimeters in diameter on the neck, trunk, and proximal extremities. Lesions are not confluent, and there is no history of preceding inflammation. At times, there is slight papillomatosis histologically, identical to that seen in confluent and reticulate papillomatosis (CARP). Unlike CARP, however, IEMP does not respond to oral minocycline. Lesions may spontaneously involute. Some cases reported as erythema dyschromicum perstans in childhood may actually represent IEMP.

KERATOSIS LICHENOIDES CHRONICA

Keratosis lichenoides chronica is a rare dermatosis characterized by its chronicity. In adults, the disease begins in the late twenties. Abnormal keratinization leads to typical lesions of papulonodular and hyperkeratotic and covered with gray scales. These lesions favor the extremities and buttocks, with the face involved in two thirds of patients. Although initially discrete, the lesions frequently coalesce to form linear and reticulate arrays of warty lichenoid lesions (Fig. 12.13). Lesions are infundibulocentric and acrosyringocentric. Keratotic plugs and prominent telangiectasia may be present. The palms and soles have discrete hyperkeratotic

Fig. 12.13 Keratosis lichenoides chronica.

papules. There is an associated sharply marginated erythema, scaling, and telangiectasia of the face, superficially resembling seborrheic dermatitis or rosacea. Nail changes described include thickening of the nail plate, yellowing, longitudinal ridging, onycholysis, hyperkeratosis of the nail bed, paronychia, and warty lesions of the periungual areas. In addition, painful oral ulcerations occur in 25% of cases, and oral or genital involvement occurs in 50% of adult patients. Other findings include hoarseness from vocal cord edema and involvement of the eyelids (one third of patients), conjunctiva, iris, or anterior chamber. Cases have been reported in association with hepatitis, lymphoma, thyroid disease, and other systemic illnesses, but no specific links to true comorbid conditions exist.

Childhood cases are rare and differ from adult cases. Infants are affected in the first year of life and have prominent facial purpura and erythema, especially on the cheeks, and children develop alopecia more often than adults. More than half of childhood cases are familial, suggesting autosomal recessive inheritance.

Histologically, there is irregular acanthosis or epidermal atrophy with hyperkeratosis and zones of parakeratosis. A lichenoid infiltrate, consisting primarily of lymphocytes, and vacuolar alteration at the basal cell layer, but concentrated around the infundibula or acrosyringia. Marked follicular plugging and plugging of the acrosyringia are characteristic.

Topical calcipotriol, phototherapy (NB-UVB or PUVA), oral retinoids, photodynamic therapy, and sometimes systemic immunosuppressive agents, or combination therapy may all prove beneficial, though most reports highlight phototherapy and/or systemic retinoids. Keratosis lichenoides chronica rarely responds to topical or systemic steroids.

LICHEN NITIDUS

Clinical Features

Lichen nitidus (LN) is a chronic inflammatory disease characterized by minute, shiny, flat-topped, pale, exquisitely discrete, uniform papules, rarely larger than 1–2 mm. Children and young adults are primarily affected. Pruritus is usually minimal or absent but may be more prominent in more generalized cases. Linear arrays of papules (Koebner phenomenon) are common, especially on the penis, forearms, and dorsal hands (Fig. 12.14). Initially, lesions are localized and often remain limited to a few areas, chiefly the penis (Fig. 12.15) and lower abdomen, the inner surface of the thighs, and the flexor aspects of the wrists and dorsal hands/forearms. In other cases, the disease assumes a more widespread distribution, and the papules fuse into erythematous, finely scaly plaques. The reddish color varies with tints of yellow, brown, or violet. Unusual variants of LN include vesicular, hemorrhagic, linear, purpuric (resembling a pigmented purpuric dermatosis), perforating, and spinous follicular (resembling lichen spinulosus).

Palm and sole involvement may occur in LN, and the disease may be restricted to these areas. It presents with multiple tiny, hyperkeratotic papules. The papules may coalesce to form diffuse hyperkeratotic plaques that fissure. The differentiation of LN from hyperkeratotic hand eczema and LP of the palms is aided by the presence of a keratotic plug in the center of lesions of palmoplantar LN. Nail involvement with pitting, beaded, longitudinal ridging, and nailfold inflammation has been reported. Isolated LN on the eyelid has been reported. Oral involvement, with gray-yellow papules or petechiae of the hard palate or papules on the tongue, is rare.

Fig. 12.14 Lichen nitidus. Note Koebner phenomenon. (Courtesy Curt Samlaska, MD.)

Fig. 12.15 Lichen nitidus, characteristic lesions of the penis. (Courtesy Curt Samlaska, MD.)

A variant of LN, termed *actinic lichen nitidus*, has been reported in dark-skinned patients from the Middle East and Indian subcontinent. Cases seen in African Americans have also been termed *pinpoint*, *papular polymorphous light eruption* (PMLE), or known by the older term *summer actinic lichenoid eruption*. These cases all have lesions clinically and histologically identical to LN, which are limited to the sun-exposed areas of the dorsal hands, brachioradial area, and posterior neck. The LN histology may represent subacute or chronic lesions of pinpoint PMLE. Actinic LN/pinpoint papular PMLE usually responds to sun protection, with or without topical corticosteroids. Hydroxychloroquine has been used successfully in one Moroccan case.

The cause of LN is unknown. Rare familial cases do occur. LN is clinically and histologically distinct from lichen planus, and immunohistochemical studies also suggest they are distinct disorders, however, patients have had overlap of both disorders (and other lichenoid eruptions, including LN and lichen striatus), suggesting some common pathogenic basis. LN (with larger-than normal inflammatory aggregates) has been described in the setting of Crohn disease as well. LN has occurred after tattoo placement, either as an immunologic reaction to the material or due to koebnerization. One case reported LN developing within sites of vitiligo in a patient with alopecia universalis and Sjögren syndrome. Both LP and LN have been reported secondary to hepatitis B immunization and during treatment of hepatitis with IFN-α. Lichenoid eruptions have been described with increasing frequency in the setting of cancer treatment with checkpoint inhibitors, including reports of generalized LN with tremeliumumab.

LN has a characteristic histologic appearance. Dermal papillae are widened and contain a dense infiltrate composed of lymphocytes, histiocytes, and melanophages. There is an accumulation of both CD68+ histiocytes and S-100+, CD1a+ Langerhans cells in the dermal collections. Multinucleate giant cells are often present, imparting a granulomatous appearance to the infiltrate. The epidermal rete ridges on either side of the papilla form a claw-like collarette. The overlying epidermis is attenuated, and there is usually vacuolar alteration of its basal layer. Transepidermal inflammation and debris can occur in the rare subtype of perforating LN. At times, the infiltrate may extend down adjacent hair follicles and eccrine ducts, making distinction of LN from lichen scrofulosorum and lichen striatus difficult. One case series describes patients with mild cutaneous PRP displaying LN-like histopathology.

The course of LN is slowly progressive, with a tendency for remission. The lesions may remain stationary for years but often eventually disappear spontaneously and entirely. Treatment is not required because it is usually asymptomatic and self-healing. However, topical corticosteroids or CNIs can be used for localized disease. NB UVB and PUVA can be effective in generalized cases, but care must be taken to be sure that the LN in not of the actinic variety. Anecdotal reports suggest therapeutic benefit from oral retinoids (acitretin). As in LP, refractory LN cases requiring aggressive therapy may respond to cyclosporin A.

LICHEN STRIATUS

Lichen striatus is a fairly common, self-limited eruption seen primarily in young children (mean age 3 years). Girls are affected two to three times more frequently than boys. Lesions begin as small papules that are erythematous and slightly scaly (Fig. 12.16). In more darkly pigmented persons, hypopigmentation is prominent and may be purely macular. The 1–3 mm papules coalesce to form a band 1–3 cm wide, either continuous or interrupted, which over a few weeks progresses down the extremity or around the trunk, following lines of Blaschko. An extremity is more often involved, but trunk lesions or lesions extending from the trunk onto an extremity can also occur. About 10% of cases occur on the head and face. Multiple bands infrequently occur, including bilateral cases. Lesions are usually asymptomatic, but pruritus may occur, especially in patients who are also atopic.

Nail involvement can occur if the process extends down the digit to the nail. Typically, the lichen striatus appears first on the skin, but the skin and nail abnormality may appear simultaneously. Infrequently, only the nail may be involved for months, with later appearance of the band on the skin, or the nail may remain the sole area of involvement throughout the course of the disease. Unilateral lichen striatus may be associated with bilateral nail involvement. Nail plate thinning, longitudinal ridging, splitting, and nail bed hyperkeratosis may be seen. Often, only a part of the nail is involved. The histology of involved nails is identical to that of the skin lesions.

Fig. 12.16 Lichen striatus.

The active lesions of lichen striatus last for an average of 1 year but may persist for up to 4 years. Eventually, all the lesions, including dystrophic nails, spontaneously resolve without scarring. Hypopigmentation may persist for several years. Hyperpigmentation is uncommon (<5%) and should suggest a diagnosis of linear LP instead. Relapses can occur in up to 5% of cases, either in the same distribution or in a different anatomic region.

The histologic features of lichen striatus vary, partly reflecting the stage of evolution of the lesion. There may be a spongiotic dermatitis, but most frequently a lichenoid component is present. There is a bandlike infiltrate with necrotic keratinocytes at the dermoepidermal junction. Granulomatous inflammation is occasionally present. Typically, there is a dense lymphoid infiltrate around the eccrine sweat glands and ducts. This helps distinguish lichen striatus from lichen planus. One study showed Ki-67 cells increased in linear LP but not in LS. It is important to exclude mycosis fungoides as occasionally histology of LS may resemble the adnexal inflammation of folliculotropic MF.

The blaschkolinear nature of the eruption has prompted some to suggest LS represents a somatic mutation in a group of cells, which then develops the characteristic eruption in response to some environmental trigger. Multiple reports exist of simultaneous cases in siblings and families. There is also a seasonal variation, with most cases occurring in the spring and summer. Epidemic outbreaks have been reported, suggesting a viral etiology or trigger. Cases have occurred following vaccinations and viral infections such as varicella, influenza, and human herpes virus infections, and following IFN therapy. LS has been reported in children with atopic dermatitis, and in conjunction with vitiligo, though it is important to distinguish LS from segmental vitiligo in those patients. Trauma has also been reported to precipitate an outbreak of lichen striatus. Medication-induced causes are rare beyond those previously mentioned, though one report described LS developing with etanercept treatment of rheumatoid arthritis.

Adult cases of lichen striatus differ from those in childhood and are rarer and more papulovesicular, affecting multiple regions, resolving more rapidly (<2 months), and relapsing more frequently (up to one third of patients). Histologically, the lesions show more spongiotic and less lichenoid features, leading some authors to call these cases "adult blaschkitis" or "Grosshans-Marot disease." This splitting of terms probably has no clinical utility.

Usually, the diagnosis of lichen striatus is straightforward, in a young child with sudden onset of an eruption following the lines of Blaschko. The differential diagnosis could include linear LP, linear psoriasis, inflammatory linear verrucous epidermal nevus, epidermal nevus, linear cutaneous LE, and verruca plana. Histologic evaluation will usually distinguish these entities, but is rarely required.

Treatment is usually not necessary. Parents may be reassured of the uniformly excellent prognosis. Topical corticosteroids and topical CNIs may accelerate the resolution of lesions. The combination of tazarotene and topical steroid treatment has led to rapid resolution in one series. Laser treatment has been reported to clear residual discoloration. In children with an acquired nail dystrophy of one or two digits, lichen striatus must be considered, and watchful waiting might be considered before biopsying the nail.

LICHEN SCLEROSUS (LICHEN SCLEROSUS ET ATROPHICUS)

Lichen sclerosus is a chronic disease of the skin and mucosa. The terms *lichen sclerosus et atrophicus*, *kraurosis vulvae*, and *balanitis xerotica obliterans* are synonymous but have been replaced by the single term *lichen sclerosus* (LS). LS can present from childhood to old age. Although it occurs in all races, whites and Hispanics are more frequently affected, and it is rare in African Americans. Both genders develop LS both before and after puberty, with females predominating at all ages. The prevalence is about 1.7% in the general adult female population, and about one-tenth as frequent in premenarchal girls. Transgender patients require careful evaluation as disease may occur at both surgical sites of transformed genitalia and at sites particular to the patients' gender identity, such as perianal involvement in a male-to-female patient. Patients may develop LS after bone marrow transplantation, though it is challenging to distinguish from chronic graft-versus-host.

The pathogenesis of LS is poorly understood. Autoimmune diseases (thyroid disease, vitiligo, morphea, alopecia areata, pernicious anemia) occur in one fifth to one third of women with LS but are much less common in men, with rates similar to the general population. Psoriasis is increased in women with LS, reported to occur in 7.5%–17% of patients. Autoantibodies to extracellular matrix protein 1 (ECM-1) are found in 80% of LS patients, compared with 4% of controls and 7%–10% of patients with other autoimmune diseases. The titer of the ECM-1 autoantibody correlates with the disease severity.

In females, there is a bimodal age distribution—prepubertal and postmenopausal. The initial lesions of LS are white, polygonal, flat-topped papules, plaques, or atrophic patches (Fig. 12.17). Lesions may be surrounded by an erythematous to violaceous halo. In atrophic lesions, the skin is smooth, slightly wrinkled, soft, and white. Bullae, often hemorrhagic, telangiectasias, and fixed areas of purpura may occur on the patches. About 40% of patients with LS are asymptomatic. However, when women referred to specialists are questioned, virtually 100% are symptomatic. Itching is frequently severe, especially in the anogenital area. In the genital area, fissuring and erosion may occur. This may result in dysuria, urethral and vaginal discharge, dyspareunia, and burning pain. Normal anatomic structures may be obliterated, with loss of the labia minora, clitoral hood, and urethral meatus. In women, this perineal involvement typically affects the vulvar and perianal areas, giving a figure-8 or hourglass appearance. Introital stenosis or fusion may occur. The vaginal and cervical mucosae are not

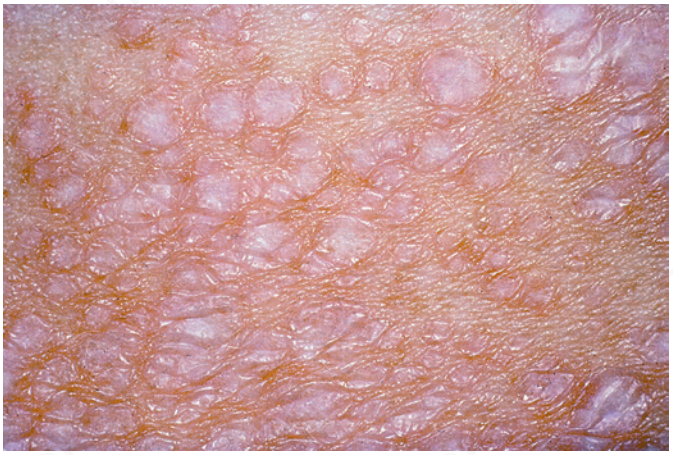

Fig. 12.17 Lichen sclerosus et atrophicus.

Fig. 12.18 Lichen sclerosus et atrophicus. (Courtesy Steven Binnick, MD.)

involved by LS, in contrast to LP. Prepubertal girls may also be affected and usually have vulvar and perianal lesions (Fig. 12.18). Even a relatively brief delay in diagnosis may be associated with atrophy and/or scarring.

Vulvar disease is associated with similar skin changes to those in adult women, and pruritus may be a prominent symptom. Perianal involvement may produce significant symptomatology of constipation, stool holding, and rectorrhagia caused by rectal fissures. Infantile perineal protrusion refers to a pyramidal soft tissue swelling covered by red or rose-colored skin along the median perineal raphe (skin between posterior fourchette and anus). This occurs only in girls and appears to be a manifestation of LS in some prepubertal girls. Two thirds of girls with LS have been evaluated for sexual abuse, largely because of the purpura and ecchymoses that accompany the lesions. If risk of sexual abuse is suspected, appropriate investigations must be performed.

There is clearly a relationship between the hormonal milieu and LS. Postmenopausal women are preferentially affected. Pregnancy leads to improvement and often complete resolution.

Fig. 12.19 Lichen sclerosus et atrophicus. (Courtesy Shyam Verma, MBBS, DVD.)

Oral contraceptive (OC) use is common in premenopausal women with LS. These OCs are often antiandrogenic. Stopping OCs and treating with standard topical agents lead to significant improvement, suggesting that the antiandrogen OCs may have accelerated the appearance of the LS. However, treatment of postmenopausal women with estrogen supplementation does not alter the incidence or course of their LS.

In males, lesions are atrophic and may be greatly hypopigmented or depigmented, resembling vitiligo, although melanosis mimicking melanoma has been reported. Lesions usually involve only the glans penis and the inner foreskin of the uncircumcised male. Infrequently, LS may extend on to the penile shaft and scrotum. If the glans is involved, hemorrhage is common, and shallow erosions may occur. LS of the glans does not usually lead to nonhealing erosions of the glans, but rather simply skin fragility. Patients often have itching and pain, but may be asymptomatic while ongoing inflammation is occurring. Phimosis and paraphimosis are common complications of LS in men (Fig. 12.19). Between 15% and 100% of circumcision specimens from prepubertal boys show features of LS. Sixty percent of acquired phimosis in boys and at least 10% in adult men are associated with LS. Most men with LS are uncircumcised, and exposure to urine appears to be an important trigger for LS in males, including in obese patients with urinary microincontinence. Circumcision is effective treatment for penile LS, with cure rates of 75%–100%. Urethral meatal stenosis may occur and requires surgical correction. One study of 301 male patients with LS revealed penile intraepithelial neoplasia in 13%, which often required biopsy diagnosis and surgical intervention. Perianal involvement by LS is rare in men and boys with penile LS, but may occur in transgender male-to-female patients.

Extragenital lesions are uncommon, but may develop in 6%–20% of patients, and are most frequent on the upper back, chest, and breasts and are usually asymptomatic. The tongue and oral mucosa may also be involved, either alone or with lesions elsewhere. Extragenital bulloue LS may rarely occur as well, with a blistering or hemorrhagic appearance. Oral LS is a rare diagnosis and appears to occur without associated skin or genital involvement. Peristomal LS around colostomy sites may occur. LS has been reported following radiation, including on the breast after radiotherapy for breast cancer, and given the histologic similarities may be hard to distinguish from radiation dermatitis. Patients having only extragenital lesions with histologic features of both LS and morphea have been reported. About one quarter of these patients

have LS-like changes overlying the morphea lesions (a recognized histopathologic variant of morphea), and in three quarters the extragenital LS lesions are distinct from the morphea lesions. Genital LS is much more common in patients (usually women) with localized plaque or generalized morphea. In one study, up to 40% of patients with morphea also had genital LS. The genital area of patients with morphea should be examined for the presence of LS. Rarely, in Europe, *Borrelia* has been reported to cause extragenital LS, and treatment with antibiotics has arrested the progression of the lesions.

Lichen Sclerosus and Cancer

Although the risk is not as high as was proposed early in this century, LS of the genitalia is a condition with increased risk for genital SCC in both women and men. The lifetime risk for women who are carefully followed appears to be 5% or less but is clearly higher than for the general population. A large Finnish study of 7616 patients demonstrated a markedly elevated risk of vulvar cancer and slightly increased risk of vaginal cancer in patients with LS. About one third of cases of vulvar SCCs are associated with LS. HPV is more prevalent in male patients with LS than in female patients, with HPV16 most prevalent but multiple genotypes present; HPV alone is not the cause of LS. Human papillomavirus (HPV) appears to be associated with only about 15% of SCCs arising in women with LS. Hypertrophic vulvar lesions and age beyond 60 are risk factors for the development of SCC in women with LS. Such lesions and patients should be evaluated carefully. In men with LS, the risk for genital SCC is less than in women with LS. However, about 25% of cases of penile SCC are associated with LS. Oncogenic HPV types do not appear to be associated with LS-related penile cancer. Successful treatment and control of LS-related inflammation appears to reduce the risk of malignancy, but patients require long-term surveillance.

Histopathology

Early lesions of LS are characterized by an interface dermatitis with vacuolar alteration of keratinocytes. With evolution, the epidermis is thinned and the rete ridges are effaced. Compact orthokeratosis and follicular and eccrine plugging are present. The upper dermis is edematous, with the upper dermal collagen homogenized. Immediately beneath the altered papillary dermis, there is a sparse, bandlike and perivascular lymphoid infiltrate. In pruritic lesions, coexistent changes of lichen simplex chronicus may be seen, with epidermal acanthosis rather than atrophy.

Differential Diagnosis

Extragenital LS must be differentiated from guttate morphea and LP, especially of the atrophic type. Anogenital LS must be distinguished from genital LP, lichen simplex chronicus, vulvar intraepithelial neoplasia (SCC in situ), and extramammary Paget disease. The white color and atrophic surface are characteristic, and such areas are most fruitful if biopsied.

Treatment

The use of superpotent topical corticosteroids has dramatically changed the management of anogenital LS. These are universally accepted as the treatment of choice for all forms of genital LS. Most patients will respond to once-daily application of these agents and can subsequently be tapered to less frequent applications (once or twice a week) or to lower-strength corticosteroids. Ointment formulations are generally better tolerated, but vehicle preference and side-effect profile may vary by patient and affect adherence. Most patients can be controlled but not cured, and require ongoing maintenance therapy. Most women can achieve a symptom-free state with 30 g of clobetasol ointment used over 3 months, and patients who continued with intermittent maintenance therapy remained symptom free and developed less scaring than noncompliant patients. Patients occasionally are reluctant to use high-potency steroids due to the risk of atrophy—it is important to educate patients about the benefits of disease control outweighing those risks. Patients should be educated how to correctly apply the medication to cover the affected area, which may require a mirror and can be challenging for older patients. During treatment, coexistent candidiasis may be present or develop, and can be managed with topical or oral agents. Penile, vulvar, and prepubertal LS in girls have all been documented to respond to this form of treatment. Phimosis in young boys should be treated initially with potent topical steroids. The degree of symptomatic improvement far exceeds the objective improvement. The majority of patients have dramatic reduction in their itching and burning with topical clobetasol. However, the visible white, atrophic, scarred vulvar skin is often only minimally improved. In one study, 95% of compliant patients achieved complete symptom control; none had disease progression. In partially compliant patients, only 75% achieved complete symptom control, and 35% experienced progression. None of the fully compliant women developed vulvar SCC, but 5 of 45 (11%) of the partially compliant women did. This adds limited evidence to the impression that good control of LS is associated with better outcomes—symptomatically, functionally, and with respect to cancer development. Vulvar pain associated with LS may have a neuropathic component (as in vulvodynia), and treatment with tricyclic antidepressants (e.g., amitriptyline), gabapentin, and duloxetine hydrochloride may be tried.

Topical tacrolimus 0.1% and 0.03% ointments and pimecrolimus 1% cream have also been demonstrated to be effective in genital LS. However, since superpotent corticosteroids have proven so effective in genital LS, topical CNIs should be reserved for patients in whom topical corticosteroids are ineffective or not tolerated. Close clinical follow-up is recommended because the long-term risk of applying topical CNIs to skin predisposed to malignant degeneration is not known. Topical calcipotriol may also be of benefit. Topical testosterone was no more effective than emollient and in one trial was worse than emollients as maintenance therapy. It is no longer recommended. Hydroxychloroquine, calcitriol, topical 8% progesterone cream, topical calcipotriol, topical tretinoin, cyclosporine, and hydroxyurea can be considered in refractory cases. In one patient, intralesional adalimumab cleared LS of the glans penis. UVA-I phototherapy led to moderate improvement in some patients unresponsive to topical steroids. Patients who initially failed topical steroid treatment may respond to topical corticosteroids following the UV treatment. Intralesional steroid/anesthetic injections can be helpful for persistently symptomatic areas. Emerging reports exist of improvement with intradermal injections of autologous platelet-rich plasma. Surgical treatment can be effective, starting with cryotherapy, which has been reported as helpful in three quarters of patients with severe vulvar itch. Photodynamic therapy has brought significant improvement in multiple reports and can be considered in refractory cases. Extragenital LS is very difficult to treat. If superpotent topical steroids are ineffective, PUVA, UVA I, NB UVB, calcipotriol, or antimalarials may be tried. Given the appearance of LS-like lesions in chronic GVHD and the success of ECP in chronic GVHD, ECP has been tried in a few severe cases of extragenital LS with success.

13 Acne

Bonus images for this chapter can be found online at expertconsult.inkling.com

ACNE VULGARIS

Clinical Features

Acne vulgaris is a chronic inflammatory disease of the pilosebaceous follicles, characterized by comedones, papules, pustules, nodules, and often scars. The comedo is the primary lesion of acne. It may be seen as a flat or slightly elevated papule with a dilated central opening filled with blackened keratin (open comedo or blackhead) (Fig. 13.1). Closed comedones (whiteheads) are usually 1-mm yellowish papules that may require stretching of the skin to visualize. Macrocomedones, which are uncommon, may reach 3–4 mm in size. The papules and pustules are 1–5 mm in size and are caused by inflammation, so erythema and edema occur (Fig. 13.2). They may enlarge, become more nodular (Fig. 13.3), and coalesce into plaques of several centimeters that are indurated or fluctuant, contain sinus tracts, and discharge serosanguineous or yellowish pus.

Patients typically have a variety of lesions in various states of formation and resolution. In light-skinned patients, lesions often resolve with a reddish purple macule that is short lived. In dark-skinned individuals, macular hyperpigmentation results and may last several months (Fig. 13.4). Acne scars are heterogeneous in appearance. Morphologies include deep, narrow, ice pick scars seen most often on the temples and cheeks; canyon-type atrophic lesions on the face (Fig. 13.5); whitish yellow papular scars on the trunk and chin; anetoderma-type scars on the trunk; and hypertrophic and keloidal elevated scars on the neck and trunk.

Acne affects primarily the face, neck, upper trunk (Fig. 13.6), and upper arms. On the face, acne occurs most frequently on the cheeks and to a lesser degree on the nose, forehead, and chin. The ears may be involved, with large comedones in the concha, cysts in the lobes, and sometimes preauricular and retroauricular comedones and cysts. On the neck, especially in the nuchal area, large cystic lesions may predominate.

Acne typically begins at puberty and is often the first sign of increased sex hormone production. When acne begins at age 8–12 years, it is frequently comedonal in character, affecting primarily the forehead and cheeks. It may remain mild in its expression, with only an occasional inflammatory papule. However, as hormone levels rise into the middle teenage years, more severe inflammatory pustules and nodules occur, with spread to other sites. Young men tend to have an oilier complexion and more severe widespread disease than young women. Women may experience a flare of their papulopustular lesions about 1 week before menstruation. Acne may also begin in 20- to 35-year-old women who have not experienced teenage acne. This acne frequently manifests as papules, pustules, and deep, painful, persistent nodules on the jawline, chin, and upper neck.

Acne is primarily a disease of the adolescent, with 85% of all teenagers being affected to some degree. It occurs with greatest frequency between ages 15 and 18 in both genders. Generally, involution of the disease occurs before age 25; however, great variability in age at onset and of resolution occurs. About 12% of women and 3% of men will continue to have clinical acne until age 44. A few will have inflammatory papules and nodules into late adulthood.

Neonatal acne is a common condition that develops a few days after birth, has male preponderance, and is characterized by transient facial papules or pustules that usually clear spontaneously in a few days or weeks (Fig. 13.7). Neonatal cephalic pustulosis (infantile acne) includes cases that persist beyond the neonatal period or that have an onset after the first 6 weeks of life. Most patients' disease remits by age 1 year, although occasionally cases extend into childhood and through puberty. In prolonged cases, topical benzoyl peroxide, erythromycin, or the retinoids may be effective. With more inflammatory disease, oral erythromycin, 125 mg twice daily, or trimethoprim, 100 mg twice daily, may be added to topical medications. Oral isotretinoin has been used in the infantile period and is effective. Midchildhood acne may evolve from persistent infantile acne or begin after age 1 year. It is uncommon and has a male predominance. Grouped comedones, papules, pustules, and nodules can occur alone or in any combination, usually limited to the face (Fig. 13.8). The duration is variable, from a few weeks to several years, and occasionally extends into more severe pubertal acne. Often, there is a strong family history of moderately severe acne. A pediatric endocrinology workup is indicated for midchildhood acne and for earlier-onset patients with physical findings suggestive of a hormonal disorder, such as sexual precocity, virilization, or growth abnormality. Acne onset from age 7–12 is categorized as preadolescent acne. This is the time of adrenarche, and unless there are signs of androgen excess, no workup is needed.

Pathogenesis

Acne vulgaris is exclusively a follicular disease, with the principal abnormality being comedo formation. It is produced by the impaction and distention of the follicles with a keratinous plug in the lower infundibulum. The keratinous plug is caused by hyperproliferation and abnormal differentiation of keratinocytes. Androgens, alterations in lipid composition, and an abnormal response to local cytokines are all hypothesized to be causally important. Androgen stimulation of the sebaceous glands is critical. Acne begins after sebum secretion increases, and women with hyperandrogenic states often manifest acne, along with hirsutism and menstrual abnormalities. Treatment directed at reducing sebaceous secretion, such as isotretinoin, estrogens, or antiandrogens, is effective in clearing acne.

As the retained cells block the follicular opening, the lower portion of the follicle is dilated by entrapped sebum. Disruption of the follicular epithelium permits discharge of the follicular contents into the dermis. The combination of keratin, sebum, and microorganisms, particularly *Propionibacterium acnes*, leads to the release of proinflammatory mediators and the accumulation of lymphocytes, neutrophils, and foreign body giant cells. This in turn causes the formation of inflammatory papules, pustules, and nodulocystic lesions.

Additional factors may exacerbate acne or, in a predisposed patient, cause the onset of acne. Comedogenic greasy or occlusive products such as hair pomades may induce closed comedones and at times inflammatory lesions. Other types of cosmetics may initiate or worsen acne, but acne cosmetica is uncommon because most cosmetics are tested for comedogenicity.

Many types of mechanical or frictional forces can aggravate existing acne. A common problem is the overexuberant washing some patients think may help rid them of their blackheads or oiliness. A key feature of mechanical or frictional acne is an unusual

Fig. 13.1 Acne vulgaris, with comedones, on the chin.

Fig. 13.3 Inflammatory acne with papules and nodules.

Fig. 13.4 Postinflammatory hyperpigmentation at sites of acne lesions.

distribution of the acne lesions. Provocative factors include chin straps, violins, hats, collars, surgical tape, orthopedic casts, chairs, and seats. One acne patient who had laser hair removal developed flares of inflammatory lesions localized to the acne-prone sites after each laser session; the legs and abdomen were spared. All these factors are likely to irritate the follicular epithelium and exacerbate the changes that lead to comedogenesis and follicular rupture. Prophylactic measures designed to interdict these various mechanical forces are beneficial.

The role of diet in causing or exacerbating acne is being actively investigated. A high-glycemic diet, skim milk, and whey protein may negatively influence acne. Dietary regimens used for therapeutic intervention have yet to be defined, however.

In all women or children with acne, the possibility of a hyperandrogenic state should be considered. In women, the presence of irregular menses, hirsutism, seborrhea, acanthosis nigricans, or androgenic alopecia increases the likelihood of finding clinically significant hyperandrogenism. Additionally, gynecologic endocrine evaluation may be indicated in women who have acne resistant to conventional therapy, who relapse quickly after a course of isotretinoin, or who experience sudden onset of severe acne. Screening tests to exclude a virilizing tumor include serum dehydroepiandrosterone sulfate (DHEAS) and testosterone, obtained 2 weeks before the onset of menses. DHEAS levels may be very high in adrenal tumors (>800 μg/dL) or less dramatic in congenital adrenal hyperplasia (400–800 μg/dL). Ovarian tumor is suggested by testosterone levels greater than 200 ng/dL. Many patients with late-onset 21-hydroxylase deficiency congenital adrenal hyperplasia will have normal levels of DHEAS. Although 17-hydroxyprogesterone and adrenocorticotropic hormone (ACTH) stimulation tests have been used in this setting, the baseline 17-hydroxyprogesterone may be normal and ACTH stimulation may result in overdiagnosis of the syndrome. It is not clear that screening for adult-onset 21-hydroxylase deficiency improves patient outcome. Cushing syndrome is also to be considered in the differential diagnosis.

The diagnosis of polycystic ovarian syndrome (PCOS) requires that two of three of the following criteria be present: oligoovulation

Fig. 13.5 Acne scarring. (Courtesy Steven Binnick, MD.)

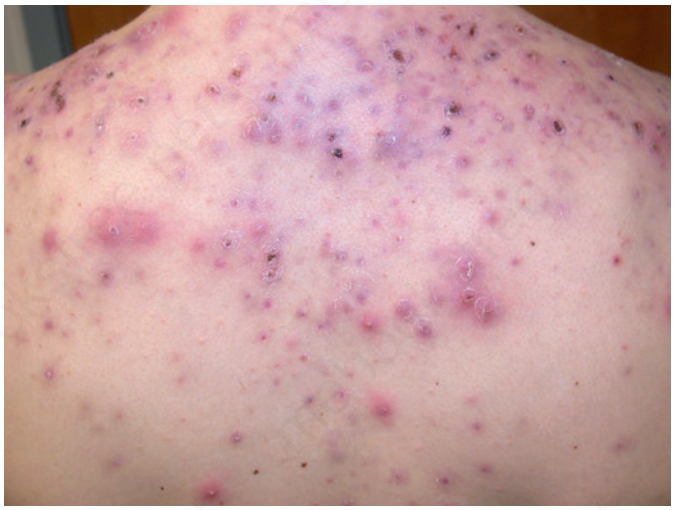

Fig. 13.6 Severe truncal acne.

Fig. 13.7 Neonatal cephalic pustulosis (infantile acne).

Fig. 13.8 Childhood acne.

or anovulation, biochemical or clinical signs of hyperandrogenism, and echographic polycystic ovaries. Thus the diagnosis of PCOS may be made clinically by the presence of anovulation (<9 periods per year or periods >40 days apart) and signs of hyperandrogenism, such as acne and hirsutism. Approximately 15% of women of childbearing age will meet the criteria for PCOS. This diagnosis has important implications for affected patients. Systemic disease such as insulin resistance (which may manifest as acanthosis nigricans), obesity, cardiovascular disease, obstructive sleep apnea, nonalcoholic steatohepatitis, endometrial cancer and infertility (with chronic anovulation), and psychiatric disease. Nearly half of PCOS patients have metabolic syndrome. In women with hirsutism of the chest and acanthosis nigricans of the axillae, PCOS is frequently found. Suggested biochemical investigation includes total testosterone, free testosterone, dehydroepiandrosterone (DHEAS), androstenedione, luteinizing hormone, and follicle-stimulating hormone. PCOS is a complex disorder and referral for investigation for ovarian cysts, interpretation of abnormal results, consideration of other testing such as thyroid-stimulating hormone and prolactin, and management of any associated disorders is recommended.

Acne neonatorum is explained by infantile production of androgens, which wanes at 6–12 months. Occasional patients have persistent acne, although acne developing after age 1 and before age 7 (with onset of adrenarche) may be a form of acne cosmetica, acne venenata, drug-induced acne or part of an endocrinologic disorder. A workup should be initiated if acne develops between ages 1 and 7 and no obvious external factor is present. In the absence of any discovered abnormalities, the qualitative or quantitative alteration of cutaneous androgen, metabolism, and increased end-organ sensitivity could be postulated as pathogenic mechanisms for preadolescent acne.

Pathology

Comedones reveal a thinned epithelium and a dilated follicular canal filled with lamellar lipid-impregnated keratinous material. In pustular cases, there are folliculocentric abscesses surrounded by a dense inflammatory exudate of lymphocytes and polymorphonuclear leukocytes. In addition to these findings, indolent nodular lesions frequently show plasma cells, foreign body giant cells, and proliferation of fibroblasts. Epithelial-lined sinus tracts may form.

Treatment

General Principles

It is important to take a complete historical record of prior therapies, including all over-the-counter (OTC) products. The dose, timing, combinations, side effects, and response to interventions should be obtained. Corticosteroids, anabolic steroids, neuroleptics, epidermal growth factor inhibitors, lithium, and cyclosporine may worsen acne. A family history of acne and, if present, its tendency to scarring should be noted. Women should be queried regularly about menstrual irregularities and hair growth in a male pattern, as well as use of cosmetics.

Treatment may fail because of drug interactions, coexisting conditions, or antibiotic resistance, but the most common and important cause is lack of adherence to the treatment plan. Utilizing medications that are well tolerated, have convenient dosing regimens, and are cosmetically acceptable will help. Thorough patient education is essential: explain how lesions form, define the expected response to and the duration and side effects of treatment, and give clear, unambiguous instructions. Patients should know the difference between active inflammatory lesions and the purplish red or hyperpigmented macules of inactive resolved lesions. Topical application should be to the entire affected area rather than to specific lesions, and oral and topical medications should be used daily as preventive treatment.

A high-glycemic diet may worsen acne, although the strength of its influence is unknown. The authors in general do not counsel patients to alter their diets unless large quantities of skim milk are being ingested or obesity is present. A trial lessening skim milk intake is worthwhile, with appropriate calcium and vitamin D supplementation given. In obese patients, dietary counseling is recommended, especially if PCOS, or other syndromes known to be associated with insulin resistance and metabolic syndrome (e.g., HAIR-AN syndrome) are present. For some patients who want a more "natural" approach to therapy and a change in diet, a low-glycemic diet may be recommended. Scrubbing of the face increases irritation and may worsen acne. Use of only prescribed medications and avoidance of potentially drying OTC products, such as astringents, harsh cleansers, and antibacterial soaps, should be emphasized. Noncomedogenic cosmetics are recommended, and pressed powders and oil-based products should be avoided.

Medical Therapy

Systemic and topical retinoids, systemic and topical antimicrobials, and systemic hormonal therapy are the main therapeutic classes of treatment available. Treatment guidelines are outlined in Box 13.1. Pregnancy and lactation labeling is undergoing significant changes which will allow a better understanding of the potential risks. This will likely result in less stringent recommendations regarding topical therapies. Such changes are ongoing and in this section pregnancy categories will still be referenced.

Topical Treatment. All topical treatments are preventive, and use for 8–12 weeks is required to judge their efficacy. The entire acne-affected area is treated, not just the lesions, and long-term use is the rule. In many patients, topical therapy may be effective as maintenance therapy after initial control is achieved with a combination of oral and topical treatment.

Topical Retinoids. It has long been appreciated that topical retinoids are especially effective in promoting normal desquamation of the follicular epithelium, reducing comedones and inhibiting the development of new lesions. Additionally, they have a marked antiinflammatory effect, inhibiting the activity of leukocytes, the release of proinflammatory cytokines and other mediators, and the expression of transcription factors and toll-like receptors involved in immunomodulation. These agents also help penetration of other active agents. Thus the topical retinoids should be used in most patients with acne and are the preferred agents in maintenance therapy.

Tretinoin was the first of this group of agents to be used for acne. Popular forms of tretinoin are 0.025% and 0.05% in a cream base and the micronized gels because these are less irritating than standard gels and liquids. Its incorporation into microspheres and a polyolprepolymer also helps limit irritation and make the product more stable in the presence of light and oxidizers. Tretinoin treatment may take 8–12 weeks before improvement occurs. When patients are tolerating the medication and are slow to respond, retinoic acid gel or solution may be used. Tretinoin should be applied at night and is in pregnancy category C.

BOX 13.1 Acne Treatment

MILD

1. Comedonal
   - Topical retinoid ± physical extraction (first line)
   - Alternate retinoid, benzoyl peroxide, salicylic acid, azelaic acid (second line)
2. Papular/pustular
   - Benzoyl peroxide or topical antimicrobial combination + topical retinoid, benzoyl peroxide wash if mild truncal lesions (first line)
   - Alternate antimicrobial combination + alternate topical retinoid, azelaic acid, sodium sulfacetamide–sulfur (second line)

MODERATE

1. Papular/pustular
   - In men, oral antibiotic + topical retinoid + benzoyl peroxide (first line)
   - Alternate antibiotic, alternate topical retinoid (second line); if moderately severe, isotretinoin
   - In women, spironolactone and/or oral contraceptive + topical retinoids ± benzoyl peroxide; oral antibiotic + topical retinoid + benzoyl peroxide (alternative)
   - Isotretinoin if relapses quickly off oral antibiotics, does not clear, or scars

SEVERE

1. Nodular/conglobate
   - Isotretinoin
   - Oral antibiotic + topical retinoid + benzoyl peroxide
   - In women, spironolactone + oral contraceptive + topical retinoid ± topical or oral antibiotics and/or benzoyl peroxide

Adapalene is a well-tolerated retinoid-like compound that has efficacy equivalent to the lower concentrations of tretinoin. Because it is light stable, adapalene may be applied in either the morning or the evening. It is in pregnancy category C.

Tazarotene is comparatively strong in its action, but also relatively irritating. It should be applied once at night or every other night, and as it is in pregnancy category X, contraceptive counseling should be provided.

Initially using retinoids every other night or adding a moisturizer with their use may lessen their irritant effects. They are also particularly useful in patients of color because retinoids may lighten postinflammatory hyperpigmentation.

Benzoyl Peroxide. Benzoyl peroxide has a potent antibacterial effect. *Propionibacterium acnes* resistance does not develop during use. Its concomitant use during treatment with antibiotics will limit the development of resistance, even if only given for short 2- to 7-day pulses. Although benzoyl peroxide is most effective in inflammatory acne, some studies have shown it to be comedolytic as well. The wash formulations may be used for mild truncal acne when systemic therapies are not required. These need to be in place 2 minutes to be effective.

Treatment is usually once or twice daily. Benzoyl peroxide may irritate the skin and produce peeling. Water-based formulations of lowest strength are least irritating and do not compromise efficacy. Application limited to once a day or every other day will also help. Allergic contact dermatitis will rarely develop, suggested by the complaint of itch rather than stinging or burning. Benzoyl peroxide is in pregnancy category C.

Topical Antibacterials. Topical clindamycin and erythromycin are available in a number of formulations. In general, they are well tolerated and are effective in mild inflammatory acne. These

topical products are in pregnancy category B. Use of these topical antibiotics alone, however, is not recommended because they may induce antibiotic resistance. As mentioned, concurrent therapy with benzoyl peroxide will limit this problem. Concomitant use with a topical retinoid will hasten the response and allow for more rapid discontinuance of the antibiotic.

Dapsone is available topically in a gel formulation. Hemolytic anemia may occur, and skin discoloration is possible when benzoyl peroxide is applied after topical dapsone. Additionally, concomitant oral use of trimethoprim-sulfamethoxazole will increase the systemic absorption of topical dapsone. Dapsone is in pregnancy category C. A topical minocycline product is being actively investigated.

Sulfur, Sodium Sulfacetamide, Resorcin, and Salicylic Acid. Although benzoyl peroxide, retinoids, and topical antibiotics have largely supplanted these older medications, sulfur, resorcin, and salicylic acid preparations are still useful and moderately helpful if the newer medications are not tolerated. They are frequently found in OTC preparations. Sulfacetamide-sulfur combination products are mildly effective in both acne and rosacea, but should be avoided in patients with known hypersensitivity to sulfonamides.

Azelaic Acid. This dicarboxylic acid is usually well tolerated and has mild efficacy in both inflammatory and comedonal acne. Azelaic acid may help to lighten postinflammatory hyperpigmentation and is in pregnancy category B.

Combination Topical Therapy. Several products are available that combine antibiotics such as clindamycin and benzoyl peroxide or combine retinoids and either antibiotics or benzoyl peroxide. In general, these medications increase adherence because they require less frequent application, and they may also limit irritation compared with the cumulative topical application of each product separately. However, combination topical therapy limits flexibility and may cause more irritation than a single product used alone.

Oral Antibiotics. Oral antibiotics are indicated for moderate to severe acne; in patients with inflammatory disease who do not tolerate or respond to topical combinations; for the treatment of chest, back, or shoulder acne; and in patients for whom absolute control is deemed essential, such as those who scar with each lesion or who develop inflammatory hyperpigmentation. It generally takes 8–12 weeks to judge efficacy. Starting at a high dose and stopping it after achieving control is preferred. Limitation on the use of antibiotics is best. Working to maintain control eventually with topical retinoids or retinoid–benzoyl peroxide combination therapy is ideal. A subset of patients will require longer term use if alternate therapies such as isotretinoin or hormonal agents are inappropriate. In these patients reevaluation at regular intervals to judge continued need is recommended.

There is concern that oral antibiotics may reduce the effectiveness of oral contraceptives (OCs). It is appropriate for this as-yet unproved (except with rifampin, which is not used for acne) association be discussed with patients and a second form of birth control offered.

Tetracycline. Tetracycline's availability and utility are limited.

Doxycycline. The usual dose of doxycycline is 50–100 mg once or twice a day, depending on the disease severity. Photosensitivity reactions can occur with this form of tetracycline and can be dramatic. Vaginitis or perianal itching may result and occurs in about 5% of patients, with *Candida albicans* usually present in the involved site. The only other common side effects are gastrointestinal (GI) symptoms such as nausea. To reduce the incidence of esophagitis, tetracyclines should not be taken at bedtime. An enteric-coated formulation is available and limits the GI side effects. Staining of growing teeth occurs, precluding use of tetracyclines in pregnant women and in children under age 9 or 10. The tetracyclines should also be avoided when renal function is impaired.

Fig. 13.9 Minocycline hyperpigmentation.

Sub–antimicrobial-dose doxycycline hyclate, given as 20 mg twice daily or as a sustained-release 40-mg once-daily dose, will also serve to limit antibiotic use, as antiinflammatory activity is being utilized, but no antibiotic resistance results because of the low dose. A sustained-release 40-mg formulation of doxycycline monohydrate is also available.

Minocycline. Minocycline is effective in treating acne vulgaris. The usual dose is 50–100 mg once or twice daily, depending on the severity of disease. Its absorption is less affected by milk and food than is doxycycline. Vertigo may occur, and beginning minocycline therapy with a single dose in the evening is prudent. An extended-release preparation is also available, which limits the vestibular side effects. Pigmentation in areas of inflammation, of oral tissues, in postacne osteoma or scars, in a photodistributed pattern, on the shins, or in the sclera, nail bed, ear cartilage, or teeth or in a generalized pattern may also be seen (Fig. 13.9). Additionally, lupus-like syndromes, a hypersensitivity syndrome (fever, hepatitis, and eosinophilia), serum sickness, pneumonitis, and hepatitis are uncommon but potentially serious adverse effects of minocycline.

Amoxicillin. For those who cannot take tetracyclines because of side effects, or in pregnant women requiring oral antibiotic therapy, amoxicillin may be useful. Amoxicillin and the much less effective erythromycin are in pregnancy category B. Amoxicillin can be given in doses ranging from 250 mg daily to 500 mg three times daily. Side effects are allergic reactions, which may be serious, and GI upset. Many patients of acne age have taken amoxicillin in the past and are aware of their allergy status.

Clindamycin. Past experience has shown that clindamycin provides an excellent response in the treatment of acne. However, the potential for the development of pseudomembranous colitis and the availability of isotretinoin have limited its use. The initial dose of clindamycin is 150 mg three times daily, reduced gradually as control is achieved.

Other Antibiotics. Sulfonamides may be effective in many cases unresponsive to other antibiotics; however, the potential for severe drug eruptions limits their use by dermatologists. Trimethoprim-sulfamethoxazole (TMP-SMX; Bactrim, Septra), in double-strength dose twice daily, is recommended initially when given to moderately to severely affected patients who have failed other oral medication. Trimethoprim alone, 300 mg twice daily, is also useful. Oral dapsone has been used in severe acne conglobata (AC) but is rarely used today. Isotretinoin is favored.

Bacterial Resistance. *Propionibacterium acnes* antimicrobial resistance has been a clinically relevant problem. However, with

the limited use of erythromycin, clindamycin, and tetracycline, this consideration is less problematic. Doxycycline resistance may occur, and minocycline is a suitable alternative if this problem is suspected. Although concomitant use of benzoyl peroxide will help limit cutaneous drug resistance problems, *Staphylococcus aureus* in the nares, streptococci in the oral cavity, and enterobacteria in the gut may also become resistant. Also, close contacts, including treating dermatologists, may harbor such drug-resistant bacteria. Strategies to prevent antibiotic resistance include limiting the duration of treatment, stressing the importance of adherence to the treatment plan, restricting the use of antibiotics to inflammatory acne, encouraging repeat treatment with the same antibiotic unless it has lost its efficacy, avoiding the use of dissimilar oral and topical antibiotics at the same time, and using isotretinoin if unable to maintain clearance without oral antibacterial therapy.

Hormonal Therapy. Hormonal interventions in women may be beneficial even in the absence of abnormal laboratory tests. The workup for the woman with signs of hyperandrogenism, such as acne, menstrual irregularities, hirsutism, or androgenic alopecia, is presented earlier. Women with normal laboratory values respond to hormonal therapy. Results take longer to be seen with these agents, with first evidence of improvement often not apparent for 3 months and continued improved response seen for at least 6 months. Excellent candidates for hormonal treatment include women with PCOS, late-onset adrenal hyperplasia, or another identifiable endocrinologic condition and women with late-onset moderate to severe acne, acne unresponsive to other oral and topical therapies, or acne that has relapsed quickly after isotretinoin treatment. Women with acne primarily located on the lower face and neck and with deep-seated nodules that are painful and long-lasting (Fig. 13.10) are often quite responsive to hormonal intervention. As emphasis is placed on limiting antibiotic therapy, hormonal treatment may considered a first-line therapy in most women needing an oral intervention.

Oral Contraceptives. The OCs block both adrenal and ovarian androgens. Ortho Tri-Cyclen, Estrostep Fe, Alesse, Yasmin, Beyaz, and Yaz are examples of OCs that have beneficial effects on acne. The progestins that these contain have either low androgenic activity or antiandrogenic activity. Both the physician and the patient should be familiar with the adverse reactions associated with OCs, such as nausea, vomiting, abnormal menses, melasma, weight gain, breast tenderness, and rarely thrombophlebitis, pulmonary embolism, and hypertension.

Spironolactone. Antiandrogen treatment during pregnancy will result in feminization of a male fetus, and thus spironolactone is usually prescribed in combination with OCs. It may be effective in doses from 25–200 mg/day. Most women will tolerate a starting dose of 100 mg at night. Most also tolerate 150 mg/day (50 in the AM, 100 at night), but many will have side effects at 200 mg/day (100 twice daily). Side effects include irregular menstrual periods, breast tenderness, headache, dizziness, lightheadedness, fatigue, and occasionally diuresis; the non–central nervous system (CNS) effects are dose dependent. Four large recent retrospective studies of over 700 patients confirm the majority experience significant improvement, and many cleared with combination oral and/or topical intervention. Its use during pregnancy will result in feminization of a male fetus. Combination use with OCs serves to limit this problem and improve results. Several months of treatment are usually required to see benefit.

Fig. 13.10 Adult woman with lower face acne.

Dexamethasone. Dexamethasone, 0.125–0.5 mg given once at night, reduces androgen excess and may alleviate cystic acne. Although corticosteroids are effective in the treatment of adult-onset adrenal hyperplasia, antiandrogens are often used in this setting.

Prednisone. Although corticosteroids may produce steroid acne, they are also effective antiinflammatory agents in severe and intractable acne vulgaris. In severe cystic acne and AC, corticosteroid treatment is effective; however, side effects restrict its use. Prednisone is generally only given to patients with severe inflammatory acne during the first 1 or 2 months of treatment with isotretinoin, for initial reduction of inflammation, and to reduce isotretinoin-induced flares.

Other Hormonal Agents. Finasteride, flutamide, estrogen, gonadotropin-releasing agonists, and metformin (by decreasing testosterone levels) have all showed a beneficial effect on acne. Because of side effects, expense, and other considerations, however, these agents are not typically used.

Oral Retinoid Therapy

Isotretinoin. Isotretinoin is approved only for severe cystic acne. However, it is useful in less severe forms of acne to prevent the need for continuous treatment and the repeated office visits required. A consensus of experts found that oral isotretinoin is warranted for severe acne, poorly responsive acne that improves by less than 50% after 3 months of therapy with combined oral and topical antibiotics, acne that relapses after oral treatment, scars, and acne that induces psychological distress. Other indications are gram-negative folliculitis, inflammatory rosacea, pyoderma faciale, acne fulminans, and AC.

This retinoid is a reliable remedy in almost all acne patients (Fig. 13.11). The dose of isotretinoin is 0.5–1 mg/kg/day in one or two daily doses. For severe truncal acne in patients who tolerate higher doses, up to 2 mg/kg/day may be given. In practice, most patients are started at 20–40 mg to avoid an early flare, then increased to 40–80 mg/day to limit side effects, which generally are dose related. Doses as low as 0.1 mg/kg/day are almost as effective as the higher doses in clearing acne; the disadvantage is that lower doses are less likely to produce a prolonged remission, even after 20 weeks of treatment. To achieve potentially prolonged remission, patients should receive 120–150 mg/kg over the treatment course. An easy way to calculate the total isotretinoin dose needed is to multiply the patient's weight in kilograms by 3. The product is the total number of 40-mg capsules needed to reach the low end of the dosage spectrum. Two groups reported treating patients with 1.5–2 mg/kg for a total dose of approximately 300 mg/kg. These patients had a low relapse rate, although side effects often limit tolerance of such dosages.

The major advantage of isotretinoin is that it is the only acne therapy that is not open ended (i.e., leads to a remission that may last many months or years). Approximately 40%–60% of patients remain acne free after a single course of isotretinoin. Approximately one half of the relapsing patients will need only topical therapy, with the others requiring oral treatments. Many patients in the latter category prefer to be retreated with isotretinoin because of

Fig. 13.11 (A) Severe back acne before isotretinoin. (B) Response to treatment.

its reliable efficacy and predictable side effects, which will be similar to those experienced in the first course. Many treated patients will require at least a second course of isotretinoin in 2 years.

Some subsets of patients tend to relapse more often. In patients under age 16 years, 40% need a second course of isotretinoin within 1 year and 73% within 2 years. Adult women and patients with mild acne tend to relapse more often and more quickly than severely affected 17- to 22-year-olds. Although patients' tolerance and response to repeated courses are similar to their experience with the first course, adult women who relapse may be better managed with hormonal therapies and mild acne treated with standard therapy.

In adult acne patients, who frequently tolerate the side effects of isotretinoin less well, lower doses and intermittent therapy are possible. In 80 adult acne patients treated with 0.5 mg/kg/day for 1 week in every 4 weeks over 6 months, acne resolved in 88%, and 39% relapsed after 1 year. In nine patients age 56–75 treated with 0.25 mg/kg/day for 6 months, all cleared and all except one remained clear 36 months later.

Patient education is critical in isotretinoin therapy. Its most serious adverse effect is the risk of severe damage to the fetus if given during pregnancy. Retinoid embryopathy is a well-defined syndrome characterized by craniofacial, cardiovascular, CNS, and thymus abnormalities. It is crucial that a woman of childbearing potential follow closely the manufacturer's recommendations. The use of consent forms, contraception education, and unequivocal documentation of the absence of pregnancy through monthly laboratory testing are important components of a U.S. Food and Drug Administration (FDA)–mandated verification program designed to prevent pregnancy during treatment. Women should not become pregnant until stopping medication for at least 1 month. Isotretinoin is not mutagenic, and there is no risk to a fetus while the male partner is taking the drug.

A second major area of educational emphasis concerns the psychological effects of the medication. Reports of depression, psychosis, suicidal ideation, suicide, and attempted suicide have prompted numerous studies of the mental health of patients taking isotretinoin. Although the usual outcome is improved mood because the disease clears, and a systematic review and meta-analysis found treatment did not appear to be associated with an increased risk of depression, a small number of patients have developed depression and have positive dechallenge and rechallenge tests. Close monitoring for depression, fully educating the patient, and enlisting the help of a roommate or family member to look for changes in mood are methods used to assess the psychological status of the patient taking isotretinoin.

Inflammatory bowel disease (IBD) is a third concern. Patients with IBD have been successfully treated with isotretinoin without flaring, but new-onset IBD in patients exposed to isotretinoin has been a concern. The age of onset of IBD overlaps with the age when acne will frequently be treated with isotretinoin and antibiotics. A meta-analysis has concluded that there was no increased risk of IBD or the subtypes. Long-term use of tetracycline medications and severe acne itself may be predisposing factors for IBD. Due to the past controversy, patients should be educated and monitored appropriately.

Other side effects of isotretinoin are dose dependent and generally not serious. Dry lips, skin, eyes, and oronasal mucosa occur in up to 90% of patients. These effects can be treated with moisturization. Dryness of the nasal mucosa leads to colonization by *S. aureus* in 80%–90% of treated patients. Skin abscesses, staphylococcal conjunctivitis, impetigo, facial cellulitis, and folliculitis may result. Such colonization can be avoided by the use of bacitracin ointment applied to the anterior nares twice daily during isotretinoin therapy. Arthralgias may occur but, as with other side effects, do not require interruption of therapy unless severe. Monitoring of serum lipids is done when initiating and increasing the dose because some patients will develop hypertriglyceridemia. This may be controlled by avoiding smoking and alcohol and following a low-fat diet. It should be emphasized that patients who develop this complication, as well as their family, are at risk for the development of the metabolic syndrome.

Liver function tests should be checked at regular intervals when initiating and increasing the dose. Isotretinoin should be taken with a high-fat meal to ensure excellent absorption. A formulation not requiring this type of meal is available.

Tumor Necrosis Factor Inhibitors. Adalimumab, etanercept, and infliximab have been reported in individual patients to improve or clear severe resistant acne. Some cases have been part of an inflammatory syndrome (e.g., SAPHO, PAPA, PASS) or found in patients with IBD. Paradoxically, acne has also been reported as an adverse reaction to these medications.

Intralesional Corticosteroids. Intralesional corticosteroids are especially effective in reducing inflammatory nodules. Triamcinolone acetonide at 10 mg/mL (Kenalog-10) is best diluted with

sterile normal saline solution to 2.5 mg/mL. Injecting less than 0.1 mL directly into the center of the nodule will help safeguard against atrophy and hypopigmentation.

Physical Modalities

Local surgical treatment is helpful in quickly resolving the comedones, although many clinicians wait until after 2 or more months of topical retinoid therapy to extract the remaining comedones. The edge of the follicle is nicked with a No. 11 scalpel blade, and the contents are expressed with a comedo extractor. Scarring is not produced by this procedure. Light electrode desiccation is an alternative. In isotretinoin-treated patients, macrocomedones present at weeks 10–15 may be expressed, because they tend to persist throughout therapy.

The use of photodynamic therapy and various forms of light, laser, or radiofrequency energy is under investigation. Such interventions clearly are capable of destroying sebaceous glands and killing *P. acnes*, but the methods to deliver such treatment in an efficient, cost-effective, safe, relatively pain free, and practical manner are still evolving. These treatments will be a welcome addition with the potential to provide care without the concerns associated with systemic drugs. More studies of larger patient populations with appropriate controls are needed to evaluate the role of light and related energy in the spectrum of acne therapy.

Complications

Even with the excellent treatment options available, scarring may occur. This may be quite prominent and often results from the cystic type of acne, although smaller lesions may produce scarring in some individuals. Pitted scars, wide-mouthed depressions, and keloids, primarily seen along the jawline and chest, are common types of scarring. These may improve spontaneously over 1 year or longer. Many treatment options are available. Procedures reported to be effective in improving appearance include chemical peeling; ablative, nonablative, and vascular laser therapy; skin needling or rolling; dermabrasion; scar excision; subcision; punch grafts alone or followed by dermabrasion or laser smoothing; intralesional corticosteroids or fluorouracil; fractionated laser resurfacing; fat transfer; and use of filler substances.

Other complications from acne are prominent residual hyperpigmentation, especially in darker-skinned patients (Fig. 13.12); pyogenic granuloma formation, which is more common in acne fulminans and in patients treated with high-dose isotretinoin; osteoma cutis, which consists of small, firm papules resulting from long-standing acne vulgaris; and solid facial edema. The latter is a persistent, firm facial swelling that is an uncommon but distressing result of acne vulgaris or acne rosacea. Both corticosteroids and isotretinoin have been reported to be effective treatments.

ACNE CONGLOBATA

Cystic acne is the mildest form of AC, an unusually severe type of acne. This form is characterized by numerous comedones (many of which are double or triple) and large abscesses with interconnecting sinuses, cysts, and grouped inflammatory nodules (Fig. 13.13). The cysts occur on the back, buttocks, chest, forehead, cheeks, anterior neck, and shoulders (Fig. 13.14). They contain a thick, yellowish, viscid, stringy, blood-tinged fluid. After incision and drainage, there is frequently a prompt refilling with the same type of material. Pronounced scars remain after healing.

Dissecting cellulitis of the scalp and hidradenitis suppurativa (HS) may be seen with AC, an association known as the "follicular occlusion triad." Gamma-secretase gene mutations may be responsible for familial cases of HS; one family with dominantly inherited AC also has expressed this trait. Additionally patients may present with the combination of pyoderma gangrenosum, AC, and suppurative hidradenitis (PASH) alone or with coexisting axial spondyloarthritis (PASS syndrome).

This severe and painful disease occurs most frequently in young men; it may extend and persist into adulthood and even into the fifth decade of life, especially over the posterior neck and back. Women are less frequently affected. Athletes and bodybuilders should be questioned about the use of anabolic steroids, which may induce such aggressive acne.

The therapy of choice is isotretinoin, 0.5–1 mg/kg/day to a total dose of 150 mg/kg, with a second course if resolution does not occur after a rest period of 2 months. Pretreatment with prednisone and low initial doses of isotretinoin, as described for acne fulminans, are recommended to avoid flaring of disease. Adalimumab, infliximab, and external beam radiation are other reported therapies. Four patients with PASH syndrome responded to intravenous combination antibiotic therapy given for 3–6 weeks followed by 4–6 week cycles of combined oral antibiotic therapy.

ACNE FULMINANS

Acne fulminans is a rare form of extremely severe cystic acne that occurs primarily in teenage boys. It is characterized by highly inflammatory nodules and plaques that undergo swift suppurative degeneration, leaving ragged ulcerations with hemorrhagic crusts, mostly on the chest and back. The face is usually less severely involved. Isotretinoin, especially when given in high initial doses, or anabolic steroids, may induce this condition.

Less commonly systemic signs and symptoms may accompany acne fulminans. Fever, polyarthralgia and polymyalgia, destructive arthritis, erythema nodosum, and myopathy have been reported. Leukocytosis, anemia, and focal lytic bone lesions often affecting the sternum, clavicles, hips and sacroiliac joints may be seen.

Prednisone is necessary during the initial 4–8 weeks to heal the dramatic lesions of acne fulminans. If isotretinoin induced the flare, it must be discontinued during this phase. After resolution of the inflammation 10–20 mg daily of isotretinoin is added. This should be slowly increased to standard doses and continued for a full 120–150 mg/kg cumulative course. Large cysts may be opened and the contents expressed. Intralesional corticosteroids will aid their resolution. Infliximab, etanercept, cyclosporine and dapsone are alternatives if isotretinoin is contraindicated.

SAPHO AND RELATED SYNDROMES

The SAPHO syndrome is characterized by synovitis, acne, pustulosis, hyperostosis, and osteitis. Skin findings may include acne fulminans, AC, pustular psoriasis, hidradenitis suppurativa, dissecting cellulitis of the scalp, Sweet syndrome, Sneddon-Wilkinson disease, and palmoplantar pustulosis. These may be present at the outset of the skeletal changes, but most often precede bone findings, or in 15% of adult cases and 70% of childhood cases, do not occur at all. The chest wall and mandible are the most common sites for musculoskeletal complaints in adults; the long bones, particularly the tibia, predominate in children. Bone changes of the anterior chest wall on nuclear scans are the most specific diagnostic findings.

Acquired hyperostosis syndrome (AHYS) and, in a familial setting of a dominantly inherited disorder, pyogenic sterile arthritis, pyoderma gangrenosum, and acne (PAPA syndrome) present with similar clinical scenarios. PAPA syndrome is caused by mutations in the gene for proline-serine-threonine-phosphatase interacting protein 1.

Systemic retinoids and tumor necrosis factor (TNF) antagonists, particularly infliximab, have been successful in treating these patients. If isotretinoin is used, it should be initiated at a low dosage, such as 10 mg/day, in combination with prednisone for the first month to prevent flaring of the disease. Anakinra, ustekinumab, methotrexate, sulfasalazine, and cyclosporine are other, less well-documented but likely effective choices. Pamidronate and other bisphosphonates such as ibandronate, alendronate, and zoledronic acid, are effective in treating the osteoarticular manifestations.

OTHER ACNE VARIANTS

Tropical Acne

Tropical acne is unusually severe acne occurring in the tropics during the seasons when the weather is hot and humid. Nodular, cystic, and pustular lesions occur chiefly on the back, buttocks, and thighs (Fig. 13.15). Characteristically, the face is spared. Conglobate abscesses occur often, especially on the back. Comedones are sparse. Acne tropicalis usually occurs in young adults who may have had acne vulgaris at an earlier age. This is especially true of those in the armed forces stationed in the tropics and carrying backpacks. Treatment is that for cystic acne, but acne tropicalis may persist until the patient moves to a cooler, less humid climate.

Acne Estivalis

Also known as Mallorca acne, this rare form of acne starts in the spring, progresses during the summer, and resolves completely in the fall. Acne estivalis affects almost exclusively women age 25–40. Dull-red, dome-shaped, hard, small papules, usually not larger than 3–4 mm, develop on the cheeks and usually extend on to the sides of the neck, chest, shoulders, and characteristically the upper arms. Comedones and pustules are notably absent or sparse. Acne estivalis does not respond to antibiotics but benefits from application of retinoic acid.

Excoriated Acne

Also known as picker's acne and acne excoriée des jeunes filles, excoriated acne is seen primarily in young women with a superficial type of acne. The primary lesions are trivial or even nonexistent, but the compulsive habit of picking the face and squeezing minute

Fig. 13.15 Tropical acne.

comedones produces secondary lesions that crust and may leave scars.

Excoriated acne may be a sign of depression or anxiety. If the patient admits to picking but being unable to stop this habit, improvement may follow support and acne therapy. However, most patients will require interventions with selective serotonin reuptake inhibitors, behavior modification, or psychotherapy. Other pharmacologic treatments that have been successful in case reports include doxepin, clomipramine, naltrexone, pimozide, and olanzapine.

ACNEIFORM ERUPTIONS

Acneiform eruptions are follicular eruptions characterized by papules and pustules resembling acne. Breaks in the epithelium and spillage of follicular contents into the dermis lead to the lesions. Eruptions are not necessarily confined to the usual sites of acne vulgaris, often have a sudden onset, are monomorphous, and usually appear in a patient well past adolescence. If secondary to a drug, an eruption begins within days of initiation of the medication, may be accompanied by fever and malaise, and resolves when the drug is stopped.

Acneiform eruptions may originate from skin exposure to various industrial chemicals, such as fumes generated in the manufacture of chlorine and its byproducts. These chlorinated hydrocarbons may cause chloracne, consisting of cysts, pustules, folliculitis, and comedones. The most potent acneiform-inducing agents are the polyhalogenated hydrocarbons, notably dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin). Cutting and lubricating oils, pomades, crude coal tar applied to the skin for medicinal purposes, heavy tar distillates, coal tar pitch, and asbestos are known to cause acneiform eruptions. Acne venenata or contact acne is another term applied to this process. Topical steroids, especially the fluorinated types or when applied under occlusion, topical tacrolimus and pimecrolimus may all induce a papulopustular eruption.

Acneiform eruptions are also induced by systemic medications such as iodides from radiopaque contrast media or potassium iodide, bromides in drugs such as propantheline bromide, testosterone, cyclosporine, antiepileptic medications, lithium, TNF-α antagonists, epidermal growth factor inhibitors, inhibitors of the RAS/RAF/MEK/ERK pathway, and systemic corticosteroids. When medium or high doses of corticosteroids are taken for as briefly as 3–5 days, a distinctive eruption may occur, known as steroid acne. It is a sudden outcropping of inflamed papules, most numerous on the upper trunk and arms (Fig. 13.16) but also seen on the face. The lesions typically present as papules rather than comedones; however, a histologic study confirmed they begin follicularly with microcomedone formation. Tretinoin 0.05% cream applied once or twice daily, may clear the lesions within 1–3 months despite the continuation of high doses of corticosteroid. Oral antibiotics and other typical acne medications are also effective. Epidermal growth factor inhibitors, including monoclonal antibodies and tyrosine and multikinase inhibitors used in cancer therapy, produce a folliculitis in the majority of treated patients as do inhibitors of the downstream signaling pathway. Often, oral minocycline and topical benzoyl peroxide are given prophylactically at the outset of the cancer therapy to prevent what may be a dose-limiting reaction. Radiation therapy for malignancy also can induce acne in the radiation port.

Fig. 13.16 Steroid acne.

Comedonal lesions may be limited to the nasal crease, in the flexural areas in children and on the temple and malar skin in Favre-Racouchot syndrome.

GRAM-NEGATIVE FOLLICULITIS

Gram-negative folliculitis occurs in patients who have had moderately inflammatory acne for long periods and have been treated with long-term antibiotics, mainly tetracyclines. During antibiotic treatment, patients develop either superficial pustules 3–6 mm in diameter, flaring out from the anterior nares, or fluctuant, deep-seated nodules (Fig. 13.17). Culture of these lesions usually reveals a species of *Klebsiella*, *Escherichia coli*, *Enterobacter*, or, from the deep cystic lesions, *Proteus*.

With long-term, broad-spectrum antibiotic therapy, the anterior nares may become colonized with these gram-negative organisms. As the use of long-term antibiotic therapy declines, this disease has become less common.

Isotretinoin is very effective and is the treatment of choice in gram-negative folliculitis. This treatment not only clears the acne component of the disease but also eliminates the colonization of

Fig. 13.17 Gram-negative folliculitis.

Fig. 13.19 Hidradenitis of the axilla.

Fig. 13.18 Acne keloidalis nuchae.

the anterior nares with gram-negative organisms. If isotretinoin cannot be tolerated or is contraindicated, amoxicillin or TMP-SMX may be effective in suppressing the disease.

ACNE KELOIDALIS

Acne keloidalis is most frequently encountered in young adult black, Hispanic, or Asian men who otherwise are in excellent health. It is not associated with acne vulgaris and is a primary cicatricial alopecia variant. There is a persistent folliculitis and perifolliculitis of the back of the neck that presents as inflammatory papules and pustules. Over time, fibrosis ensues with coalescence of firm papules into keloidal plaques, as on the neck (Fig. 13.18). At times, sinus tract formation results.

Histologically, acne keloidalis is characterized by perifollicular, chronic lymphocytic and plasmacytic inflammation, and lamellar fibroplasia most intense at the level of the isthmus and lower infundibulum of terminal hairs. In the keloidal masses the connective tissue becomes sclerotic, forming hypertrophic scars or keloids. Persistent free hairs in the dermis may be responsible for the prolonged inflammation and eventual scarring.

Topical therapy with potent steroid ointments or foams alone, or following twice-daily tretinoin gel, is useful for the follicular papules. Oral antibiotics of the tetracycline group may be added and are helpful in suppressing the inflammatory response. Ultraviolet B may improve it. Triamcinolone acetonide by intralesional injection, using 5–10 mg/mL into the inflammatory follicular lesions and 40 mg/mL into the hypertrophic scars and keloids, is useful in reducing inflammation and fibrosis. Smaller lesions may be excised to a level below the hair follicle and closed. This may be followed by 40 mg/mL triamcinolone by intralesional injection every 3 weeks. For larger lesions, deep excision or CO_2 laser ablation left to heal by primary intention may be necessary. Laser hair removal with the neodymium:yttrium-aluminum-garnet (Nd:YAG) laser may be used as a preventive measure against acne keloidalis.

HIDRADENITIS SUPPURATIVA

Clinical Features

Hidradenitis suppurativa is a chronic disease characterized by recurrent abscess formation, primarily within the folded areas of skin that contain both terminal hairs and apocrine glands. The primary site of inflammation is not the gland but the terminal hair. Plewig uses the term *dissecting terminal folliculitis* to unify diseases primarily affecting the terminal hair follicle, such as hidradenitis suppurativa, acne keloidalis nuchae, pilonidal sinus, and dissecting cellulitis of the scalp. The axilla is the most frequently affected site (Fig. 13.19). The inguinal and submammary areas are favored in women (Fig. 13.20), with the buttock, perianal area, and atypical areas (e.g., retroauricular, trunk) more often affected in men, although any and all areas may be involved in either gender. This postpubertal process has a prevalence of 0.1% in the United States. It disproportionately affects women, African Americans, and young people in the 18- to 29-year-old age range. Pediatric cases are uncommon; a hormonal investigation is essential in such patients.

The disease is characterized by the development of tender, red nodules, which at first are firm but soon become fluctuant and

Fig. 13.20 Hidradenitis of the groin.

painful. Rupture of the lesion, suppuration, formation of sinus tracts, and extensive scarring are distinctive. As one area heals, recurrent lesions form, so that the course of the disease is protracted. It may eventually lead to the formation of honeycombed, fistulous tracts with chronic infection. When a probe is used to explore the suppurating nodule, a burrowing sinus tract is usually detected that may extend for many centimeters, running horizontally just underneath the skin surface.

Disease severity varies, as does the impact on quality of life from this chronic, recurrent, painful, odiferous, messy condition. The majority affected by HS are mildly affected. Severe debilitation occurs more often in men than in women. Men also more often have a history of acne and pilonidal cysts. Squamous cell carcinoma (SCC, after an average 19 years of active disease), interstitial keratitis, spondyloarthropathy, urethral vesical and rectal fistulas, anemia, hypoproteinemia, pyoderma gangrenosum (PG), and amyloidosis have been reported to complicate hidradenitis suppurativa, but are rare. The diagnosis of PG is dependent on the presence of a rapidly expanding, painful ulcer with undermined edges. It occurs a median of 19 years after the onset of hidradenitis and may be at sites distant from or within the area of hidradenitis. Some of these patients may have associated conglobate acne (PASH) or PASS syndrome (see under Acne Conglobata). Significant lymphedema of the penis and groin, along with alteration of the anatomy because of surgical intervention, often makes physical examination of these sites difficult. The risk of SCC occurring as an ulceration or thickening in a skin crease, which can metastasize and cause death, requires attention to detail in this regard.

Etiology

Detailed histologic studies of HS reveal that terminal follicle hyperkeratosis is followed by rupture of the follicular epithelium and release of keratin, sebum, bacteria, and hairs into the dermis. The resulting inflammatory process leads to the characteristic clinical findings. The microbiome is altered and secondary bacterial infection with *S. aureus*, *Streptococcus pyogenes*, and various gram-negative organisms may occur. The initiating event is unknown. Comorbidities include inflammatory joint disorders, psychological disorders (anxiety and depression), obesity, metabolic syndrome, hypertension, dyslipidemia, diabetes, inflammatory bowel disease, and polycystic ovarian syndrome. Mechanical friction, often worsened by obesity, is an exacerbating factor, as is bacterial infection. There is an autosomal dominant inherited form of this disease. Mutations in the gamma-secretase genes *NCSTN*, *PSENEN*, and *PSEN1* have been identified. Mutation-positive patients have severe and extensive disease, and may have onset before age 13.

Differential Diagnosis

Hidradenitis is to be differentiated from common furuncles, which are typically unilateral. Hidradenitis must also be differentiated from Bartholin abscess, scrofuloderma, actinomycosis, granuloma inguinale, and lymphogranuloma venereum.

Treatment

Daily cleansing with chlorhexidine gluconate (Hibiclens) solution or benzoyl peroxide wash is an important preventive measure. Additionally, laser hair removal, if performed, should be done in unaffected sites as a preventive therapy. Other general preventive strategies include reduction of friction by wearing loose-fitting clothing and weight loss, if needed, avoidance of excessive sweating through the use of topical aluminum chloride or botulinum toxin A injections, smoking cessation, and heat avoidance. The recognition and treatment of any comorbid condition or complication is essential.

The earliest lesions often heal quickly with intralesional steroid therapy, which may be used initially in combination with topical clindamycin or oral doxycycline or minocycline. The disease itself causes sterile abscesses, but culture of the pus may reveal *S. aureus* or gram-negative organisms. The latter are usually cultured in patients with chronic disease given long-term antibiotic therapy; antibiotics should be selected based on sensitivities of the cultured organism for as short a time as practical to limit resistance. Antibiotics that may be useful in suppressing the disease include the tetracyclines, amoxicillin, TMP-SMX DS, or dapsone. The combination of clindamycin and rifampin, both given in doses of 300 mg twice daily, has been extensively studied in Europe and found to be quite effective. In severely affected patients, admission and treatment with intravenous ertapenem was reported to calm the disease so outpatient oral management might be effective. Incision and drainage is strongly discouraged.

The TNF antagonists have all been used; adalimumab is FDA approved following two large prospective trial that showed efficacy when dosed at 40 mg per week. Infliximab is also quite effective and may clear the condition during use. Isotretinoin is most effective in young women with mild to moderate disease, but a remission seldom follows their use. Secondary infection with *S. aureus* often occurs. Cyclosporine, acetretin, anakinra, or ustekinumab may work well in select cases. In women, spironolactone and OCs and finasteride in men or postmenopausal women may be a helpful adjuvant. Oral prednisone is uncommonly used to improve response to a primary agent when acute flares intervene; it should be given only in limited duration.

Photodynamic therapy and lasers have also been investigated to various degrees in hidradenitis. Methyl-aminolevulinate or 5-aminolevulinic acid given before blue or red light activation (photodynamic therapy) has had reports of success in some cases, but also anecdotal reports of lack of efficacy. It is inconvenient, costly, and often painful and does not produce remission, so further studies are required before such treatment can be recommended. Nd:YAG laser treatment has been reported to be effective in a prospective, randomized controlled trial of 22 severely affected patients. After a series of three monthly sessions, significant improvement was seen.

Once inflammation is controlled residual fibrosis is best addressed by excision of the affected areas. Wide surgical excision, using intraoperative color marking of sinus tracts, is most effective at limiting recurrence and has been shown to improve quality of life; however, it has moderate morbidity, especially in the groin and perianal areas with pain and symptomatic scarring being the

most common complication. The recurrence rate is low in the axillary and perianal areas; however, the inguinal folds and especially the submammary sites more often recur so that excision of the latter site is uncommonly recommended. CO_2 laser may also destroy lesions and sinus tracts. The open areas may be closed or left to heal secondarily.

Management in special situations such as pediatric cases and in pregnancy are addressed in excellent reviews by Liy-Wong et al. and Perng et al., respectively.

DISSECTING CELLULITIS OF THE SCALP

Also known as perifolliculitis capitis abscedens et suffodiens, this is an uncommon chronic suppurative disease of the scalp characterized by numerous follicular and perifollicular inflammatory nodules. These nodules suppurate and undermine to

Fig. 13.21 Dissecting folliculitis. (Courtesy Curt Samlaska, MD.)

form intercommunicating sinuses as long as 5 cm (Fig. 13.21). Scarring and alopecia ensue, although seropurulent drainage may last indefinitely. Adult black men are most often affected, and the vertex and occiput of the scalp are the favored sites.

The primary lesions are follicular and perifollicular erythematous papules that progress to abscesses. This disease is a variant of dissecting terminal hair folliculitis, along with hidradenitis suppurativa, acne keloidalis nuchae, and pilonidal sinus. Coagulase-positive *S. aureus* may be found in the lesions. Care to rule out tinea capitis, which may mimic this condition, is necessary.

Treatment with oral antibiotics such as the tetracyclines, TMP-SMX, or the quinolones may produce good results. If *S. aureus* is cultured, the combination of oral rifampin and clindamycin has produced excellent results. The combination of intralesional steroid injections and isotretinoin at a dose of 0.5–1.5 mg/kg/day for 6–12 months may be successful. Starting at a lower dose, such as 10 mg/day, for the first month or two may prevent a flare of the condition. The length of remission with isotretinoin is variable, but treatment may be repeated with similar results expected. The anti-TNF medications infliximab and adalimumab and the retinoid alitretinoin have been helpful in individual cases.

A surgical approach is sometimes necessary. Marsupialization or excision of sinus tracts may help limit inflammation. The Nd:YAG laser used to remove hair has led to long-term improvement. Excision of the entire scalp has been necessary in select patients.

Fig. 13.22 Erythrotelangiectatic rosacea.

ACNE MILIARIS NECROTICA (ACNE VARIOLIFORMIS)

Acne miliaris necrotica consists of follicular vesicopustules, sometimes occurring as solitary lesions that usually are extremely itchy. They appear anywhere in the scalp or adjacent areas, rupture early, and dry up after a few days. In some patients, especially those who manipulate the lesions, *S. aureus* may be cultured. If the lesions leave large scars, the term acne varioliformis is used; they are not separate diseases.

Treatment is with culture-directed antibiotics, or if the culture is negative, oral doxycycline. Doxepin is helpful if patients manipulate their lesions.

ROSACEA

Clinical Features

Rosacea is characterized by a persistent erythema of the convex surfaces of the face, with the cheeks and nose most frequently affected, followed by involvement of the brow and chin. There is a tendency to spare the periocular skin. Rosacea occurs most often in light-skinned women age 30–50. However, the severe type with phymatous changes occurs almost exclusively in men. Additional common features include telangiectasia, flushing, erythematous papules, and pustules. These tend to cluster in patterns, allowing for the identification of several subsets of patients. Although therapeutic decisions generally depend on individual signs and symptoms manifested, understanding the polar subtypes of erythrotelangiectatic (ETR) and glandular rosacea also has treatment-related implications. Whereas ETR patients are easily irritated and at times reveal a dermatitis surface, glandular patients are generally tolerant of interventions such as benzoyl peroxide and tretinoin.

The erythrotelangiectatic type is characterized by a prominent history of a prolonged (>10 minutes) flushing reaction to various stimuli, such as emotional stress, hot drinks, alcohol, spicy foods, exercise, cold or hot weather, or hot baths and showers (Fig. 13.22). Often, a burning or stinging sensation accompanies the flush, but with no sweating, lightheadedness, or palpitations. The skin is finely textured, may have a roughness and scaling of the affected central facial sites, and is easily irritated. Over time, a purplish suffusion and prominent telangiectasia may result.

The papulopustular subset of patients manifests a strikingly red central face accompanied by erythematous papules often surmounted by a pinpoint pustule (Fig. 13.23). The history of flushing is also present in most patients, but usually symptoms of irritancy are not prominent. The skin is of normal or at times slightly sebaceous quality, and edema of the affected sites may be present. Such edema may dominate the clinical presentation, with

Fig. 13.23 Papulopustular rosacea.

Fig. 13.24 Glandular rosacea.

the forehead, eyelids, and cheeks variably affected. This has been termed Morbihan disease and is most likely to complicate the papulopustular and glandular types.

In the glandular type of rosacea, men with thick, sebaceous skin predominate. The papules are edematous, the pustules are often 0.5–1.0 cm in size, and nodulocystic lesions may be present (Fig. 13.24). They tend to cluster in the central face, but in affected women the chin is favored. There is frequently a history of adolescent acne, and typical scars may be seen. Flushing is less common, as is telangiectasia, but persistent edema may be problematic. Rhinophyma most often occurs in this glandular subtype (Fig. 13.25). Large, hypertrophic, hyperemic nodular masses are centered over the distal half of the nose. Differentiation of this hypertrophic tissue from a basal cell skin cancer or a cutaneous B-cell lymphoma is at times difficult. Rarely, such soft tissue overgrowth can affect the chin, ears, or forehead. Hugely dilated follicles contain long, vermicular plugs of sebum and keratin. The histologic features are pilosebaceous gland hyperplasia with fibrosis, inflammation, and telangiectasia.

Fig. 13.25 Rhinophyma.

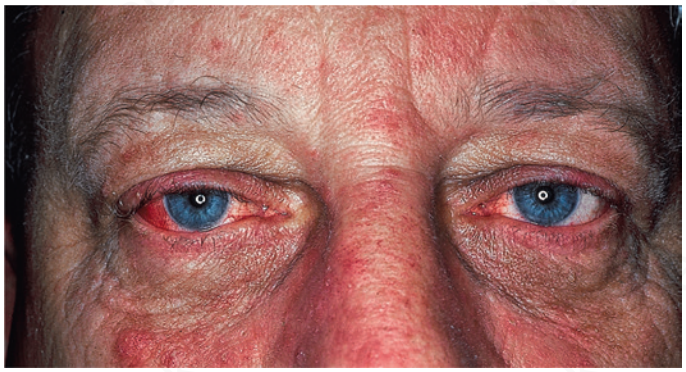

Fig. 13.26 Ocular rosacea.

Etiology

The cause of rosacea remains unknown. Many patients have an abnormal vasomotor response to thermal and other stimuli, as previously described. Early in the process, dysregulation of the innate immune system and neurovascular control is documented. Additionally, chronic solar damage is an important contributor in producing damage to the dermal matrix and ground substance, especially in the erythrotelangiectatic subtype. Chronic vasodilation, edema, and compromise of lymphatic drainage occur and lead to telangiectasia and fibrosis. Pilosebaceous unit abnormalities or androgen influences are not typically thought to be part of the pathogenesis of this condition; however, some evidence points to abnormalities being present in the patients with the glandular type. As expected, the pathogenic factors will vary among the subsets of patients. *Demodex* and *Helicobacter pylori* have been extensively investigated and do not appear to be central to the etiology of rosacea.

Other Clinical Considerations

Ocular Findings

Blepharitis, recurrent chalazion, and conjunctivitis may be seen in all subsets of rosacea (Fig. 13.26). The eye itself may be affected, with keratitis, iritis, and episcleritis. An abnormal Schirmer test occurs in 40% of rosacea patients. Complaints are often of a gritty, stinging, itchy, or burning sensation in the eye. Light sensitivity and a foreign body sensation are also present at times. Ocular rosacea occurs equally in men and women. Such eye findings may occur before the skin disease. These findings have therapeutic implications, and patients will not always complain of them to

their dermatologist, so these signs and symptoms should be actively sought when evaluating rosacea patients.

Extrafacial Lesions

Flushing may involve the ears, lateral facial contours, neck, upper chest, and scalp. Papules and pustules may be present in persistent erythema of the scalp or the earlobes.

Topical Corticosteroid Use

Long-term use of topical corticosteroids on the face may result in persistent erythema, papules, and pustules. The sites involved in steroid-induced rosacea correspond to the areas of application and are not necessarily limited to the central convexities. Treatment is discontinuance of the corticosteroid and institution of topical tacrolimus in combination with short-term doxycycline or minocycline. Topical tacrolimus itself has paradoxically been reported to induce a rosacea-like reaction, so coverage with an oral antibiotic while discontinuing topical steroids is necessary. Resolution with discontinuance of treatment is expected within 2 months. Additionally, drinking alcohol after application of tacrolimus or pimecrolimus may induce flushing, which may be confused with new-onset flushing related to rosacea.

Perioral Dermatitis

Although perioral dermatitis has been classified with rosacea variants, its distribution, signs, and symptoms vary such that it is discussed separately later in this chapter.

Granulomatous Lesions

Some patients with persistent facial erythema of the convexities, on biopsy of an erythematous papule, show a granulomatous response closely resembling sarcoidosis or a necrotizing granuloma. Many experienced clinicians will accurately predict such findings from the clinical examination. The most important consideration in this case is that the patient's response to treatment may be slower. When involvement of granulomatous facial papules includes the eyelids and upper lip and is not associated with vascular manifestations, such as flushing, erythema, or telangiectasia, the term *granulomatous facial dermatitis* is preferred. This condition is discussed separately.

Differential Diagnosis

The persistent erythema of the central face should be differentiated from that seen in polycythemia vera, carcinoid, mastocytosis, and connective tissue disease (lupus erythematosus, dermatomyositis, mixed connective tissue disease). These conditions do not have associated papules and pustules and will manifest a variety of systemic symptoms and extrafacial signs, and specific laboratory markers are available to confirm clinical suspicions. Haber syndrome is a genodermatosis characterized by a rosacea-like facial dermatosis and multiple verrucous lesions on non–sun-exposed skin. Onset of the facial lesions is in the first two decades of life, in contrast to the later onset of rosacea. Whereas rosacea may occur in human immunodeficiency virus (HIV) disease, a papulonodular eruption of the face that may simulate rosacea also occurs in patients with acquired immunodeficiency syndrome (AIDS) or other immunodeficiency states. On expressing the contents of hair follicles with a comedo extractor, numerous *Demodex* mites are seen. In such cases, success with permethrin cream and lindane has been reported. Lotions containing 5% benzoyl peroxide and 5% precipitated sulfur (Sulfoxyl) are also reported to be helpful.

Treatment

Treatments are directed at specific findings manifested by rosacea patients. Because erythema, telangiectases, papules and pustules, phymas, flushing, ocular symptoms, and skin sensitivity are variably present in the three subsets of disease, the specific approach used will differ according to the phenotypic findings. Some treatments, however, are useful in all patients.

General Nonpharmacologic and Nonsurgical Interventions

Sunscreens are an important component of therapy for all rosacea patients and should be applied each morning. Sunscreens containing physical blockers in a dimethicone or cyclomethicone vehicle generally are better tolerated, especially by the erythrotelangiectatic patients, than those with chemical agents and may be beneficial by strengthening the barrier function of the skin. General avoidance of irritants such as astringents, peeling or acidic agents, and abrasive or exfoliant preparations is recommended. Cosmetic coverage of the erythema and telangiectases is best with a light-green or yellow-tinted foundation set with powder.

If flushing is induced by specific trigger factors, these should be avoided as much as possible. The central face may be predisposed to rosacea because the edema and lack of movement of tissues with muscular movement may lead to lymphedema and inflammation. Circular massage for several minutes a day has led to impressive improvement. Custom-made compressive masks may also be helpful. This benign intervention may be considered and should be studied. Artificial tears and cleansing the lids with warm water twice daily will help ocular symptoms.

Topical Therapy

Metronidazole, sodium sulfacetamide and sulfur cleansers and creams, ivermectin, and azelaic acid are utilized in rosacea. These are the most commonly prescribed medications, are available in a variety of vehicles and are especially useful in treating the inflammatory papules in papulopustular patients. Benzoyl peroxide is a better choice in the papules and nodules seen in the glandular subset of rosacea patients. It is well tolerated by them. If oral antibiotics are needed, the topical products may be used to maintain remission after discontinuance of oral preparations.

Pimecrolimus or tacrolimus may also improve select patients' erythema, especially those with an accompanying roughness or scaling of the skin surface. Both agents help the irritated erythrotelangiectatic and at times the papulopustular patients but are not effective in the glandular type, and tacrolimus in its ointment base may exacerbate the inflammatory component in these patients. These drugs calm inflammation and abate symptoms but require brief (no longer than 1 week) pretreatment with a potent topical corticosteroid to be tolerated initially. The role of topical retinoids requires study. Many rosacea patients may tolerate a nighttime application of tretinoin if Cetaphil lotion is used immediately before use. Retinoids may help repair sun-damaged skin and normalize some of the abnormalities present. The α_2-adrenergic receptor agonist brimonidine is available as a gel for the treatment of facial redness. It is applied once in the morning, which induces vasoconstriction for up to 12 hours. Irritation, exacerbation of flushing, and allergy is not uncommon. Oxymetazoline, an alpha1A-adrenoceptor agonist, is a cream applied once in the morning to treat persistent erythema. It may also induce dermatitis or worsening of the disease.

Oral Therapy

Oral antibiotics, particularly doxycycline, in a subantimicrobial dose of 40-mg extended-release formulation, or 50–100 mg once or twice daily, usually controls more aggressive papular and pustular

lesions and helps treat ocular lesions. Oral antibiotics should be discontinued once clearance of the inflammatory lesions is obtained; usually, 2 or 3 months is necessary. The topical approved preparations listed earlier should be used as long-term maintenance after clearance with the oral medications, because the disease will recur in most patients if all therapy is stopped. If significant ocular symptoms are present, oral antibiotics are an effective and convenient method of relieving both the skin and the eye concerns. Cyclosporine ophthalmic emulsion is an effective topical for ocular rosacea. Isotretinoin given in lower doses than in acne vulgaris (0.3 mg/kg), and at times as a long-term suppressant, may be necessary for management of more resistant disease, including patients with a granulomatous histology. Isotretinoin produces dramatic improvement even in cases resistant to other forms of therapy, but relapse often occurs in a few weeks or months. The authors rarely use oral metronidazole (side effects) or the macrolides (lack of efficacy) despite their reported utility in rosacea.

Oral medications for reduction of flushing are infrequently helpful. Occasionally, an escalating dose of propranolol, carvedilol, or clonidine is helpful in reducing symptomatic flushing, but many affected patients find the side effects occur before the beneficial effects are evident. One method is to start propranolol at 10 mg three times daily, and if no response is seen in 2 weeks, to increase the dose by 10 mg at one dose, then again every 2 weeks until side effects require discontinuation or response occurs. Responses are mostly seen at a dose of 20–40 mg three times daily. Carvediol is started at 3.125 mg twice daily with slow titration to 12.5 mg twice daily depending on tolerance and response.

Surgical Intervention

Surgical approaches to the reshaping of rhinophyma have included the use of a heated scalpel, electrocautery, dermabrasion, laser ablation, tangential excision combined with scissors sculpting, and radiofrequency. Often, a combination of these approaches is used to obtain the best esthetic result. Lasers and light devices are useful for treating the erythema and telangiectases, but the cost is not covered by insurance, which limits their availability. In a comparative study, the pulsed dye laser and intense pulsed-light device both significantly reduced erythema, telangiectasia, and patient-reported symptoms and performed similarly well. Some vascular and CO_2 fractionated lasers may also help in dermal collagen remodeling and nonablative rejuvenation, such that the dermal matrix may be strengthened. For the patient incapacitated by flushing, burning, and stinging, endoscopic transthoracic sympathectomy may be considered, but this extreme measure should only rarely be considered because serious complications may result. An approach to these patients should include not only the medications previously discussed, but for those with significant dysesthesia, treatment with neuroleptics (e.g., gabapentin), tricyclic antidepressants, and pain-modifying antidepressants (e.g., duloxetine) may be necessary.

Other Considerations

Many articles investigating possible associated conditions have been published. Research methods differ, there are conflicting results in some cases, or the findings are yet to be confirmed. Continued research in this area is needed. There is a genetic predisposition to rosacea, with approximately half of the severity score accounted for by genetics and half by the environment. An advocacy group that supports research and education in rosacea, the National Rosacea Society, is an excellent resource for patients.

PYODERMA FACIALE (ROSACEA FULMINANS)

Pyoderma faciale is an uncommon eruptive facial disorder consisting of a dramatically fulminant onset of superficial and deep abscesses, cystic lesions (Fig. 13.27), and sometimes sinus tracts. Edema and at times an intense reddish or cyanotic erythema accompany this pustular process. The lesions often contain greenish or yellowish purulent material. The condition occurs mostly in postadolescent women. It is distinguished from acne by the absence of comedones, rapid onset, fulminating course, and absence of acne on the back and chest. Pyoderma faciale is differentiated from rosacea by the inconsistent history of flushing and of preexisting erythema or telangiectases of the convex portions of the face, and the large abscesses and nodules. After therapy, a residual erythema often persists.

Treatment is similar to that of acne fulminans. Oral steroids are given for several weeks, followed by the addition of isotretinoin, 10–20 mg daily, increasing to 0.5–1 mg/kg only after the acute inflammatory component is under control. Steroids may usually be discontinued after several weeks of isotretinoin, but the latter should be given for a full 120–150 mg/kg total dose. Because patients are predominantly women of childbearing age, pregnancy issues require full discussion. Indeed, four of Plewig et al.'s patients were pregnant and thus could not use isotretinoin. In such patients, amoxicillin, erythromycin, azithromycin, or clindamycin, all pregnancy category B drugs, may be considered.

PERIORAL DERMATITIS

Perioral dermatitis is a common eruption consisting of discrete papules and pustules on an erythematous and at times scaling base. It is a distinctive dermatitis confined symmetrically around the mouth, with a clear zone of about 5 mm between the vermilion border and the affected skin (Fig. 13.28). There is no itching, although an uncomfortable burning sensation may be present. It occurs in women age 20–35, however children are also commonly affected. The use of fluorinated topical corticosteroids is the most frequently identified cause. Exposure may be in the form of creams, ointments, or inhalers.

Treatment of perioral dermatitis includes discontinuing topical corticosteroids or protecting the skin from the inhaled product. Tacrolimus ointment 0.1% or pimecrolimus cream will prevent

flaring after stopping steroid use. In patients without steroid exposure, oral or topical antibiotics such as doxycycline in adults and erythromycin in children, and topical adapalene, azelaic acid, ivermectin, and metronidazole have all been successful in clearing the eruption.

Periorbital Dermatitis

Periorbital (periocular) dermatitis is a variant of perioral dermatitis occurring on the lower eyelids and skin adjacent to the upper and lower eyelids. Fluorinated topical corticosteroids have been implicated as the cause. If intranasal inhaled corticosteroids are used, a perinasal distribution may be seen. Prompt response to the same treatment employed in the perioral site is expected.

GRANULOMATOUS FACIAL DERMATITIS

Several dermatoses of the face characterized by granulomas are included in this category. Patients with persistent facial erythema involving one or more convex surfaces of the face may have lesions that show a granulomatous reaction histologically, and they are included within rosacea. Some patients have no other stigmata of rosacea, and their nosology is unclear. These other entities, which meet no other criteria for rosacea other than having pink papules on the face, are included here. Skowron et al. proposed the term *facial idiopathic granulomas with regressive evolution (FIGURE)*.

Lupus Miliaris Disseminatus Faciei

Firm, yellowish-brown or red, 1–3 mm, monomorphous, smooth-surfaced papules are present not only on the butterfly areas but also on the lateral areas, below the mandible, periorificially, and rarely in the axillae. The eyelid skin is characteristically involved in patients with lupus miliaris disseminatus faciei (LMDF) (Fig. 13.29). The discrete papules appear as yellowish brown lesions on diascopy and as caseating epithelioid cell granulomas histologically. Patients usually lack a history of flushing, do not have persistent erythema or telangiectasia, have involvement of the eyelids, and heal with scarring, as opposed to rosacea patients. Long-term therapy with minocycline or isotretinoin may be used, often with gratifying results. Eventually, self-involution is expected but may take several years. Tranilast, cyclosporine and nonablative fractionated laser resurfacing are other reported treatments.

Granulomatous Perioral Dermatitis in Children

In otherwise healthy prepubertal children, a profusion of grouped papules may develop on the perioral, periocular, and perinasal areas (Fig. 13.30). Eight of the initial 59 reported patients also had generalized lesions. Besides extremity and truncal lesions, several girls had dramatic lesions of the labia majora. Both genders are affected equally. Children with skin of color (Afro-Caribbean, African American, and Asian) dominate the reports, but white patients are also susceptible. Because the histologic appearance is granulomatous, sarcoidosis is often considered. Topical corticosteroids, however, may worsen the condition, and systemic involvement is not present. Topical metronidazole, ivermectin, erythromycin, sulfacetamide-sulfur combinations, and an oral macrolide or tetracycline-type antibiotic all are often effective. In some patients, the combination of prednisone and dapsone has proved beneficial.

14 Bacterial Infections

Bonus images for this chapter can be found online at expertconsult.inkling.com

Bacterial infections in the skin often have distinct morphologic characteristics that should alert the clinician that a potentially treatable and reversible condition exists. These cutaneous signs may be an indication of a generalized systemic process or simply an isolated superficial infection. Patients who have immunodeficiencies or are immunosuppressed may acquire severe or refractory pyogenic infections. Patients with atopic dermatitis are also predisposed to bacterial infections due to down regulation of antimicrobial peptides. The categorization of bacterial infections in this chapter first addresses diseases caused by gram-positive bacteria, followed by those caused by gram-negative bacteria, and then several miscellaneous diseases caused by the *Rickettsiae*, mycoplasmas, *Chlamydiae*, and spirochetes.

INFECTIONS CAUSED BY GRAM-POSITIVE ORGANISMS

STAPHYLOCOCCAL INFECTIONS

The skin lesions induced by the gram-positive staphylococci usually appear as pustules, furuncles, or erosions with honey-colored crusts. However, bullae, widespread erythema and desquamation, or vegetating pyodermas may also be due to *Staphylococcus aureus* infection. Purulent purpura may indicate bacteremia or endocarditis that can be caused by *S. aureus* or, in immunocompromised patients, *S. epidermidis*. Two distinctive cutaneous lesions that occur with endocarditis are the Osler node and Janeway lesion or spot. The Osler node is a painful, erythematous nodule with a pale center located on the fingertips. The Janeway spot is a nontender, angular hemorrhagic lesion of the soles and palms (Fig. 14.1). These lesions are likely caused by septic emboli leading to clogging of the distal vessels.

From 20%–40% of adults are colonized with *S. aureus* in the nares but the bacteria can also colonize hands and perineum, so this estimate is likely underestimating staphylococcal colonization. One study found that if only nares were cultured, 40% of carriage was missed and perineal colonization correlated better with the strain isolated from the abscess. Carriers are particularly prone to infections with *S. aureus* because of its continuous presence on the skin and nasal mucosa. Spread of infection in the hospital setting is frequently traced to the hands of a health care worker. Proper handwashing or sanitizing technique is essential in preventing spread of infection. Human immunodeficiency virus (HIV)–infected patients are at least twice as often nasal carriers, and they tend to harbor *S. aureus* in higher frequency and density at other sites of the body, thus predisposing them to skin and systemic infection.

Antibiotic resistance has become more common in *S. aureus*. Methicillin-resistant *S. aureus* (MRSA) is an important pathogen in nosocomial and community-acquired skin infections. MRSA infection may be suspected from knowledge of local patterns of resistance, lack of response to initial methicillin-sensitive *S. aureus* (MSSA)–directed therapy (e.g., cephalexin), and factors predisposing to colonization and infection with this organism. Predisposing factors for MRSA include age (>65), exposure to others with MRSA infection, prior antibiotic therapy, trauma to the skin, rectal or nasal colonization, crowded households, child care attendance, contact sports, chronic skin disease, pets, and recent hospitalization or chronic illness. The bacteria can be found on bed linens, remote controls, hand towels, and other inanimate objects, making decolonization very challenging. The primary treatment for an abscess remains drainage although newer literature suppports the addition of oral antibioitcs that may help lessen recurrence. Ideally, antibiotic choice is guided by culture and sensitivities. Often clindamycin, trimethoprim-sulfamethoxazole (TMP-SMX, alone or combined with rifampin), and doxycycline are effective. TMP-SMX and doxycycline do not cover group A streptococci; therefore if a mixed infection is suspected, adding cephalexin or penicillin is necessary, or clindamycin alone may treat both pathogens. Complicated infections with the most resistant strains may require antibiotics that nearly universally cover *S. Aurues* such as vancomycin, linezolid or tedizolid. Bacterial culture is the gold standard for establishing antibiotic susceptibility profiles and is increasingly necessary as resistance becomes more common. Superficial and localized infections may only require topical antibiotic therapy. Systemic antibiotics combined with topical therapy are recommended for patients with more widespread and deeper infections. A semisynthetic penicillin or a first-generation cephalosporin is recommended, unless MRSA is suspected, as detailed earlier. Treatment should generally be given for 7–10 days, although longer courses may sometimes be necessary

Primary Cutaneous Staphylococcal Infections

Staphylococcus can affect the skin locally and the therapy and prevention are similar so will be discussed together at the end of the section.

Impetigo

The bullous variety of impetigo caused by *S. aureus* occurs characteristically in newborns and young children, although it may occur at any age. The majority is caused by phage types 71 or 55 coagulase-positive *S. aureus* or a related group 2 phage type. Bullous impetigo may be an early manifestation of HIV infection. The neonatal type is highly contagious and can spread rapidly nurseries and day cares. In most cases, the disease begins between the fourth and tenth days of life with the appearance of bullae, which may appear on any part of the body but have a predilection for the face and perineum. Sources of the primary

Fig. 14.1 Janeway lesion in subacute bacterial endocarditis.

Fig. 14.2 Bullous impetigo. (Courtesy Steven Binnick, MD.)

infection may be the umbilical stump, circumcision, or other area of skin breakdown. Constitutional symptoms are absent at first, but staphylococcal scalded skin or more rarely disseminated infection can occur in neonates. Bacteremia, pneumonia, or meningitis rarely may develop. Any infection in a neonate under 6 weeks should be treated more aggressively, with strong consideration given for oral antibiotics. Herpes simplex infections in neonates can be lethal, so if there is any suspicion for herpes simplex virus (HSV), polymerase chain reaction (PCR) should be done to rule this out.

In warm climates particularly, adults may have bullous impetigo, most often in the axillae or groins, but also on the hands. The lesions are strikingly large, fragile bullae, suggestive of pemphigus and intact bullae may not be present (Fig. 14.2). When these rupture, they leave circinate, weepy, or crusted lesions, and in this stage it may be called impetigo circinata. Children with bullous impetigo (Fig. 14.3) may give a history of an insect bite at the site of onset of lesions. Smaller vesicles can be seen with streptococcal infections or herpes simplex. *Impetigo contagiosa* is a term used to encompass vesicles that might be from a staphylococcal, streptococcal, or combined infection (Fig. 14.4). It is characterized by discrete, thin-walled vesicles that rapidly become pustular and then rupture especially in the setting of atopic dermatitis. Impetigo on the scalp is a frequent complication of pediculosis capitis. In streptococcal-induced impetigo, regional lymphadenopathy is common, but not serious.

Most studies find that 50%–70% of cases are caused by *S. aureus*, with the remainder from either *S. pyogenes* or a combination of these two organisms. Streptococci may represent an early

Fig. 14.3 Bullous impetigo.

Fig. 14.4 Impetigo.

pathogen in the development of impetigo, with staphylococci replacing streptococci as the lesion matures. Group B streptococci are associated with newborn impetigo, and groups C and G are rarely isolated from impetigo, unlike the usual group A.

Impetigo occurs most frequently in early childhood, although all ages may be affected. It occurs in the temperate zone, mostly during the summer in hot, humid weather. Common sources of infection for children are pets, dirty fingernails, and other children in schools, day care centers, or crowded housing areas; sources for adults include infected children and self-inoculation from nasal or perineal carriage. Impetigo often complicates pediculosis capitis, scabies, HSV, insect bites, poison ivy, eczema, and other exudative, pustular, or itching skin diseases.

Group A β-hemolytic streptococcal skin infections (but not those from *S. aureus*) are sometimes followed by acute glomerulonephritis (AGN). Nephritogenic streptococci are generally associated with impetigo rather than with upper respiratory tract infections. The important factor predisposing to AGN is the serotype of the streptococcus producing the impetigo. Type 49, 55, 57, and 60 strains and strain M-type 2 are related to nephritis.

The incidence of AGN with impetigo varies from about 2%–5% (10%–15% with nephritogenic strains of streptococcus) and occurs most frequently in childhood, generally before age 6. The prognosis in children is mostly excellent, but in adults it is not as good. Treatment, however early and appropriate, is not believed to reduce the risk of AGN.

Impetigo may simulate several diseases. The circinate patches can be mistaken for tinea, but clinically are more crusted and eroded whereas tinea is scaling. Impetigo may be mistaken for *Toxicodendron* contact dermatitis due to the vesicles and bullae seen in both. Contact dermatitis is often in linear patterns and on exposed areas whereas impetigo tends to be discrete individual round bullae and erosions. Impetigo is also not associated with the eyelid puffiness, the linear lesions, or the itchiness typically present in dermatitis. In ecthyma, the lesions are crusted ulcers.

When treating impetigo, it is necessary to soak off the crusts frequently, after which an antibacterial ointment should be applied. Applying antibiotic ointment as a prophylactic to sites of skin trauma will prevent impetigo in high-risk children attending day care centers. In one study, infections were reduced by 47% with antibiotic ointment versus 15% with placebo. Additionally, if recurrent staphylococcal impetigo develops, a culture of the anterior nares may yield this organism. Such carrier states may be treated by application of mupirocin ointment to the anterior nares twice daily or by a 10-day course of rifampin, combined with dicloxacillin (for MSSA) or TMP-SMX (for MRSA).

Folliculitis

Folliculitis is the infection of hair follicles. *S. aureus* is the most common cause of folliculitis.

Superficial pustular folliculitis (impetigo of Bockhart) is a superficial folliculitis with thin-walled pustules at the follicle orifices. Susceptible locations are the extremities and scalp, although it is also seen on the face, especially periorally. These fragile, yellowish white, domed pustules develop in crops and heal in a few days.

Staphylococcal folliculitis can affect any hair-bearing areas, often on the trunk and extremities, but may affect areas such as the eyelashes, axillae, pubis, and thighs (Figs. 14.5 and 14.6). On the pubis, it may be transmitted among sexual partners, and "mini" epidemics of folliculitis and furunculosis of the genital and gluteal areas may be considered a sexually transmitted disease (STD). In the beard area, it is called sycosis vulgaris (sycosis barbae).

Sycosis vulgaris, also known as "barber's itch" or sycosis barbae, is a perifollicular, chronic, pustular staphylococcal infection of the bearded region characterized by inflammatory papules and pustules, and a tendency to recurrence (Fig. 14.7). The disease begins with erythema and burning or itching, usually on the upper lip near the nose. In 1 or 2 days, one or more pinhead-sized pustules, pierced by hairs, develop. These rupture after shaving or washing and leave an erythematous spot, which is later the site of a fresh crop of pustules. In this manner, the infection persists and gradually spreads, at times extending deep into the follicles. A hairless, atrophic scar bordered by pustules and crusts may result. Marginal blepharitis with conjunctivitis is usually present in severe cases of sycosis.

Sycosis vulgaris is to be distinguished from tinea, acne vulgaris, pseudofolliculitis barbae, and herpetic sycosis. Tinea barbae rarely affects the upper lip, which is a common location for sycosis. In tinea barbae, involvement is usually in the submaxillary region or on the chin, and spores and hyphae are found in the hairs. Pseudofolliculitis barbae manifests torpid papules at sites of ingrowing beard hairs in black men. In HSV infection, duration is usually only a few days, and even in persistent cases there are vesicles, which help to differentiate HSV from sycosis vulgaris.

Staphylococcal folliculitis has also been reported frequently in patients with acquired immunodeficiency syndrome (AIDS) and may be a cause of pruritus. An atypical, plaquelike form has been reported. Treatment of folliculitis is addressed later in this chapter.

Furunculosis

A furuncle, or boil, is an acute, round, tender, circumscribed, perifollicular staphylococcal abscess that generally ends in central suppuration (Fig. 14.8). A carbuncle is merely two or more confluent furuncles, with separate heads.

The lesions begin in hair follicles and often continue for a prolonged period by autoinoculation. Some lesions disappear before rupture, but most undergo central necrosis and rupture through the skin, discharging purulent, necrotic debris. Sites of predilection are the nape, axillae, and buttocks, but furuncles may occur anywhere. The integrity of the skin surface may be impaired by irritation, pressure, friction, hyperhidrosis, dermatitis, dermatophytosis, shaving, and other factors. Local barrier compromise predisposes to infection by providing a portal of entry for the ubiquitous *S. aureus*. The proximate cause is either contagion or autoinoculation from a carrier focus, usually in the nose or perineum. Furuncles are caused by invasion deeper into the skin and are commonly associated with MRSA. Hospital-acquired MRSA is often more resistant to antibiotics, although in recent years multidrug-resistant strains have been seen in patients who seemingly have no risk factors.

Certain systemic disorders may predispose to furunculosis: alcoholism; malnutrition; blood dyscrasias; disorders of neutrophil function; iatrogenic or other immunosuppression (e.g., AIDS); and diabetes (Fig. 14.9). Patients with several of these diseases, as well as those receiving renal dialysis or isotretinoin or acitretin therapy, are often nasal carriers of *S. aureus*. Additionally, atopic dermatitis also predisposes to the *S. aureus* carrier state, which helps explain the observed increases in the incidence of infections in these diseases. Epidemics of staphylococcal infections occur in hospitals. Marked resistance to antibacterial agents in these cases is common. Attempts to control these outbreaks center on meticulous handwashing. In nurseries, a fall in neonatal colonization and infections with *S. aureus* and non–group A streptococci may be achieved by using a 4% solution of chlorhexidine for skin and umbilical cord care.

Folliculitis may be treated with topical therapy or antibacterial washes. Topical antibiotics such as bacitracin, mupirocin, retapamulin ointment, and topical clindamycin are topical antistaphylococcal antibiotics. In addition to treating the individual pustules, benzoyl peroxide washes, dilute sodium hypochlorite baths (½ US cup bleach added to a 40-gallon tub of bathwater), and chlorhexadine washes are antimicrobials that can be helpful to decolonize the skin surface. Skin surface staphylococcal carriage in abrasions and eczematous areas may be addressed with these topical antibiotics, topical chlorhexidine washes, or dilute sodium hypochlorite (bleach) baths. Mupirocin ointment applied to the anterior nares daily for 5 days along with bleach baths may help prevent recurrence.

Early furuncles are incipient and acutely inflamed, and incision may not be possible because the abscess may not have collected yet; warm compresses and oral antibiotics are administered. When a furuncle has become localized and shows definite fluctuation, incision with drainage is indicated. When the inflammation is acute, hot wet soaks with aluminum acetate solution diluted 1:20 are beneficial. An anhydrous formulation of aluminum chloride (Drysol, Xerac-AC) is effective when used once nightly for chronic folliculitis, especially of the buttocks. Although drainage alone is effective for many lesions, a recent randomized trial showed that even in abscesses smaller than 5 cm antibiotic therapy with either clindamycin or TMP-SMX in addition to incision and drainage both increased initial cure rate and decreased rebound rate. In furuncles of the external auditory canal, upper lip, and nose, spontaneous drainage is common and a trial of antibiotic therapy may be attempted before surgical incision and drainage. In these patients, antibiotic ointment should be applied and antibiotics given internally. Warm saline-solution compresses should be applied liberally.

For folliculitis, a first-generation cephalosporin or penicillinase-resistant penicillin (e.g., dicloxacillin) is indicated, unless MRSA is suspected (see earlier). Methicillin-resistant and in some parts of the world vancomycin-resistant strains occur and, if suspected, are treated with trimethoprim-sulfamethoxazole, clindamycin, doxycycline, minocycline or linezolid based on cultures. In patients with staphylococcal infections unresponsive to empiric therapy, antibiotic-resistant strains should be suspected and sensitivities checked.

Despite treatment, recurrences of some boils may be anticipated. Usually, no underlying predisposing disease is present; rather, autoinoculation and intrafamilial spread among colonized individuals are responsible.

One of the most important factors in prevention is to avoid autoinoculation. It is important to emphasize that the nasal carrier state predisposes to chronic furunculosis. The skin surface in the region of the furuncles may be a source of colonization, especially if there are cuts, excoriation, or eczematous changes. In addition, the hazard of contamination from the perianal and intertriginous

areas must be considered. In general, indications for elimination of the carriage state are recurrent infection, evidence of spread to others, and high-risk individuals in the household. In addition the tubs of moisturizer used by atopic dermatitis patients can be a source of re-inoculation.

Routine precautions to take in attempting to break the cycle of recurrent folliculitis and furunculosis include a daily 4% for a week chlorhexidine wash, with special attention to the axillae, groin, and perianal area; laundering of bedding and clothing on a daily basis initially; use of bleach baths; and frequent handwashing. Additionally, the application of mupirocin ointment twice daily to the nares of patients and family members every fourth week has been found to be effective. Rifampin for 10 days, combined with dicloxacillin for MSSA or TMP-SMX for MRSA, or low-dose clindamycin for 3 months may also be effective in eradicating the nasal carriage state. The use of bacitracin ointment inside the nares twice daily throughout the course of isotretinoin therapy eliminates, or greatly reduces, the risk of inducing nasal carriage of *S. aureus* and thus staphylococcal infections.

Pyogenic Paronychia

Paronychia is an inflammatory reaction involving the folds of the skin surrounding the fingernail (Fig. 14.10). It is characterized by acute or chronic tender, and painful swelling of the tissues around the nail that at first will be red and then pustular, caused by an abscess in the nailfold. When the infection becomes chronic, horizontal ridges appear at the base of the nail. With recurrent bouts, new ridges appear.

The primary predisposing factor that is identifiable is separation of the eponychium (cuticle) from the nail plate. The separation is usually caused by trauma as a result of moisture-induced maceration of the nailfolds from frequent wetting of the hands. The relationship is close enough to justify treating chronic paronychia as a work-related condition in bartenders, food servers, nurses, and others who often wet their hands. The moist grooves of the nail and nailfold become secondarily invaded by pyogenic cocci and yeasts. Alternatively children with atopic dermatitis can inoculate bacteria under the nail by scratching infected atopic dermatitis resulting in a paronychia of the distal finger under the nail. The causative bacteria are usually *S. aureus*, *Streptococcus pyogenes*, *Pseudomonas* species, *Proteus* species, or anaerobes. The pathogenic yeast is most frequently *Candida albicans*.

The bacteria usually cause acute abscess formation *(Staphylococcus)*, or erythema and swelling *(Streptococcus)*, and *C. albicans* most frequently causes a chronic swelling. If an abscess is suspected, applying light pressure with the index finger against the distal volar aspect of the affected digit will better demonstrate the extent of the collected pus by inducing a well-demarcated blanching. Smears of purulent material will help confirm the clinical impression and drain the abscess allowing more rapid improvement. Myrmecial warts may mimic paronychia. Subungual black macules, followed by edema, pain, and swelling, have been reported as a sign of osteomyelitis caused by *S. aureus* or *Streptococcus viridans*, in children with atopic dermatitis.

Treatment of pyogenic paronychia consists mostly of protection against trauma and concentrated efforts to keep the affected fingernails meticulously dry. Rubber or plastic gloves over cotton gloves should be used whenever the hand must be placed in water. Acutely inflamed pyogenic abscesses should be incised and drained. The abscess may often be opened by pulling the nailfold away from the nail plate but sometime the area must be cleansed with alcohol and a needle or blade be used to drain the abscess. In acute suppurative paronychia, especially if stains show pyogenic cocci, a semisynthetic penicillin or a cephalosporin with excellent staphylococcal activity should be given orally. If these are ineffective, MRSA or a mixed–anaerobic bacteria infection should be suspected. Treatment dictated by the sensitivity of the cultured organism will improve cure rates. Rarely, long-term antibiotic therapy may be required.

Although *Candida* is the most frequently recovered organism in chronic paronychia, topical or oral antifungals lead to cure in only about 50% of cases. If topical corticosteroids are used to decrease inflammation and allow for tissue repair, there may be a higher cure rate. Often, an antifungal liquid such as miconazole is combined with a topical corticosteroid cream or ointment in candidal chronic paronychia.

Fig. 14.10 Acute paronychia.

Botryomycosis

Botryomycosis is an uncommon, chronic, indolent disorder characterized by nodular, crusted, purulent lesions (Fig. 14.11). Sinuses that discharge sulfur granules are present. These heal with atrophic scars. The granules most frequently yield *S. aureus* on culture, although cases caused by *Pseudomonas aeruginosa*, *Escherichia coli*, *Proteus*, *Bacteroides*, and *Streptococcus* have been reported.

Fig. 14.11 Botryomycosis. (Courtesy Dermatology Division, University of Campinas, Brazil.)

Botryomycosis often occurs in patients with altered immune function, such as those with neutrophilic defects. Other predisposing factors include diabetes, HIV infection, alcoholism, and Job syndrome. Appropriate antibiotics, surgical drainage, and surgical excision are methods used to treat botryomycosis.

Blastomycosis-like Pyoderma

Large, verrucous plaques with elevated borders and multiple pustules occur. Most patients with blastomycosis-like pyoderma have some underlying systemic or local host compromise. Bacteria such as *S. aureus*, *P. aeruginosa*, *Proteus*, *E. coli*, or streptococci may be isolated. Antibiotics appropriate for the organism isolated are curative; however, response may be delayed and prolonged therapy required. Acitretin may also be useful.

Invasive and Systemic Staphylococcal Infections

Pyomyositis

S. aureus abscess formation within the deep, large, striated muscles usually presents with fever and muscle pain and is called pyomyositis. It is typically hematogenous in origin. Pyomyositis is more common in the tropics, where it may affect adults but most frequently occurs in children. In temperate climates, it occurs in children and patients with AIDS. The most frequent site in tropical disease is the thigh, whereas in HIV-infected patients, the deltoid muscle is most often involved, followed closely by the quadriceps. Swelling and occasionally erythema or yellow or purplish discoloration are visible signs of pyomyositis, but these are late findings. Non–*S. aureus* infections may also cause this same clinical picture. Magnetic resonance imaging (MRI) with gadolinium injection will help delineate the extent of disease. Drainage of the abscess and appropriate systemic antibiotics are the recommended treatment.

Staphylococcal Scalded Skin Syndrome

Staphylococcal scalded skin syndrome (SSSS) is a generalized, confluent, superficially exfoliative disease, occurring most often in neonates and children under 5 years of age. It occurs rarely in adults, usually with renal compromise or immunosuppression as a predisposing factor. SSSS is a febrile, rapidly evolving, desquamative infectious disease in which the skin exfoliates in sheets. SSSS is differentiated from Stevens-Johnson syndrome (SJS)/toxic epidermal necrolysis (TEN) based on the level of the epidermal separation and the fact that SSSS does not affect mucous membranes. The skin does not separate at the dermoepidermal junction, as in toxic (drug-induced) TEN, but within the granular layer. The lesions are thus much more superficial and less severe than in TEN, and healing is much more rapid. SSSS is caused by exfoliative exotoxins types A and B, elaborated by the staphylococcus in remote sites. Usually, staphylococci are present at a distant focus, such as the pharynx, nose, ear, or conjunctiva. Septicemia or a cutaneous infection may also be the causative focus.

Clinical manifestations of SSSS begin abruptly with skin redness and tenderness concentrated in the perioroficial areas of the face along with the intertriginous areas (neck, groin, axillae and inguinal folds). Fever is variable and the peeling first starts usually around the eyes, nose and mouth. The redness is often described as simulating a sunburn. The areas of red eventually slough with large sheets of skin being lost (Fig. 14.12). There is sparing of the palms, soles, and mucous membranes. Nikolsky sign is positive and blisters will often form where children are picked up or where electrocardiogram leads are attached and removed. Generalized exfoliation follows within the next hours to days, with large sheets of epidermis separating. Rarely true bullae can form if the sloughing skin is not disrupted. Group 2 *S. aureus*, usually phage types 71 or 55, is

Fig. 14.12 Staphylococcal scalded skin syndrome.

the causative agent in most cases. If taken, cultures should be obtained from a primary site of infection if one can be identified or the nares, perianal area or periocular areas. The red skin and desquamation are sterile because the split is caused by the distant effects of the exfoliative toxins, unlike in bullous impetigo, where *S. aureus* is present in the lesions.

Rapid diagnosis of SSSS can be made by examining frozen sections of a blister roof and observing that the full thickness of the epidermis is not necrotic, as in TEN, but rather is cleaved below the granular layer. The exfoliative toxins A, B, and D specifically cleave desmoglein 1, the antigenic target of autoantibodies in pemphigus foliaceus, thus accounting for the clinical and histologic similarity to pemphigus observed in SSSS and bullous impetigo. In mucous membranes, desmoglein 3 is more prominent than desmoglein 1 and thus because the toxin only targets desmoglien 1 mucous membranes are characteristically spared in SSSS. Treatment of choice is a penicillinase-resistant penicillin such as dicloxacillin combined with fluid therapy and general supportive measures. Addition of clindamycin may help target the bacteria's ability to form the toxin due to its antiribosomal mechanism but as clindamycin resistance is becoming more common, clindamycin should not be used alone without cultures that prove susceptibility to clindamycin. Recent studies have shown SSSS is more commonly caused by MSSA. If MRSA is cultured and response is sluggish, antibiotics directed according to the susceptibility of the recovered organism are needed. The prognosis is excellent in children, but mortality rates in adults can reach 60%.

Gram-Positive Toxic Shock Syndromes

Toxic shock syndrome (TSS) is an acute, febrile, multisystem illness, with one of its major diagnostic criteria being a widespread macular erythematous eruption. It is usually caused by toxin-producing strains of *S. aureus*, most of which were initially isolated from the cervical mucosa in menstruating young women. Patients who don't have TSST-1 toxin antibodies are more susceptible to TSS. Currently, cases are most often caused by infections in wounds, catheters, contraceptive diaphragms, infections of bone, lung, or soft tissue or nasal packing. Mortality in these nonmenstrual cases is higher (up to 20%) compared with menstrual-related cases (<5%), probably as a result of delayed diagnoses. Also, a similar syndrome has been defined in which the cause is group A, or rarely group B, streptococci. This latter multiorgan disease has

Fig. 14.13 Desquamation of the palms and soles.

systemic components similar to classic staphylococcal TSS; however, the infection is usually a rapidly progressive, destructive soft tissue infection such as necrotizing fasciitis. Underlying chronic illness, recent varicella, and use of nonsteroidal antiinflammatory drugs (NSAIDs) may predispose to TSS. It has a case-fatality rate of 30%. The streptococci are usually of M-types 1 and 3, with 80% of the isolates producing pyrogenic exotoxin A.

The Centers for Disease Control and Prevention (CDC) case definition of staphylococcal TSS includes a temperature of 38.9°C (102°F) or higher, an erythematous eruption, desquamation of the palms and soles 1–2 weeks after onset (Fig. 14.13), hypotension, and involvement of three or more other systems: gastrointestinal (GI; vomiting, diarrhea), muscular (myalgias, increased creatinine kinase level), mucous membrane (hyperemia), renal (pyuria without infection or raised creatinine or blood urea nitrogen levels), hepatic (increased bilirubin/serum glutamic oxaloacetic transaminase/serum glutamic pyruvic transaminase), hematologic (platelets <100 000/mm^3), or central nervous system (CNS; disorientation). In addition, serologic tests for Rocky Mountain spotted fever, leptospirosis, and rubeola, and cultures of blood, urine, and cerebrospinal fluid (CSF) should be negative. Procalcitonin, an indicator of severe bacterial infection, may be a biologic marker for the toxic shock syndromes. Bulbar conjunctival hyperemia and palmar edema are two additional clinical clues. Streptococcal TSS is defined by isolation of group A β-hemolytic streptococci, hypotension, and two or more of the following: renal impairment, coagulopathy, hepatic involvement, acute respiratory distress syndrome, a generalized erythematous macular eruption that may desquamate, and soft tissue necrosis, myositis, or gangrene.

Histologic findings are spongiosis and neutrophils scattered throughout the epidermis, individual necrotic keratinocytes, perivascular and interstitial infiltrates composed of lymphocytes and neutrophils, and edema of the papillary dermis. TSS must be differentiated from viral exanthems, Kawasaki disease, scarlet fever, recurrent toxin-mediated perianal erythema, drug eruptions, Rocky Mountain spotted fever, systemic lupus erythematosus (SLE), TEN, and SSSS.

Treatment of TSS consists of systemic antibiotics such as vancomycin, which may be combined with nafcillin, in critically ill adult patients; vigorous fluid therapy to treat shock; and drainage of the *S. aureus*–infected site.

STREPTOCOCCAL SKIN INFECTIONS

Specific diseases caused by direct infection with *Streptococcus pyogenes* and its toxins, as discussed in this chapter, also have immune-mediated consequences, including acute rheumatic fever, chronic rheumatic heart disease, guttate psoriasis and acute poststreptococcal glomerulonephritis. The first two only occur after pharyngitis or tonsillitis but guttate psoriasis can occur after perianal streptococcal infection especially in younger children. Although most of such complications occur in resource-poor countries, the global burden of these sequelae is significant.

Ecthyma

Ecthyma is an ulcerative streptococcal or less commonly staphylococcal pyoderma. The disease begins with a vesicle or vesicopustule, which enlarges and in a few days becomes thickly crusted. The vesicles of streptococcal ecthyma can mimic HSV especially in the setting of atopic dermatitis. When the crust is removed, there is a superficial, saucer-shaped ulcer with a raw base and elevated edges (Fig. 14.14). In urban areas, these lesions are caused by *S. aureus* and are seen in intravenous drug users and HIV-infected patients.

The lesions tend to heal after a few weeks, leaving scars, but rarely may proceed to gangrene when resistance is low. Debilitated patients often have a focus of pyogenic infection elsewhere. Local adenopathy may be present. Uncleanliness, malnutrition, and trauma are predisposing causes.

Fig. 14.14 Ecthyma.

Treatment includes cleansing with soap and water after soaking off the crust with compresses, followed by the application of mupirocin, retapamulin, or bacitracin ointment, twice daily. Oral dicloxacillin or a first-generation cephalosporin is also indicated, with adjustments made according to the cultured organism's susceptibilities.

Scarlet Fever

Scarlet fever is a diffuse, erythematous exanthem that occurs during the course of streptococcal pharyngitis. It affects primarily children, who develop the eruption 24–48 hours after onset of pharyngeal symptoms. The tonsils are red, edematous, and covered with exudate. The tongue has a white coating through which reddened, hypertrophied papillae project, giving the so-called white strawberry tongue appearance (as opposed to the red strawberry tongue of Kawasaki that lacks an exudate). By the fourth or fifth day the coating disappears, the tongue is bright red, and the red strawberry tongue remains.

The cutaneous eruption begins on the neck, then spreads to the trunk and finally the extremities (Fig. 14.15). Within the widespread erythema are 1–2 mm papules, which give the skin a rough, sandpaper quality. There is accentuation over the skinfolds, and a linear petechial eruption, called Pastia lines, is often present in the antecubital and axillary folds. There is facial flushing and circumoral pallor. A branny desquamation occurs as the eruption fades, with peeling of the palms and soles taking place about 2 weeks after the acute illness. The latter may be the only evidence that the disease has occurred.

The eruption is produced by erythrogenic exotoxin-producing group A streptococci. Cultures of the pharynx will recover these organisms. Rarely, scarlet fever may be related to a surgical wound or burn infection with streptococci. An elevated antistreptolysin O or DNase B titer may provide evidence of recent infection if cultures are not taken early. A condition known as staphylococcal scarlatina has been described that mimics scarlet fever; however, the strawberry tongue is not seen.

Penicillin, erythromycin, or dicloxacillin treatment is curative for scarlet fever, and the prognosis is excellent.

Fig. 14.15 Scarlet fever.

Fig. 14.16 (A and B) Erysipelas.

Recurrent Toxin-Mediated Perineal Erythema

This condition manifests as a perineal, erysipelas-like erythema that resolves with desquamation. Strawberry tongue, erythema of the hands with desquamation, and a mild fever 1 or 2 days before the eruption are other signs. In some patients, a staphylococcal or streptococcal pharyngitis, impetigo, or perianal streptococcal dermatitis is present. There may be recurrences in individual patients. Streptococcal pyrogenic exotoxins A and B or TSS toxin 1 may be responsible for the skin findings.

Erysipelas

Also once known as St. Anthony's fire and ignis sacer, erysipelas is an acute β-hemolytic group A streptococcal infection of the skin involving the superficial dermal lymphatics. Occasional cases caused by streptococci of group C or G are reported in adults. Group B *streptococcus* is often responsible in the newborn and may be the cause of abdominal or perineal erysipelas in postpartum women. It is characterized by local redness, heat, swelling, and a highly characteristic raised, indurated border (Fig. 14.16A). The onset is often preceded by prodromal symptoms of malaise for several hours, which may be accompanied by a severe constitutional reaction with chills, high fever, headache, vomiting, and joint pains. There is usually a polymorphonuclear leukocytosis of 20,000 cells/mm^3 or more. However, many cases present solely as an erythematous lesion without associated systemic complaints.

The skin lesions may vary from transient hyperemia followed by slight desquamation to intense inflammation with vesicles or bullae. The eruption begins at any one point as an erythematous patch and spreads by peripheral extension. In the early stages, affected skin is bright red, hot to the touch, branny, and swollen. A distinctive feature of the inflammation is the advancing edge of the patch. This is raised and sharply demarcated and feels like a wall to the palpating finger. In some cases, vesicles or bullae that contain seropurulent fluid occur and may result in local gangrene.

The legs and face are the most common sites affected. On the face, the inflammation generally begins on the cheek near the nose or in front of the lobe of the ear and spreads upward to the scalp, with the hairline sometimes acting as a barrier against further extension. On the legs, edema and bullous lesions are prominent features in many patients (Fig. 14.16B). Septicemia, deep cellulitis, necrotizing fasciitis, and abscess formation may be complications, especially in obese patients and those with chronic alcohol abuse. Predisposing causes are surgical wounds, which may lead to gluteal and thigh involvement; fissures in the nares, in the auditory meatus, under the earlobes, on the anus or penis, and between or under the toes, usually the little toe; abrasions or scratches; venous insufficiency; obesity; lymphedema; and chronic leg ulcers.

Recognition of erysipelas generally is not difficult. It may be confused with contact dermatitis from plants, drugs, or dyes and with angioneurotic edema, but with each of these, fever, pain, and

tenderness are absent and itching is severe. A butterfly pattern on the face may mimic lupus erythematosus, and ear involvement may suggest relapsing polychondritis.

Systemic penicillin is rapidly effective although since *S. Aureus* cellulitis maybe in the differnetial diagnosis, use of an antibiotic that will cover both is often indicated. Improvement in the general condition occurs in 24–48 hours, but resolution of the cutaneous lesion may require several days. Vigorous treatment with antibiotics should be continued for at least 10 days. Locally, ice bags and cold compresses may be used. Leg involvement, especially when bullae are present, will more likely require hospitalization with intravenous antibiotics. Elderly patients, those with underlying immunocompromise, a longer duration of illness before presentation, and patients with leg ulcers will require longer inpatient stays. A small group will have recurrent disease, in whom long-term antibiotic prophylaxis may be beneficial.

Cellulitis

Cellulitis is a suppurative inflammation involving the subcutaneous tissue. Often, cellulitis follows a wound. On the leg, tinea pedis is a common portal of entry. Mild local erythema and tenderness, malaise, fever and chills may be present but are not necessary for diagnosis. The erythema rapidly becomes intense and spreads (Fig. 14.17). The area may infiltrated and pit on pressure. The central part may become nodular and surmounted by a vesicle that ruptures and discharges pus and necrotic material. Streaks of lymphangitis may spread from the area to the neighboring lymph glands (Fig. 14.18). Gangrene, metastatic abscesses, and severe sepsis may follow. These complications are unusual in immunocompetent adults, but children and immunocompromised adults are at higher risk.

The diagnosis of bacterial cellulitis is usually made on clinical grounds. It is uncommon for blood studies, including cultures, and skin biopsies or aspirates to be positive. If, however, an open wound is present, a culture may be positive. Streptococci continue to cause approximately 75% of cases and staphylococci the majority of the remainder. Stasis dermatitis may mimic cellulitis. It does not hurt or cause fever, may be circumferential or centered over the medial malleoli, and is usually bilateral. Allergic contact dermatitis is itchy but not painful. Eosinophilic cellulitis is an exuberant response to an insect bite and can simulate cellulitis but typically has less pain and instead of neutrophilia, there is often an eosinophilia. Erythema migrans (Lyme disease) can also present with a red patch but is typically less painful than cellulitis.

Patients with cellulitis without systemic toxicity can be managed as outpatients. Initial empiric therapy with dicloxacillin or cephalexin for 5 days will usually suffice. If MRSA is strongly suspected because of risk factors, treatment strategies are as outlined for staphylococcal infections at the start of this chapter.

Fig. 14.17 Cellulitis.

Chronic Recurrent Erysipelas, Chronic Lymphangitis

Erysipelas or cellulitis may be recurrent. Predisposing factors include alcoholism, diabetes, immunodeficiency, tinea pedis, venous stasis, lymphedema with or without lymphangiectasias, prosthetic surgery of the knee, a history of saphenous phlebectomy, lymphadenectomy, or irradiation. Chronic lymphedema is the end result of recurrent bouts of bacterial lymphangitis and obstruction of the major lymphatic channels of the skin. The final result is a permanent hypertrophic fibrosis called elephantiasis nostras. It must be differentiated from lymphangioma, acquired lymphangiectasia, and other causes such as neoplasms or filariasis.

During periods of active lymphangitis, antibiotics in large doses are beneficial, and their use must be continued in smaller maintenance doses, for long periods to achieve their full benefits. Compression therapy to decrease lymphedema may aid in the prevention of recurrence.

Necrotizing Fasciitis

Necrotizing fasciitis is an acute necrotizing infection involving the fascia. It may follow surgery, perforating trauma or may occur de novo. In young children, there are peaks of incidence in the neonatal period and children 1–2 years of age and the fasciitis was more often truncal and caused by one pathogen than in older patients. Within 24–48 hours, redness, pain, and edema quickly progress to central patches of dusky-blue discoloration, with or

Fig. 14.18 Lymphangitis.

Fig. 14.19 Necrotizing fasciitis.

without serosanguineous blisters (Fig. 14.19). Anesthesia of the involved skin is characteristic. By the fourth or fifth day, these purple areas become gangrenous. Many forms of virulent bacteria have been cultured from necrotizing fasciitis and it may be polymicrobial. Pathogens isolated include microaerophilic β-hemolytic streptococci, hemolytic staphylococcus, coliforms, enterococci, *Pseudomonas*, and *Bacteroides*. Both aerobic and anaerobic cultures should always be taken.

Early surgical debridement is an essential component of successful therapy. Laboratory studies may help in assessing the risk of a patient having necrotizing fasciitis. One scoring system gives points for abnormalities in C-reactive protein, white blood cell count, hemoglobin, sodium, creatinine, and glucose. Based on the total score, patients are stratified into low-risk, medium-risk, and high-risk categories. Aside from direct surgical visualization, the most definitive confirmatory test is MRI. At the bedside, the clinician may infiltrate the site with anesthetic, make a 2-cm incision down to the fascia, and probe with the finger. Lack of bleeding, a murky discharge, and lack of resistance to the probing finger are ominous signs. If done, a biopsy should be obtained from normal-appearing tissue near the necrotic zone. Treatment should include early surgical debridement, appropriate IV antibiotics, and supportive care. Intravenous immune globulin (IVIG) has not been shown to improve mortality rates. Mortality rate may be 20% even in the best of circumstances. Poor prognostic factors are age over 50, underlying diabetes or atherosclerosis, delay of more than 7 days in diagnosis and surgical intervention, and infection on or near the trunk rather than the more often involved extremities. Neonatal necrotizing fasciitis most frequently occurs on the abdominal wall and has a higher mortality rate than in adults.

Blistering Distal Dactylitis

Blistering distal dactylitis is characterized by tense superficial blisters occurring on a tender erythematous base over the volar fat pad of the phalanx of a finger or thumb or occasionally a toe (Fig. 14.20). The typical patient is age 2–16 years. Group A β-hemolytic streptococci is most typical although if more purulent Bullous impetigo from *S. aureus* can have a similar appearance. These organisms may be cultured from blister fluid.

Fig. 14.20 Blistering dactylitis.

Fig. 14.21 Perianal dermatitis.

Perianal Dermatitis

Clinically, perineal dermatitis presents most often as a superficial, perianal, well-demarcated rim of erythema (Fig. 14.21); fissuring may also be seen. Pain or tenderness, especially prominent on defecation, may lead to fecal retention in affected patients, who are usually between ages 1 and 8. It may not resemble cellulitis, but rather dermatitis. It may also affect the vulvar and penile tissues. Group A streptococci are most often the cause; however, *S. aureus* may be recovered rarely, and when this occasionally occurs in adults, the usual cause is group B streptococci. The vast majority of infections are caused by streptococci, so a systemic penicillin or erythromycin combined with a topical antiseptic or antibiotic is the treatment of choice. Perianal streptococcal infections can lead to flares of guttate psoriasis especially in young children who are less likely to get streptococcal pharyngitis. The duration should be 14–21 days, depending on clinical response. Posttreatment swabs and urinalysis to monitor for poststreptococcal glomerulonephritis are recommended.

Streptococcal Intertrigo

Infants and young children may develop a fiery-red erythema and maceration in the neck, axillae, or inguinal folds. There are no satellite lesions. It may be painful and have a foul odor. Streptococcal intertrigo can be mistaken for candidal intertrigo but streptococcal infections are generally more painful and macerated and lack the satellite pustules of candida infections. Group A β-hemolytic streptococci are the cause, and topical antibiotics and oral penicillin are curative in streptococcal intertrigo.

Fig. 14.22 Erythema marginatum.

Erythema Marginatum

Delayed nonsuppurative sequelae of streptococcal infections include erythema nodosum, poststreptococcal glomerulonephritis, and rheumatic fever. The latter only follows pharyngitis or tonsillitis, but two skin signs are among the diagnostic criteria of rheumatic fever: erythema marginatum and subcutaneous nodules. The remaining major signs making up the revised Jones criteria are carditis, polyarthritis, and chorea. Erythema marginatum appears as a spreading, patchy erythema that migrates peripherally and often forms polycyclic configurations (Fig. 14.22). It is evanescent, appearing for a few hours or days on the trunk or proximal extremities and typically spares the face. Heat may make it more visible, and successive crops may appear over several weeks. It is usually part of the early phase of the disease, coexisting with carditis but usually preceding the arthritis. Children younger than 5 years are more likely to manifest the eruption than older patients. A skin biopsy will show a perivascular and interstitial polymorphonuclear leukocyte predominance. In contrast, the subcutaneous nodules occur over bony prominences and appear as a late manifestation. The lesions of erythema marginatum usually are asymptomatic and resolve spontaneously.

Group B Streptococcal Infection

Streptococcus agalactiae is the major cause of bacterial sepsis and meningitis in neonates. It may cause any type of cellulitis including orbital cellulitis or facial erysipelas in these patients. Up to 25% of healthy adults harbor group B streptococci in their genital or GI tract. A guideline by Money et al. emphasizes prevention of such disastrous infections in the newborn through culture identification of mothers at risk and prophylactic antibiotics before delivery in culture-positive women. Skin and soft tissue infections caused by *Strep. agalactiae* in adult commonly can lead to invasive disease and bacteremia. *S. agalactiae* has been reported to cause balanitis, vulvar pain due to fine fissures with minimal erythema, toxic shock–like syndrome, cellulitis, perianal dermatitis, recurrent erysipelas, or blistering dactylitis in adults. Diabetes mellitus, neurologic impairment, cirrhosis, and peripheral vascular disease predispose patients to infection with *S. agalactiae.* In the postpartum period, abdominal or perineal erysipelas may be caused by this organism.

Streptococcus iniae Infections

Cellulitis of the hands may be caused by the fish pathogen *Streptococcus iniae*. The bacteria is inoculated when punctures and cuts occur while cleaning freshly killed fish before cooking. Freshwater dolphins and farm-raised fish both can carry the bacteria. Preparation of other raw seafood may also lead to *S. iniae* infection. Within 24 hours, fever, lymphangitis, and cellulitis without skin necrosis or bulla formation occur. Treatment with penicillin is curative. A similar scenario occurred with a newly described species, *Streptococcus hongkongensis* sp nov. Amoxicillin-clavulanate was effective in the one reported case.

MISCELLANEOUS GRAM-POSITIVE SKIN INFECTIONS

Erysipeloid of Rosenbach

The most frequent form of erysipeloid is a sharply marginated and often polygonal patch of purplish erythema (Fig. 14.23). The first symptom is pain at the site of inoculation, followed by swelling and erythema. The erythema slowly spreads to produce a sharply defined, slightly elevated zone that extends peripherally as the central portion fades away. If the finger is involved, the swelling and tenseness make movement difficult. Vesicles frequently occur.

Another characteristic of the disease is its migratory nature; new purplish red patches appear at nearby areas. If the infection originally involved one finger, eventually all the fingers and the dorsum of the hand, the palm, or both may become infected, with the erythema appearing and disappearing; or extension may take place by continuity. The disease involutes without desquamation or suppuration. A diffuse or generalized eruption in regions remote from the site of inoculation may occur, with fever and arthritic symptoms. Rarely, septicemia may eventuate in endocarditis, with prolonged fever and constitutional symptoms.

The infection is caused by *Erysipelothrix rhusiopathiae*. *E. rhusiopathiae* is present on dead matter of animal origin. Swine are more frequently infected than any other animal. Turkeys are also often infected, and the disease may arise from handling contaminated dressed turkeys. It is also present in the slime of saltwater fish, on crabs, and on other shellfish. The disease is widespread along the entire Atlantic seacoast among commercial fishermen. The infection also occurs among veterinarians and in the meatpacking industry, principally from handling pork products. *E. rhusiopathiae* is a rod-shaped, nonmotile, gram-positive organism that tends to form long-branching filaments. The organism is cultured best on media fortified with serum, at room temperature.

Fig. 14.23 Erysipeloid.

Treatment

The majority of the mild cases of erysipeloid run a self-limited course of about 3 weeks. In some patients, after a short period of apparent cure, the eruption reappears either in the same area or, more likely, in an adjacent, previously uninvolved area. Penicillin, 1 g/day for 5–10 days, or ampicillin, 500 mg four times daily, is the best treatment for localized disease. If penicillin cannot be used, imipenem or piperacillin-tazobactam are effective. For systemic forms, 12–20 million units/day of IV penicillin for up to 6 weeks may be necessary.

Werner K, et al: Erysipeloid (*Erysipelothrix rhusiopathiae* infection) acquired from a dead kakapo. Arch Dermatol 2011; 147: 1456.

Pneumococcal Cellulitis

Cellulitis may be caused by *Streptococcus pneumoniae*. Children present with facial or periorbital cellulitis, which may manifest a violaceous hue or bullae. Most patients under 36 months of age are previously healthy. Fever, leukocytosis, and septicemia are almost universal. Response to treatment with penicillin or, in resistant cases, vancomycin is excellent. Most responsible strains are included in the pneumococcal vaccine, so this condition has become rare, as has *Haemophilus influenzae* cellulitis. Chronically ill or immunosuppressed adults may develop pneumococcal cellulitis or other soft tissue infections, such as abscesses or pyomyositis. In patients with diabetes or substance abuse, extremity involvement is the rule, whereas in those with SLE, nephritic syndrome, hematologic disorders, or HIV disease, the head, neck, and upper torso are typically affected. Skin involvement may also be seen as a surgical wound infection. Because septicemia, tissue necrosis, and suppurative complications are common, aggressive management is crucial, with surgical drainage and IV antibiotics directed at the susceptibility of the cultured organism.

Khan T, Martin DH: *Streptococcus pneumoniae* soft tissue infections in human immunodeficiency virus. Am J Med Sci 2011; 342: 235.

Anthrax

Cutaneous anthrax is uncommon in much of the world; human infection generally results from contact with infected animals or the handling of hides or other animal products from stock that has died from splenic fever. Cattlemen, woolsorters, tanners, butchers, and workers in the goat-hair industry are most liable to infection. Human-to-human transmission has occurred from contact with dressings from lesions. The spores of *Bacillus anthracis* persist and may be aerosolized, so it is a bioterrorism threat.

Anthrax is an acute infectious disease characterized by a rapidly necrosing, painless eschar with associated edema and suppurative regional adenitis (Fig. 14.24). Four forms of the disease occur in humans: *cutaneous*, accounting for 95% of cases worldwide and almost all U.S. cases; *inhalational*, known as woolsorter's disease; *gastrointestinal*, the first case of which occurred in the United States in 2010; and *injectional*, more than 50 cases of which occurred in the United Kingdom and Germany. It is a complication of IV drug use, primarily in heroin addicts.

Fig. 14.24 Anthrax with severe edema. (Courtesy Steve Krivda, MD.)

The first clinical manifestation of the cutaneous form is an inflammatory papule, which begins about 3–7 days after inoculation, usually on an exposed site. The inflammation develops rapidly, and a bulla surrounded by intense edema and infiltration forms within another 24–36 hours. It then ruptures spontaneously, and a black eschar is visible, surrounded by vesicles situated on a red, hot, swollen, and indurated area. The lesion is neither tender nor painful. This is of diagnostic importance. Pustules are almost never present. The regional lymph glands become tender and enlarged and frequently suppurate.

In patients with severe disease, the inflammatory signs increase; there is extensive edematous swelling, and other bullae and necrotic lesions develop, accompanied by a high temperature and prostration, terminating in death in a few days or weeks. This may occur in up to 20% of untreated patients. In mild cases, the constitutional symptoms are sometimes slight; the gangrenous skin sloughs, and the resulting ulcer heals.

Internally, inhalational anthrax and GI infection are manifested as necrotic hemorrhagic lesions followed by bacteremia, always ending in death. Patients with injectional disease present with fever and swelling of an extremity.

The disease is produced by *Bacillus anthracis*, a large, square-ended, rod-shaped gram-positive organism that occurs singly or in pairs in smears from the blood or in material from the local lesion, or in long chains on artificial media, where it tends to form spores. The bacillus possesses three virulence factors: a polyglutamate acid capsule inhibiting phagocytosis; an edema toxin, composed of edema factor and a transport protein termed protective antigen; and lethal toxin, composed of lethal factor plus protective antigen.

A biopsy should be obtained. This allows for immunohistochemical and PCR studies, as well as routine histology and tissue Gram stain. Microscopically, there is loss of the epidermis at the site of the ulcer, with surrounding spongiosis and intraepidermal vesicles. Leukocytes are abundant in the epidermis. The dermis is edematous and infiltrated with abundant erythrocytes and neutrophils. Vasodilation is marked. The causative organisms are numerous and are easily seen, especially with Gram stain.

The diagnosis is made by demonstration of the causative agent in smears and cultures of the local material. The characteristic gangrenous lesion, surrounded by vesiculation, intense swelling and redness, lack of pain, and the patient's occupation are accessory factors. PCR identification is readily available due to its bioterrorism threat. Staphylococcal carbuncle is the most easily confused entity, but here tenderness is prominent.

Early diagnosis and prompt treatment with ciprofloxacin (500 mg) or doxycycline (100 mg), twice daily for 60 days, are curative in the cutaneous form when there are no systemic symptoms, lesions are not on the head or neck and are without significant edema, and the patient is not a child younger than 2 years. In these latter conditions, more aggressive IV therapy is required, as outlined in the CDC management guidelines available at the CDC website. Asymptomatic exposed individuals should be given prophylactic treatment with a 6-week course of doxycycline or ciprofloxacin. A vaccine is available.

Listeriosis

Listeria monocytogenes is a gram-positive bacillus with rounded ends that may be isolated from soil, water, animals, and asymptomatic individuals. Human infection probably occurs through the GI tract; in the majority of patients, however, the portal of entry is unknown. Infections in humans usually produce meningitis or encephalitis with monocytosis. Risk factors include alcoholism, advanced age, pregnancy, and immunosuppression.

Cutaneous listeriosis is a rare disease. Veterinarians may contract cutaneous listeriosis from an aborting cow. The organism in the skin lesions is identical to that isolated from the fetus. The eruption consists of erythematous tender papules and pustules scattered over the hands and arms. There may be axillary lymphadenopathy, fever, malaise, and headache.

Neonates are also at risk. Endocarditis, meningitis, and encephalitis caused by *Listeria* may be accompanied by petechiae, pustules, and papules in the skin.

Cases of listeriosis may easily be missed on bacteriologic examination, because the organism produces few colonies on original culture and may be dismissed as a streptococcus or as a contaminant diphtheroid because of the similarity in gram-stained specimens. Serologic tests help to make the diagnosis.

Listeria monocytogenes is sensitive to most antibiotics. Ampicillin combined with gentamicin is the treatment of choice, and TMP-SMX is an effective alternate.

Zelenik K, et al: Cutaneous listeriosis in a veterinarian with evidence of zoonotic transmission. Zoonoses Public Health 2014; 61: 238.

Cutaneous Diphtheria

Cutaneous diphtheria is common in tropical areas. Most of the U.S. cases are in nonimmunized migrant farmworker families and in elderly alcoholics. Travelers to developing countries may also import disease.

Skin lesions are caused by infection with *Corynebacterium diphtheria* or *ulcerans*, usually in the form of ulcerations. The ulcer is punched out and has hard, rolled, elevated edges with a pale-blue tinge. Often, the lesion is covered with a leathery, grayish membrane. Regional lymph nodes may be affected. Other types of skin involvement include eczematous, impetiginous, vesicular, and pustular lesions. Postdiphtherial paralysis and potentially fatal cardiac complications may occur. These are mediated by a potent exotoxin, which stops protein production at the ribosome level.

Treatment consists of intramuscular (IM) injections of diphtheria antitoxin, 20,000–40,000 U, after a conjunctival test has been

performed to rule out hypersensitivity to horse serum. Erythromycin, 2 g/day, is the drug of choice, unless large proportions of resistant organism are known in the area. In severe cases, IV penicillin G, 600,000 U/day for 14 days, is indicated. Rifampin, 600 mg/day for 7 days, will eliminate the *C. diphtheria* carrier state. The reservoir for *C. ulcerans* is thought to be animals.

Corynebacterium jeikeium Sepsis

Corynebacterium jeikeium colonizes the skin of healthy individuals, with the highest concentration being in the axillary and perineal areas. Hospitalized patients are more heavily colonized. Patients with granulocytopenia, indwelling catheters, prosthetic devices, exposure to multiple antibiotics, and valvular defects are at highest risk for the development of sepsis or endocarditis. A papular eruption, cellulitis, subcutaneous abscesses, tissue necrosis, hemorrhagic pustules, and palpable purpura may be seen on the skin. Vancomycin is the drug of choice. Mortality rate is greater than 30% in those with leukopenia.

Olson JM, et al: Cutaneous manifestations of *Corynebacterium jeikeium* sepsis. Int J Dermatol 2009; 48: 886.

Erythrasma

Erythrasma is characterized by sharply delineated, dry, brown, slightly scaling patches occurring in the intertriginous areas (Fig. 14.25), especially the axillae, the genitocrural crease, and the webs between the fourth and fifth toes and less often the third and fourth toes. There may also be patches in the intergluteal cleft, perianal skin, and inframammary area. The vulvar mucosa can be affected by thick, desquamating, yellowish hyperkeratosis. Rarely, widespread eruptions with lamellated plaques occur. The lesions are asymptomatic except in the groin, where there may be some itching and burning. Patients with extensive erythrasma have been found to have diabetes mellitus or other debilitating diseases.

Erythrasma is caused by the diphtheroid *Corynebacterium minutissimum*. This non–spore-forming, rod-shaped, gram-positive organism may occasionally cause cutaneous granulomas or bacteremia in immunocompromised patients. Two other diseases caused by *Corynebacterium*, pitted keratolysis and trichomycosis axillaris, may occur as a triad with erythrasma. In the differential diagnosis, tinea cruris caused by fungi, intertrigo, seborrheic dermatitis, inverse psoriasis, candidiasis, and lichen simplex chronicus must be considered.

Fig. 14.25 Erythrasma. (Courtesy Steven Binnick, MD.)

The Wood's light is the diagnostic medium for erythrasma. The affected areas show a coral-red fluorescence, which results from the presence of a porphyrin. Washing of the affected area before examination may eliminate the fluorescence. Topical erythromycin solution or topical clindamycin is easily applied and rapidly effective. Oral erythromycin (250 mg four times daily for 2 weeks) and clarithromycin (single 1-g dose) are equally effective.

Arcanobacterium haemolyticum Infection

This pleomorphic, nonmotile, non–spore-forming, β-hemolytic, gram-positive bacillus causes pharyngitis and an exanthem in young adults. Acute pharyngitis in the 10- to 30-year-old age group is only caused by group A streptococci in 10%–25% of cases. Some of the remainder is caused by *Arcanobacterium haemolyticum*.

The exanthem is an erythematous morbilliform or scarlatiniform eruption involving the trunk and extremities. Although it usually spares the face, palms, and soles, atypical acral involvement has been reported. The general clinical presentation may include mild pharyngitis, severe diphtheria-like illness, or even septicemia. It may also cause cellulitis or ulcerations in the elderly.

Cultures for *A. haemolyticum* should be done on 5% blood agar plates and observed for 48 hours. The diagnostic features are enhanced by a 5%–8% CO_2 atmosphere during incubation at 37°C. Routine pharyngeal specimens are done on sheep blood agar and will miss the growth of this organism because of its slow hemolytic rate and growth of normal throat flora. The treatment of choice is erythromycin, or in the case of severe infection, high-dose penicillin G.

Miyamoto H, et al: Bacteriological characteristics of *Arcanobacterium haemolyticum* isolated from seven patients with skin and soft-tissue infections. J Med Microbiol 2015; 64: 369.

Intertrigo

Intertrigo is a superficial inflammatory dermatitis occurring where two skin surfaces are in apposition. It is discussed here because of its clinical association with several bacterial diseases in this chapter. As a result of friction (skin rubbing skin), heat, and moisture, the affected fold becomes erythematous, macerated, and secondarily infected. There may be erosions, fissures, and exudation, with symptoms of burning and itching. Intertrigo is most frequently seen during hot and humid weather, chiefly in obese persons. Children and elderly persons are also predisposed. This type of dermatitis may involve the retroauricular areas; the folds of the upper eyelids; the creases of the neck, axillae, and antecubital areas; finger webs; inframammary area; umbilicus; inguinal, perineal, and intergluteal areas; popliteal spaces; and toe webs.

As a result of the maceration, a secondary infection by bacteria or fungi is induced. The inframammary area in obese women is most frequently the site of intertriginous candidiasis. The groin is also frequently affected by fungal (yeast or dermatophyte)

infection. Bacterial infection may be caused by streptococci, staphylococci, *Pseudomonas*, or *Corynebacterium*. If *Pseudomonas* is involved, it may stain the underwear bluish green. Streptococcal intertrigo favors the neck, axillary, and inguinal folds of young children. There is a well-demarcated, fiery-red, moist, shiny surface and a foul smell, with an absence of satellite lesions.

The differential diagnosis includes seborrheic dermatitis, intertriginous psoriasis, erythrasma, and if the groin lesions are fissured, Langerhans cell histiocytosis.

Treatment of intertrigo is directed at elimination of maceration. Appropriate antibiotics or fungicides are applied locally. Separating the apposing skin surfaces with gauze or InterDry Ag textile is helpful. The latter has an antimicrobial silver complex impregnated within the fabric that when placed in the folded area not only wicks away moisture, but also retains the activity against fungi and bacteria for up to 5 days. Botulinum toxin type A has been used to dry out areas predisposed to recurrent disease. Castellani paint is also useful, as is an antibacterial ointment. Low-potency topical corticosteroids and topical tacrolimus are helpful to reduce inflammation, but these should always be used in conjunction with a topical antifungal or antimicrobial agent.

Pitted Keratolysis

In pitted keratolysis, a bacterial infection of the plantar stratum corneum, the thick, weight-bearing portions of the soles become gradually covered with shallow, asymptomatic, discrete round pits 1–3 mm in diameter, some of which become confluent, forming furrows (Fig. 14.26). Men with very sweaty feet during hot, humid weather are most susceptible. Rarely, palmar lesions may occur. No discomfort is produced, although the lesions are often malodorous.

Fig. 14.26 Pitted keratolysis. (Courtesy Shyam Verma, MBBS, DVD.)

Most disease is caused by *Kytococcus sedentarius*. It produces two serine proteases that can degrade keratin. Clinical diagnosis is not difficult, based on its unique appearance. Histologic examination generally demonstrates keratin pits lined by small cocci as well as filamentous bacteria.

Topical erythromycin, mupirocin, or clindamycin is curative in pitted keratolysis. Miconazole or clotrimazole cream and Whitfield ointment are effective alternatives. Both 5% benzoyl peroxide gel and a 10%–20% solution of aluminum chloride may be used. Botulinum toxin helps if there is associated hyperhidrosis.

CLOSTRIDIAL INFECTIONS AND GANGRENE OF THE SKIN

Gangrene of the skin results from loss of the blood supply of a particular area and, in some cases, from bacterial invasion that promotes necrosis and sloughing of the skin. The various forms of bacterial infection causing gangrene are discussed here. The infectious causes are often severe and acute and may involve deep tissues; MRI may delineate the depth of involvement. Vascular gangrene, purpura fulminans, and diabetic gangrene are covered in Chapter 35 and necrotizing fasciitis earlier in this chapter.

Gas Gangrene (Clostridial Myonecrosis)

Gas gangrene is the most severe form of infectious gangrene (Fig. 14.27); it develops in deep lacerations of muscle tissue. The incubation period is only a few hours. Onset is usually sudden and is characterized by a chill, a rise in temperature, marked prostration, and severe local pain. Gas bubbles (chiefly hydrogen) produced by the infection cause crepitation when the area is palpated. A mousy odor is characteristic. A plain radiograph will demonstrate the air. Gas gangrene is caused by a variety of *Clostridium* species, most frequently *Clostridium perfringens*, *C. oedematiens*, *C. septicum*, *C. difficile*, and *C. haemolyticum*. These are thick, gram-positive rods. *Clostridium* spores are resistant to skin sterilization chemicals; if injecting a site that is being soiled by stool incontinence, a mechanical wash before the sterile procedure, followed by an occlusive sterile dressing, is recommended.

Fig. 14.27 Clostridial ulcer. (Courtesy Steven Binnick, MD.)

A subacute variety of gas gangrene may be caused by an anaerobic streptococcus (peptostreptococcus), *Bacteroides*, or *Prevotella*. This nonclostridial myositis may be clinically similar, but with delayed onset (several days). The purulent exudate has a foul odor, and gram-positive cocci in chains are present. It is important to distinguish these two entities, because involved muscle may recover in nonclostridial myositis, and debridement may safely be limited to removal of grossly necrotic muscle. Infections with both clostridial and nonclostridial organisms such as *Streptococcus faecalis*, *S. anginosus*, *Proteus*, *E. coli*, *Bacteroides*, and *Klebsiella* species may also cause crepitant cellulitis, when the infection is limited to the subcutaneous tissue. Treatment of all clostridial infections is wide surgical debridement and intensive antibiotic therapy with IV penicillin G and clindamycin. In occasional cases of clindamycin-resistant *C. perfringens*, vancomycin may be an effective alternative. Hyperbaric oxygen therapy may be of value if immediately available. Infected patients with cirrhosis and diabetes have a poorer prognosis.

Chronic Undermining Burrowing Ulcers (Meleney Gangrene)

Chronic burrowing ulcer was first described by Meleney as postoperative progressive bacterial synergetic gangrene. It usually follows drainage of peritoneal abscess, lung abscess, or chronic empyema. After 1 or 2 weeks, the wound markings or retention suture holes assume a carbunculoid appearance, finally differentiating into three skin zones: outer, bright red; middle, dusky purple; and inner, gangrenous with a central area of granulation tissue. The pain is excruciating. In Meleney postoperative progressive gangrene, the essential organism is a microaerophilic, nonhemolytic streptococcus (peptostreptococcus) in the spreading periphery of the lesion, associated with *S. aureus* or Enterobacteriaceae in the zone of gangrene.

This disease is differentiated from ecthyma gangrenosum, which begins as vesicles, rapidly progressing to pustulation and gangrenous ulceration in debilitated patients, and is caused by *P. aeruginosa*. Pyoderma gangrenosum occurs in a different setting, lacks the bacterial findings, and does not respond to antibiotic therapy. Fusospirochetal gangrene occurs after a human bite.

Wide excision and grafting are primary therapy for Meleney gangrene. In polymicrobial infections imipenem or meropenem should be given as adjunctive therapy.

Fournier Gangrene of the Penis or Scrotum

Fournier syndrome is a gangrenous infection of the penis, scrotum, or perineum that may be caused by infection with group A streptococci or with mixed enteric bacilli and anaerobes. This is usually considered a form of necrotizing fasciitis because it spreads along fascial planes. Peak incidence is between ages 20 and 50, although cases have been reported in children. Diabetes mellitus, obesity, poor personal hygiene, long-standing oral corticosteroid therapy, and chronic alcoholism are predisposing factors. Culture for aerobic and anaerobic organisms should be carried out, and appropriate antibiotics started; surgical debridement and general support should be instituted.

Fig. 14.28 Actinomycosis.

Actinomycosis

Actinomyces are anaerobic, gram-positive, filamentous bacteria that colonize the mouth, colon, and urogenital tract. Infections are seen most often in the cervicofacial area but also on the abdominal region, thoracic area, or pelvis. Middle-aged men are affected most often. Diabetic and immunosuppressed patients and alcoholics with poor dental hygiene are particularly at risk. The lesions begin as firm nodules or plaques and develop draining sinuses. Grains or sulfur granules may be present in the exudate, as in fungal mycetomas. In the cervicofacial region, the infection is known as lumpy jaw. The underlying bone may be involved with periostitis or osteomyelitis. Mandibular infection is seen four times as often as maxillary involvement (Fig. 14.28). The abdomen may be involved after a ruptured appendix or GI surgical procedure. Extension of the infection into the abdominal wall may produce draining sinuses on the abdominal skin. In the thoracic region, lung infection may spread to the thoracic wall.

Oropharyngeal actinomycosis is usually caused by *Actinomyces israelii* and *A. gerencseriae*. The condition is often clinically misdiagnosed as a malignancy; the histologic appearance of the characteristic granules allows diagnosis. Sulfur granules consist of fine, delicate branching filaments. Eosinophilic clubs composed of immunoglobulin are seen at the periphery of the granule (Splendore-Hoeppli phenomenon). They resemble rays; hence the name, ray fungus (*Actinomyces*). Gram stain demonstrates long, gram-positive filaments.

The crushed granule is used for inoculating cultures containing brain-heart infusion blood agar, incubated under anaerobic conditions at 37°C. Culture is difficult; therefore direct microscopy is important.

Penicillin G in large doses, 10–20 MU/day for 1 month, followed by 4–6 g/day of oral penicillin for another 2 months, may produce successful and lasting results. Other effective medications have been ampicillin, erythromycin, tetracyclines, ceftriaxone, and clindamycin. Surgical incision, drainage, and excision of devitalized tissue are important.

Nocardiosis

Nocardiosis usually begins as a pulmonary infection from which dissemination occurs. Dissemination occurs most frequently in association with debilitating conditions, such as Hodgkin disease, periarteritis nodosa, leukemia, AIDS, organ transplants, or SLE. Skin involvement is seen in 10% of disseminated cases in the form of abscesses, erosions, or vesiculopustular lesions (Fig. 14.29). Primary cutaneous disease also occurs in healthy individuals in the form of a draining abscess or lymphangitic nodules after a cutaneous injury.

Nocardia asteroides is usually responsible for the disseminated form of nocardiosis. *Nocardia brasiliensis* is the most common cause of primary cutaneous disease. A prick by a thorn or briar, other penetrating injury, or an insect bite or sting may be the inciting event.

Nocardia are gram-positive, partially acid-fast, aerobic, filamentous bacteria. Some are branched, but filaments tend to be shorter and more fragmentary than those of *Actinomyces*. Biopsy reveals fine filamentous bacteria surrounded by neutrophilic abscesses. Only in mycetoma (see Chapter 15) are sulfur granules present. On Sabouraud dextrose agar, without antibacterial additives, there are creamy or moist, white colonies, which later become chalky and orange colored.

The drug of first choice for cutaneous nocardial infection is TMP-SMX, 5–10 mg/kg/day in two to four divided doses for 3 months, or 6 months if immunocompromised. Minocycline is an alternative. Linezolid is active, but potential adverse effects limit its use. Imipenem plus TMP-SMX or amikacin are effectively used in combination for disseminated infection.

INFECTIONS CAUSED BY GRAM-NEGATIVE ORGANISMS

PSEUDOMONAS INFECTIONS

Ecthyma Gangrenosum

In the severely ill patient with ecthyma gangrenosum, opalescent, tense vesicles or pustules are surrounded by narrow, pink to violaceous halos. These lesions quickly become hemorrhagic and violaceous and rupture to become round ulcers with necrotic black centers (Fig. 14.30). They are usually on the buttocks and extremities and are often grouped closely together. Ecthyma gangrenosum occurs in debilitated persons who may be suffering from leukemia, in the severely burned patient, in pancytopenia or neutropenia, or in patients with a functional neutrophilic defect, terminal carcinoma, or other severe chronic disease. Healthy infants may develop lesions in the perineal area after antibiotic therapy in conjunction with maceration of the diaper area.

The classic vesicle suggests the diagnosis. The contents of the vesicles or hemorrhagic pustules will show gram-negative bacilli on Gram staining, and cultures will be positive for *P. aeruginosa*. Because this is usually a manifestation of sepsis, the blood culture will also show *P. aeruginosa*. However, in healthy infants with diaper-area lesions, in patients with HIV infection, and in other occasional cases, early lesions may occur at a portal of entry, allowing for diagnosis and treatment before evolution into sepsis occurs. Although ecthyma gangrenosum is classically associated with *P. aeruginosa* infection, similar hemorrhagic pustules may occur from a variety of other gram-negative organisms (e.g., *Serratia marcescens*, *Klebsiella pneumoniae*, *Aeromonas hydrophilia*, *Xanthomonas maltophilia*,

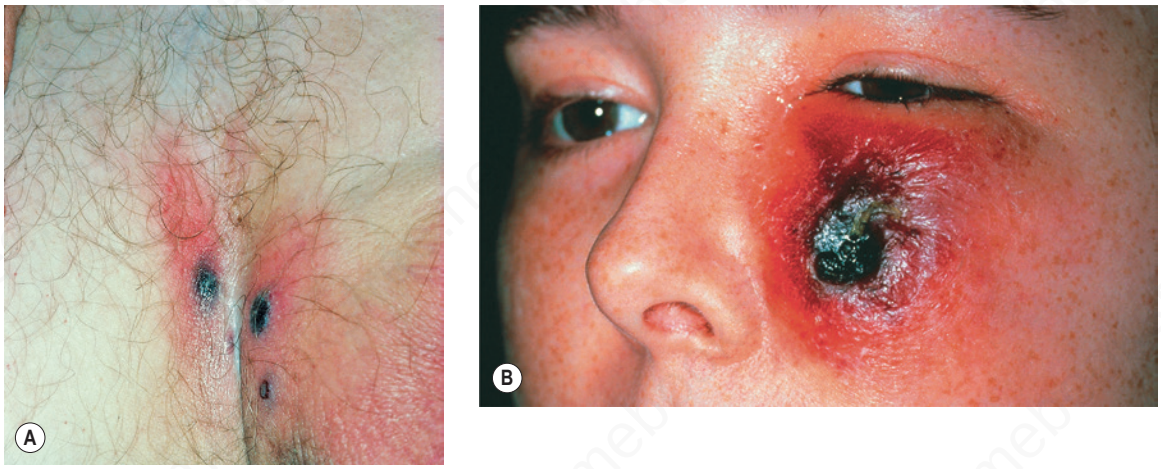

Fig. 14.30 (A and B) Ecthyma gangrenosum.

Morganella morganii, *E. coli*, *Citrobacter freundii*), fungal infections (e.g., *Candida albicans*, *Aspergillus fumigatus*, *Fusarium solani*, *Scytalidium dimidiatum*), and at times, *S. aureus*.

Recommended treatment is the immediate institution of IV antipseudomonal penicillin. The addition of granulocyte-macrophage colony-stimulating factor to stimulate both proliferation and differentiation of myeloid precursors is an adjunct in a patient with myelodysplasia or treatment-induced neutropenia. Patients have a poorer prognosis if there are multiple lesions, if there is a delay in diagnosis and institution of appropriate therapy, and if neutropenia does not resolve by the end of a course of antibiotics. Instrumentation or catheterization increases the risk of this infection.

Other lesions also seen with *Pseudomonas* septicemia include sharply demarcated areas of cellulitis, macules, papules, plaques, and nodules, characteristically found on the trunk. *Pseudomonas mesophilica*, *Burkholderia cepacia*, *Citrobacter freundii*, and *Stenotrophomonas maltophilia* may also produce such skin lesions in immunocompromised individuals.

Green Nail Syndrome

Green nail syndrome is characterized by onycholysis of the distal portion of the nail and a striking greenish discoloration in the separated areas (Fig. 14.31). It is frequently associated with paronychia in persons who do wet work. Overgrowth of *P. aeruginosa* accounts for the pigment. Soaking the affected finger in a 1% acetic acid solution twice a day has been found to be helpful. Trimming the onycholytic nail plate, followed by application of Neosporin solution twice a day, is also effective.

Green foot syndrome results from colonization of rubber sports shoes with *P. aeruginosa*. The organism produces pyoverdin, which stains the foot and toenails.

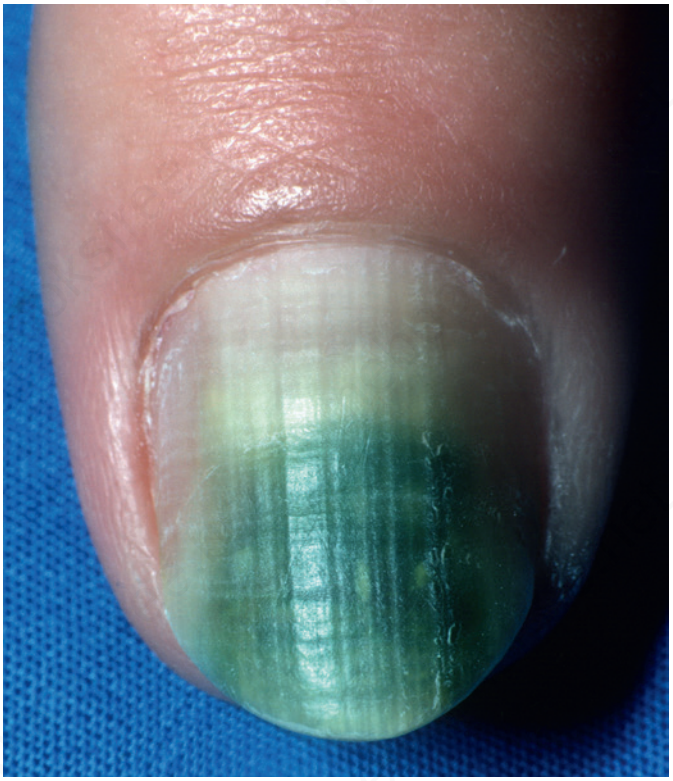

Fig. 14.31 Green nail syndrome secondary to pseudomonal infection. (Courtesy Steven Binnick, MD.)

Gram-Negative Toe Web Infection

Toe web infection often begins with dermatophytosis. With increasing inflammation and maceration, dermatophytosis may progress to dermatophytosis complex, in which many types of gram-negative organisms may be recovered as it becomes more difficult to culture dermatophytes. Eventually, denudation with purulent or serous discharge and marked edema and erythema of the surrounding tissue may be seen (Fig. 14.32). Prolonged immersion may also cause hydration and maceration of the interdigital spaces, with overgrowth of gram-negative organisms. *P. aeruginosa* is the most prominent, but frequently a mixture of other gram-negative organisms, such as *E. coli* and *Proteus*, are present. Patients may have red, painful nodules of the calf that do not drain, spontaneously involute, then reappear 1–2 weeks later. Culture of these subcutaneous abscesses will reveal *Pseudomonas* or other gram-negative bacteria, which likely originate in the macerated toe webs.

Early dermatophytosis may simply be treated with topical antifungal agents. However, once the scaling and peeling progress to white maceration, soggy scaling, bad odor, edema, and fissuring, treatment must also include topical antibiotics or acetic acid compresses. Drying of the interdigital spaces with a fan is a helpful adjunct. Full-blown gram-negative toe web infection with widespread denudation and erythema, purulence, and edema requires systemic antibiotics. A third-generation cephalosporin or a fluoroquinolone is recommended.

Blastomycosis-like Pyoderma

Large verrucous plaques with elevated borders and multiple pustules may occur as a chronic vegetating infection. Most patients have an underlying systemic or local host compromise. Bacteria such as *P. aeruginosa*, *S. aureus*, *Proteus*, *E. coli*, and streptococci may be isolated. Appropriate antibiotics for the cultured organism may be augmented by acitretin.

Pseudomonas aeruginosa Folliculitis (Hot Tub Folliculitis)

Pseudomonal folliculitis is characterized by pruritic follicular, maculopapular, vesicular, or pustular lesions occurring within 1–4 days after bathing in a hot tub, whirlpool, or public swimming pool (Fig. 14.33). As the water temperature rises, free chlorine levels fall, even though total chlorine levels appear adequate. This

Fig. 14.32 Gram-negative toe web infection. (Courtesy Ken Geer, MD.)

Fig. 14.33 Hot tub folliculitis. (Courtesy Steven Binnick, MD.)

allows the bacteria to proliferate. Diving suits may become colonized, and wearing them may result in *P. aeruginosa* folliculitis. One case occurred limited to the hand and wrist occluded under colonized rubber gloves.

Most lesions occur on the sides of the trunk, axillae, breasts, buttocks, and proximal extremities. Associated complaints may include earache, sore throat, headache, fever, and malaise. Rarely, systemic infection may result; breast abscess and bacteremia have been reported. Large community outbreaks have occurred associated with public pools, and 27 employees of a cardboard manufacturing facility who were exposed to wet work developed *Pseudomonas* folliculitis of the extremities as an occupational disorder. *Aeromonas hydrophilia* was found to be responsible for a clinically similar folliculitis that affected two siblings playing in an inflatable swimming pool.

The folliculitis involutes usually within 7–14 days without therapy, although multiple prolonged recurrent episodes have occasionally been reported. In patients with fever, constitutional symptoms, or prolonged disease, a third-generation oral cephalosporin or a fluoroquinolone such as ciprofloxacin or ofloxacin may be useful. Preventive measures have been water filtration, automatic chlorination to maintain a free chlorine level of 1 ppm, maintenance of water at pH 7.2–7.8, and frequent changing of the water. Bromination of the water and ozone ionization are other options.

Pseudomonas hot foot syndrome was reported in a group of 40 children who developed painful, erythematous plantar nodules or pustules after wading in a community pool whose floor was coated with abrasive grit. One biopsy showed neutrophilic eccrine hidradenitis; another revealed dermal microabscesses. Most were treated symptomatically, and resolution occurred within 2 weeks. Other patients have developed it after exposure to sauna and hot tubs.

External Otitis

Swelling, maceration, and pain may be present. In up to 70% of cases, *P. aeruginosa* may be cultured. External otitis is especially common in swimmers. Local application of antipseudomonal and antiinflammatory Cortisporin otic solution or suspension, or 2% acetic acid compresses with topical corticosteroids, will help clear this infection. In patients with otorrhea or pus emanating from the canal, if the symptoms have been present for 1 week or more, or if diabetes or an immunologic defect is present, cleansing the canal, visualizing the tympanic membrane for perforation, and other precautions will be most readily handled by an otolaryngology consultation. Application of otic Domeboro solution after swimming will help prevent recurrence. Fungi such as *Candida* and *Aspergillus* are other causes. Antifungal solutions (e.g., ciclopiroxolamine) combined with corticosteroid solutions are effective in otomycosis. There is also a threat of external otitis occurring after ear surgery (Fig. 14.34). If the patient is a swimmer or has diabetes, acetic acid compresses for 1 or 2 days before surgery may prevent this complication.

Fig. 14.34 Pseudomonas external otitis after shave biopsy.

External otitis must be distinguished from allergic contact dermatitis due to neomycin in Cortisporin otic suspension. Allergic contact dermatitis produces severe pruritus, although tenderness may also be noted. Dermatitis may extend down the side of the cheek in a pattern suggesting drainage of the suspension.

A severe type, referred to as malignant external otitis, occurs in elderly patients with diabetes or in those immunocompromised with HIV infection, receiving chemotherapy, or living with organ transplants. The swelling, pain, and erythema are more pronounced, with purulence and a foul odor. Facial nerve palsy develops in 30% of patients, and cartilage necrosis may occur. This is a life-threatening infection in these older, compromised individuals and requires swift institution and prolonged administration (4–6 weeks) of oral quinolone antibiotics.

Lastly, commercial ear piercing of the upper ear cartilage may lead to infection with *Pseudomonas*, with resulting cosmetic deformity.

Gram-Negative Folliculitis

Although gram-negative folliculitis is usually caused by Enterobacteriaceae, *Klebsiella*, *Escherichia*, *Proteus*, or *Serratia*, occasional cases caused by *Pseudomonas* have been seen. They differ from gram-negative infection in patients with acne in that the site of *Pseudomonas* colonization is the external ear, and topical therapy alone to the face and ears is sufficient for cure. Also, an outbreak of gram-negative pustular dermatitis on the legs, arms, torso, and buttocks occurred in a group of college students who hosted a mud-wrestling social event.

MALACOPLAKIA (MALAKOPLAKIA)

This rare granuloma was originally reported only in the genitourinary tract of immunosuppressed renal transplant recipients, but malacoplakia may also occur in the skin and subcutaneous tissues of other immunocompromised patients, as with HIV infection. Patients are unable to resist infections with S. *aureus*, *P. aeruginosa*, and *E. coli*. There is defective intracellular digestion of the bacteria once they have been phagocytosed.

The granulomas may arise as masslike lesions or nodules, abscesses, or ulcerations. They favor the perineum but also affect the abdominal wall, thorax, extremities, and axilla. The tongue is also a site of appearance, usually presenting as a mass lesion. Histologically, foamy eosinophilic Hansemann macrophages contain calcified, concentrically laminated, intracytoplasmic bodies (Michaelis-Gutmann). Scattered immunoblasts, neutrophils, and lymphocytes are found in the dermis.

Successful treatment of malacoplakia depends on the isolated organism; a fluoroquinolone such as ciprofloxacin or ofloxacin typically is useful.

HAEMOPHILUS INFLUENZAE CELLULITIS

Haemophilus influenzae type B causes a distinctive bluish or purplish red cellulitis of the face, accompanied by fever in children younger than 2 years. This condition is rarely seen in countries where the vaccination is available. The importance of recognizing *H. influenzae* cellulitis is related to the bacteremia that often accompanies the cellulitis. The bacteremia may lead to meningitis, orbital cellulitis, osteomyelitis, or pyarthrosis. Cultures of the blood and needle aspirates of the cellulitis should yield the organism. Cefotaxime or ceftriaxone is effective. In a family with children under age 4, the index case, both parents, and children at risk (unvaccinated) should be given rifampin to clear the nasal carriage state and prevent secondary cases. *H. influenzae* type A not covered by the vaccine. Reports of this organism and nontypable *H. influenzae* causing invasive infection, including cellulitis in sites such as the leg and neck in immunocompromised adults are increasing.

CHANCROID

Chancroid (soft chancre) is an infectious, ulcerative STD caused by the gram-negative bacillus *Haemophilus ducreyi* (the Ducrey bacillus). One or more tender ulcers on the genitalia and painful inguinal adenitis that may suppurate, are characteristic of the disease. Men outnumber women manyfold. The incidence of chancroid is decreasing worldwide. *H. ducreyi* is now increasingly recognized as a cause of chronic limb ulceration in the South Pacific region.

Chancroid begins as an inflammatory macule or pustule 1–5 days, or rarely as long as 2 weeks, after intercourse. It generally appears on the distal penis or perianal area in men or on the vulva, cervix, or perianal area in women. However, many cases of extragenital infection on the hands, eyelids, lips, or breasts have been reported. Autoinoculation frequently forms kissing lesions on the genitalia, and women are apt to have more numerous lesions. The pustule ruptures early with the formation of a ragged ulcer that lacks the induration of a chancre, usually being soft with an indefinite inflammatory thickening. The ulcers appear punched out or have undermined, irregular edges surrounded by mild hyperemia (Fig. 14.35). The base is covered with a purulent, dirty exudate. The ulcers bleed easily and are very tender.

Fig. 14.35 Chancroid.

A number of clinical variants have been described, including granuloma inguinale–like, giant ulcers, serpiginous ulcers, transient chancroid, and follicular and papular variants.

About half the cases of genital chancroid manifest inguinal adenitis. Suppuration of the bubo (inguinal lymph node) may occur despite early antibiotic therapy. The lymphadenitis of chancroid, mostly unilateral, is tender and may rupture spontaneously. Left untreated, the site of perforation of the broken-down bubo will progress to a destructive painful ulcer.

As a result of mixed infection, phagedenic and gangrenous features may develop. Chronic, painful, destructive ulcers, which begin on the prepuce or glans and spread by direct extension along the shaft of the penis, are present. They may sometimes attack the scrotum or pubes. The edges of the ulcer are likely to be elevated, firm, and undermined. The granulating base, which bleeds easily, is covered with a thick, purulent exudate and dirty, necrotic detritus. The neighboring skin may be edematous and dusky red, and the regional lymph glands may be swollen, although this is not necessarily a marked feature. There is severe mutilation as a result of sloughing, with no evidence of spontaneous healing. Complications such as penile amputation from a deep, transverse ulcer may result.

This type of phagedena (spreading and sloughing ulceration) is a rare complication of chancroidal infections together with secondary bacterial infection. Treatment is by the use of antibiotics locally and internally, directed against secondary bacteria, as well as the primary process. Multiple infections may be present, such as chancroid, syphilis, HIV, or granuloma inguinale.

On histologic investigation, the ulcer may include a superficial necrotic zone with an infiltrate consisting of neutrophils, lymphocytes, and red blood cells. Deep to this, new vessel formation is present, with vascular proliferation. Deeper still is an infiltrate of lymphocytes and plasma cells. Ducrey bacilli may or may not be seen in the sections.

The definitive diagnosis of chancroid requires identification by culture. Solid-media culture techniques have allowed definitive diagnosis and sensitivity testing; however, culture is unavailable in many settings, and recovery is only about 80% successful. Specimens for culture should be taken from the purulent ulcer base and active border without extensive cleaning. They should be inoculated in the clinic; transport systems have not been evaluated. The selective medium contains vancomycin, and cultures are done in a water-saturated environment with 1%–5% CO_2, at a temperature of 33°C. Occasional outbreaks are caused by vancomycin-sensitive strains. In these cases, culture will only be successful using vancomycin-free media.

Smears are only diagnostic in 50% of cases in the best hands. A probable diagnosis is made by a clinically compatible examination and negative testing for conditions that may mimic chancroid such as herpes progenitalis. A history of recurrent grouped vesicles at the same site should help eliminate the chance of a misdiagnosis. Traumatic ulcerations should also be ruled out; these occur mostly along the frenulum or as multiple erosions on the prepuce. Adenopathy is absent, and some degree of phimosis is present.

The clinical features that differentiate chancroid from a syphilitic chancre are described in Chapter 18. However, the diagnosis of chancroid does not rule out syphilis. Either the lesion may already be a mixed sore or the subsequent development of syphilis should be anticipated, because the incubation period of the syphilis is much longer than that of chancroid. Serologic tests for syphilis should be obtained initially, then monthly for the next 3 months, and serologic testing for HIV infection should also be done. Chancroidal genital ulcer disease facilitates the transmission of HIV infection. In HIV-infected patients, chancroid may have a prolonged incubation period, the number of ulcers may be increased, extragenital sites are more frequently affected, antibiotic therapy fails more often, and healing is slower when it does occur.

Treatment

The treatment of choice for chancroid is azithromycin, 1 g orally in a single dose or ceftriaxone, 250 mg intramuscularly in a single dose. Erythromycin, 500 mg four times a day for 7 days and ciprofloxacin, 500 mg orally twice a day for 3 days, are also recommended treatments. Ciprofloxacin should not be used in pregnant or lactating women or in children younger than 17 years. Partners who have had sexual contact with the patient within the 10 days before the onset of symptoms should be treated with a recommended regimen.

Phimosis that does not subside after irrigation of the preputial cavity may have to be relieved by a dorsal slit. Circumcision should be deferred for at least 2 or 3 months. If frank pus is already present, repeated aspirations (not incisions) may be necessary.

GRANULOMA INGUINALE (GRANULOMA VENEREUM, DONOVANOSIS)

Granuloma inguinale is a mildly contagious, chronic, granulomatous, locally destructive disease characterized by progressive, indolent, serpiginous ulcerations of the groins, pubes, genitalia, and anus. The disease begins as single or multiple subcutaneous nodules, which erode through the skin to produce clean, sharply defined lesions, which are usually painless (Fig. 14.36A). More than 80% of cases demonstrate hypertrophic, vegetative granulation tissue, which is soft, has a beefy-red appearance, and bleeds readily. Approximately 10% of cases have ulcerative lesions with overhanging edges and a dry or moist floor (Fig. 14.36B). A membranous exudate may cover the floor of fine granulations, and the lesions are moderately painful. Occasional cases are misdiagnosed as carcinoma of the penis. The lesions enlarge by autoinoculation and peripheral extension with satellite lesions and by gradual undermining of tissue at the advancing edge.

The genitalia are involved in 90% of cases, inguinal region in 10%, anal region in 5%–10%, and distal sites in 1%–5%. Lesions are limited to the genitalia in approximately 80% of patients and to the inguinal region in less than 5%. They most frequently occur on the prepuce or glans in men and on the labia in women. The incubation period is unknown; it may vary between 8 and 80 days, with a 2- to 3-week period being most common.

Persisting sinuses and hypertrophic scars, devoid of pigment, are fairly characteristic of granuloma inguinale. The regional lymph nodes are usually not enlarged. In later stages, as a result of cicatrization, the lymph channels are sometimes blocked, and pseudoelephantiasis of the genitals (esthiomene) may occur. Mutilation of the genitals and destruction of deeper tissues are observed in some patients. Dissemination from the inguinal region may be by hematogenous or lymphatic routes. There may be involvement of liver, other organs, eyes, face, lips, larynx, chest, and, rarely, bones. During childbearing, the cervical lesions may extend to the internal genital organs. Squamous cell carcinoma may rarely supervene.

Fig. 14.36 (A and B) Granuloma inguinale.

Granuloma inguinale is caused by the gram-negative bacterium *Klebsiella granulomatis*. It is sexually transmitted in the majority of cases, with conjugal infection occurring in 12%–52% of marital or steady sexual partners. Also, it is speculated that *K. granulomatis* is an intestinal inhabitant that leads to granuloma inguinale through autoinoculation, or sexually through vaginal intercourse if the vagina is contaminated by enteric bacteria, or through rectal intercourse, heterosexual or homosexual. *K. granulomatis* probably requires direct inoculation through a break in the skin or mucosa to cause infection. Those affected are generally young adults.

On histologic investigation, in the center of the lesion, the epidermis is replaced by serum, fibrin, and polymorphonuclear leukocytes. At the periphery, the epidermis demonstrates pseudoepitheliomatous hyperplasia. In the dermis, there is a dense granulomatous infiltration composed chiefly of plasma cells and histiocytes, and scattered throughout are small abscesses containing polymorphonuclear leukocytes. Characteristic pale-staining macrophages that have intracytoplasmic inclusion bodies are found. The parasitized histiocytes may measure 20 μm or more in diameter. The ovoid Donovan bodies measure 1–2 μm and may be visualized by using Giemsa or silver stains. The best method, however, is toluidine blue staining of semithin, plastic-embedded sections. Crushed smears of fresh biopsy material stained with Wright or Giemsa permit the demonstration of Donovan bodies and provide rapid diagnosis.

Granuloma inguinale may be confused with ulcerations of the groin caused by syphilis or carcinoma, but it is differentiated from these diseases by its long duration and slow course, by the absence of lymphatic involvement, and in the case of syphilis, by a negative test for syphilis and failure to respond to antisyphilitic treatment. It should not be overlooked that other venereal diseases, especially syphilis, often coexist with granuloma inguinale. Additionally, all patients presenting with STDs should be tested for HIV infection and their sexual partners evaluated. Lymphogranuloma venereum (LGV) at an early stage would most likely be accompanied by inguinal adenitis. In later stages, when stasis, excoriations, and enlargement of the outer genitalia are common to granuloma inguinale and LGV, the absence of a positive LGV complement fixation test and the presence of Donovan bodies in the lesions permit the diagnosis of granuloma inguinale.

Treatment

Azithromycin, 1 g once weekly, all for at least 3 weeks is the recommended regimen. Therapy should be continued until all lesions have healed completely. Alternative regimens are TMP-SMX (1 double-strength tablet), ciprofloxacin, 750 mg, or doxycycline (100 mg) twice daily or erythromycin 500 mg four times daily all for a minimum of 3 weeks. The addition of an IV aminoglycoside such as gentamicin, 1 mg/kg every 8 hours, should be considered if lesions do not respond within the first few days and in HIV-infected patients.

GONOCOCCAL DERMATITIS

Primary gonococcal dermatitis is a rare infection that occurs after primary inoculation of the skin from an infected focus. It may present as grouped pustules on an erythematous base on the finger, simulating herpetic whitlow, with or without an ascending lymphangitis. Scalp abscesses in infants may occur secondary to direct fetal monitoring in mothers with gonorrhea. It may also cause an inflammation of the median raphe or a lymphangitis of the penis with or without accompanying urethritis. Treatment is the same as that of gonorrheal urethritis. Ceftriaxone as a 125-mg single IM dose together with a single dose of azithromycin 1 g orally is recommended.

Gonococcemia

Gonococcemia is characterized by a hemorrhagic vesiculopustular eruption, bouts of fever, and arthralgia or actual arthritis of one or several joints. The skin lesions begin as tiny sparse erythematous macules (Fig. 14.37). They evolve into either tender vesicopustules on an erythematous or hemorrhagic base, or purpuric macules that may be as large as 2 cm in diameter. These purpuric lesions occur acrally, mostly on the palms and soles, and over joints. They are accompanied by fever, chills, malaise, migratory polyarthralgia, myalgia, and tenosynovitis. Involution of the lesions takes place in about 4 days.

Many patients are women with asymptomatic anogenital infections in whom dissemination occurs during pregnancy or menstruation. Liver function abnormalities, myocarditis, pericarditis, endocarditis, and meningitis may complicate this infection. In severe or recurrent cases, complement deficiency, especially of the late (C5, C6, C7, or C8) components, should be investigated.

The causative organism is *Neisseria gonorrhoeae*. These organisms can at times be demonstrated in the early skin lesion histologically, by smears, and by cultures. Gonococci may be found in the blood, genitourinary tract, pharynx, joints, and skin. The skin lesions of

Fig. 14.37 Gonococcemia.

gonococcemia may be identical to those seen in meningococcemia, nongonococcal bacterial endocarditis, rheumatoid arthritis, the rickettsial diseases, SLE, periarteritis nodosa, Haverhill fever, and typhoid fever. Septic emboli with any gram-negative organism or *Candida* classically manifest as hemorrhagic pustules.

The treatment of choice for disseminated gonococcal infection is ceftriaxone, 1 g/day intravenously plus azithromycin 1 g orally for a minimum of 1 week. Serologic testing for HIV infection should also be done, as well as screening for syphilis. Sex partners within 30 days for symptomatic infection and 60 days for asymptomatic infection should be referred for treatment.

Skerlev M, Čulav-Košćak I: Gonorrhea. Clin Dermatol 2014; 32: 275.

MENINGOCOCCEMIA

Acute meningococcemia presents with fever, chills, hypotension, and meningitis. Half to two thirds of patients develop a petechial eruption, most frequently on the trunk and lower extremities, which may progress to ecchymoses, bullous hemorrhagic lesions, and ischemic necrosis (Fig. 14.38). Often, acral petechiae are present, and petechiae may be noted on the eyelids. Angular infarctive lesions with an erythematous rim and gun-metal gray interior are characteristic of meningococcal sepsis. Occasionally, a transient, blanchable, morbilliform eruption is the only cutaneous finding. The oral and conjunctival mucous membranes may be affected.

Meningococcemia primarily affects young children, males more frequently than females. Patients with asplenia, immunoglobulin deficiencies, or inherited or acquired deficiencies of the terminal components of complement or properdin are predisposed to infection.

A rare variant is chronic meningococcemia. There are recurrent episodes of fever, arthralgias, and erythematous macules that may

Fig. 14.38 Meningococcemia.

evolve into lesions with central hemorrhage. Acral hemorrhagic pustules, similar to those found in gonococcal sepsis, may be seen. Patients are generally young adults with fevers lasting 12 hours interspersed with 1–4 days of well-being.

Meningococcemia is caused by the fastidious gram-negative diplococcus *Neisseria meningitidis*. It has a polysaccharide capsule that is important in its virulence and serotyping. The human nasopharynx is the only known reservoir, with carriage rates in the general population estimated to be 5%–10%.

IV ceftriaxone, 2 g twice daily, or penicillin G, 300,000 units/kg/day up to 24 MU/day for 7 days, is the treatment of choice. One dose of ciprofloxacin, 500 mg, is given after the initial course of antibiotics to clear nasal carriage. Household members and day care and close school contacts should receive prophylactic therapy. Rifampin, 600 mg every 12 hours for 2 days, is an alternative prophylactic therapy for children and ceftriaxone as a single IM dose of 250 mg for pregnant women. A polyvalent vaccine is effective against groups A, C, Y, and W-135 and is recommended for high-risk groups.

VIBRIO VULNIFICUS INFECTION

Infection with *Vibrio vulnificus*, a gram-negative rod of the non-cholera group of vibrios, may produce either a rapidly expanding cellulitis or a life-threatening septicemia in patients exposed to the organism. This infection mainly occurs along the Atlantic seacoast. It may be acquired through the GI tract; after being ingested with raw oysters or other seafood, the bacterium enters the bloodstream at the level of the duodenum. Pulmonary infection by the aspiration of seawater has been reported. Localized skin infection may result after exposure of an open wound to seawater.

Skin lesions characteristically begin within 24–48 hours of exposure, with localized tenderness followed by erythema, edema, and indurated plaques. Lesions occur in almost 90% of patients and are most common on the lower extremities. A purplish discoloration develops centrally and then undergoes necrosis, forming hemorrhagic bullae or ulcers (Fig. 14.39). Other reported lesions include hemorrhagic bullae, pustules, petechiae, generalized macules or papules, and gangrene.

If the skin is invaded primarily, septicemia may not develop, but the lesions may be progressive, and at times, limb amputation

Fig. 14.39 *Vibrio vulnificus* infection. (Courtesy Curt Samlaska, MD.)

may be necessary. With septicemia, cellulitic lesions are the result of seeding of the subcutaneous tissue during bacteremia. Patients with advanced liver disease are at particular risk for developing septicemia. Other predisposing disorders are immunosuppression, alcoholism, adrenal insufficiency, diabetes, renal failure, male gender, and iron-overload states. The virulence of the bacterium is related to the production of exotoxin and various other factors. The mortality in patients with septicemia is greater than 50%.

Treatment of this fulminant infection, which rapidly produces septic shock, includes antibiotics, surgical debridement, and appropriate resuscitative therapy. Doxycycline together with ceftriaxone is the treatment of choice. In patients with preexisting hepatic dysfunction or immunocompromise and whose wounds are exposed to or acquired in saltwater, prophylactic antibiotic coverage with doxycycline, 100 mg every 12 hours, and cleansing with 0.025% sodium hypochlorite solution may prevent progressive infection.

CHROMOBACTERIOSIS AND *AEROMONAS* INFECTIONS

Chromobacterium is a genus of gram-negative rods that produce various discolorations on gelatin broth. Chromobacteria have been shown to be common water and soil saprophytes of the southeastern United States and Australia. Several types of cutaneous lesions are caused by chromobacteria, ranging from fluctuating abscesses and local cellulitis to anthrax-like carbuncular lesions with lymphangitis and fatal septicemia. *Chromobacterium violaceum*, the most common species, produces a violet pigment. Patients with chronic granulomatous disease may be at particular risk. A fluoroquinolone in combination with an aminoglycoside is best for treatment. After several weeks of parenteral antimicrobial therapy, an oral agent (e.g., TMP-SMX, tetracycline, fluoroquinolone) is given for 2 or 3 months.

A gram-negative bacterium, *Aeromonas hydrophilia*, another typical soil and water saprophyte, may cause similar skin infections as *C. violaceum*, manifesting as cellulitis, pustules, furuncles, gas gangrene, or ecthyma gangrenosum–like lesions, after water-related trauma and abrasions. Folliculitis caused by *A. hydrophilia* may mimic *Pseudomonas* folliculitis. The treatment of choice is ciprofloxacin.

Edwardsiella tarda and *Shewanella* species are two other rare causes of gram-negative infections caused by marine exposures and injuries.

SALMONELLOSIS

Salmonella is a genus of gram-negative rods that exist in humans either in a carrier state or as a cause of active enteric or systemic infection. Most cases of typhoid fever caused by *Salmonella typhi* are acquired by ingestion of contaminated food or water. Pets such as lizards, snakes, and turtles carry salmonellae, and acquisition of the organism in petting zoos has also been reported. Poultry and poultry products are the most important sources and are believed to be the cause in about half of common-source epidemics. Handwashing and thorough cooking of meats are recommended preventive measures.

After an incubation period of 1–2 weeks, there is usually an acute onset of fever, chills, headache, constipation, and bronchitis. After 7–10 days of fever and diarrhea, skin lesions, rose-colored macules or papules ("rose spots") 2–5 mm in diameter, appear on the anterior trunk, between the umbilicus and nipples. They occur in crops, each group of 10–20 lesions lasting 3–4 days, the total duration of the exanthem being 2–3 weeks in untreated cases. Rose spots occur in 50%–60% of patients. A more extensive erythematous eruption occurring early in the course, erythema typhosum, is rarely reported, as are erythema nodosum, urticaria, and ulcers or subcutaneous abscesses.

The diagnosis is confirmed by culturing the organism from blood, stool, skin, or bone marrow. If the organism is not grown on *Shigella-Salmonella* medium or is not analyzed correctly, *S. typhi* may be erroneously reported as a coliform. The preferred antibiotic for therapy is ciprofloxacin or ceftriaxone.

Occasionally, *S. typhi* may cause skin lesions without systemic infection. Also, infection with nontyphoid *Salmonella*, such as *S. enterica*, may cause enteric fever with rose spots.

SHIGELLOSIS

Shigellae are small, gram-negative rods that cause bacillary dysentery, an acute diarrheal illness. Most cases are a result of person-to-person transmission; however, widespread epidemics have resulted from contaminated food and water. Small, blanchable, erythematous macules on the extremities, as well as petechial or morbilliform eruptions, may occur. Men who have sex with men (MSM) may develop a furuncle on the penis caused by *Shigella flexneri*. Shigellosis may then occur as a purely cutaneous form of STD. *Shigella* and *Salmonella* are among the organisms reported

to induce the postdysenteric form of Reiter syndrome. Therapy with a fluoroquinolone is curative.

Carter JD, et al: Reactive arthritis. Rheum Dis Clin North Am 2009; 35: 21.

HELICOBACTER CELLULITIS

Fever, bacteremia, cellulitis, and arthritis may all be caused by *Helicobacter cinaedi* or *H. canis.* Generally, these manifestations occur in HIV-infected patients; however, malignancy, diabetes, and alcoholism are other predisposing conditions. Occasionally, *Helicobacter* has been reported to cause postsurgical wound infections and sepsis in otherwise healthy individuals. The cellulitis may be multifocal and recurrent and may have a distinctive red-brown or copper color with minimal warmth. Ciprofloxacin is generally effective for treatment.

Shimizu S, et al: Cutaneous manifestations of *Helicobacter cinaedi* infection. Acta Derm Venereol 2013; 93: 165.

RHINOSCLEROMA

Rhinoscleroma is a chronic, inflammatory, granulomatous disease of the upper respiratory tract characterized by sclerosis, deformity, remission, and eventual debility. Death resulting from obstructive sequelae may occur. The infection is limited to the nose, pharynx, and adjacent structures. The disease begins insidiously with nasal catarrh, increased nasal secretion, and subsequent crusting. Gradually, there ensues a nodular or rather diffuse sclerotic enlargement of the nose, upper lip, palate, or neighboring structures (Fig. 14.40). The nodules at first are small, hard, subepidermal, and freely movable, but they gradually fuse to form sclerotic plaques that adhere to the underlying parts. Ulceration is common. The lesions have a distinctive stony hardness, are insensitive, and are of a dusky purple or ivory color. Hyperpigmentation can be expected in dark-complexioned individuals. In the more advanced stages of rhinoscleroma, the reactive growth produces extensive mutilation of the face and marked disfigurement. Complete obstruction of the nares, superficial erosions, and seropurulent exudation may occur.

Fig. 14.40 Rhinoscleroma. (Courtesy Jason Robbins, MD.)

A microorganism, *Klebsiella pneumoniae*, ssp. *rhinoscleromatis*, first isolated by von Frisch, is the causative agent. The rhinoscleroma bacillus is a gram-negative rod, short, nonmotile, round at the ends, always encapsulated in a gelatinous capsule, and measuring 2–3 µm. It is found in the throats of scleroma patients only.

The disease occurs in both genders and is most common during the third and fourth decades of life. Although endemic in tropical countries in Africa and Central America, it is occasionally found in the United States. Rare familial cases have been reported, in which the condition may present in childhood.

In the primary stage of nasal catarrh, the histologic picture is that of a mild, nonspecific inflammation. When proliferation and tumefaction develop, the granulomatous tumor consists largely of plasma cells, Mikulicz cells, an occasional hyaline degenerated plasma cell (Russell body), a few spindle cells, and fibrosis. The bacilli are found within foamy macrophages (Mikulicz cells) and are best visualized with the Warthin-Starry silver stain.

Rhinoscleroma has such distinctive clinical and histologic features that the diagnosis is not difficult. Heat-killed antigen gives a confirmatory positive complement fixation reaction with scleroma patients' serum. Clinically, rhinoscleroma can be confused with syphilitic gumma, sarcoid, leishmaniasis, frambesia (yaws), keloid, lepra, hypertrophic forms of tuberculosis, and rhinosporidiosis.

Treatment

Rhinoscleroma is usually progressive and resistant to therapy. However, it may respond well to the fluoroquinolones, although therapy should be prolonged, lasting at least 3 or 4 months, to limit the chance of relapse. Corticosteroids are useful in the acute phase. Surgical intervention or CO_2 laser treatments may be needed to prevent airway obstruction or to correct deformities.

PASTEURELLOSIS

Primary cutaneous (ulceroglandular) *Pasteurella haemolytica (Mannheimia haemolytica)* infection may occur in patients with skin injury and exposure to this organism. *P. haemolytica* is a common pathogen of domestic animals associated with shipping fever in cattle and septicemia in lambs and newborn pigs. The open sites become inflamed, lymphangitis and fever develop, and axillary lymph nodes become enlarged. Diagnosis is based on demonstration of the bacteria on culture of the lesions.

Pasteurella multocida is a small, nonmotile, gram-negative, bipolar-staining bacterium. It is known to be part of the normal oral and nasal flora of cats and dogs, but it may also be an animal pathogen. The most common type of human infection follows injuries from animal bites, principally cat and dog bites, but also cat scratches. After animal trauma, erythema, swelling, pain, and tenderness develop within a few hours of the bite, with a gray-colored serous or sanguinopurulent drainage from the puncture wounds (Fig. 14.41). There may or may not be regional lymphadenopathy or evidence of systemic toxicity such as chills and fever. Septicemia may follow the local infection in rare cases, and tenosynovitis and osteomyelitis appear with some frequency.

Fig. 14.41 *Pasteurella multocida* infection.

Treatment is with amoxicillin-clavulanate 875/125 mg twice daily in addition to careful cleansing and tetanus prophylaxis.

DOG AND HUMAN BITE PATHOGENS

It is recommended that all cat bites and scratches, all sutured wounds of any animal source, and any other animal injuries of an unusual type or source be treated with antibiotics in addition to careful cleansing and tetanus prophylaxis. Although *Pasteurella* species (*P. canis* in dogs and *P. multocida* in cats) are usually present in bite site cultures, a complex mix of various other pathogens, such as streptococci, staphylococci, *Moraxella*, *Neisseria*, *Fusobacterium*, *Bacteroides*, and those individually discussed next, make the combination amoxicillin-clavulanate the best choice of initial therapy.

Capnocytophaga canimorsus is a gram-negative rod that is part of the normal oral flora of dogs and cats. It is associated with severe septicemia after dog bites. Patients who have undergone splenectomy are at particular risk. Alcoholism, chronic respiratory disease, and other medical conditions also predispose to infection; only one quarter of patients were healthy before infection with *C. canimorsus*. A characteristic finding is a necrotizing eschar at the site of the bite. Fever, nausea, and vomiting occur abruptly within 1–3 days, and the eschar develops soon thereafter. Disseminated intravascular coagulation and extensive dry gangrene may complicate the course. Sepsis after a dog bite is another hazard faced by splenectomized patients, in addition to their particular problems with pneumococcus, *Haemophilus influenzae* group B, babesiosis, *Neisseria meningitidis*, and group A streptococcus. *C. canimorsus* is difficult to identify by conventional cultures. Laboratory personnel need to be aware of the clinical suspicion of infection with this organism. A false-positive latex agglutination test for cryptococcal antigen in the CSF may occur. Treatment is with intensive IV antibiotics. In less severely affected patients, amoxicillin-clavulanate may be effective.

Neisseria species and *Bergeyella zoohelcum* are other oral and nasal commensals in dogs; thus most reports of human disease follow animal bites. *Eikenella corrodens*, a facultative gram-negative bacillus, is a normal inhabitant of the human mouth. Most infections are caused by human bites or fist fights and are often accompanied by *Streptococcus* and *Staphylococcus* organisms. Early prophylactic treatment is with amoxicillin-clavulanate; IV antibiotics are required once clinical infection is present.

GLANDERS

Once known as equinia, farcy, and malleus, glanders is a rare, usually fatal infectious disease that occurs in humans by inoculation with *Burkholderia mallei*. It is encountered in those who handle horses, mules, or donkeys. The distinctive skin lesion is an inflammatory papule or vesicle that arises at the site of inoculation, rapidly becomes nodular, pustular, and ulcerative, and forms an irregular excavation with undermined edges and a base covered with a purulent and sanguineous exudate. In a few days or weeks, other nodules (called "farcy buds") develop along the lymphatics in the adjacent skin or subcutaneous tissues and subsequently break down. In the acute form, the skin involvement may be severe and accompanied by extreme diarrhea. Patients with the chronic form have few skin lesions and milder constitutional symptoms, but repeated cycles of healing and breakdown of nodules may occur for weeks.

The respiratory mucous membranes are especially susceptible to glanders. After accidental inhalation, catarrhal symptoms are first present, and there may be epistaxis or a mucoid nasal discharge, which is a characteristic feature of the disease. The diagnosis is established by finding the gram-negative organism in this discharge or in the skin ulcers and should be confirmed by serum agglutination. This organism has been fatal to many laboratory workers, and exposure in this setting is increasing, with *B. mallei* as well as *B. pseudomallei* considered bioterrorism threats.

Treatment is chiefly by immediate surgical excision of the inoculated lesions and antibiotics. Amoxicillin-clavulanate, doxycycline, or TMP-SMX for up to 5 months may be effective in disease limited to the skin, whereas parenteral ceftazidime can be used for severe or septic infection. Imipenem and doxycycline in combination cured an infected laboratory worker.

Bovine farcy also occurs and is caused by *Mycobacterium farcinogenes* and *M. senegalense*. It is present mostly in sub-Saharan Africa and presents as a suppurative granulomatous inflammation of the skin and lymphatics.

MELIOIDOSIS

Melioidosis (Whitmore disease) is a specific infection caused by a glanders-like bacillus, *Burkholderia pseudomallei*. The disease has an acute pulmonary and septicemic form in which multiple miliary abscesses in the viscera occur, resulting in rapid death. Less often, it runs a chronic course, with subcutaneous abscesses and multiple sinuses of the soft tissues. Its clinical characteristics are similar to glanders, disseminated fungal infections, and tuberculosis. Severe urticaria and necrotizing fasciitis are uncommon complications.

Melioidosis is endemic in India, Southeast Asia, and northern Australia and should be suspected in military personnel and travelers who have characteristic symptoms of a febrile illness and have been in that region. Patients with diabetes and chronic renal failure are at high risk of severe disease. Recrudescence of disease after a long latency period may occur. Diagnosis is made from the recovery of the bacillus from the skin lesions or sputum and by serologic tests.

Effective therapy is guided by the antibiotic sensitivity of the specific strain. For the acute septicemic phase, ceftazidime, meropenem, or imipenem is indicated for 2 weeks, followed by maintenance oral therapy with TMP-SMX. The majority of chronic cutaneous infections respond well to oral treatment alone. Maintenance oral therapy in both situations should continue for 3 to 6 months.

INFECTIONS CAUSED BY *BARTONELLA*

Bartonellae are aerobic, fastidious, gram-negative bacilli. Several species cause human diseases, including *Bartonella henselae* (cat-scratch disease and bacillary angiomatosis), *B. quintana* (trench fever and bacillary angiomatosis), *B. bacilliformis* (verruga peruana and Oroya fever), and *B. grahamii* (cat-scratch disease). These agents are transmitted by arthropod vectors in some cases. Unique to this genus is the ability to cause vascular proliferation, as seen in bacillary angiomatosis and verruga peruana. The bartonellae in affected tissue stain poorly with tissue Gram staining and are usually identified in tissue using modified silver stains such as Warthin-Starry. They are difficult to culture, making tissue identification of characteristic bacilli an important diagnostic test. Electron microscopy and PCR can be used if routine staining is negative.

Cat-Scratch Disease

Cat-scratch disease is relatively common. About 12,000 cases are reported annually in the United States, with the majority occurring in children and young adults. Cat-scratch disease is the most frequent cause of chronic lymphadenopathy in children and young adults.

Bartonella henselae is the primary cause of cat-scratch disease. The infectious agent is transmitted from cat to cat by fleas and from cats to humans by cat scratches or bites. Rarely, dog bites may transmit this infection. *B. henselae* can be found in the primary skin and conjunctival lesions, lymph nodes, and other affected tissues. In geographic areas where cat fleas are present, about 40% of cats are asymptomatically bacteremic with this organism. An immunocompromised patient with typical cat-scratch disease caused by *Bartonella grahamii* has been reported. This organism infects rodents and is likely acquired by cats through hunting.

Fig. 14.42 Primary cat-scratch lesion with lymphadenopathy.

The primary skin lesion appears within 3–5 days after the cat scratch and may last for several weeks (Fig. 14.42). It is present in 50%–90% of patients. The primary lesion is not crusted, and lymphangitis does not extend from it. The primary lesion may resemble an insect bite but is not pruritic. It heals within a few weeks, usually with no scarring.

Lymphadenopathy, the hallmark of the disease, appears 1 or 2 weeks after the primary lesions or 10–50 days (average 17) after inoculation. Usually, the lymphadenopathy is regional and unilateral. Because most inoculations occur on the upper extremities, epitrochlear and axillary lymphadenopathy is most common (50%), followed by cervical (25%) or inguinal (18%). Generalized lymphadenopathy does not occur, but systemic symptoms such as fever, malaise, and anorexia may be present. Without treatment, the adenopathy resolves over a few weeks to months, with spontaneous suppuration occurring in 10%–50% of patients. If the primary inoculation is in the conjunctiva, there is chronic granulomatous conjunctivitis and preauricular adenopathy—the so-called oculoglandular syndrome of Parinaud. Infrequently, acute encephalopathy, osteolytic lesions, hepatic and splenic abscesses, hypercalcemia, and pulmonary manifestations have been reported. In addition, erythema nodosum and a diffuse exanthem may accompany cat-scratch disease.

Diagnosis is made largely on clinical features. The primary skin lesion or lymph node may be biopsied and the infectious agent identified. Involved lymph nodes and skin lesions demonstrate granulomatous inflammation with central "stellate" necrosis. A serologic test is available, and although not reproducibly positive early in the disease, a titer of more than 1:256 is considered diagnostic of acute infection. A PCR test is becoming increasingly available. Other infectious and neoplastic causes of localized lymphadenopathy, such as tularemia, sporotrichosis, atypical mycobacterial infection, and Hodgkin disease, may need to be excluded.

The vast majority of cases of cat-scratch disease resolve spontaneously without antibiotic therapy. Fluctuant lymph nodes should be aspirated, not incised and drained. The treatment of choice is azithromycin 500 mg the first day followed by 250 mg

Fig. 14.43 Bacillary angiomatosis.

for 4 days in adults, in children the dose is weight based and given as a liquid.

Trench Fever

Trench fever is caused by *Bartonella quintana*, which is spread from person to person by the body louse. Urban cases of trench fever caused by this agent are now most often seen in louse-infested homeless persons. Patients present with fever that initially lasts about 1 week and then recurs about every 5 days. Other symptoms are headache and neck, shin, and back pain. Endocarditis may occur. There are no skin lesions. Treatment has not been studied systematically. Combination IV gentamicin and oral doxycycline is recommended.

Bacillary Angiomatosis

Bacillary angiomatosis describes a clinical condition characterized by vascular skin lesions resembling pyogenic granulomas (Fig. 14.43). Only two organisms have been proven to cause bacillary angiomatosis: *Bartonella henselae* (cause of cat-scratch disease) and *B. quintana* (cause of trench fever). The skin lesions caused by these two organisms are identical. If bacillary angiomatosis is caused by *B. henselae*, there is usually a history of cat exposure, and the same *Bartonella* can also be isolated from the blood of the source cat. Bacillary angiomatosis caused by *B. quintana* is associated with homelessness and louse infestation. The incubation period is unknown but may be years.

Bacillary angiomatosis occurs primarily in the setting of immunosuppression, especially AIDS, and may be the presenting sign of this condition. The helper T-cell count is usually less than 50 cells/mL. Other immunosuppressed patients, such as those with leukemia or transplant, may acquire the condition. Rarely, bacillary angiomatosis can occur in HIV-negative patients with no apparent immune impairment. In immunoincompetent hosts, the bacteria proliferate locally and are frequently blood-borne. The local proliferation of bacteria produces the angiogenic vascular endothelial growth factor (VEGF), leading to endothelial cell proliferation and the characteristic skin lesions. Immunocompetent hosts generally resist this bacterial proliferation, resulting in granulomatous and necrotic, rather than angiomatous, lesions.

Several different forms of cutaneous lesions occur. The most common form resembles pyogenic granuloma, which may exhibit a surrounding collarete of scale. Less often, subcutaneous masses, plaques, and ulcerations may occur. A single patient may exhibit several of these morphologies. Lesions are tender and bleed easily. Subcutaneous nodules may be poorly marginated. Lesions may number from one to thousands, usually with the number gradually increasing over time if the patient is untreated.

In the setting of bacillary angiomatosis, the infection must be considered disseminated. Bacteremia is detected in about 50% of affected AIDS patients, leading to involvement of many visceral sites, most frequently the lymph node, liver and spleen, and bone. Less frequently, pulmonary, GI, muscle, oral, and brain lesions can occur. *B. henselae* is usually associated with lymph node and liver and spleen involvement, whereas *B. quintana* more often causes bone disease and subcutaneous masses. Visceral disease can be confirmed by appropriate radiologic or imaging studies. Bone lesions are typically lytic, resembling osteomyelitis. In the liver and spleen, "peliosis" occurs. Liver function tests characteristically demonstrate a very elevated lactic dehydrogenase level, an elevated alkaline phosphatase level, slight elevation of the levels of hepatocellular enzymes, and a normal bilirubin level. Lesions on other epithelial surfaces, in muscle, and in lymph nodes are usually angiomatous.

Biopsies of bacillary angiomatosis skin lesions have the same low-power appearance as a pyogenic granuloma, with the proliferation of endothelial cells, forming normal small blood vessels. It is distinguished from pyogenic granuloma by the presence of neutrophils throughout the lesion, not just on the surface, as seen in a pyogenic granuloma. The neutrophils are sometimes aggregated around granular material that stains slightly purple. This purple material represents clusters of organisms, which can often be confirmed by a modified silver stain such as Steiner. Tissue Gram stain does not routinely stain the bacteria in bacillary angiomatosis lesions. Bacillary angiomatosis is easily distinguished histologically from Kaposi sarcoma. In patch or plaque lesions of Kaposi sarcoma, the new blood vessels are abnormal in appearance, being angulated. Endothelial proliferation in Kaposi sarcoma is seen in the dermis around the eccrine units, follicular structures, and existing normal vessels. Nodular Kaposi sarcoma is a spindle cell tumor with slits rather than well-formed blood vessels. Neutrophils and purple granular material are not found in Kaposi sarcoma, but intracellular hyaline globules are present.

The natural history of bacillary angiomatosis is extremely variable. In most patients, however, lesions remain stable or the size or number of lesions gradually increases over time. The initial lesions are usually the largest, and multiple satellite or disseminated smaller lesions occur, representing miliary spread. Untreated bacillary angiomatosis can be fatal, with patients dying of visceral disease or respiratory compromise from obstructing lesions.

The diagnosis of bacillary angiomatosis is virtually always made by identifying the infectious agent in affected tissue. The organisms can also be cultured from the lesions and the patient's blood. However, these organisms grow very slowly, so cultures may not be positive for more than 1 month. Thus tissue and blood cultures are usually confirmatory in nature. Antibodies to *Bartonella* can be detected in most patients but background positivity in the general population of cat owners, this test is not generally useful. PCR is becoming increasingly available.

Treatment

Bacillary angiomatosis is dramatically responsive to clarithromycin 500 mg twice daily or azithromycin 250 mg daily. Treatment should continue for at least 6 months after the treated HIV patient's CD count is above 200 cells/microliter. Once treatment is begun, symptoms begin to resolve within hours to days. A Jarisch-Herxheimer reaction may occur with the first dose of antibiotic.

If patients relapse after an apparently adequate course of treatment, chronic suppressive antibiotic therapy should be considered. Erythromycin and doxycycline may also be effective. TMP-SMX, ciprofloxacin, penicillins, and cephalosporins are not effective. Prophylactic regimens containing a macrolide antibiotic or rifampin prevent the development of bacillary angiomatosis.

Oroya Fever and Verruga Peruana

Oroya fever and verruga peruana represent two stages of the same infection. Oroya fever (Carrión disease) is the acute febrile stage, and verruga peruana the chronic delayed stage. These conditions are limited to and endemic in Peru and a few neighboring countries in the Andes and are restricted to valleys 500–3200 m above sea level. Both these conditions are caused by *Bartonella bacilliformis*, which is transmitted by a sandfly, usually *Lutzomyia verrucarum*. Humans represent the only known reservoir. Men represent about three quarters of cases, and all ages may be affected.

After an incubation period averaging 3 weeks, the acute infection, Oroya fever, develops. Symptomatology is highly variable. Some patients have very mild symptoms. Others may have high fever, headache, and arthralgias. Severe hemolytic anemia can develop, sometimes with leukopenia and thrombocytopenia. Untreated, the fatality rate is 40%–88%, and with antibiotic treatment, is still 8%. After the acute infection resolves, a latency period follows, lasting from weeks to months. The verruga peruana eruptions then occur; these are angiomatous, pyogenic granuloma–like lesions, virtually identical clinically and histologically to the lesions of bacillary angiomatosis (Fig. 14.44). The lesions may be large and few in number (mular form), small and disseminated (miliary form), or nodular and deep. Visceral disease has not been found in verruga peruana, which is rarely fatal. Lesions usually heal spontaneously over several weeks to months without scarring. A lasting immunity results from infection.

The diagnosis of Oroya fever is made by identifying the bacteria within or attached to circulating erythrocytes using a Giemsa stain. Verruga peruana can be diagnosed by skin biopsy, showing the same features as bacillary angiomatosis, but with the organisms staining with Giemsa.

The antibiotic treatment of choice for Oroya fever is chloramphenicol, 2 g/day, because *Salmonella* coinfection is the most frequent cause of death. Protection from sandfly bites is all important.

PLAGUE

Plague normally involves an interaction among *Yersinia pestis*, wild rodents, and fleas parasitic on the rodents. Infection in humans with *Y. pestis* is accidental and usually presents as bubonic plague. Other clinical forms include pneumonic and septicemic plague. In the milder form, the initial manifestations are general malaise, fever, and pain or tenderness in areas of regional lymph nodes, most often in the inguinal or axillary regions. In more severe infections, findings of toxicity, prostration, shock, and occasionally hemorrhagic phenomena prevail. Less common symptoms include abdominal pain, nausea, vomiting, constipation followed by diarrhea, generalized macular erythema, and petechiae. Rarely, vesicular and pustular skin lesions occur.

Plague is caused by *Y. pestis*, a pleomorphic, gram-negative bacillus. The principal animal hosts involved have been rock squirrels, prairie dogs, chipmunks, marmots, skunks, deer mice, wood rats, rabbits, and hares. Transmission occurs through contact with infected rodent fleas or rodents, pneumonic spread, or infected exudates. *Xenopsylla cheopis* (Oriental rat flea) has traditionally been considered the vector in human outbreaks, but *Diamanus montanus*, *Thrassis bacchi*, and *Opisocrostis hirsutus* are species of fleas on wild animals responsible for spreading sylvatic plague in the United States. Rodents carried home by dogs or cats are a potential source—and an important one in veterinarians—of infection. The bites, scratches, or contact with other infectious material while handling infected cats are important factors as residential development continues in areas of plague foci in the western United States. Most U.S. cases occur in the Rocky Mountain states.

Blood, bubo or parabubo aspirates, exudates, and sputum should be examined by smears with Gram stain or specific fluorescent antibody techniques, culture, and animal inoculation. A retrospective diagnosis can be made by serologic analysis.

The most effective drugs against *Y. pestis* are gentamicin and streptomycin, which should be given intravenously. Almost all cases are fatal if not treated promptly.

RAT-BITE FEVER

Rat-bite fever is a systemic illness usually acquired by direct contact with rats or other small rodents, which carry the gram-negative organisms *Spirillum minor* and *Streptobacillus moniliformis* among

their oropharyngeal flora. *S. moniliformis* is the principal cause in the United States, whereas *S. minor* is seen mostly in Asia. Crowded living conditions, homelessness, working with rats in medical research or in pet shops, or having one as a pet are predisposing factors in some infected patients. Although it usually follows a rat bite, infection may follow the bites of squirrels, cats, weasels, pigs, and a variety of other carnivores that feed on rats.

There are at least two distinct forms of rat-bite fever: "sodoku," caused by *Spirillum minor;* and septicemia, caused by *Streptobacillus moniliformis*, otherwise known as epidemic arthritic erythema or Haverhill fever. The latter usually follows the bite of a rat, but some cases have been caused by contaminated milk. The clinical manifestations of these two infections are similar in that both produce a systemic illness characterized by fever, rash, and constitutional symptoms. However, clinical differentiation is possible.

In the streptobacillary form, incubation is brief, usually lasting 10 days after the bite, when chills and fever occur. Within 2–4 more days, the generalized morbilliform eruption appears and spreads to include the palms and soles. It may become petechial. Arthralgia is prominent, and pleural effusion may occur. Endocarditis, pneumonia, and septic infarcts often follow, and 10% of untreated patients may die of these causes.

Although infection with *S. minor* also begins abruptly with chills and fever, the incubation period is longer, 1–4 weeks. The bite site is often inflamed and may become ulcerated. Lymphangitis may be present. The eruption begins with erythematous macules on the abdomen, resembling rose spots, which enlarge, become purplish red, and form extensive indurated plaques. Arthritis may rarely occur. Endocarditis, nephritis, meningitis, and hepatitis are potential complications. About 6% of untreated patients die.

In both types of rat-bite fever, a leukocytosis of 15,000–30,000 cells/mm^3 is present, sometimes with eosinophilia. A biologic false-positive Venereal Disease Research Laboratories (VDRL) test is found in 25%–50% of patients. The course of *S. minor* infection without treatment is generally from 1–2 weeks, though relapses may occur for months.

The diagnosis is confirmed by culturing the causative organism from the blood or joint aspirate, or demonstration of an antibody response in the streptobacillary form. *S. minor* is demonstrable by animal inoculation with the patient's blood, usually in the guinea pig or mouse. Their blood will show large numbers of organisms in Wright-stained smears. Demonstration of *S. minor* in a darkfield preparation of exudate from an infected site establishes the diagnosis.

Rat-bite fever must be differentiated from erysipelas, pyogenic cellulitis, viral exanthems, gonococcemia, meningococcemia, and Rocky Mountain spotted fever.

Prompt cauterization of bites by nitric acid may prevent the disease. Cleansing of the wound, tetanus prophylaxis, and amoxicillin-clavulanate 875/125 mg are recommended for patients seen shortly after a bite. Both types respond readily to penicillin or doxycycline therapy.

TULAREMIA

Tularemia, also known as Ohara disease or deer fly fever, is a febrile disease caused by *Francisella tularensis*, a short, nonmotile, non-spore-forming, gram-negative coccobacillus. Tularemia is characterized by sudden onset, with chills, headache, and leukocytosis, after an incubation period of 2–7 days. Its clinical course is divided into several general types. The causative organism poses a bioterrorism threat.

Fig. 14.45 Tularemia. (Courtesy Stephen D. Hess, MD, PhD.)

The vast majority of tularemia cases are the ulceroglandular type, which begins with a primary papule or nodule that rapidly ulcerates at the site of infection. This usually occurs through contact with tissues or body fluids of infected mammals from an abrasion or scratch (Fig. 14.45), usually on the fingers, neck, or conjunctiva. The bites of a tick, *Dermacentor andersoni* or *Amblyomma americanum*, and of a deer fly, *Chrysops discalis*, also transmit this disease, and in such cases, primary lesions are usually found on the legs or the perineum. The primary ulcer is tender, firm, indolent, and punched out, with a necrotic base that heals with scar formation in about 6 weeks. A lymphangitis spreads from the primary lesion; the regional lymph glands become swollen, painful, and inflamed, and tend to break down, forming suppurative subcutaneous nodules resembling those of sporotrichosis. The ulcers extend in a chain from the ulcer to the enlarged lymphatic glands.

The course of the ulceroglandular type is marked in the early stages by headache, anorexia, and vomiting, as well as articular and muscular pains. The fever is at first continuous, varying between 102°F and 104°F (38.8°C and 40°C), and later shows morning remissions, then falls by lysis to normal. Other skin lesions encountered in the disease course are not characteristic and are probably of a toxic or reactive nature. A macular, papular, vesicular, or petechial exanthem may occur. Erythema multiforme and erythema nodosum often occur.

In the typhoidal type, the site of inoculation is not known, and there is no local sore or adenopathy. This form of tularemia is characterized by persistent fever, malaise, GI symptoms, and the presence of specific agglutinins in the blood serum after the first week. Other, uncommon types include an oculoglandular form, in which primary conjunctivitis is accompanied by enlargement of the regional lymph nodes. The pneumonic type occurs rarely in laboratory workers and is most severe. The oropharyngeal form may occur after ingestion of infected and inadequately cooked meat. In the glandular type, there is no primary lesion at the site of infection, but there is enlargement of regional lymph glands followed by generalized involvement. Several cases, mostly in

children, have been acquired from cat bites, the cats having previously bitten infected rabbits.

The most frequent sources of human infection are the handling of wild rabbits and the bite of deer flies or ticks. Outbreaks of tularemia occur chiefly at times of the year when contact with these sources of infection is likely. No instance of the spread of the infection from person to person by contact has been reported. The disease occurs most often in the western and southern United States, although cases have been reported in almost all states and in Japan. In Russia and other countries in the Northern Hemisphere, tularemia may be contracted from polluted water contaminated by infected rodent carcasses.

A definite diagnosis is made by staining smears obtained from the exudate with specific fluorescent antibody. *F. tularensis* can be cultured only on special media containing cystine glucose blood agar or other selective media. Routine culture media do not support growth. The bacilli can be identified by inoculating guinea pigs intraperitoneally with sputum or with bronchial or gastric washings, exudate from draining lymph nodes, or blood. The agglutination titer becomes positive in the majority of patients after 2 weeks of illness. A fourfold rise in titer is diagnostic; a single convalescent titer of 1:160 or greater is diagnostic of past or current infection. PCR is also successful in identifying the infectious agent.

The main histologic feature of tularemia is that of a granuloma; the tissue reaction consists primarily of endothelial cells and the formation of giant cells. Central necrosis and liquefaction occur, accompanied by polymorphonuclear leukocyte infiltration. Surrounding this is a tuberculoid granulomatous zone, and peripherally lymphocytes form a third zone. Small secondary lesions may develop. These pass through the same stages and tend to fuse with the primary lesion.

All butchers, hunters, cooks, and others who dress rabbits should wear protective gloves. Thorough cooking destroys the infection in a rabbit, thus rendering an infected animal harmless as food. Ticks should be removed promptly, and tick repellents may be of value for people with occupations that require frequent exposure.

Streptomycin given intravenously is the treatment of choice. IV gentamicin, or oral doxycycline or ciprofloxacin are alternatives.

BRUCELLOSIS

Brucellosis is also known as undulant fever. *Brucellae* are gram-negative rods that produce an acute febrile illness with headache, or at times an indolent chronic disease characterized by weakness, malaise, and low-grade fever. Brucellosis is acquired primarily by contact with infected animals or animal products. Workers in the meatpacking industry are mainly at risk; however, veterinarians, pet owners, and travelers who consume unpasteurized milk or cheese may also contract the disease. Approximately 5%–10% of patients develop skin lesions. The large variety of cutaneous manifestations reported include erythematous papules, diffuse erythema, abscesses, erysipelas-like lesions, leukocytoclastic vasculitis, thrombocytopenic purpura, SJS, and erythema nodosum–like lesions. Biopsy may reveal noncaseating granulomas. Diagnosis is by culture of blood, bone marrow, or granulomas and may be confirmed by a rising serum enzyme-linked immunosorbent assay (ELISA) or agglutination titer. PCR is available as well. Treatment is with doxycycline and gentamicin in combination.

RICKETTSIAL DISEASES

Rickettsiae are obligate, intracellular, gram-negative bacteria. The natural reservoirs of these organisms are the blood-sucking arthropods; when transmitted to humans through insect inoculation, the rickettsiae may produce disease. Most of the human diseases incurred are characterized by skin eruptions, fever, headache, malaise, and prostration. Diagnosis is usually made on a clinical basis and is confirmed by indirect fluorescence antibody testing, which may be verified by Western blot or PCR. Therapy is with doxycycline, 100 mg twice daily for 7 days. In addition to the diseases discussed in the following sections, Q fever, caused by *Coxiella burnetii*, is an acute febrile illness from this general class that infrequently has skin manifestations, but these are nonspecific and nondiagnostic in nature.

TYPHUS GROUP

Louse-borne epidemic typhus, caused by *Rickettsia prowazekii;* mouse, cat, or rat flea-borne endemic typhus, caused by *Rickettsia typhi;* and scrub typhus, a mite-borne infection caused by *Rickettsia tsutsugamushi*, constitute the typhus group.

Epidemic Typhus

Humans contract epidemic typhus from an infestation by body lice (*Pediculus humanus* var. *corporis*), which harbor the rickettsiae. *R. prowazekii* is not transmitted transovarially because it kills the louse 1–3 weeks after infection. For many years, humans were the only known vector, but several cases of sporadic disease have been reported involving direct or indirect contact with the flying squirrel, and a reservoir exists in this animal. While the louse feeds on the person's skin, it defecates. The organisms in the feces are scratched into the skin. Some 2 weeks after infection, the prodromal symptoms of chills, fever, aches, and pains appear. After 5 days, a pink macular eruption appears on the trunk and axillary folds and rapidly spreads to the rest of the body, but usually spares the face, palms, and soles. These macules may later become hemorrhagic (Fig. 14.46), and gangrene of the fingers, toes, nose, and earlobes may occur.

Fig. 14.46 Epidemic typhus. (Courtesy Richard DeVillez, MD.)

Mortality rate is 6%–30% in epidemics, with the highest death and complication rates occurring in patients over age 60.

Serologic testing using immunofluorescent antibody (IFA) and Western blot for specificity becomes positive after the 8th–12th day of illness. Doxycycline, 100 mg twice daily for 7 days, is curative. Prophylaxis is by vaccination and delousing; people who succumb are usually living under miserable sanitary conditions, as occur during war and after natural disasters. Vaccination is suggested only for special high-risk groups.

Brill-Zinsser disease may occur as a recrudescence of previous infection, with a similar but milder course of illness that more closely resembles endemic typhus.

Endemic Typhus

Endemic (murine) typhus is a natural infection of rats and mice by *R. typhi*, sporadically transmitted to humans by the rat flea, *Xenopsylla cheopis*. In south Texas, the disease is transmitted by the cat flea, *Ctenocephalides felis*, with opossums as the natural reservoir of disease. Endemic typhus has the same skin manifestations as epidemic typhus, but these are less severe, and gangrene does not supervene. Approximately 50% of patients with murine typhus have a skin eruption. Serologic testing using IFA and Western blot for specificity becomes positive in 50% of patients at 1 week and almost all by 2 weeks. Fever and severe headache are suggestive early symptoms. Endemic typhus occurs worldwide. In the United States the southeastern states bordering the Gulf of Mexico, especially Texas, and California and Hawaii have been the most common sites of incidence. It most often occurs in urban settings, with peak incidence in the summer and fall. Treatment is the same as that for louse-borne (epidemic) typhus.

Scrub Typhus

Also known as tsutsugamushi fever, scrub typhus is characterized by fever, chills, intense headache, skin lesions, and pneumonitis. The primary lesion is an erythematous papule at the site of a mite bite, most often on the scrotum, groin, or ankle. It becomes indurated, and a multilocular vesicle rests atop the papule. Eventually, a necrotic ulcer with eschar and surrounding indurated erythema develops, and there is regional lymphadenopathy. About 10 days after a mite bite, fever, chills, and prostration develop, and within another 5 days, pneumonitis and the skin eruption evolve. The erythematous macular eruption begins on the trunk, extends peripherally, and fades in a few days. Deafness and tinnitus occur in about one fifth of untreated patients.

Scrub typhus is caused by *R. tsutsugamushi*. The vector is the trombiculid red mite (chigger), which infests wild rodents in scrub or secondary vegetation in transitional terrain between forests and clearings in Far Eastern countries such as Japan, Korea, Southeast Asia, and Australia. Serologic diagnosis and treatment are as for other forms of rickettsias; however, in areas of the world where there is reduced susceptibility to tetracyclines, such as Thailand, rifampin is more reliable.

SPOTTED FEVER GROUP

The spotted fever group includes Rocky Mountain spotted fever, caused by *Rickettsia rickettsii;* Mediterranean (boutonneuse) fever, which when seen in Africa has been called Kenyan or South African tick-bite fever, caused by *R. conorii;* North Asian tick-borne rickettsiosis, caused by *R. sibirica;* Queensland tick typhus, caused by *R. australis;* African tick-bite fever, caused by *R. africae;* Flinders Island spotted fever, caused by *R. honei;* Yucatan spotted fever, caused by *R. felis* carried by the cat flea vector *Ctenocephalides felis;* Japanese spotted fever, caused by *R. japonica;* a spotted fever in the United States caused by *R. parkeri* and one in California caused by *Rickettsia* 364D; Russian vesicular rickettsiosis, caused by *R. akari* and a novel case in Brazil caused by *Rickettsia* sp. in the Atlantic rainforest. Additionally, tick-borne lymphadenopathy (TIBOLA) and *Dermacentor*-borne necrosis–eschar–lymphadenopathy (DEBONEL) are linked to a disease transmitted by the *Dermacentor* tick; they have distinctive features. The tick usually attaches to the scalp and will cause an eschar and sometimes alopecia. Adenopathy, fever, and a spotted eruption occur.

Only the first two types of spotted fever listed, Rocky Mountain and Mediterranean, are discussed here in detail. All spotted fevers are characterized by headache, fever, and a rash, the latter most frequently being a pink papular eruption, which may have petechiae, and in the case of African tick-bite fever, eschars. All are treated with doxycycline, 100 mg twice daily for 7 days. Most patients respond well, and complications are minimal. Ticks are the vectors of all except Yucatan spotted fever. Tick prevention strategies are outlined in Chapter 20.

Rocky Mountain Spotted Fever

At 1–2 weeks after the tick bite, chills, fever, and weakness occur. An eruption appears, but unlike typhus, it begins on the ankles, wrists, and forehead rather than the trunk. The initial lesions are small, red macules, which blanch on pressure and rapidly become papular in untreated patients. Spread to the trunk occurs over 6–18 hours, and the lesions become petechial and hemorrhagic over 2–4 days (Fig. 14.47).

A vasculitis of the skin is the pathologic process, and *R. rickettsii* can be found in these initial macules by applying a fluorescent antibody technique to frozen sections. This is a very specific, but not very sensitive, method. In the 10%–20% of patients without a rash, the risk of a delay in diagnosis and a fatal outcome is greatest, with the case-fatality rate rising precipitously if antibiotics are not initiated before the fifth day. An eschar is occasionally present at the tick-bite site and is a subtle clue to the diagnosis. In untreated patients with severe disease, a multisystem disorder appears, with renal, pulmonary, CNS, and peripheral nervous system abnormalities and hepatomegaly most often found. Mortality in older patients approaches 60%, but is much lower in younger patients.

Ticks spread the causative organism, *R. rickettsii*. Principal offenders are the wood tick *(Dermacentor andersoni)*, the dog tick (*D. variabilis* and *R. sanguineus* in Arizona), and the Lone Star tick *(Amblyomma americanum)*. Antibodies become positive in the second or third week of illness, too late to be of help when the decision to institute therapy is necessary. This decision is made by clinical considerations. A clue may be the recent illness of a pet dog, because *R. rickettsii* will cause symptomatic illness in infected dogs. Treatment is with doxycycline, 100 mg twice daily for 7 days.

Fig. 14.47 Rocky Mountain spotted fever. (Courtesy Paul Honig, MD.)

Fig. 14.48 Boutonneuse fever.

Fig. 14.49 Rickettsialpox.

Mediterranean Spotted Fever

Boutonneuse fever, or Mediterranean fever, is an acute febrile disease endemic in southern Europe and northern Africa; it is the prototype of the spotted fever group of diseases. It affects primarily children and is characterized by a sudden onset with chills, high fever, headache, and lassitude. The tick bite produces an indurated papule known as tache noire, which becomes a necrotic ulcer. The erythematous macular and papular eruption develops on the trunk, palms, and soles (Fig. 14.48).

The causative organism is *Rickettsia conorii*, transmitted by the dog tick, *Rhipicephalus sanguineus*. As with all rickettsial diseases, the diagnosis is confirmed with serology and treatment is with doxycycline. Even without therapy, the prognosis is good, and complications are rare with Mediterranean fever.

RICKETTSIALPOX

First recognized in New York in 1946, rickettsialpox has been found in other U.S. cities and in Russia. It is an acute febrile disease characterized by the appearance of an initial lesion at the site of the mite bite about a week before the onset of the fever. This firm, 5–15 mm, round or oval vesicle persists for 3–4 weeks and heals with a small, pigmented scar. Regional lymphadenitis is present. The fever is remittent and lasts about 5 days. Chills, sweats, headache, and backache accompany the fever. A rash resembling varicella develops 3 or 4 days after onset of fever (Fig. 14.49). This secondary eruption is papulovesicular, numbers about 5 up to 50 lesions, and is generalized in distribution. It fades in about 1 week.

The rodent mite, *Allodermanyssus (Liponyssoides) sanguineus*, transmits the causative organism, *Rickettsia akari*. The house mouse, *Mus musculus*, is the reservoir. All cases have occurred in neighborhoods infested by mice, on which the rodent mite has been found. Diagnosis is confirmed by serologic testing. The disease is self-limited, and complete involution occurs in, at most, 2 weeks. Doxycycline is the agent of choice for treatment of rickettsialpox.

EHRLICHIOSIS

The tick-borne ehrlichial organisms, which affect phagocytic cells, manifest as a febrile illness accompanied by headache and a rash. Human monocytic ehrlichiosis (HME) is caused by *Ehrlichia chaffeensis;* human granulocytic anaplasmosis (HGA) by *Anaplasma phagocytophilia* groups; Sennetsu fever, a mononucleosis-type illness, by *Ehrlichia sennetsu;* and *Ehrlichia ewingii* all produce a similar symptomatic illness. HME is transmitted by *Amblyomma americanum* or *Dermacentor variabilis*. It is most common in men age 30–60. The predominant U.S. regions reporting ehrlichiosis are the south-central, southeastern, and mid-Atlantic states. The same *Ixodes* ticks that transmit Lyme disease and babesiosis transmit HGA, and the infection occurs in the same geographic areas, the northeast and Pacific northwestern United States. Coinfection with these agents occurs.

Skin eruptions are present in only about one third of HME patients and 10% of HGA patients. The lesions are usually present on the trunk and are nondiagnostic. A mottled or diffuse erythema, a fine petechial eruption, lower extremity vasculitis, and a macular, papular, vesicular, or urticarial morphology have all been seen. Acral edema with desquamation and petechiae of the palate may be present. Involvement of the kidneys, lungs, and CNS occurs in severe cases.

If the diagnosis is suspected, a complete blood count will usually show thrombocytopenia and leukopenia. The leukocytes should be inspected microscopically for intracytoplasmic microcolonies called morulae, seen more frequently in HGA than HME. IFA testing and PCR analysis are positive, but asymptomatic infection is common, and seroprevalence rates are high in endemic areas. Culture of the organism is diagnostic. Doxycycline is the treatment of choice, 100 mg twice daily for 7 days. Life-threatening disease is usually seen in the immunosuppressed population.

LEPTOSPIROSIS

Leptospirosis is a systemic disease caused by many strains of the genus *Leptospira*. After an incubation period of 8–12 days, Weil disease (icteric leptospirosis) starts with an abrupt onset of chills, followed by high fever, intense jaundice, petechiae, and purpura on both skin and mucous membranes, and renal disease, manifested by proteinuria, hematuria, and azotemia. Death may occur in 5%–10% of patients as a result of renal failure, vascular collapse, or hemorrhage. Leukocytosis of 15,000–30,000 cells/mm^3 and lymphocytosis in CSF are usually present.

Pretibial fever (Fort Bragg fever, anicteric leptospirosis) has an associated acute exanthematous infectious erythema, generally most marked on the shins. High fever, conjunctival suffusion, nausea, vomiting, and headache characterize the septicemic first stage. This lasts 3–7 days, followed by a 1- to 3-day absence of fever. During the second stage, when immunoglobulin M (IgM) antibody develops, headache is intense, fever returns, and ocular manifestations, such as conjunctival hemorrhage and suffusion, ocular pain, and photophobia, are prominent. At this time, the eruption occurs. It consists of 1–5 cm erythematous patches or plaques that histologically show only edema and nonspecific perivascular infiltrate. The skin lesions resolve spontaneously after 4–7 days. There may be different clinical manifestations from identical strains of *Leptospira*.

Leptospira interrogans, serotype *icterohaemorrhagiae*, has been the most common cause of Weil disease, whereas pretibial fever is most often associated with serotype *autumnalis*. Humans acquire both types accidentally from urine or tissues of infected animals or indirectly from contaminated soil or from drinking or swimming in contaminated water. Travelers to the tropics who engage in water sports are at risk. In the continental United States, dogs and cats are the most common animal source; worldwide, rats are more often responsible. Leptospira enter the body through abraded or diseased skin and the GI or upper respiratory tract.

Leptospirosis may be diagnosed by finding the causative spirochetes in the blood by darkfield microscopy during the first week of illness, as well as by blood cultures, guinea pig inoculation, and the demonstration of rising antibodies during the second week of the disease. The microagglutination serologic test is the test of choice, but PCR and ELISA testing are also available.

Treatment with tetracyclines and penicillin shortens the disease duration if given early. Doxycycline, 100 mg/day for 1 week, is effective in mild disease; however, IV penicillin is necessary in severely affected patients. A dose of 200 mg once weekly may help prevent infection while visiting a hyperendemic area.

BORRELIOSIS

Spirochetes of the genus *Borrelia* are the cause of Lyme disease. This multisystem infection first presents with skin findings, and over time, multiple cutaneous signs may occur. These microorganisms are also the cause of relapsing fever, an acute illness characterized by paroxysms of fever. The more common type of relapsing fever is tick-borne, occasionally being reported in the United States. A louse-borne type is endemic only in Ethiopia. The nonspecific macular or petechial eruption occurs near the end of the 3- to 5-day febrile crisis.

Lyme Disease

Borrelia burgdorferi sensu lato species complex are responsible for inducing Lyme disease. These spirochetes are transmitted to humans by various members of the family of hard ticks, Ixodidae. Thirteen genomic strains are recognized to be geographically prominent and cause varying skin and systemic disease manifestations. *Borrelia burgdorferi* sensu stricto causes Lyme disease in the United States. *Borrelia lonestari* (a relapsing fever type of *Borrelia*, not in the *B. burgdorferi* sensu lato complex) causes disease in the southern states. It is transmitted by the bite of the Lone Star tick *(Amblyomma americanum)*, is the cause of southern tick-associated rash illness (STARI), or Masters disease, a condition characterized by erythema migrans, headache, stiff neck, myalgia, and arthralgia. *Borrelia garinii* and *Borrelia afzelii* are two major strains present in Europe, with *B. garinii* the principal agent of Lyme neuroborreliosis and *B. afzelii* associated with acrodermatitis chronica atrophicans, lymphocytoma, and in some cases, morphea and lichen sclerosis et atrophicus. If disease is not treated in the early stage, chronic arthritis and neurologic and cardiac complications frequently develop. Other strains are present in Europe and Asia, with a few reports implicating them in rare cases of Lyme disease.

Diagnosing early Lyme disease depends on recognition of the skin eruption. Approximately 50% of patients recall a tick bite, which leaves a small, red macule or papule at the site. The sites most often involved are the legs, groin, and axilla, with adults having lower extremity lesions most often and children more likely to manifest erythema migrans on the trunk. Between 3 and 32 days (median 7) after the bite, there is gradual expansion of the redness around the papule (Fig. 14.50A). The advancing border is usually slightly raised, warm, red to bluish red, and free of any scale. Centrally, the site of the bite may clear, leaving only a ring of peripheral erythema, or it may remain red, becoming indurated, vesicular, or necrotic. In Europe, the large annular variety is most common, whereas in the United States the lesions are usually homogeneous or have a central redness. The annular erythema usually grows to a median diameter of 15 cm but may range from 3–68 cm (Fig. 14.50B). It is accompanied by a burning sensation in half of patients; rarely is it pruritic or painful. Localized alopecia may develop at the site of erythema migrans.

Fig. 14.50 (A and B) Erythema migrans.

Fig. 14.51 Erythema migrans.

From 25%–50% of patients will develop multiple secondary annular lesions, similar in appearance to the primary lesion, but without indurated centers and generally of smaller size (Fig. 14.51). The lesions, 2–100 in number, spare the palms and soles. Without treatment, erythema migrans and the secondary lesions fade in a median of 28 days, although some may be present for months. Of untreated patients, 10% experience recurrences of erythema migrans over the following months. Diffuse urticaria, malar erythema, and conjunctivitis may be present during this early period. Malaise, fever, fatigue, headaches, stiff neck, arthralgia, myalgia, lymphadenopathy, anorexia, and nausea and vomiting may accompany early signs and symptoms of infection. Nonspecific findings include an elevated erythrocyte sedimentation rate in 50% and an elevated IgM level, mild anemia, and elevated liver function tests in 20% of patients. Usually, the symptoms are of mild severity, mimicking a slight flulike illness, except in patients coinfected with babesiosis, as in approximately 10% of cases in southern New England. *Ehrlichia* coinfections may also occur, because the latter two diseases are also tick-transmitted infections.

Males and females are equally affected, and the age range most often affected is of bimodal type, with an early peak at 5–19 and a later peak at 55–69 years. Onset of illness is generally between May and November, with more than 80% of cases in the Northern Hemisphere identified in June, July, or August. In the United States tick transmission of Lyme disease is by *Ixodes scapularis* in the Northeast and Midwest, and *Ixodes pacificus* is incriminated in the West. European cases are transmitted by the ticks *Ixodes ricinus* and *I. persulcatus*, and in Asia by *I. ovatus* and *I. persulcatus*.

The different subtypes of *Borrelia* present in Europe account for the clinical illness resulting from infection being somewhat different from that seen in the United States. In Europe a wider array of skin manifestations occur. There, erythema migrans occurs more often in females, is less likely to have multiple lesions, and the lesions last longer if untreated. European cases may also manifest *Borrelia*-induced lymphocytoma. It occurs from the time of erythema migrans until 10 months later. These are B-cell proliferations and present as red, indurated papules and plaques, which occur most often on the areola or earlobe. Acrodermatitis chronica atrophicans (see below) and some cases of morphea, atrophoderma of Pasini and Pierini, anetoderma, and lichen sclerosus et atrophicus are late cutaneous sequelae *of Borrelia afzelii* or *B. garinii* infection in Europe. Some patients with morphea-type lesions may have histopathologic features of an interstitial granulomatous dermatitis with histiocytic pseudorosettes present.

About 10% of untreated U.S. patients eventually develop a chronic arthritis of the knees, which in half of patients leads to severe disability. The arthritis symptoms are unusual in Europe. Cardiac involvement occurs most often in young men, with fluctuating degrees of atrioventricular block or complete heart block occurring over a brief time, 3 days to 6 weeks, early in the course of the illness. In European cases, a dilated cardiomyopathy may eventuate. Neurologic findings include stiff neck, headache, meningitis, cognitive deficits, paresthesias and radiculopathy, Bell palsy, optic neuritis, vestibular neuronitis, oculomotor palsy, and cranial and peripheral neuropathies and are much more frequently manifested in European patients. In Europe, infection may lead to Bannwarth syndrome, which is characterized by focal, severe, radicular pains; lymphocytic meningitis; and cranial nerve paralysis.

Several cases of transplacental transmission of *Borrelia* resulting in infant death have been reported. However, studies of Lyme disease in pregnancy have generally failed to implicate an association with fetal malformations directly.

Biopsy of erythema migrans reveals a superficial and deep perivascular and interstitial mixed-cell infiltrate. Lymphocytes, plasma cells, and eosinophils may be seen, the latter especially prominent when the center of the lesion is biopsied. Warthin-Starry staining may reveal spirochetes in the upper dermis.

The clinical finding of erythema migrans is the most sensitive evidence of early infection. Serologic conversion in U.S. patients is as follows: 27% when symptoms present for fewer than 7 days, 41% with symptoms for 7–14 days, and 88% with symptoms longer than 2 weeks. For this reason, the diagnosis should be made through recognition of erythema migrans. Although culture with PCR analysis is specific, it is not sensitive and is not available in most areas. Serologic testing is then the confirmatory test. The

screening examination is ELISA, which is 89% sensitive and 72% specific. Western blot is used to confirm the result. There are three antigenic bands used in the IgM test and 10 in the IgG test. Two of three in the IgM and 5 of 10 in the IgG must be positive to diagnose Lyme disease. False-positive tests occur in syphilis, pinta, yaws, leptospirosis, relapsing fever, infectious mononucleosis, and disease associated with autoantibody formation. The VDRL is negative in *B. burgdorferi* infection. Patients with erythema migrans secondary to STARI usually have negative serology for Lyme disease.

Treatment

The treatment of choice in adults with Lyme disease is doxycycline, 100 mg twice daily for 3 weeks. Amoxicillin, 500 mg thrice daily for 21 days, or cefuroxime axetil, 500 mg twice daily for 21 days, is also effective. Doxycycline is also effective against *Ehrlichia*, but the β-lactams are not. Children under age 9 should be treated with amoxicillin, 20 mg/kg/day in divided doses. Pregnant women with localized early Lyme disease should take amoxicillin; however, if disseminated disease is present, parenteral penicillin G or ceftriaxone is used. Immunodeficient patients may also benefit from IV penicillin or ceftriaxone, although the data are not robust for this recommendation.

More aggressive regimens are necessary for carditis and neurologic and arthritic involvement, with parenteral dosing regimens often indicated.

Tick control environmental measures and personal avoidance strategies are worthwhile when outdoor activities are planned in tick-infested areas. Inspecting for ticks after returning from outdoor activity is a good preventive measure. The tick needs to be attached for more than 24 hours to transmit disease in the United States. Nymphs are small and may be difficult to see; be aware of the freckle that moves. Prophylactic antibiotic therapy, with one dose of 200-mg doxycycline after a known tick bite with a partially engorged *Ixodes scapularis* in high-incidence areas, is 87% effective. An effective vaccine was withdrawn from the market because of poor sales.

Acrodermatitis Chronica Atrophicans

Also known as primary diffuse atrophy, acrodermatitis chronica atrophicans (ACA) is characterized by the appearance on the extremities of diffuse reddish or bluish red, paper-thin skin. The underlying blood vessels are easily seen through the epidermis. It occurs almost exclusively in Europe. The disease begins on the backs of the hands and feet, then gradually spreads to involve the forearms, the arms, and the lower extremities, knees, and shins. Occasionally, even the trunk may become involved. In the beginning, the areas may be slightly edematous and scaly, but generally they are level with the skin and smooth. After several weeks to months, the skin has a smooth, soft, thin, velvety feel and may easily be lifted into fine folds. It may have a peculiar pinkish gray color and a crumpled-cigarette-paper appearance. Well-defined, smooth, edematous, bandlike thickenings develop and may extend from a finger to the elbow (ulnar bands) or may develop in the skin over the shins. With progression of ACA, marked atrophy of the skin occurs.

Subcutaneous fibrous nodules may form, chiefly over the elbows, wrists, and knees. Nodules may be single or multiple and are firm and painless. Diffuse extensive calcification of the soft tissues may be revealed by radiographic examination. Xanthomatous tumors may occur in the skin. Hypertrophic osteoarthritis of the hands is frequently observed. Occasionally, atrophy of the bones of the involved extremities is encountered. Ulcerations and carcinoma may supervene on the atrophic patches. ACA is slowly progressive but may remain stationary for long periods. Patches may change slightly from time to time, but complete involution never occurs.

A spirochetosis, ACA is a late sequel of infection with *Borrelia afzelii*, transmitted by the tick *Ixodes ricinus*. Almost all patients with ACA have a positive test for antibodies to the spirochete, and Warthin-Starry stains demonstrate *B. afzelii* in tissue in some cases. The organism has been cultured from skin lesions of ACA.

Histologically, there is marked atrophy of the epidermis and dermis without fibrosis. The elastic tissue is absent, and the cutaneous appendages are atrophic. In the dermis, a bandlike lymphocytic infiltration is seen, which varies in abundance according to the stage of the disease. The epidermis is slightly hyperkeratotic and flattened, and beneath it, there is a distinctive narrow zone of connective tissue in which the elastic tissue is intact.

Antibiotic therapy, as for other forms of borreliosis, cures most patients with ACA.

MYCOPLASMA

Mycoplasma organisms are distinct from true bacteria in that they lack a cell wall and differ from viruses in that they grow on cell-free media. *Mycoplasma pneumoniae* (Eaton agent) is an important cause of acute respiratory disease in children and young adults. In the summer, it may account for an estimated 50% of pneumonias. Skin eruptions occur during the course of infection in approximately 25% of patients. The most frequently reported is a Stevens-Johnson–like syndrome. Although the skin lesions in these cases may be vesiculobullous or targetoid, a wide variety of eruptions occur, including urticarial, vesiculopustular, maculopapular, scarlatiniform, petechial, purpuric, and morbilliform lesions. These are distributed primarily on the trunk, arms, and legs. Ulcerative stomatitis, conjunctivitis, urogenital, anal or esophageal erosions may be present. Erythema nodosum, acute hemorrhagic edema of infancy, subcorneal pustular dermatosis, and Gianotti-Crosti syndrome have been occasionally reported, as well as isolated mucositis without skin lesions (Fuchs syndrome).

The diagnosis of *M. pneumoniae* infection is made in the acute situation by clinical means, but definitive diagnosis is made by enzyme immunoassay, PCR, or complement fixation techniques. Cold agglutinins with a titer of 1:128 or more are usually caused by *M. pneumoniae* infection. Occasionally, acrocyanosis may occur secondary to cold agglutinin disease, which clears with antibiotic therapy. Treatment is with either a macrolide (erythromycin, azithromycin, or clarithromycin) or doxycycline for 7 days.

CHLAMYDIAL INFECTIONS

Two species of *Chlamydiae*, *Chlamydia trachomatis* and *Chlamydia psittaci*, have been recognized. The two species share a major common antigen, and there are numerous serotypes within each species. In humans, *Chlamydia* causes trachoma, inclusion conjunctivitis, nongonococcal urethritis, cervicitis, epididymitis, proctitis, endometritis, salpingitis, pneumonia in the newborn, psittacosis (ornithosis), and lymphogranuloma venereum.

LYMPHOGRANULOMA VENEREUM

LGV is an STD caused by microorganisms of the *Chlamydia trachomatis* group and characterized by suppurative inguinal adenitis with matted lymph nodes, inguinal bubo with secondary ulceration, and constitutional symptoms. After an incubation period of 3–20 days, a primary lesion consisting of a 2–3 mm herpetiform vesicle or erosion develops on the glans penis, prepuce, or coronal sulcus, or at the meatus. In MSM, the lesion may be in the rectum. In women, it occurs on the vulva, vagina, or cervix. The lesion is painless and soon becomes a shallow ulceration. The initial symptom may be urethritis or proctitis. Extragenital primary infections of LGV are rare. An ulcerating lesion may appear at the site of infection on the fingers, lips, or tongue. In patients with HIV infection, a painful perianal ulcer may occur. Primary lesions heal in a few days.

About 2 weeks after the appearance of the primary lesion, enlargement of the regional lymph nodes occurs (Fig. 14.52). In one third of patients, the lymphadenopathy is bilateral. In the rather characteristic inguinal adenitis of LGV in men, the nodes in a chain fuse together into a large mass. The color of the skin overlying the mass usually becomes violaceous, the swelling is tender, and the bubo may break down, forming multiple fistulous openings. Adenopathy above and below the Poupart ligament produces the characteristic, but not diagnostic, groove sign. Along with the local adenitis, there may be systemic symptoms of malaise, joint pains, conjunctivitis, loss of appetite, weight loss, and fever, which may persist for several weeks. Patients with septic temperatures, enlarged liver and spleen, and even encephalitis have occasionally been observed.

Primary lesions of LGV are rarely observed in female patients or in MSM; they also have a lower incidence of inguinal buboes. Their bubo is typically pararectal in location. The diagnosis is recognized only much later, when the patient presents with an increasingly pronounced inflammatory stricture, which may be annular or tubular, of the lower rectal wall. Because most of the lymph channels running from the vulva drain into the nodes around the lower part of the rectum, an inflammatory reaction in these nodes results in secondary involvement of the rectal wall. The iliac nodes may also be involved. LGV may start in the rectum as proctitis, which may then progress to the formation of a stricture. The clinical hallmark is bloody, mucopurulent rectal discharge. Untreated rectal strictures in men and women may eventually require colostomy. With or without rectal strictures, patients in later stages of the disease may show elephantiasis of the genitals with chronic ulcerations and scarring of the vulva or penis (esthiomene).

Fig. 14.52 Lymphogranuloma venereum.

Cutaneous eruptions take the form of erythema nodosum, erythema multiforme, photosensitivity, and scarlatiniform eruptions. Arthritis associated with LGV involves the finger, wrist, ankle, knee, or shoulder joints. Marked weight loss, pronounced secondary anemia, weakness, and mental depression are often encountered in the course of the anorectal syndrome. Colitis resulting from LGV is limited to the rectum and rectosigmoid structures. Perianal fistulas or sinuses are often seen in cases of anorectal LGV. The various extragenital manifestations include glossitis with regional adenitis, unilateral conjunctivitis with edema of the lids caused by lymphatic blockage with lymphadenopathy, acute meningitis, meningoencephalitis, and pneumonia.

The diagnosis by nucleic acid amplification tests identifies *C. trachomatis* in a wide variety of specimens, including urine; urethral, rectal, and ulcer swabs; bubo aspirates; and biopsy specimens. In the complement fixation test a titer of 1:64 is highly suggestive. Microhemagglutination inhibition assays are also available and not only confirm the diagnosis, but also identify the strain. Three serotypes, designated L1, L2, and L3, are known for the LGV chlamydia. Characteristic surface antigens allow separation of the LGV chlamydia from the agents that cause trachoma, inclusion conjunctivitis, urethritis, and cervicitis, which also belong to the *C. trachomatis* group.

LGV occurs in all races, and the highest incidence is found in the 20- to 40-year-old age-group. Asymptomatic female contacts who shed *C. trachomatis* from the cervix are an important reservoir of infection. The classic disease in men is uncommon in the United States, whereas anorectal LGV continues to increase in MSM.

The characteristic changes in the lymph nodes consist of an infectious granuloma with the formation of stellate abscesses. There is an outer zone of epithelioid cells with a central necrotic core composed of debris of lymphocytes and leukocytes. In lesions of long duration, plasma cells may be present. Stellate abscess also occurs in cat-scratch disease, atypical mycobacterial infection, tularemia, and sporotrichosis.

Treatment

The recommended treatment of LGV is doxycycline, 100 mg twice daily for 3 weeks. An alternative is erythromycin, 500 mg four times daily for 21 days. Sexual partners within the prior 30 days should also be treated. The fluctuant nodules are aspirated from above through healthy, adjacent, normal skin to prevent rupture.

It should be emphasized again that all venereal infections may be mixed infections and that observation for simultaneous or subsequent development of another venereal disease should be unrelenting. This includes serologic testing for HIV disease.

15 Diseases Resulting From Fungi and Yeasts

Bonus images for this chapter can be found online at expertconsult.inkling.com

SUPERFICIAL AND DEEP MYCOSES

Fungal infections, including dermatophytes and candida, are the most common type of infection worldwide. Cutaneous infections are divided into superficial (those that affect mostly the skin) and deep (those that are typically more invasive) mycoses. In addition immunosuppressed patients are at high risk for opportunistic fungal infections, including from molds and other saprophytic fungi that are not typically pathogens in normal hosts.

Most mycotic infections are superficial and are limited to the stratum corneum, hair, and nails. In contrast, most deep mycoses are evidence of disseminated infection, typically with a primary pulmonary focus. Although blastomycosis, histoplasmosis, and coccidioidomycosis generally present as skin lesions, they are almost always evidence of a systemic infection. A few deep mycoses result from direct inoculation into the skin by a thorn or other foreign body, including cutaneous lymphangitic sporotrichosis, primary cutaneous phaeohyphomycosis, and chromomycosis. Phaeohyphomycosis may begin as a skin infection, but similar to all nondermatophyte fungi, immunosuppressed patients are at great risk of dissemination and death. Even cutaneous sporotrichosis may occasionally disseminate. Cutaneous aspergillosis can occur due to cutaneous embolization from a systemic (often a pulmonary) focus, but in immunosuppressed populations, direct inoculation of any saprophytic infection can lead to severe infection and then disseminate. In burn victims, *Aspergillus* can colonize the burn eschar. This colonization may often be treated with debridement alone. Deep incisional biopsies are required to determine whether viable tissue has been invaded beneath the eschar. Evidence of viable tissue invasion suggests a likelihood of systemic dissemination and is usually an indication for systemic antifungal therapy.

The major fungi that cause only stratum corneum, hair, and nail infection are the dermatophytes. They are classified in three genera: *Microsporum*, *Trichophyton*, and *Epidermophyton*. The identity of the pathogen may be important for determining a zoonotic reservoir of infection (e.g., cats or dogs for *Microsporum canis* infections, cattle for *Trichophyton verrucosum*, and rats for granular zoophilic *Trichophyton mentagrophytes*).

Susceptibility and Prevalence

Local immunosuppression from a potent topical corticosteroid or calcineurin inhibitor may promote larger lesions of cutaneous spread of dermatophyte infection. A defective cutaneous barrier, as in patients with ichthyosis, can also predispose to widespread tinea infection. Close contact with other infected individuals can lead to local breakouts of tinea especially tinea capitis. Maceration of the feet due to sweating, athletics, and swimming can increase the risk of tinea pedis.

Dermatophytes almost exclusively infect the skin. Patients with blood type A are somewhat more prone to chronic disease, and those with autosomal recessive CARD9 deficiency are susceptible to invasive dermatophyte fungal infection with dissemination to lymph nodes and the central nervous system (CNS). Many individuals will carry *Trichophyton rubrum* asymptomatically, which may be an autosomal dominant inherited tendency. When they are exposed to a hot, humid climate or occlusive footwear, these patients often become symptomatic. Reported prevalence rates are therefore greatly affected by climate, footwear, and lifestyle.

Antifungal Therapy

Specific therapeutic recommendations will be made in each section; the following is an overview of available options. Topical agents provide safe, cost-effective therapy for limited superficial fungal infections. When considering the use of an oral antifungal agent, factors include the type of infection, organism, spectrum, pharmacokinetic profile, safety, compliance, age, and cost. Laboratory monitoring recommendations for systemic antifungals change frequently so the reader is advised to read the latest guidelines before prescribing systemic therapy. Griseofulvin has a long safety record but requires longer courses of therapy than newer agents. Topical antifungals remain very cost-effective for limited cutaneous disease. Dermatophyte infection involving hair-bearing areas (scalp, beard, thick hair on arms or legs) often requires oral therapy due to infection of the hair follicle. Infants may respond to topical therapy even in hair-bearing areas due to immature hair follicles. Lesions accidentally pretreated with topical steroids or calcineurin inhibitors may also require systemic therapy.

Various classes of antifungals are in use. The imidazoles include clotrimazole, miconazole, econazole, sulconazole, oxiconazole, voriconazole, efinaconazole, fenticonazole, and ketoconazole. They work by inhibition of cytochrome P450 14α-demethylase, an essential enzyme in ergosterol synthesis. Nystatin is a polyene that works by irreversibly binding to ergosterol, an essential component of fungal cell membranes but is used for *Candida* infections and is not effective for treating dermatophytes. Naftifine, terbinafine, and butenafine are allylamines, and their mode of action is inhibition of squalene epoxydation. The triazoles include itraconazole and fluconazole, which affect the CYP450 system.

For both itraconazole and griseofulvin, fatty food increases absorption. For itraconazole and ketoconazole, antacids, H2 antagonists, and proton pump inhibitors lower absorption. Terbinafine is less active against *Candida* and *Microsporum* species (spp.) in vitro. In vivo, adequate doses can be effective against these organisms. Terbinafine has limited efficacy in the oral treatment of tinea versicolor but is effective topically. Although few drug interactions have been reported with terbinafine, and the bioavailability is unchanged in food, hepatotoxicity, leukopenia, toxic epidermal necrolysis, and taste disturbances occur infrequently. Ketoconazole has a wide spectrum of action against dermatophytes, yeasts, and some systemic mycoses, but has the potential for hepatotoxicity. The U.S. Food and Drug Administration (FDA) has advised that systemic ketoconazole should not be used for skin and nail infections and should only be used for systemic fungal infections when no other medication is available (http://www.fda.gov/Drugs/DrugSafety/ucm500597.htm).

Fluconazole is mainly used to treat *Candida* infections, but has shown efficacy in the treatment of dermatophytoses both in daily and in weekly doses. It also has benefit in infants and young children because fluconazole has approval for candidal infections in infants and therefore is a reasonable off-label option for dermatophyte infections when needed in this population. Griseofulvin is FDA approved for tinea capitis in children over 2 and terbinafine only over age 4 years, but fluconazole has approval in infancy for

various fungal infections. Although pulse therapy with fluconazole has been shown effective, patients may have trouble remembering intermittent dosing schedules. Both terbinafine and itraconazole have been shown to be effective and well tolerated in several studies of the treatment of tinea capitis and onychomycosis in children. However, itraconazole has been associated with reports of heart failure.

Voriconazole has exceptional activity against a wide variety of yeasts, as well as many other fungal pathogens, but has been associated with photosensitivity, premature photoaging, actinic keratoses, squamous cell carcinoma, melanoma, and porphyria. Posaconazole has significant in vitro activity against *Candida* spp., although some resistance has been reported to this drug.

The echinocandins inhibit β-(1,3)-glucan synthesis, thus damaging fungal cell walls. These drugs are active against most *Candida* spp. and fungistatic against *Aspergillus* spp. The echinocandins have limited activity against zygomycetes, *Cryptococcus neoformans*, or *Fusarium* spp. Caspofungin was the first drug in this class to be marketed in the United States for refractory invasive aspergillosis. Micafungin also belongs to this antifungal class. Adverse events are uncommon but include phlebitis, fever, elevated liver enzymes, and mild hemolysis. The drugs must be given intravenously. Metabolism is mainly hepatic. In the setting of *Candida* sepsis, results are similar to those achieved with amphotericin B, with substantially lower toxicity. The echinocandins may be used together with other antifungal agents in the treatment of life-threatening systemic fungal infections, such as disseminated aspergillosis refractory to other regimens.

THE SUPERFICIAL MYCOSES

TINEA CAPITIS

Tinea capitis, known colloquially as scalp "ringworm," can be caused by all of the pathogenic dermatophytes. In the United States most cases are caused by *Trichophyton tonsurans*. Pet exposure (especially cat) is associated with tinea capitis caused by *Microsporum canis*. As people travel and emigrate from other countries, the diversity of fungi causing tinea capitis in a region can rise.

Tinea capitis occurs mainly in children, although it may be seen at all ages. Boys have tinea capitis more frequently than girls; however, in epidemics caused by *T. tonsurans*, both genders are often affected equally. African American children have a higher incidence of *T. tonsurans* infections than other groups. The infection is also common among Latin American children.

Trichophyton tonsurans can produce black dot tinea (Fig. 15.1), scaling alopecic plaques, subtle seborrheic-like scaling, and/or inflammatory kerion. Black dot tinea occurs due to the fungi invading the follicle (endothrix) and may also be caused by *Trichophyton violaceum*, an organism rarely seen in the United States. Both of these organisms produce chains of large spores within the hair shaft (large-spore endothrix). They do not fluoresce with Wood's light.

The *Microsporum canis* complex includes a group of organisms that produce small spores visible on the outside of the hair shaft (small-spore ectothrix). These fungi fluoresce under Wood's light examination. The *M. canis* complex includes *M. canis*, *M. canis distortum*, *Microsporum ferrugineum*, and *M. audouinii*. *M. canis* infections begin as scaly, erythematous, papular eruptions with loose and broken-off hairs. The lesions typically become highly inflammatory, although *M. audouinii* produces less inflammatory lesions. Deep, tender, boggy plaques exuding pus are known as kerion celsii (Fig. 15.2). Kerion may be followed by scarring and permanent alopecia in the areas of inflammation and suppuration, although with early treatment hair regrowth is common. Prompt administration of oral antifungals is most important but systemic corticosteroids for a short period, along with appropriate antifungal therapy, can greatly diminish the inflammatory response and reduce the risk of scarring, and this therapy should be considered in the patient with highly inflammatory lesions.

Many children are asymptomatic carriers of *T. tonsurans* and represent a source of infection for classmates and siblings. Numerous studies have shown that 5%–15% of urban children in Western countries have positive scalp dermatophyte cultures. In one study, 60% of African American children with a positive scalp culture were asymptomatic.

The prevalence of dermatophytes varies throughout the world. Where animal herding is an important part of the economy, zoonotic fungi account for a significant proportion of cases of tinea. In south-central Asia, *T. violaceum* is the most common dermatophytic species isolated, with *M. audouinii* a close second. Other common organisms include *Trichophyton schoenleinii*, *T. tonsurans*, *Microsporum gypseum*, *T. verrucosum*, and *T. mentagrophytes*. In East Asia, *T. violaceum* and *M. ferrugineum* are important pathogens. In Europe, African and Caribbean immigrants account for a large proportion of new patients with tinea capitis. Important

Fig. 15.1 Tinea capitis.

Fig. 15.2 Kerion. (Courtesy Steven Binnick, MD.)

pathogens include *T. tonsurans*, *M. audouinii* var. *langeronii*, *Trichophyton soudanense*, and *T. violaceum*. *Trichophyton megninii* is a rare cause of tinea capitis largely restricted to southwestern Europe. In Africa, large-scale epidemics are associated with *T. soudanense*, *T. violaceum*, *T. schoenleinii*, and *Microsporum* spp. In Australia, the predominantly Caucasian population experiences infections, mostly with *M. canis*, but *T. tonsurans* is now equal in prevalence in some areas of the continent. Recent immigrants have a high incidence of tinea capitis with organisms common in their regions of origin. Among African and Arab immigrants, *T. soudanense*, *T. violaceum*, and *M. audouinii* are particularly common.

Favus

Favus, which is extremely rare in the United States, appears chiefly on the scalp but may affect the glabrous skin and nails. On the scalp, concave sulfur-yellow crusts form around loose, wiry hairs. Atrophic scarring ensues, leaving a smooth, glossy, thin, paper-white patch. On the glabrous skin, the lesions are pinhead to 2 cm in diameter with cup-shaped crusts called scutulae, usually pierced by a hair as on the scalp. The scutulae have a distinctive mousy odor. When the nails are affected, they become brittle, irregularly thickened, and crusted under the free margins. Other types of dermatophytes such as *T. rubrum* may appear similar clinically.

Favus is prevalent in the Middle East, southeastern Europe, South Africa and the countries bordering the Mediterranean Sea.

Pathogenesis and Natural History

The incubation period of anthropophilic (affecting humans) tinea capitis is 2–4 days, although the period is highly variable, and asymptomatic carriers are common. The hyphae grow downward into the follicle, on the hair's surface, and the intrafollicular hyphae break up into chains of spores. There is a period of spread (4 days to 4 months) during which the lesions enlarge and new lesions appear. At about 3 weeks, hairs break off a few millimeters above the skin surface. Within the hair, hyphae descend to the upper limit of the keratogenous zone and here form Adamson "fringe" on about the 12th day. During a refractory period (4 months to several years) fewer new lesions develop. The clinical appearance is constant, with the host and parasite at equilibrium. This may be followed by a period of involution in which the formation of spores gradually diminishes. Zoonotic (from animals) fungal infections often are more highly inflammatory but undergo similar phases of evolution.

Diagnosis

Wood's Light

Ultraviolet (UV) light of 365-nm wavelength commonly known as the Wood's light, is used to demonstrate fungal fluorescence. Infections caused by *M. audouinii*, *M. canis*, *M. ferrugineum*, *M. distortum*, and *T. schoenleinii* will fluoresce. In a darkroom, the skin under this light fluoresces faintly blue, and dandruff usually is bright blue-white. Infected hair fluoresces bright green or yellow-green due to the presence of pteridine. Large-spore endothrix organisms (e.g., *T. tonsurans*, *T. violaceum*) and *T. verrucosum* (a cause of large-spore ectothrix) do not fluoresce making woods light less helpful because *T. tonsurans* is the most common type of tinea capitis.

Laboratory Examination

Tinea capitis can be a clinical diagnosis if the classic scaling, alopecic plaques with nuchal or posterior cervical lymphadenopathy are seen in a child. In one study 97% percent of children with tinea capitis demonstrated posterior cervical or nuchal lymphadenopathy, making this a very useful negative predictor if absent. For more diffuse "seborrheic" patterns or without significant alopecia or if another diagnosis is being considered, a culture can prove the diagnosis. Cultures from a kerion (inflammatory tinea capitis) may be false negative due to the exuberant inflammatory response so treatment is typically empiric. For demonstration of the fungus in a highly inflammatory plaque, two or three loose hairs are carefully removed with epilating forceps from the suspected areas. If fluorescence occurs, it is important to choose these hairs. Bear in mind that hairs infected with *T. tonsurans* do not fluoresce. In black dot ringworm or in patients with seborrheic scale, small broken fragments of infected hair or scaling can be scraped or brushed off with a sterile toothbrush. The hairs are placed on a slide and covered with a drop of a 10%–20% potassium hydroxide (KOH) solution. A coverslip is then applied, and the specimen is warmed until the hairs are macerated. Dimethyl sulfoxide (DMSO) can be added to the KOH solution in concentrations of up to 40%. This additive allows for rapid clearing of keratin without heating. Once the keratin in the hairs has dissolved somewhat, they can be examined first with a low-power objective and then with a high-power objective for detail. The mycelia may be seen under low-power microscopy, but better observation of both hyphae and spores is obtained by the 10× objective with the condenser lowered down or the light aperture closed by two thirds. A staining method using 100 mg of chlorazol black E dye in 10 mL of DMSO and adding it to a 5% aqueous solution of KOH can be helpful. Toluidine blue 0.1% can also be used on thin specimens, but contains no clearing agent to dissolve keratin. The patterns of endothrix and ectothrix involvement described earlier, together with local prevalence data, allow for identification of the organism.

Exact identification of the causative fungus is generally determined by culture, although molecular sequencing offers a more rapid alternative. For culture, several infected hairs are plated on Sabouraud dextrose agar, Sabouraud agar with chloramphenicol, Mycosel agar, or dermatophyte test medium (DTM). Laboratories differ in how they prefer the sample to be collected, but using a toothbrush to gently remove scale and loose hairs and transfer to the laboratory in a sterile container or a bacterial culturette moistened with sterile saline and then rubbed on the affected areas are the most common methods. On the first three media, a distinctive growth appears within 1–2 weeks. Most frequently, the diagnosis is made by the gross appearance of the culture growth, together with the microscopic appearance. With *Trichophyton* spp., growth on different nutrient agars is often required to identify the organisms beyond genus. DTM not only contains antibiotics to reduce growth of contaminants, but also contains a colored pH indicator to denote the alkali-producing dermatophytes although laboratory regulations have limited this use in academic centers. A few nonpathogenic saprophytes will also produce alkalinization, and in the occasional case of onychomycosis of toenails caused by airborne molds, a culture medium containing an antibiotic may inhibit growth of the true pathogen.

Differential Diagnosis

Tinea capitis must be differentiated clinically from chronic staphylococcal folliculitis, pediculosis capitis (head lice), psoriasis, seborrheic dermatitis, secondary syphilis, trichotillomania, alopecia areata, lupus erythematosus (LE), lichen planus, lichen simplex chronicus, and various inflammatory follicular conditions. The distinctive clinical features of tinea capitis are broken-off stumps of hairs, often in rounded patches in which there are crusts or pustules and few hairs. The broken-off hairs are loose. Diffuse seborrheic scaling with hair loss is a common presentation of *T. tonsurans* infections. Dermoscopy can reveal comma-shaped and corkscrew hairs. Horizontal bands and translucent hairs

in *M. canis* infections have been demonstrated on high-power dermoscopy.

In alopecia areata, the affected patches are bald, the skin is smooth and shiny without signs of inflammation or scaling, and exclamation point hairs can be seen on dermoscopy. Stumps of broken-off hairs are infrequently found, and no fungi are demonstrable. In seborrheic dermatitis, the involved areas are covered by fine, dry, or greasy scales. Hair may be lost, but the hairs are not broken and lymphadenopathy is generally absent. Atopic dermatitis can affect the scalp but is rarely only localized to the scalp. In psoriasis, well-demarcated, sometimes diffuse, areas of erythema and white or silver scaling are noted. Although in children psoriasis may first manifest in the scalp, there is usually some evidence of psoriasis elsewhere. Lichen simplex chronicus is frequently localized to the inferior margin of the occipital scalp. In trichotillomania, as in alopecia areata, inflammation and scaling are absent and the patterns of hair loss are unusual clinically. Serologic testing, scalp biopsies, and immunofluorescent studies may be indicated if the alopecia of secondary syphilis or LE is a serious consideration. It should be noted that adult patients with LE are susceptible to tinea capitis, which may be photosensitive and difficult to distinguish from LE plaques without biopsy and KOH examinations.

Treatment

Numerous clinical trials have demonstrated the effectiveness of itraconazole, terbinafine, and fluconazole. Griseofulvin remains the most frequently used antifungal agent in children, but because there are data that terbinafine may be more effective in *T. tonsurans* infections and the course of therapy is shorter, terbinafine is gaining favor, and both are considered first line. Griseofulvin has a long safety record. A meta-analysis of published studies shows mean efficacy for griseofulvin treatment of about 68% for *Trichophyton* spp. and 88% for *Microsporum*. For the ultramicronized form, doses start at 10 mg/kg/day. Griseofulvin must be given with a fatty food to ensure absorption. The ultramicrosized form absorbs more easily so doses are lower. The dose of micronized is 20 mg/kg/day (not to exceed 500 mg twice a day), although some advocate up to 25 mg/kg/day in recalcitrant cases. Treatment should continue for 6–8 weeks, or for at least 2 weeks after clinical or laboratory determined cure. For *Trichophyton* infections, terbinafine is usually effective in doses of 3–6 mg/kg/day for 3–6 weeks. In the United States it is FDA approved over 4 years of age, but some authors advocate for its use in younger children. Published dosing guidelines are based on the terbinafine granules, which can be difficult to obtain. Similar dosing that is used for onychomycosis in children based on the tablets is reasonable: 250-mg tablet for patients over 40 kg, 125 mg (½ tablet) for those 20–40 kg, and 62.5 mg (¼ tablet) for those under 20 kg. Terbinafine should not be mixed with acidic foods such as apple sauce because they may limit absorption. *Microsporum* infections require higher doses and longer courses of therapy with terbinafine, so griseofulvin is preferred in these infections.

Second-line agents include fluconazole (not to exceed adult dose) at doses of 3–6 mg/kg/day for 3–6 weeks lower doses lead to lower cure rates. Fluconazole 6mg/kg/week for 8–12 weeks has also been reported. Itraconazole has been shown to be effective in doses of 5 mg/kg/day (not to exceed adult dose) for 2–3 weeks, but reports of heart failure with itraconazole have limited its use. In neonates and children under 2 topical therapy is occasionally effective, likely due to the less mature hair follicles, but oral antifungals are recommended by a recent review.

Selenium sulfide shampoo or ketoconazole shampoo left on the scalp for 5 minutes three times a week can be used as adjunctive therapy to oral antifungal agents to reduce the shedding of fungal spores. Combs, brushes, and hats should be cleaned carefully, and natural bristle brushes must be discarded.

Prognosis

Recurrence is uncommon when adequate amounts of griseofulvin, fluconazole, or terbinafine have been taken, although exposure to infected persons, asymptomatic carriers, or contaminated fomites will increase the relapse rate. Without medication, there may be spontaneous clearing at about age 15 years, except with *T. tonsurans*, which often persists into adult life.

DERMATOPHYTIDS

In cases of inflammatory tinea capitis, widespread "id" eruptions may appear concomitantly on the trunk and extremities. These are vesicular, lichenoid, papulosquamous, or pustular and represent a systemic reaction to fungal antigens either during the infection or therapy for the infection. Although the eruptions are usually refractory to topical corticosteroids, they typically clear rapidly after treatment of the fungal infection.

An id reaction can be seen on the hands and sides of the fingers when there is an acute fungus infection of the feet. These lesions are mostly vesicular and are extremely pruritic and even tender. Secondary bacterial infection may occur; however, fungus is not demonstrable in the hand lesions. The onset can be accompanied by fever, anorexia, generalized adenopathy, spleen enlargement, and leukocytosis. Dermatophytid reactions from inflammatory tinea capitis may occasionally present as widespread eruption, usually follicular, lichenoid, or papulosquamous. An id reaction characterized by fine papules on the trunk, face, ears and extremities can occur during systemic therapy especially with griseofulvin for tinea capitis. Rarely, the eruption may be morbilliform or scarlatiniform. The erysipelas-like dermatophytid has been reported on the shin but must be differentiated from cellulitis that occurs as a result of skin breaks from tinea pedis.

The histologic picture of an id is characterized by spongiotic vesicles and a superficial, perivascular, predominantly lymphohistiocytic infiltrate. Eosinophils may be present. Diagnosis of a dermatophytid reaction depends on the demonstration of a fungus at some site remote from the suspect lesions of the dermatophytid, the absence of fungus in the id lesion, and involution of the lesion as the fungal infection subsides.

TINEA BARBAE

Ringworm of the beard, also known as tinea sycosis and barber's itch, is more common among those in agricultural pursuits, especially those in contact with farm animals, but may also be seen in wrestlers and through incidental contact. The involvement is mostly one sided on the neck or face. Typical scaling alopecic patches can occur in addition to a more inflammatory superficial, crusted, partially bald patches with folliculitis (Fig. 15.3) or deep, nodular, suppurative lesions possibly indicating a zoonotic infection.

The deep type develops slowly and produces nodular thickenings and kerion-like swellings, usually caused by *T. mentagrophytes* or *T. verrucosum*. As a rule, the swellings are confluent and form diffuse, boggy infiltrations with abscesses. The overlying skin is inflamed, the hairs are loose or absent, and pus may be expressed through the remaining follicular openings. Generally, the lesions are limited to one part of the face or neck in men. The superficial crusted type is characterized by a less inflammatory pustular folliculitis and may be associated with *T. violaceum* or *T. rubrum*. The affected hairs can sometimes be easily extracted. Rarely, *Epidermophyton floccosum* may cause widespread verrucous lesions known as verrucous epidermophytosis.

Fig. 15.3 Tinea barbae.

Fig. 15.4 Tinea faciei.

Fig. 15.5 Tinea corporis.

Diagnosis

The clinical diagnosis of tinea barbae is confirmed by the microscopic mounts of extracted hairs or a biopsy and culture of the tissue specimen.

Differential Diagnosis

The differential diagnosis includes staphylococcal folliculitis (sycosis vulgaris) and herpetic infections. Tinea barbae differs from sycosis vulgaris by usually sparing the upper lip and by often being unilateral. In sycosis vulgaris, the lesions are pustules and papules, pierced in the center by a hair, which is loose and easily extracted after suppuration has occurred. Herpetic infections usually demonstrate umbilicated vesicles. Tzanck preparations have a low diagnostic yield, but viral culture or direct fluorescent antibody is virtually always positive.

Treatment

As in tinea capitis, oral antifungal agents are required to cure tinea barbae. Topical agents are only helpful as adjunctive therapy. Oral agents are used in the same doses and for the same durations as in tinea capitis.

TINEA FACIEI

Fungal infection of the face is frequently misdiagnosed (Fig. 15.4). Typical annular rings are usually lacking, and the lesions are exquisitely photosensitive. Frequently, a misdiagnosis of LE is made. Biopsies for direct immunofluorescence often demonstrate some reactants on sun-exposed skin, adding to the possible diagnostic confusion. Erythematous, slightly scaling, indistinct borders may be present at the periphery of the lesions and are the best location for KOH examination. If topical corticosteroids have been used, the lesions will expand and fungal folliculitis is a frequent finding. A biopsy may be required to establish the diagnosis. A high index of suspicion is required, because fungal hyphae may be few in number or confined to hair follicles. The inflammatory pattern may be psoriasiform spongiotic or vacuolar interface. The latter pattern has the potential to perpetuate confusion with LE.

Usually, the infection is caused by *T. rubrum*, *T. mentagrophytes*, or *M. canis*. Tinea faciei caused by *Microsporum nanum* has been described in hog farmers. If hair follicles are infected such as long the eyebrow or beard area in older children or the infection is widespread, oral medication is required. Otherwise, the infection generally responds well to topical therapy.

TINEA CORPORIS (TINEA CIRCINATA)

Tinea corporis includes all superficial dermatophyte infections of the skin other than those involving the scalp, beard, face, hands, feet, and groin. This form of ringworm is characterized by one or more circular, sharply circumscribed, slightly erythematous, dry, scaly, sometimes hypopigmented patches. An advancing scaling edge is usually prominent (Fig. 15.5). Progressive central clearing produces annular outlines that give them the name "ringworm." Lesions may widen to form rings many centimeters in diameter. In some cases, concentric circles or polycyclic lesions form, making intricate patterns. Although more common on the feet, lesions of tinea corporis can also form vesicles and bullae (bullous tinea). Widespread tinea corporis may be the presenting sign of acquired immunodeficiency syndrome (AIDS) or may be related to the use of a topical corticosteroid or calcineurin inhibitor.

In the United States *T. rubrum*, *M. canis*, and *T. mentagrophytes* are common causes, although infection can be caused by any of the dermatophytes. Multiple small lesions are usually caused by exposure to a pet with *M. canis*. Other zoonotic fungi, such as granular zoophilic *T. mentagrophytes* related to Southeast Asian

bamboo rats, can cause widespread epidemics of highly inflammatory tinea corporis.

Tinea gladiatorum is a common problem for wrestlers. Opponents, equipment, and mats represent potential sources of infection.

Diagnosis

The diagnosis of tinea corporis is by finding the fungus by KOH examination of skin scrapings under the microscope as described earlier. When evaluating tinea corporis, the lines of juncture of normal keratinocytes dissolve into a branching network that may easily be mistaken for fungus structures ("mosaic false hyphae"). This is the most common artifact misinterpreted as a positive KOH examination. Cotton and synthetic fibers from socks may also mimic hyphae. In addition, skin scrapings can be cultured on a suitable medium as described earlier for tinea capitis. Growth of the fungus on culture medium is apparent within 1 week or 2 weeks at most, and in most cases is identifiable to the genus level by the gross and microscopic appearance of the culture. (Biopsy of a chronic refractory dermatosis often reveals tinea incognito.)

Other diseases that may closely resemble tinea corporis are pityriasis rosea, impetigo, nummular dermatitis, secondary and tertiary syphilids, seborrheic dermatitis, and psoriasis. These are distinguished by KOH examination and culture.

Treatment

Localized disease without fungal folliculitis may be treated with topical therapy. Sulconazole (Exelderm), oxiconazole (Oxistat), miconazole (Monistat cream or lotion, or Micatin cream), clotrimazole (Lotrimin or Mycelex cream), econazole (Spectazole), naftifine (Naftin), ketoconazole (Nizoral), ciclopirox olamine (Loprox), terbinafine (Lamisil), efinaconazole, and butenafine (Mentax) are currently available and effective and therapy should be guided based on cost effectiveness. Most treatment times are between 2 and 4 weeks with twice-daily use. Econazole, ketoconazole, oxiconazole, and terbinafine may be used once a day. With terbinafine, the course can be shortened to 1 week. Combination products with a potent corticosteroid such as clotrimazole/betamethasone frequently produce widespread tinea and fungal folliculitis. Their use should be avoided.

Extensive disease or infection of hair follicles requires systemic antifungal treatment. When tinea corporis is caused by *T. tonsurans*, *T. mentagrophytes*, or *T. rubrum*, griseofulvin, terbinafine, itraconazole, and fluconazole are all effective.

Trichophyton species generally respond to shorter courses of terbinafine and Microsporum species respond better to griseofulvin.

Other Forms of Tinea Corporis

Fungal Folliculitis Tinea Incognita and Majocchi Granuloma

Tinea incognita is a term applied to lesions of tinea that have an atypical appearance due to therapy with topical steroids or calcineurin inhibitors. The lesions are often widespread and may lack an advancing, raised, scaly border. Alternatively multiple edges may be present and there may be a lack of central clearing, rather the center may be eczematous (Fig. 15.6). The diagnosis may be established by KOH examination or biopsy.

Treatment of tinea with a topical steroid or calcineurin inhibitor can lead to deeper, more inflammatory infections of the hair follicles. It presents as a circumscribed, annular, raised, crusty, and boggy granuloma in which the follicles are distended with viscid purulent material. These occur most frequently on the shins or wrists. The lesions are often seen in areas of occlusion or shaving, or when a topical corticosteroid has been used. In immunosuppressed patients, the lesions may be deep and nodular. Often, patients have been treated with both topical corticosteroids and antifungal agents. If a topical antifungal has been used recently, KOH examination and culture may be negative. A biopsy may be required to establish the diagnosis. Oral therapy is necessary to cure the lesions. Occasionally, a deep, pustular type of tinea circinata resembling a carbuncle or kerion is observed on the glabrous skin (Fig. 15.7). This type of lesion is a fungal folliculitis caused most often by *T. rubrum* or *T. mentagrophytes* infecting hairs at the site of involvement.

Fig. 15.6 Double-edged border in steroid-modified tinea.

Tinea Imbricata (Tokelau)

Tinea imbricata is a superficial fungal infection limited to southwest Polynesia, Melanesia, Southeast Asia, India, and Central America. It is characterized by concentric rings of scales forming extensive patches with polycyclic borders. Erythema is typically minimal. The eruption begins with one or several small, rounded macules on the trunk and arms. The small macular patch splits in the center and forms large, flaky scales attached at the periphery. As the resultant ring spreads peripherally, another brownish macule appears in the center and undergoes the process of splitting and peripheral extension. This cycle is repeated over and over again. When fully developed, the eruption is characterized by concentrically arranged rings or parallel, undulating lines of scales overlapping each other like shingles on a roof (*imbrex* means "shingle").

The causative fungus is *Trichophyton concentricum*, although a similar pattern may be produced by *T. mentagrophytes* and *T. tonsurans*. Microscopically, the scrapings show interlacing, septate, mycelial filaments that branch dichotomously. Polyhedral spores are also present. Terbinafine has been shown to be very effective while the recurrence rate may be high with griseofulvin.

Fig. 15.7 Majocchi granuloma.

Fig. 15.8 One-hand involvement with tinea. Patient had both feet involved. (Courtesy Steven Binnick, MD.)

Tinea Cruris

Tinea cruris, also known as "jock itch" and "crotch itch," occurs more commonly in men on the upper and inner surfaces of the thighs, especially during the summer when the humidity is high. It begins as a small, erythematous, and scaling or vesicular and crusted patch that spreads peripherally and partly clears in the center, so that the patch is characterized chiefly by its curved, well-defined border, particularly on its lower edge. The border may have vesicles, pustules, or papules. It may extend downward on the thighs and backward on the perineum or about the anus. The scrotum is rarely involved.

Etiology and Differential Diagnosis. Dermatophyte infection of the groin is usually caused by *T. rubrum*, *T. mentagrophytes*, or *E. floccosum*. Infection with *Candida albicans* may closely mimic tinea cruris, but is usually moister, more inflammatory, and associated with satellite macules and can involve the scrotum. *Candida* often produces collarette scales and satellite pustules.

The crural region is also a common site for erythrasma, seborrheic dermatitis, pemphigus vegetans, and intertriginous psoriasis. Erythrasma often has a copper color and is diagnosed by Wood's light examination, which produces coral-red fluorescence. Seborrheic dermatitis generally involves the central chest and axillae in addition to the groin. Pemphigus vegetans produces macerated and eroded lesions. Diagnosis of tinea cruris is established by KOH examination, fungal culture, biopsy or (if caused by a fluorescent fungus) immunofluorescence. Inverse psoriasis may be associated with collarette scales or with serpiginous arrays of pustules at the border of inflammatory lesions. When more typical lesions of psoriasis are lacking, a biopsy may be required to establish the diagnosis.

Treatment. The reduction of perspiration and enhancement of evaporation from the crural area are important prophylactic measures. The area should be kept as dry as possible by the wearing of loose underclothing and trousers. Plain talcum powder or antifungal powders are helpful. Specific topical and oral treatment for tinea cruris is the same as that described earlier for tinea corporis.

TINEA OF HANDS AND FEET

Dermatophytosis of the feet, "athlete's foot," is the most common fungal disease. *T. rubrum* causes the majority of infections although it can be caused by many other dermatophytes, including *T. tonsurans*. There may be an autosomal dominant predisposition to this form of infection or it may just be being spread within families. *T. rubrum* typically produces a relatively noninflammatory type of dermatophytosis characterized by a dull erythema and pronounced silvery scaling that may involve the entire sole and sides of the foot, giving a moccasin or sandal appearance. The eruption may also be limited to a small patch adjacent to a fungus-infected toenail or to a patch between or under the toes. In some patients, an extensive patchy, scaly eruption covers most of the trunk, buttocks, and extremities. Rarely, there is a patchy hyperkeratosis.

Generally, dermatophyte infection of the hands is of the dry, scaly, and erythematous type suggestive of *T. rubrum* infection. Other areas are frequently affected at the same time, especially the combination of both feet and one hand (Fig. 15.8). Tinea pedis caused by anthropophilic *T. mentagrophytes (interdigitale)* presents with three distinct appearances: (1) multilocular bullae involving the thin skin of the plantar arch and along the sides of the feet and heel, (2) erythema and desquamation between the toes, and (3) white superficial onychomycosis. In the human immunodeficiency virus (HIV)–positive population, this latter syndrome is usually caused by *T. rubrum*. Interdigital tinea must be distinguished from simple maceration caused by a closed web

Fig. 15.9 Bullous tinea pedis.

space, which does not respond to antifungal therapy. Interdigital tinea must also be distinguished from gram-negative toe web infection and candidal infection. Diabetic patients develop interdigital fungal infections at a younger age than patients without diabetes.

T. mentagrophytes often produces acutely inflammatory multilocular bullae (Fig. 15.9). The burning and itching that accompany the formation of the vesicles may cause great discomfort, which is relieved by opening the tense vesicles. They contain a tenacious, clear, straw-colored fluid. Extensive or acute eruptions on the soles may be incapacitating. The fissures between the toes, as well as the vesicles, may become secondarily infected with pyogenic cocci, which may lead to recurrent attacks of lymphangitis and inguinal adenitis. Gram-negative toe web infections may also supervene. Hyperhidrosis is frequently present in this type of dermatophytosis. The sweat between the toes and on the soles has a high pH, and damp keratin is a good culture medium for the fungi.

Dermatophytid of the hands may be associated with inflammatory tinea of the feet and begins with the appearance of groups of minute, clear vesicles on the palms and fingers and sometimes the sides and tops of the feet. The itching may be intense. Typically, both hands are involved, and the eruption tends to be symmetric.

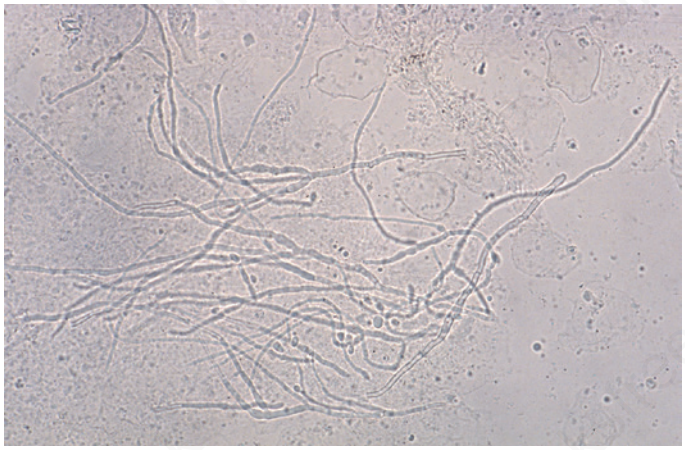

Fig. 15.10 Positive KOH examination.

Diagnosis

Demonstration of the fungus by KOH microscopic examination (Fig. 15.10) as described for tinea capitis and corporis earlier establishes the diagnosis. For bullous tinea, bullae should be unroofed, and either the entire roof is mounted intact or scrapings are made from the underside of the roof.

Material may also be placed on Sabouraud dextrose agar, Sabouraud agar with chloramphenicol, Mycosel agar, or DTM. The last three agars inhibit growth of bacterial or saprophytic contaminants. The last two may inhibit some pathogenic nondermatophytes. The alkaline metabolites produced by growth of dermatophytes change the color of the pH indicator in DTM medium from yellow to red.

Prophylaxis

Hyperhidrosis is a predisposing factor for tinea infections. Because the disease often starts on the feet, the patient should be advised to dry the toes thoroughly after bathing. Cold water laundering does not inactivate fungal elements in socks, which may serve as a source of recolonization. Dryness is essential to reduce the incidence of symptomatic reinfection.

The use of a antiseptic powder on the feet after bathing, particularly between the toes, is strongly advised for susceptible persons. Tolnaftate powder (Tinactin) or Zeasorb medicated powder is an excellent dusting powder for the feet. Plain talc, cornstarch, or rice powder may be dusted into socks and shoes to keep the feet dry. Periodic use of a topical antifungal agent may be required, especially when hot occlusive footwear is worn.

Treatment

Clotrimazole, miconazole, sulconazole, oxiconazole, ciclopirox, econazole, ketoconazole, naftifine, terbinafine, flutrimazole, bifonazole, efinaconazole, and butenafine are effective topical antifungal agents but especially in tinea manuum or exuberant tinea pedis, an oral agent may be necessary. When there is significant maceration between the toes, the toes may be separated by foam or cotton inserts in the evening. Aluminum chloride 10% solution or aluminum acetate, 1 part to 20 parts of water, can be beneficial. Interdigital tinea can also be treated with antifungal-impregnated socks. Topical antibiotic ointments, such as gentamicin (Garamycin), that are effective against gram-negative organisms are helpful additions in some moist interdigital lesions. In the ulcerative type of gram-negative toe web infections, systemic

antibiotic therapy is necessary (see Chapter 14). Keratolytic agents containing salicylic acid, resorcinol, lactic acid, and urea may be useful in some cases, although all may lead to maceration if occluded.

Treatment of fungal infection of the skin of the feet and hands with griseofulvin, 500–1000 mg/day, can be effective. Dosage for children is 10–20 mg/kg/day. The period of therapy depends on the response of the lesions. Repeated KOH scrapings and cultures should be negative. Shorter courses are possible with other antifungal agents. Recommended adult dosing for terbinafine is 250 mg/day for 1–2 weeks; for itraconazole, 200 mg twice daily for 1 week; and for fluconazole, 150 mg once weekly for 4 weeks.

TINEA NIGRA

Hortaea werneckii (formerly *Phaeoannellomyces werneckii*) is a black, yeastlike hyphomycete that is widely distributed in hot, humid environments. The organism is common in the tropics. In the United States the infection is seen along the Gulf Coast. New taxonomic analysis has led some to classify *Cladosporium castellanii* as the etiologic agent of tinea nigra in humans and confirmed that this fungus is the same as *Stenella araguata*.

Tinea nigra presents as one or several brown or black spots on the palms or soles. The lesions may be mistaken for nevi, melanoma or talon noir hemorrhage under the skin. The pigment is confined to the stratum corneum and scrapes off easily. Dermoscopy has also been used to differentiate the lesions from melanocytic tumors although a case of tinea nigra with a parallel ridge pattern simulating melanoma was reported. The fungus can easily be demonstrated by means of KOH or culture. In KOH preparations, the hyphae appear brown or golden in color. The pigment produced by the fungal hyphae is melanin. Culture will identify the organism, and polymerase chain reaction (PCR) can be useful for rapid identification of *H. werneckii*.

Topical imidazoles and allylamines, such as clotrimazole, miconazole, ketoconazole, sulconazole, econazole, and terbinafine, have been reported as effective. Griseofulvin is not effective. Simply shaving away the superficial epidermis with a blade is frequently both diagnostic and curative of tinea nigra.

Onychomycosis (Tinea Unguium)

Onychomycosis is defined as the infection of the nail plate by fungus and represents up to 30% of diagnosed superficial fungal infections. *T. rubrum* accounts for most cases, but many fungi may be causative. Other etiologic agents include *E. floccosum* and various species of *Microsporum* and *Trichophyton* fungi. It may also be caused by yeasts and nondermatophytic molds.

The four classic types of onychomycosis are as follows:

1. Distal subungual onychomycosis primarily involves the distal nail bed and the hyponychium, with secondary involvement of the underside of the nail plate of fingernails and toenails (Fig. 15.11). It is usually caused by *T. rubrum* although *T. tonsurans* is growing in prevalence in children.
2. White superficial onychomycosis (leukonychia trichophytica) is an invasion of the toenail plate on the surface of the nail. It is produced by *T. mentagrophytes*, *Cephalosporium*, *Aspergillus*, and *Fusarium oxysporum* fungi. In the HIV-positive population, it is typically caused by *T. rubrum*.
3. Proximal subungual onychomycosis involves the nail plate mainly from the proximal nailfold, producing a specific clinical picture (Fig. 15.12). It is produced by *T. rubrum* and *Trichophyton megninii* and may be an indication of HIV infection.
4. *Candida* onychomycosis produces destruction of the nail and massive nail bed hyperkeratosis. It is caused by *C. albicans* and is seen in patients with chronic mucocutaneous candidiasis and other forms of immunodeficiency.

Fig. 15.11 Distal subungual onychomycosis.

Fig. 15.12 White proximal subungual onychomycosis.

Onychomycosis caused by *T. rubrum* usually starts at the distal corner of the nail and involves the junction of the nail and its bed. A yellowish discoloration occurs, which spreads proximally as a streak in the nail. Later, subungual hyperkeratosis becomes prominent and spreads until the entire nail is affected. Gradually, the entire nail becomes brittle and separated from its bed as a result of the piling up of subungual keratin. Fingernails and toenails present a similar appearance, and the skin of the soles is likely to be involved, with characteristic branny scaling and erythema.

Onychomycosis caused by *T. mentagrophytes* is usually superficial, and there is no paronychial inflammation. The infection generally begins with scaling of the nail under the overhanging cuticle and remains localized to a portion of the nail. In time, however, the entire nail plate may be involved. White superficial onychomycosis is the name given to one type of superficial nail infection caused by this fungus in which small, chalky white spots appear on or in the nail plate. These are so superficial that they may be easily shaved off. *T. violaceum*, *T. schoenleinii*, and *T. tonsurans* occasionally invade the nails, as does *Trichosporon beigelii*.

Scopulariopsis brevicaulis and other nondermatophyte molds are infrequently isolated from onychomycosis. Infection usually begins at the lateral edge of the nail, burrows beneath the plate, and produces large quantities of cheesy debris. *Nattrassia mangiferae*

(Hendersonula toruloidea) and *Scytalidium hyalinum* have been reported to cause onychomycosis, as well as a moccasin-type tinea pedis. Other common causes of nondermatophyte molds are *Aspergillus* species, *Fusarium*, and *Acremonium*. In addition to the more common features of onychomycosis, such as nail plate thickening, opacification, and onycholysis, features of infection with these fungi include lateral nail invasion alone, paronychia, and transverse fracture of the proximal nail plate. When these agents are suspected, culture must be done with a medium that does not contain cycloheximide (found in Mycosel agar). Oral griseofulvin is not effective in the treatment of these organisms.

The pathogen is heavily influenced by heredity, geography, and footwear. In the United States most tinea pedis and onychomycosis are caused by *T. rubrum*.

Diagnosis

The demonstration of fungus is made by microscopic examination or by culture. The submitted clippings or curettings must include dystrophic subungual debris. Samples obtained by a drilling technique may have a higher yield than those obtained by curettage. Immediate examination may be made if very thin shavings or curettings are taken from the diseased nail bed and examined with KOH solution with or without an added stain. Histologic examination, PCR, and calcofluor white microscopy and culture have also been used.

Histopathologic examination with periodic acid–Schiff (PAS) stain has been found to be 41%–93% sensitive in various studies. It has proved more sensitive than either KOH or culture in several studies. Immunofluorescent microscopy without calcofluor white is comparable to PAS staining, but high background eosin fluorescence can make the sections difficult to read. Studies have shown the sensitivity of culture to be 30%–70%. Combining KOH and culture has yielded sensitivities in the range of 80%–85%.

DTM can also be used with approximately 50% sensitivity but laboratory regulations have limited its use in the United States. PCR is emerging as an alternative method of detection.

Because no single method offers 100% sensitivity, a variety of methods are still in use. KOH has the advantage of being performed rapidly in the office. Histologic examination usually provides results within 24 hours, whereas culture can take days to weeks. Identification of genus and species is only possible with culture or PCR.

Differential Diagnosis

Dystrophic nails can be caused by psoriasis, lichen planus, eczema, and contact dermatitis and may be clinically indistinguishable from fungal nails. Confirmatory tests to identify the fungus are mandatory to establish a diagnosis. Psoriasis may involve other nails with pitting, onycholysis, oil spots, and salmon patches or by heaped-up subungual keratinization. Typical features of psoriasis may be present on other areas of skin. Lichen planus may produce rough nails or pterygium formation and may involve the oral mucosa or skin. Eczema and contact dermatitis affect the adjacent nailfold. Langerhans cell histiocytosis can also lead to subungual debris and hemorrhage and may be a marker for systemic disease. Hyperkeratotic ("Norwegian") scabies can also produce dystrophic nails, but this is associated with generalized hyperkeratosis.

Onychomycosis among psoriasis patients is reported with varying prevalence but occurs in about 22%, compared with 13% for patients with other skin diseases. Onychomycosis occurs more frequently in men than in women with psoriasis.

Treatment

Many patients with onychomycosis are not symptomatic and may not seek treatment. Patients with diabetes or peripheral neuropathy may be at higher risk for bacterial cellulitis related to onychomycosis, and the benefits of treatment may be greater in this population. These factors, as well as cost, risk of recurrence, and spread to other family members should be considered as part of the decision to treat onychomycosis.

The topical management of onychomycosis has improved with the introduction of ciclopirox, eficonazole, and amorolfine nail lacquers. These agents are modestly effective at moderate cost. Eficonazole and ciclopirox must be used for 48 weeks. Topical therapy with ciclopirox achieved a 71% effective cure rate and 77% mycologic cure rate in children, possibly due to thinner nail plates or increased compliance. Eficonazole has a complete cure rate of 15%–17% but mycologic cure rate of 55%. No topical agent achieves the cure rates possible with oral therapy, but topical agents have lower risk of side effects because they are not systemic. Neodymium:yttrium-aluminum-garnet (Nd:YAG) laser therapy was recently reported to have a 50%–60% cure rate after multiple therapies.

For adults with disease involving fingernails, terbinafine is given in doses of 250 mg/day for 6 weeks; the dose for children is 250 mg daily for patients over 40 kg, 125 mg (½ tablet) for those 20–40 kg, and 62.5 mg (¼ tablet) for those under 20 kg. For toenails, the course of treatment is generally 12 weeks. In adults, Itraconazole is generally given as pulsed dosing, 200 mg twice daily for 1 week of each month, for 2 months when treating fingernails and for 3–4 months when treating toenails. Fluconazole, 150–300 mg once weekly for 6–12 months, appears to be effective. About 20% of patients will not respond to treatment. The presence of a dermatophytoma within the nail may be associated with a higher risk of failure. Dermatophytomas present as yellow streaks within the nail and may respond to unroofing and curettage. Recurrence rates may be lower with itraconazole than with terbinafine monotherapy, and combined therapy does not result in a lower rate of recurrence. See monitoring recommendations earlier in this chapter.

Several studies suggest that continuous therapy with terbinafine for 4 months is cost-effective compared with other possible agents and regimens. Most clinical trials have been industry sponsored, however, and little independent research is available for review. Terbinafine, itraconazole, and fluconazole have all been shown to be effective. Dosage depends on body weight, as previously indicated. Duration of treatment is the same as for adults.

Although data are limited, treatment with systemic antifungals is generally effective in onychomycosis caused by *Aspergillus* spp. *Scopulariopsis brevicaulis* and *Fusarium* spp. Infection may be difficult to eradicate, and treatment with both systemic antifungals and topical nail lacquers may be appropriate. Nail avulsion represents another option but is more painful and recurrence can still occur.

Candida onychomycosis is a sign of immunosuppression but can be seen infants as well. Systemic treatment with itraconazole or fluconazole is usually effective, but relapses are the rule. When treating *Candida* infections, combinations of topical and systemic treatment can be used for synergistic effect. The combination of topical amorolfine and oral itraconazole, which interferes with different steps of ergosterol synthesis, has been shown to exhibit substantial synergy in this setting. Combination treatment with topical amorolfine and two pulses of itraconazole may be as effective as three pulses of itraconazole, with lower cost.

Itraconazole pulsed treatment has been shown to have a low incidence of liver function abnormalities (alanine transaminase [ALT], aspartate transaminase [AST], alkaline phosphatase, total bilirubin). Product labeling recommends liver function tests (LFTs) for patients receiving continuous itraconazole for periods exceeding 1 month. Monitoring is required for the pulsed regimen if the patient has a history of hepatic disease, has abnormal baseline LFTs, or development of signs or symptoms suggestive of liver dysfunction.

Molds are sensitive to ozone gas, UV light, and visible light. *T. rubrum* in culture has been shown to be susceptible to UVC radiation, photodynamic therapy (PDT), psoralen with UVA (PUVA), and various forms of laser light. However, the mechanism of action and degree of effectiveness of these therapies require further study. For PDT with broad-band white light, the phthalocyanines and Photofrin displayed a fungistatic effect, whereas porphyrins caused photodynamic killing of the dermatophyte. 5,10,15-*Tris*(4-methylpyridinium)-20-phenyl-(21H,23H)-porphine trichloride and deuteroporphyrin monomethylester showed superior results in vitro. Further study of various methods of phototherapy is warranted.

CANDIDIASIS

Candidiasis is also known as candidosis or moniliasis. *Candida albicans* is a common inhabitant of the human gastrointestinal (GI) tract, genitourinary tract, and skin. Under the right conditions, *C. albicans* becomes a pathogen, and can infect the skin, nails, and mucous membranes. *Candida albicans* is an opportunistic organism, acting as a pathogen in the presence of impaired immune response, or where local conditions favor growth. Warmth and moisture favor candidal growth, as can reductions in competing flora during antibiotic therapy. The intertriginous areas, including perianal and inguinal folds, abdominal creases, inframammary creases, interdigital areas, nailfolds, and axillae, are at especially high risk. Higher skin pH can occur due to occlusion from diapers and underwear liners also favor candidal growth.

Diagnosis

Candida is often a clinical diagnosis based on red maceration in skin folds with pustules and peeling at the edges of the red patch (satellite pustules). A KOH preparation will show spores and pseudohyphae. On Gram stain the yeast forms dense, gram-positive, ovoid bodies, 2–5 μm in diameter. A combination of Gomori methenamine silver (GMS) and Congo red staining can be helpful in the differential diagnosis of fungal infections. *Blastomyces* and *Pityrosporum* are positive for both, whereas *Candida* and *Histoplasma* are GMS positive and Congo red negative.

Candida proliferates in both budding and mycelial forms in the stratum corneum or superficial mucosa. Budding yeast and pseudohyphae are easier to detect in histologic section with a PAS stain. Whereas dermatophyte hyphae tend to run parallel to the skin surface, *Candida* pseudohyphae are more prone to vertical orientation.

Topical Anticandidal Agents

Most of the topical agents marketed for tinea are also effective for candidiasis. These include clotrimazole, econazole, ketoconazole, miconazole, oxiconazole, sulconazole, naftifine, terconazole, ciclopirox olamine, butenafine, terbinafine, nystatin, and topical amphotericin B lotion. Older agents, such as gentian violet, Castellani paint, and boric acid, are still sometimes used. Mupirocin has been show in a large study to have excellent candida coverage. Oral nystatin is as effective as intravenous (IV) fluconazole at preventing invasive *Candida* infections in preterm neonates. The oral preparation is more easily administered and is lower in cost.

Other Agents

Fluconazole can be used for acute infections or more chronically for prevention in *Candida* related to genodermatoses. Posaconazole, itraconazole, voriconazole, echinocandins, anidulafungin, and amphotericin B are also used in various settings. Various flavonoid compounds, including apigenin and kaempferol, alkaloid ibogaine (an indole), and the protoberberine alkaloid berberine, have been studied for their inhibitory effects. Topical application of each of these agents accelerated elimination from cutaneous sites of inoculation.

Candidal Intertrigo

The pruritic intertriginous eruptions caused by *C. albicans* may arise between the folds of the genitals; in groins or armpits; between the buttocks (Fig. 15.13); under large, pendulous breasts; under overhanging abdominal folds; or in the umbilicus. The pink to red, intertriginous moist patches are surrounded by a thin, overhanging fringe of somewhat macerated epidermis ("collarette" scale). Some eruptions in the inguinal region may resemble tinea cruris, but usually there is less scaliness and a greater tendency to fissuring. Persistent excoriation and subsequent lichenification and drying may modify the original appearance over time. Often, tiny, superficial, white pustules are observed closely adjacent to the patches. When present, *Candida* can cause flares of inverse psoriasis, although prevalence of *Candida* is not increased in the intertriginous areas of patients with either psoriasis or atopic dermatitis.

Topical anticandidal preparations are usually effective, but recurrence is common. Combinations of a topical anticandidal agent with a midstrength corticosteroid may lead to more rapid relief. Castellani paint may also be helpful. Patients often prefer colorless paint.

Fig. 15.13 Candidiasis.

Diaper Candidiasis

The diagnosis of candidiasis may be suspected from involvement of the folds and occurrence of many small, erythematous desquamating "satellite" or "daughter" lesions scattered along the edges of the larger macules. Topical anticandidal agents are effective, sometimes compounded in zinc oxide ointment to act as a barrier against the irritating effect of urine. Recurrent diaper candidiasis may be associated with oral and gut colonization and may respond to the addition of oral nystatin suspension.

Oral Candidiasis (Thrush)

The mucous membrane of the mouth may be involved in healthy infants. In the newborn, colonization may be acquired from contact with the vaginal tract of the mother. In older children and adults, thrush is often seen after antibiotic therapy but can be a sign of immunosuppression.

The most common presentations of candida in the mouth are grayish white membranous plaques found on the surface of the tongue and buccal mucosa and maceration at the angle of the mouth (perlèche). On the mucous membranes, the base of these plaques is moist, reddish, and macerated (Fig. 15.14).

In adults, the appearance may resemble that seen in children or may be drier and more erythematous. A dry mouth predisposes to candidal growth because innate immunity molecules in the saliva inhibit candida. Broad-spectrum antibiotics also predispose to candidiasis. The papillae of the tongue may appear atrophic, with the surface smooth, glazed, and bright red. Frequently, the infection extends onto the angles of the mouth to form perlèche. This appearance is common in elderly, debilitated, and malnourished patients and in patients with diabetes. It is often the first manifestation of AIDS and is present in almost all untreated patients with advanced AIDS. The observation of oral "thrush" in an adult with no known predisposing factors warrants a search for other evidence of infection with HIV, such as lymphadenopathy, leukopenia, or HIV antibodies in the serum.

Fig. 15.14 Thrush in chronic mucocutaneous candidiasis.

Various treatment options for oral candidiasis are available. Infants are usually treated with oral nystatin suspension. An adult can let clotrimazole troches dissolve in the mouth. A single, 150-mg dose of fluconazole is effective for many mucocutaneous infections

in adults. In immunosuppressed patients, higher doses may be needed. Itraconazole, can also be effective. Although terbinafine may be ineffective in vitro, there is often adequate in vivo activity.

Perlèche

Perlèche, or angular cheilitis, is characterized by maceration and transverse fissuring of the oral commissures. The earliest lesions are poorly defined, grayish white, thickened areas with slight erythema of the mucous membrane at the oral commissure. When more fully developed, this thickening has a bluish white or mother-of-pearl color and may be contiguous with a wedge-shaped, erythematous scaling dermatitis of the skin portion of the commissure. Fissures, maceration, and crust formation ensue. Soft, pinhead-sized papules may appear. Involvement is usually bilateral. Perlèche is frequently caused by *C. albicans* but superinfection with *Staphylococcus aureus* and gram-negative bacteria may occur. Similar changes may occur in riboflavin deficiency or other nutritional deficiency.

Identical fissuring occurs at the mucocutaneous junction from drooling in persons with malocclusion caused by poorly fitting dentures and in older patients in whom atrophy of the alveolar ridges ("closing" the bite) has caused the upper lip to overhang the lower at the commissures.

If infection is caused by *C. albicans* and there is an inflammatory response, anticandidal can be combined with low to midstrength topical corticosteroids to speed healing. If the perlèche is caused by vertical shortening of the lower third of the face, dental or oral surgical intervention may be helpful. Injection of collagen into the depressed sulcus at the oral commissure can be beneficial.

Candidal Vulvovaginitis

Candida albicans is a common inhabitant of the vaginal tract. Overgrowth can cause severe pruritus, burning, and discharge. The labia may be erythematous, moist, and macerated and the cervix hyperemic, swollen, and eroded, showing small vesicles on its surface. The vaginal discharge is not usually profuse and varies from watery, to thick and white or curdlike.

Candidal infection may develop during pregnancy, in diabetes, or secondary to therapy with broad-spectrum antibiotics. Among diabetic patients, candidal overgrowth is related to the degree of hyperglycemia. Recurrent vulvovaginal candidiasis has also been associated with long-term tamoxifen treatment. Candidal balanitis may be present in an uncircumcised sexual partner. Diagnosis is established by the clinical symptoms and findings, as well as the demonstration of the fungus by KOH microscopic examination and culture. PCR is available and is the gold standard.

Oral fluconazole, is often effective. In some patients with predisposing factors, longer courses of fluconazole, or itraconazole, for 5–10 days may be needed. Topical options include miconazole, nystatin, clotrimazole, and terconazole. Clotrimazole exerts antiinflammatory as well as anticandidal effects. Probiotic, anticandidal bacteria and yogurt have demonstrated some ability to decrease *Candida* colonization.

Non-*albicans* types of *Candida* may be responsible for recalcitrant infections. *Candida glabrata* vaginitis may be refractory to azole drugs and can be difficult to eradicate. Topical boric acid, amphotericin B, and flucytosine may be helpful.

Congenital Cutaneous Candidiasis

Premature rupture of membranes together with a birth canal infected with *C. albicans* may lead to congenital cutaneous candidiasis. The eruption is usually noted within a few hours of delivery. Erythematous macules and patches progress to thin-walled pustules, which rupture, dry, and desquamate within about 1 week. Lesions are usually widespread, involving the trunk, neck, and head and sometimes the palms and soles, including the nailfolds. The oral cavity and diaper area are spared, in contrast to the usual type of acquired neonatal infection. The differential diagnosis includes other neonatal vesiculopustular disorders, including infections such as listeriosis, syphilis, staphylococcal and herpes infections, as well as noninfectious pustulosis including erythema toxicum neonatorum, transient neonatal pustular melanosis, miliaria rubra, and congenital ichthyosiform erythroderma. If infection is suspected early, the amniotic fluid, placenta, and cord should be examined for evidence of infection.

Infants with candidiasis limited to the skin have favorable outcomes; however, systemic involvement may occur. Disseminated infection is suggested by evidence of respiratory distress or other laboratory or clinical signs of neonatal sepsis. Dissemination is more common in infants who weigh less than 1500 g. In these preterm infants the *Candida* can disseminate, and congenital candidiasis is a medical emergency requiring systemic therapy. Treatment with broad-spectrum antibiotics and altered immune responsiveness can also predispose to dissemination. Infants with congenital cutaneous candidiasis should be considered for systemic therapy, especially if any risk factors for dissemination.

Perianal Candidiasis

Infection with *C. albicans* may present as pruritus ani. Perianal dermatitis with erythema, oozing, and maceration is present. Pruritus and burning can be extremely severe. Satellite lesions may be present, but their absence does not exclude candidiasis. Perianal streptococcal disease can present with similar erythema and a culture can help differentiate. Mupirocin has shown benefit in perianal candida in addition to its indication for gram-positive organisms such as *Streptococcus* and can be used while awaiting cultures if the diagnosis is not clear. *Candida* growth is also enhanced on abnormal tissue, such as extramammary Paget disease. If the tissue does not return to normal after the candidiasis is treated, a biopsy may be warranted.

Candidal Paronychia

Inflammation of the nailfold produces redness, edema, and tenderness of the proximal nailfolds and gradual thickening and brownish discoloration of the nail plates. Usually, only the fingernails are affected.

Although acute paronychia is usually staphylococcal in origin, chronic paronychia is typically multifactorial. Irritant dermatitis can lead to broken skin and maceration, which predisposes to Candida infection. Anticandidal agents may be helpful and may be used in combination with a topical corticosteroid to heal the preceding dermatitis.

Candidal paronychia is frequently seen in diabetic patients, and part of the treatment is bringing the diabetes under control. The avoidance of chronic exposure to moisture and irritants is also essential in these patients. If topical treatment fails, oral fluconazole once a week or itraconazole in pulsed dosing can be effective.

Repetitive contact urticaria or allergic contact dermatitis to foods and spices may mimic candidal paronychia. Patch and radioallergosorbent testing (RAST) may be of value.

Erosio Interdigitalis Blastomycetica

A form of candidiasis, erosio interdigitalis blastomycetica is seen as an oval-shaped area of macerated white skin on the web between and extending onto the sides of the fingers or toes. Usually, at the center of the lesion, there are one or more fissures with raw, red bases. As the condition progresses, the macerated skin peels

off, leaving a painful, raw, denuded area surrounded by a collar of overhanging white epidermis. On the hand, it is almost always the third web, between the middle and ring fingers, that is affected. The moisture beneath the ring macerates the skin and predisposes to infection. On the feet, it is the fourth interspace that is most often involved, but the areas are apt to be multiple. Clinically, this may be indistinguishable from tinea pedis. Usually, the white, sodden epidermis is thick and does not peel off freely. The disease is also seen in patients with diabetes and those who do wet work.

Diagnosis of erosio interdigitalis blastomycetica is made by culture. Lesions may respond to drying, topical anticandidal agents, or application of filter paper soaked with Castellani paint.

Candidid

As in dermatophytosis, patients with candidiasis may develop secondary id reactions (candidid). These are much less common than the reactions seen with acute inflammatory dermatophytosis. The reactions, which have been reported to clear with treatment of candidal infection, are usually of the erythema annulare centrifugum or chronic urticaria type.

Antibiotic (Iatrogenic) Candidiasis

The use of oral antibiotics, such as the tetracyclines and their related products, may induce clinical candidiasis involving the mouth, GI tract, or perianal area. In addition, vulvovaginitis may occur bacterial flora in the GI system are likely changed by suppression of some of the antibiotic-sensitive bacteria, thereby permitting other organisms such as *Candida* to flourish. Fluconazole, will treat this adequately if antibiotic therapy is given for a limited time. For more prolonged courses of antibiotic therapy, the dose of fluconazole may have to be repeated, or a longer course of a topical agent may be used.

Chronic Mucocutaneous Candidiasis

The term chronic mucocutaneous candidiasis (CMCC) designates a group of patients with heterogeneous disorders whose infection with *Candida* is chronic but limited to mucosal surfaces, skin, and nails. Onset is typically before age 6 years. Onset in adult life may herald the occurrence of thymoma. These cases may be either inherited or sporadic. Inherited types may be associated with endocrinopathy. Oral lesions are diffuse, and perlèche and lip fissures are common. The nails become thickened and dystrophic, with associated paronychia that may be the presenting sign. Hyperkeratotic, hornlike, or granulomatous lesions are often seen on the skin (Figs. 15.15 and 15.16).

Chronic mucocutaneous candidiasis occurs in a number of syndromes. Autosomal dominant signal transducer and activator of transcription 1 *(STAT1)* gain-of-function mutation, impairing interleukin-17 (IL-17)–producing T-cell development, is the best described abnormality. Autosomal recessive IL-17RA, and autosomal dominant IL-17F and IL-17RC deficiencies have been reported in CMCC patients. Autosomal dominant hyper-IgE syndrome is related to *STAT3* mutations, resulting in low IL-17 T-cell numbers. Dectin 1 and IL-22 encoding genes modulate the response to *Candida* infections through a T-helper cell type 17 (Th17) mechanism, although dectin 1 does not appear to be critical in some models of mucosal candidiasis. CARD9 deficiency predisposes to invasive candidiasis as well as invasive and disseminated dermatophytosis. Autoimmune polyendocrinopathy candidiasis ectodermal dystrophy is an autosomal recessive syndrome caused by mutations of the autoimmune regulator gene *(AIRE)*, resulting in failure of T-cell tolerance within the thymus, with decreased numbers of IL-17 T cells. Hallmarks of the syndrome include CMCC, chronic hypoparathyroidism, hypothyroidism, and Addison disease.

Fig. 15.15 Chronic mucocutaneous candidiasis.

Fig. 15.16 Chronic mucocutaneous candidiasis. (Courtesy Leslie Castelo-Soccio, MD.)

Abnormalities of type 1 cytokine production in response to *Candida* have been reported. Specifically, there may be greatly impaired IL-12 production and dramatically increased levels of IL-6 and IL-10. Reductions in natural killer (NK) cells have also been noted. In a five-generation Italian family with CMCC affecting only the nails, low serum intercellular adhesion molecule 1 (ICAM-1) was noted. The defect was linked to a 19 cM pericentromeric region on chromosome 11.

Systemic fluconazole, itraconazole, or ketoconazole is necessary to control CMCC although the FDA warns against the use of systemic ketoconazole for skin infections. Courses are typically prolonged, repeated, and given at higher doses than the usual recommended dose. Patients with achlorhydria may have problems with absorption of itraconazole and ketoconazole. Cimetidine was reported to restore deficient cell-mediated immunity in four adults from one family, at a dose of 300 mg four times daily. One patient with alopecia areata (AA) and CMCC due to a mutation in STAT-1 responded to ruxolitinib being given for their AA. Granulocyte colony-stimulating factor (G-CSF) infusion has been reported to restore IL-17 secretion, with subsequent clinical remission.

Systemic Candidiasis

Candida albicans is capable of causing disseminated disease and sepsis, invariably when host defenses are compromised. Patients at high risk include those with malignancies, especially leukemia and lymphoma, who may have impaired immune defenses; premature neonates; AIDS patients; debilitated and malnourished patients; those with a transplant who require prolonged immunosuppressive therapy; patients receiving oral cortisone; those who have had multiple surgical operations, especially cardiac surgery; and patients with indwelling IV catheters. IV drug users also are at high risk.

The initial sign of systemic candidiasis may be fever of unknown origin, pulmonary infiltration, GI bleeding, endocarditis, renal failure, meningitis, osteomyelitis, endophthalmitis, peritonitis, proximal muscle weakness and tenderness, or a disseminated macular exanthema. The cutaneous lesions begin as erythematous macules that may become papular, pustular, hemorrhagic, or ulcerative. Deep abscesses may occur. The trunk and extremities are the usual sites of involvement. Proximal muscle tenderness frequently accompanies the exanthema and may be a valuable clue to the correct diagnosis.

The demonstration of microorganisms or a positive culture will substantiate a diagnosis of candidiasis only if the microorganism is found in tissues or fluids ordinarily sterile for *Candida* and if the clinical picture is compatible. *Candida* colonization of endotracheal tubes used in supporting low-birth-weight neonates predisposes to systemic disease. If *Candida* is cultured within the first week of life, there is a high rate of systemic disease.

The mortality rate attributed to systemic candidiasis has declined because of early empiric antifungal treatment and better prophylaxis. Data in children are similar to those in adults. Although amphotericin B remains the gold standard of treatment in systemic candidiasis, other, safer options such as liposomal amphotericin are available. Fluconazole has been effective as prophylaxis with bone marrow transplantation, as well as in the treatment of oropharyngeal candidosis and candidemia in nonneutropenic patients. At high doses, fluconazole is sometimes used for *Candida* in neutropenic patients. Voriconazole, a triazole antifungal, acts by inhibiting synthesis of ergosterol in the fungal cell membrane but leads to extreme photosensitivity. Voriconazole has produced liver abnormalities, rash, and visual disturbances, and these must be monitored during therapy. Posaconazole is a triazole active against *Candida*, although some problems with resistance have been reported. Caspofungin is an echinocandin antifungal that inhibits β-1,3-D-glucan synthesis in the cell wall. Micafungin and anidulafungin are echinocandins. The newer triazoles and echinocandins have broad spectrums and are effective against invasive *Aspergillus* and *Candida* infections. A meta-analysis of studies of *Candida* sepsis concluded that clinical efficacy was similar among the agents studied, but microbiologic failure was more common with fluconazole than with amphotericin B or anidulafungin. Amphotericin B had a higher rate of adverse events than fluconazole or the echinocandins. Some data favor caspofungin or micafungin over anidulafungin in neutropenic patients. The antiarrhythmic drug amiodarone has some fungicidal activity, and low doses of amiodarone produced a synergistic effect with fluconazole in fluconazole-resistant *C. albicans*.

Despite advances in treatment, the mortality rate associated with systemic candidiasis remains high.

GEOTRICHOSIS

Geotrichum candidum is an ascomycetous anamorph, yeastlike fungus found as part of the natural flora of milk. It is also found on fruit and tomatoes and in soil. It is used commercially as a maturing agent for cheese. Individual strains may be more moldlike or yeastlike. Substantial genetic polymorphism has been noted in *G. candidum*.

In immunosuppressed individuals, *G. candidum* or *Geotrichum capitatum (Blastoschizomyces capitatus)* may act as an opportunistic pathogen, causing disseminated or mucocutaneous geotrichosis. Mucocutaneous disease is characterized by erythema, pseudomembranes, and mucopurulent sputum similar to that seen in thrush. The intestinal, bronchial, and pulmonary forms are similar to candidal infection. *G. candidum* is usually isolated as a saprophyte. If cultured repeatedly from diseased tissue, it should be assumed to be acting as a pathogen.

The diagnosis is made by the repeated demonstration of the organism by KOH microscopic examination and by its culture from sputum on Sabouraud dextrose agar. Direct examination shows branching septate mycelium and chains of rectangular cells.

In culture, there is a mealy growth at room temperature. The hyphae form rectangular arthrospores.

Treatment of mucocutaneous disease can be accomplished with oral nystatin, or nystatin (Mycostatin) suspension in some cases. For more severe or disseminated disease, liposomal amphotericin B, caspofungin, voriconazole, itraconazole, flucytosine, or combinations of these agents have been effective.

PIEDRA

Piedra is a superficial infection of the outside of the hair shaft. In black piedra, dark, pinhead- to pebble-sized formations occur on the hairs of the scalp, brows, lashes, or beard. These nodules are distributed irregularly along the length of the shaft. Black piedra, usually caused by *Piedraia hortai*, occurs mostly in the tropics, especially in South America and Asia. The nodelike masses in KOH preparations show numerous oval asci containing two to eight ascospores and mycelium. Cultures produce black colonies composed of hyphae and chlamydospores.

White piedra is typically caused by *Trichosporon (Trichosporum) beigelii* or *Trichosporon inkin* and occurs more often in temperate climates. Based on molecular analysis, the taxon *T. beigelii* has been replaced by several species. A synergistic corynebacterial infection is often present in white piedra, as demonstrated by culture and electron microscopy. *T. beigelii* has also been implicated as a cause of onychomycosis. *T. inkin* is implicated as an etiologic agent of pubic white piedra. *Trichosporon asahii* causes white piedra and onychomycosis and has been isolated from black piedra. *Trichosporon* spp. can also cause disseminated disease in immunosuppressed patients, and *T. asahii* has produced disseminated cutaneous infections in immunocompetent hosts. In white piedra, patients present with yellow or beige-colored, soft, slimy sheaths coating the hair shafts (Fig. 15.17). The sheaths are composed of hyphae, arthrospores, and bacteria. The culture shows soft, cream-colored colonies composed of blastospores and septate hyphae, which fragment into arthrospores.

Treatment of piedra involves cutting or shaving the hair, but this may not be acceptable to the patient. Oral and topical terbinafine have been effective in black piedra. For white piedra, oral itraconazole, topical imidazoles, ciclopirox olamine, 2% selenium sulfide, 6% precipitated sulfur in petrolatum, chlorhexidine solutions, Castellani paint, zinc pyrithione, amphotericin B lotion, and 2%–10% glutaraldehyde have all been used successfully.

Essential oils derived from *Cymbopogon winterians*, *Mentha piperita*, *Cinnamomum zeylanicum*, *Melaleuca alternifolia*, and *Eucalyptus globulus* have demonstrated efficacy against *Trichosporon ovoides*.

Fig. 15.17 White piedra.

TINEA VERSICOLOR (PITYRIASIS VERSICOLOR)

Tinea versicolor is caused by *Malassezia* spp. The major implicated species is *Malassezia globosa*, although *M. restricta*, *M. sympodialis*, *M. furfur*, *M. obtusa*, and *M. slooffiae* have also been implicated. Tinea versicolor typically presents as hypopigmented or hyperpigmented, coalescing scaly macules on the trunk and upper arms (Fig. 15.18). Pink, atrophic, and trichrome variants exist and can produce striking clinical pictures. The eruption is more common during the summer months and favors oily areas of skin. Sites of predilection are the sternal region and the sides of the chest, abdomen, back, pubis, neck, and intertriginous areas such as antecubital and popliteal fossae. The disease may also occur on the scalp, palms, and soles. The face may be involved in infants and immunocompromised patients. Penile lesions may develop as well, and the organism is commonly isolated from patients with balanoposthitis. Mild itching and inflammation around the patches may be present. In some patients, many follicular papules are present.

Fig. 15.18 Tinea versicolor. (Courtesy Steven Binnick, MD.)

In hypopigmented tinea versicolor, abnormally small and poorly melanized melanosomes are produced and are not transferred to keratinocytes properly. This becomes most conspicuous in dark-skinned people. This hypopigmentation may persist for weeks or

months after the fungal disease is cured. UV exposure may speed normalization of the pigment.

Diagnosis

The *Malassezia* fungus is easily demonstrated in scrapings of the profuse scales that cover the lesions. Tape stripping of the lesions can also be performed. Microscopically, there are short, thick fungal hyphae and large numbers of variously sized spores. This combination of strands of mycelium and numerous spores is commonly referred to as "spaghetti and meatballs." The fungus can be highlighted by a variety of stains, including Parker blue-black ink (mixed 1:1 with 20% KOH), 1% Chicago sky blue 6B with 8% KOH, and Gram stain. Identification by culture requires lipid enrichment of the media and is rarely done to establish the diagnosis unless there is resultant malassezia sepsis as can be seen in patients on lipid rich hyperalimentation. Wood's light examination accentuates pigment changes and may demonstrate yellow-green fluorescence of the lesions in adjacent follicles. Biopsy will demonstrate a thick basket-weave stratum corneum with hyphae and spores. In the atrophic variant, epidermal colonization with hyphae and spores is accompanied by effacement of the rete ridges, subepidermal fibroplasia, pigment incontinence, and elastolysis.

Differential Diagnosis

Tinea versicolor must be differentiated from seborrheic dermatitis, pityriasis rosea, pityriasis rubra pilaris, pityriasis alba, Hansen disease, syphilis, confluent and reticulated papillomatosis and vitiligo. In the atrophic variant of tinea versicolor, the lesions may suggest parapsoriasis, mycosis fungoides, anetoderma, LE, or steroid atrophy. The diagnosis in all forms of tinea versicolor is generally easily established by KOH examination. In seborrheic dermatitis, the patches have an erythematous yellowish tint, and the scales are soft and greasy and typical locations along the glabella, nasolabial folds and scalp are involved. In tinea versicolor the scales are furfuraceous (fluffy). Macular syphilid consists of faint pink lesions, less than 1 cm in diameter, irregularly round or oval, which are distributed principally on the nape, sides of the trunk, and flexor aspects of the extremities. The lesions are slightly indurated, with a peripheral scale, and may be copper colored. General adenopathy may be present. Serologic tests are positive in this phase of syphilis, but prozone reactions may occur, and the serum may require dilution.

Treatment

Imidazoles, triazoles, selenium sulfide, ciclopirox olamine, zinc pyrithione, sulfur preparations, salicylic acid preparations, propylene glycol, and benzoyl peroxide have been used successfully as topical agents. Selenium sulfide lotion is very cost-effective and can be applied daily for a week; it is washed off after 10 minutes and is also effective in a single, overnight application, which can be repeated monthly as prophylaxis. The scalp and trunk can be shampooed monthly with selenium sulfide to reduce scalp colonization. Zinc pyrithione soap is also cost-effective and well tolerated for treatment and prophylaxis.

In adults, Oral itraconazole, 200 mg once daily for 7 days or 400 mg single dose has been used. Fluconazole, 400 mg once, may also be effective and can be repeated monthly. Although oral terbinafine has been ineffective, it is effective topically. Twice-daily applications are superior to once-daily applications. Alternatively, 5-aminolevulinic acid PDT has been reported as effective.

Patients should be informed that the hypopigmentation or hyperpigmentation will take time to resolve and is not a sign of treatment failure. Relapse is likely if prophylactic therapy is not given occasionally, but many prophylactic options are available. After initial therapy, patients may prefer weekly washing with a topical zinc pyrithione bar or single, overnight applications of selenium sulfide, ketoconazole, econazole, or bifonazole shampoo every 30–60 days, or monthly oral therapy.

Pityrosporum Folliculitis

Pityrosporum folliculitis has been a controversial entity, but its prompt response to antifungal agents suggests that *Pityrosporum* yeast (the yeast phase of *Malassezia* spp.) are indeed pathogenic. Criteria for diagnosis include characteristic morphology, demonstration of yellow-green Wood's light fluorescence of the papules or identification of *Pityrosporum* yeast in smears or biopsies, and prompt response to antifungal treatment. Fungal stains, Gram stain, and May-Grünwald-Giemsa stain have been used. Lesions tend to be chronic, moderately itchy, monomorphic dome-shaped follicular papules and tiny pustules involving the upper back and adjacent areas. The face and scalp may be involved, and the lesions are sometimes found in association with either tinea versicolor or seborrheic dermatitis. *Pityrosporum* folliculitis is more common in organ or marrow transplant recipients and after antibiotic therapy especially for acne. *Pityrosporum* yeast is a normal part of the follicular flora, so alterations in flora may favor uncontrolled growth of the yeast. Such a case occurs when *Propionibacterium acnes* is suppressed by tetracycline therapy.

The eruption responds to oral fluconazole, 400 mg once; or itraconazole, 200 mg/day for 5–7 days. As previously noted, the FDA warns against using oral ketoconazole for skin and nail infections. Topical therapy with 2.5% selenium sulfide applied overnight is also generally effective. Other treatments include 30%–50% propylene glycol in water and topical imidazole creams. PDT may be considered in refractory disease. Topical clioquinol combined with narrow band UVB was also successful in a small trial. Relapses are common, but prophylaxis may be successful with monthly applications of selenium sulfide or maintenance doses of topical econazole.

THE DEEP MYCOSES

Most deep cutaneous fungal infections are a manifestation of systemic infection from inhalation of aerosolized fungus. When primary infection is introduced directly into the skin from puncture wounds, abrasions, or other trauma, a chancriform or verrucous lesion will form that may be accompanied by secondary

lymphangitis. Chest radiographs should be taken when investigating patients with deep mycoses, except for the classic inoculation types, such as sporotrichosis, mycetoma, chromoblastomycosis, and phaeohyphomycosis.

COCCIDIOIDOMYCOSIS

Coccidioidomycosis is also known as coccidioidal granuloma, valley fever, and San Joaquin Valley fever.

Primary Pulmonary Coccidioidomycosis

Inhalation of *Coccidioides immitis* or *C. posadasii*, followed by an incubation period of 10 days to several weeks, produces a respiratory infection that may be mild, with only a low-grade fever resembling a flulike illness. Approximately 60% of infected persons are entirely asymptomatic. Severe symptoms of chills, high fever, night sweats, severe headache, backache, and malaise may ensue in a minority. A large percentage of patients show lung changes on radiographic examination. These include hilar adenopathy, peribronchial infiltration, or an infiltrate compatible with bronchopneumonia. At the time of onset, a generalized maculopapular eruption may be present, which may be confused with a drug eruption, viral exanthem, or scarlet fever.

Within a few weeks, the pulmonary symptoms subside. In about 30% of women and in 15% of men, skin manifestations appear in the form of erythema nodosum over the shins and sometimes over the thighs, hips, and buttocks. These tender lesions may become confluent, gradually turn from purple to brown, and then disappear in about 3 weeks. Erythema nodosum is a favorable prognostic sign and occurs mostly in white individuals with transient self-limited disease. Sometimes, erythema multiforme may develop in a similar clinical setting.

Although valley fever is usually self-limited and patients recover spontaneously, a small percentage steadily progress into the chronic, progressive, disseminated form. The propensity for disseminated disease is several-fold higher in Hispanics and Native Americans and many times higher for African Americans, Filipinos, and Vietnamese. In women, pregnancy may predispose to systemic disease. Infants, the elderly population, persons with blood types B or AB, and immunosuppressed patients, such as those with AIDS, a history of organ transplantation, or a hematogenous malignancy or those receiving immunosuppressive therapy, are also at increased risk for severe disease. Donor-derived organ transplant transmission has been documented many times; risk is primarily in the first year after transplant. Autosomal dominant interferon-γ receptor 1 deficiency also may predispose to disseminated disease.

Disseminated Coccidioidomycosis (Coccidioidal Granuloma)

Dissemination occurs in less than 1% of infections, but its incidence is heavily influenced by the factors previously listed. Target organs include the bones, joints, viscera, brain, meninges, and skin. A single organ or multiple organs may be involved. Skin lesions occur in 15%–20% of patients (Fig. 15.19) with disseminated disease and may appear as verrucous nodules, as pink papules resembling basal cell carcinoma, or as subcutaneous abscesses. The face is frequently involved. Some chronic lesions develop into plaques that resemble mycosis fungoides or North American blastomycosis. In AIDS patients, umbilicated papules may mimic molluscum contagiosum. Umbilicated papules are more often associated with cryptococcosis but can occur with a variety of fungi.

Primary Cutaneous Coccidioidomycosis

The primary form occurs rarely, and skin disease should be considered a manifestation of disseminated disease unless there is a definite history of inoculation, or a colonized splinter is found in the lesion. Between 1 and 3 weeks after inoculation, an indurated nodule develops that may ulcerate. Later, nodules appear along the lymphatic vessels. Spontaneous recovery may result after several weeks, although most patients are treated with systemic agents.

Fig. 15.19 Coccidioidomycosis.

Etiology and Pathology

The causative organism, *C. immitis*, has been isolated from the soil and from vegetation. It is commonly found in the burrows of rodents, often at a depth of about 20 cm. Epidemics occur when the soil is disrupted to a depth of 20 cm or more. This can occur as a result of road work, laying of telephone or electric cable, dust storms, and earthquakes. Outbreaks occur sporadically in California and Arizona.

Coccidioides immitis is dimorphous, reproducing brittle mycelia at room temperature, and spherules in tissue. Spherules are unencapsulated with a thick, refractile wall and a granular interior. They measure 5–200 μm in diameter but average 20 μm. Endosporulation can occur, and although the organism can resemble *Rhinosporidium*, *Coccidioides* is typically much smaller and more uniform in size. It also lacks the small, central nucleus that is uniformly present in nonsporulating *Rhinosporidium*.

Culture

Coccidioides is readily grown at room temperature and is highly infectious. For this reason, culture of deep fungi should be performed only in laboratories with biocontainment hoods. PCR

primers and a DNA hybridization probe test that targets organism-specific ribosomal RNA are available for rapid identification.

Epidemiology

Coccidioidomycosis principally occurs in limited areas in the Western Hemisphere. It is endemic in northern Mexico, Argentina, Venezuela, and the southwestern United States (lower Sonoran Life Zone). In highly endemic areas, most residents will have been infected, and new residents have a good chance of becoming infected within 6 months. Very few will develop disseminated disease, although the attack rate has recently increased in both California and Arizona.

Differential Diagnosis

Clinically, it is extremely difficult to differentiate coccidioidomycosis from blastomycosis, which it closely resembles. Definite diagnosis depends on serologic testing and the demonstration of *C. immitis* or *C. posadasii* microscopically, culturally, or by PCR. A positive reaction of the delayed tuberculin type develops early on skin testing and remains high in those who resist the disease well. A negative skin test occurs with dissemination.

Immunology

Precipitin, latex agglutination, immunodiffusion, a widely used nuclei acid hybridization test, and complement fixation serologic tests have been developed. The precipitin, immunodiffusion, enzyme-linked immunosorbent assay (ELISA), and latex agglutination tests are useful in recent infection because a maximum titer is reached in 1–2 weeks. They permit detection of coccidioidal immunoglobulin M (IgM) in early coccidioidomycosis. In later infections, the complement fixation test is useful. In primary coccidioidomycosis, the titer is low, whereas in subsequent dissemination, there is a rapid rise in titer. Titers greater than 1:32 indicate disseminated disease is present and correlate with severity. They are used to follow progress in treatment and relapse after therapy. When the disease has disseminated, cerebrospinal, synovial, and peritoneal fluid can be tested for coccidioidal antibody. The *Coccidioides*-specific ELISA detects antigenuria in about 70% of patients with coccidioidomycosis and is negative in more than 99% of controls without fungal infections. Cross-reactions with other systemic mycoses occur in 10% of patients. An isolated positive enzyme immunoassay (EIA) IgM test usually means disseminated disease. Serologic titers may be falsely negative in patients receiving immunosuppressive therapy.

Treatment

Both fluconazole, 400 mg/day, and itraconazole solution, 200 mg daily, have similar efficacy in mild to moderate nonmeningeal disease. Treatment must be continued for 3–12 months. Many patients will require ongoing suppressive therapy. In patients infected with HIV, lifetime suppressive doses of 200 mg/day are advised, and potent antiretroviral therapy is associated with improved outcomes. In coccidioidomycotic meningitis or severe disseminated disease, a combination of amphotericin B and fluconazole is used. Posaconazole is a second-line agent. Voriconazole has been used successfully in meningeal disease. Azole resistance has been reported and should be suspected in patients with refractory disease. Surgical debridement of abscesses may be necessary. For primary inoculation, itraconazole 400 mg daily for 6 months is usually effective.

HISTOPLASMOSIS

Histoplasmosis is caused by inhalation of airborne spores. It may be asymptomatic or may cause limited lung disease. Dissemination to other organs, including the skin, occurs in about 1 in 2000 patients with acute infection. Immunodeficiency, old age, and systemic corticosteroids predispose to widespread disease. Donor-derived organ transplant transmission has often been documented. Cases misdiagnosed as sarcoidosis and treated with corticosteroids have disseminated widely. In disseminated disease, mucous membranes are involved much more frequently than skin. Primary cutaneous disease is exceedingly rare.

Primary Pulmonary Histoplasmosis

Primary pulmonary histoplasmosis is usually a benign, self-limited form of acute pneumonitis characterized by fever, malaise, night sweats, chest pain, cough, and hilar adenopathy. Resolution of the pneumonitis occurs rapidly, and the only residua may be calcifications in the lung and a positive skin test to histoplasmin. However, serious pneumonitis caused by histoplasmosis does occur. Such cases have been reported among cave workers in Mexico and travelers returning from Central America. A chronic pulmonary form may occur in patients with emphysema.

Approximately 10% of patients with acute symptomatic infection develop arthritis and erythema nodosum. During a large Midwestern U.S. epidemic, about 4% of patients diagnosed with histoplasmosis presented with erythema nodosum. Erythema multiforme has also been described.

Progressive Disseminated Histoplasmosis

Most patients who develop this severe, progressive, disseminated form are immunocompromised or taking systemic corticosteroids. Leukemia, lymphoma, lupus erythematosus, renal transplantation, or AIDS are frequent predisposing diseases. Cases have also been reported in patients receiving low-dose methotrexate for psoriasis and in patients receiving anti–tumor necrosis factor (TNF) therapy. Approximately 20% have no identifiable risk factor.

The reticuloendothelial system, genitourinary tract, adrenals, GI tract, adrenal glands, and heart may be involved. Ulcerations and granulomas of the oronasopharynx are the most common mucocutaneous lesions, occurring in about 20% of patients with

disseminated histoplasmosis (Fig. 15.20). Beginning as solid, indurated plaques, the lesions ulcerate and become deep-seated, painful, and secondarily infected. Perianal lesions may also occur.

Skin lesions are present in approximately 6% of patients with dissemination but may occur in 10%–25% of patients with AIDS and in renal transplant recipients. The morphologic patterns are nonspecific and protean, including umbilicated nodules, papules, plaques (Fig. 15.21), ulcers, cellulitis, abscesses, pyoderma, pustules, and furuncles. Demonstration of the organisms is readily made from histologic sections and cultures of the exudate. The most common manifestation in children is purpura, which usually appears a few days before death and is probably caused by severe involvement of the reticuloendothelial system, with emaciation, chronic fever, and severe GI symptoms. In the HIV-positive population, dyspnea, platelet count less than 100,000/mm^3, and lactate dehydrogenase level more than twofold the upper limit of normal are poor prognostic factors and independently associated with death during the first 30 days of antifungal treatment.

Primary Cutaneous Histoplasmosis

The rare primary cutaneous form is characterized by a chancre-type lesion with regional adenopathy.

African Histoplasmosis

African histoplasmosis is caused by *Histoplasma capsulatum* var. *duboisii*. Skin lesions are much more common and include superficial cutaneous granulomas, subcutaneous granulomas, and osteomyelitic lesions with secondary involvement of the skin (cold abscesses). Papular, nodular, circinate, eczematoid, and psoriasiform lesions may be seen. The granulomas are dome-shaped nodules, painless but slightly pruritic. There may be skin and mucous membrane manifestations such as ulcerations of the nose, mouth, pharynx, genitals, and anus. These ulcers are chronic, superficial lesions with no induration or noticeable inflammatory reaction. Erythema nodosum occurs frequently. Emaciation and chronic fevers are common systemic signs. Late occurrence many years after exposure may occur.

Etiology and Pathology

Histoplasmosis is caused by *H. capsulatum*, a dimorphic fungus that exists as a soil saprophyte. The organism is frequently found in bat and bird feces.

In tissue, there are 2–3 μm round bodies within the cytoplasm of large macrophages or the cytoplasm of keratinocytes. A pseudocapsule surrounds each organism. The organisms bear a striking resemblance to those of leishmaniasis but lack a kinetoplast and are distributed evenly throughout the cytoplasm, whereas leishmanial organisms often line up at the periphery of the cell. Budding forms may rarely be present, and mycelial and pleomorphic budding forms are sometimes seen in cavitary pulmonary disease, endocardial disease, aortic plaques, or skin lesions. Morphologically, these forms resemble *Candida* more than typical intracellular *Histoplasma*. On direct examination, the organism may be demonstrated in the peripheral blood, sputum, bronchial washings, cerebrospinal fluid, sternal marrow, lymph node touch smears, or ulcers when stained with Giemsa, PAS, or GMS. In African histoplasmosis, the organisms are 10–13 μm in diameter and are typically found within multinucleated giant cells.

In disseminated disease, the bone marrow is frequently involved. Blood, urine, and tissue from oral and skin lesions should also be cultured. PCR probes are available for rapid culture confirmation.

Epidemiology

Although histoplasmosis occurs throughout the world, it is most common in North America, especially in the central U.S. states along the Mississippi River basin. It is also found along the Potomac, Delaware, Hudson, and St. Lawrence rivers. It has been reported in the major river valleys of South America, Central Africa, China, and Southeast Asia but seems to spare the Nile River Valley. The disease is heavily endemic in Puerto Rico and Nicaragua.

Transmission of the disease does not occur between individuals; instead, the infection is contracted from the soil by inhalation of the spores, especially in a dusty atmosphere. The spores have been demonstrated in the excreta of starlings, chickens, turkeys,

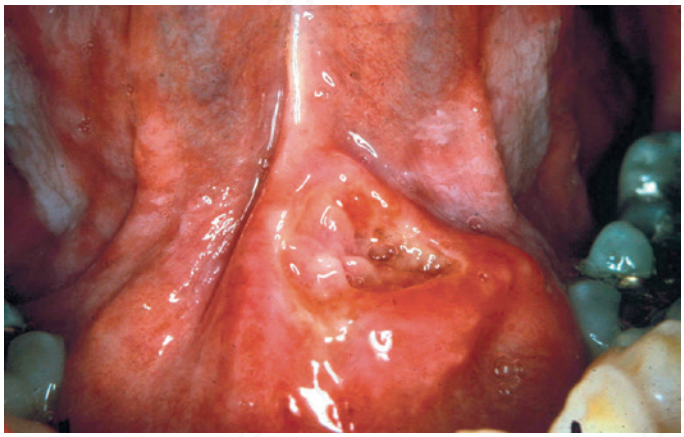

Fig. 15.20 Ulcer of disseminated histoplasmosis.

Fig. 15.21 Histoplasmosis. (Courtesy Shyam Verma, MBBS, DVD.)

and bats. The disease may be contracted by persons who enter caves inhabited by bats or birds. Epidemics have been reported from exposure to silos, abandoned chicken houses, and storm cellars.

In the 1978 histoplasmosis outbreak in Indianapolis, Indiana, 488 clinically recognized cases occurred, and 55 had disseminated disease. The actual number infected persons was probably well over 100,000. Nineteen died, none of whom was under age 1 year. Fatal or disseminated infections occurred in 74% of immunosuppressed persons, compared with 6.5% of those not immunosuppressed. Age over 54 was a worse prognostic factor than chronic lung disease in nonimmunosuppressed persons. Disseminated histoplasmosis is seen as an opportunistic infection in HIV-infected patients.

Immunology

The best diagnostic test for histoplasmosis has been urinary ELISA, but PCR assays are available and demonstrate excellent sensitivity. Serologic testing for antibodies requires that the patient has normal immune responsiveness (false negatives) and is further limited by a high rate of false-positive results, especially cross-reactions with blastomycosis. False positives also occur in the latter situation when measuring polysaccharide antigen in the serum or urine, the most sensitive and rapid test. The complement fixation test, when positive at a titer of 1:32 or greater, indicates active or recent infection. Because of the limitations of serologic studies, culture remains the gold standard.

Treatment

For mild to moderate progressive disseminated disease itraconazole, 200 mg three times daily for 3 days, followed by 200 mg once or twice daily for 12 months is given. Amphotericin B is the treatment of choice in severely ill patients and immunocompromised patients. A suppressive dose of itraconazole, 200 mg/day, follows the IV amphotericin and may be needed as lifelong treatment.

CRYPTOCOCCOSIS

Cryptococcosis generally begins as a pulmonary infection and remains localized to the lung in 90% of patients. In the remaining 10%, the organisms hematogenously disseminate to other organs, with the CNS and the skin the two most common secondary sites. Patients in the 10% group are usually immunocompromised or debilitated. The incidence of dissemination is much higher in patients with AIDS, occurring in up to 50% of this population.

Primary pulmonary cryptococcosis infection may be so mild that the symptoms of fever, cough, and pain may be absent. On the other hand, some cases may be severe enough to cause death. Radiographic studies will reveal disease at this stage.

When dissemination occurs, the organism has a special affinity for the CNS. Cryptococcosis is the most common cause of mycotic meningitis. The patient may have restlessness, hallucinations, depression, severe headache, vertigo, nausea and vomiting, nuchal rigidity, seizures, and symptoms of intraocular hypertension. Other organs, such as the liver, skin, spleen, myocardium, and skeletal system, as well as the lymph nodes, may be involved. Disseminated cryptococcosis can present in many organ systems; hepatitis, osteomyelitis, prostatitis, pyelonephritis, peritonitis, and skin involvement have all been reported as initial manifestations of disease. The incidence of skin involvement in patients with cryptococcosis is 10%–15%, although it is lower in the HIV-infected population. Cutaneous lesions may precede overt systemic disease by 2–8 months.

Skin infection with cryptococcosis occurs most frequently on the head and neck. A variety of morphologic lesions have been reported, including subcutaneous swellings, abscesses, blisters, tumor-like masses, molluscum contagiosum–like lesions (Fig. 15.22), draining sinuses, ulcers, eczematous plaques, granulomas, papules, nodules, pustules, acneiform lesions, plaques, and cellulitis. Approximately 50% of patients with HIV and disseminated cryptococcosis will develop molluscum contagiosum–like lesions. In these patients, there is often a central hemorrhagic crust. Lesions may first become evident in HIV-infected patients during highly active antiretroviral therapy (HAART), as they may with histoplasmosis and coccidioidomycosis. Solitary cutaneous lesions and indolent cellulitis may be the presenting signs of disseminated disease.

Primary inoculation cryptococcosis is a rare disease. To establish the diagnosis, there should be a clear history of implantation or a foreign body found in association with the organism. Usually, primary inoculation disease presents as a solitary skin lesion on an exposed area, frequently in the form of a whitlow. Risk factors include outdoor activities and exposure to bird droppings. *Cryptococcus neoformans* serotype D is more often associated with primary cutaneous disease. Although primary cutaneous disease exists, for all practical purposes, identification of cryptococci in the skin

Fig. 15.22 Cryptococcal infection in an HIV-infected patient. (Courtesy Michelle Weir, MD.)

indicates disseminated disease with a poor prognosis, and it requires a search for other sites of involvement.

Etiology and Pathology

The causative organism is *C. neoformans* or in subtropical or tropical areas, *Cryptococcus gattii*. It appears in tissue as a pleomorphic budding yeast. The organisms vary greatly in size and shape, in contrast to most other fungal organisms. The capsule is usually prominent, although it is inversely proportional to the extent of the granulomatous reaction. Generally, the capsule is easily identified in hematoxylin and eosin (H&E) sections, although mucicarmine, methylene blue, or alcian blue staining can also be used. Usually, multiple yeast share a common capsule. *Cryptococcus* stains well with the Fontana-Masson stain for melanin.

Epidemiology

Cryptococcosis has a worldwide distribution and affects both humans and animals. The organism has been recovered from human skin, soil, dust, and pigeon droppings; when deposited on window ledges in large cities, pigeon droppings are a source of infection. The patient with disseminated cryptococcosis usually has a concomitant debilitating disease, such as AIDS, cancer, leukemia, lymphoma, renal failure, hepatitis, alveolar proteinosis, severe diabetes mellitus, sarcoidosis, tuberculosis, or silicosis. Long-term oral prednisone or immunosuppressive therapy for chronic illnesses, such as renal transplantation, sarcoidosis, or connective tissue disease, may also be a factor. Males outnumber females 2:1. Cryptococcosis is most frequent in persons age 30–60 years.

Patients with AIDS are particularly at risk for disseminated disease. Cryptococcosis is the fourth leading cause of opportunistic infection and the second most common fungal opportunist, with 5%–9% of patients manifesting symptomatic disease. Dissemination occurs in 50% of patients with AIDS, with skin involvement reported in 6%.

Immunology

The latex slide agglutination test is sensitive and specific. It may give false-positive results in the presence of rheumatoid factor. Direct microscopic examination and latex agglutination have been used with lesional skin scrapings to aid in rapid diagnosis. The complement fixation test for cryptococcal polysaccharide, indirect fluorescence test, and ELISA for cryptococcal antigen detection are all helpful, although ELISA is capable of detecting the presence of antigen earlier and at a lower concentration than the other two tests.

Mycology

For direct examination, a drop of serum or exudate is placed on a slide and a coverslip inserted. If examination shows yeast, 1 drop of 10% KOH can be added to half the coverslip and 1 drop of India ink to the other half to demonstrate the capsule. The skin biopsy specimen should be cultured. A commercially available DNA probe detection assay allows rapid culture confirmation.

Treatment

For mild to moderately ill non-AIDS patients, fluconazole, 400 mg/day for 8–24 weeks, may be effective. In seriously ill non-HIV patients, amphotericin B intravenously initially, followed by fluconazole orally, is standard treatment. In non-AIDS meningitis and all HIV-positive patients, flucytosine is given after initial amphotericin B treatment, and in patients infected with HIV, fluconazole is given indefinitely at a suppressive dose of 200 mg/day. For primary inoculation cases, surgical treatment alone or with fluconazole or itraconazole for 3–6 months is generally effective.

NORTH AMERICAN BLASTOMYCOSIS

Most cutaneous North American blastomycosis is the result of dissemination from a primary pulmonary focus. The lesions are chronic, slowly progressive, verrucous, and granulomatous and are characterized by thick crusts, warty vegetations, discharging sinuses, and pustules along the advancing edge (Fig. 15.23). The lesions are often multiple and are located mostly on exposed skin. Papillomatous proliferation is most pronounced in lesions on the hands and feet, where the patches become very thick. The patches tend to involute centrally and to form white scars as they spread peripherally. The crusts are thick and dirty gray or brown. Beneath the crusts, exuberant granulations are covered with a seropurulent exudate, which oozes out of small sinuses that extend down to indolent subcutaneous abscesses. Lower extremity nodules and plaques clinically and histologically suggestive of Sweet syndrome have also been described.

The primary infection is almost always in the upper or middle lobes of the lungs, and most cases never develop cutaneous dissemination. When dissemination does occur, the most common site is the skin, accounting for at least 80% of cases of disseminated disease. It also frequently disseminates to bone, especially the ribs and vertebrae. Other targets are the CNS, liver, spleen, and genitourinary system.

Cutaneous blastomycosis rarely occurs as a result of primary cutaneous inoculation. Such patients have a clear history of inoculation and present with a small primary nodule and subsequent secondary nodules along the draining lymphatics, creating a picture similar to sporotrichosis. Healing takes place within several months.

Etiology and Pathology

The fungus *Blastomyces dermatitidis* causes North American blastomycosis. It is frequently found in soil and animal habitats. *B. dermatitidis* is a dimorphic fungus with a mycelial phase at room temperature and a yeast phase at 37°C. Direct microscopic examination of a KOH slide of the specimen should always be made, because culture of the fungus is difficult and the organism may be found in purulent exudates obtained from skin lesions. The specimen should be cultured. A DNA probe detection assay is available for rapid culture confirmation.

Fig. 15.23 North American blastomycosis.

Cutaneous blastomycosis usually demonstrates marked pseudoepitheliomatous hyperplasia of the epidermis with neutrophilic abscesses. Giant cells are frequently present in the dermal infiltrate. Organisms are typically few in number and are most frequently found within giant cells or intraepidermal abscesses. The organism is a thick-walled yeast, usually 5–7 μm in diameter, although giant forms have been reported in tissue. *B. dermatitidis* lacks a capsule but has a thick and distinctly asymmetric refractile wall. Broad-based budding may occasionally be noted. Rarely, acute skin lesions may lack pseudoepitheliomatous hyperplasia and demonstrate a diffuse neutrophilic dermal infiltrate. They may present as cutaneous nodules, sometimes with a localized distribution.

Primary cutaneous blastomycosis demonstrates a neutrophilic infiltrate with many budding cells of blastomycetes. In later lesions, a granulomatous infiltrate is found. The lymph nodes may show marked inflammatory changes, giant cells containing the organisms, lymphocytes, and plasma cells. Lung involvement may show many changes that are suggestive of tuberculosis with tubercle formation. Purulent abscesses may occur in the lungs and bone.

Epidemiology

North American blastomycosis is prevalent in the southeastern United States and the Ohio and Mississippi river basins, reaching epidemic proportions in Kentucky and Mississippi; the latter has the highest prevalence of blastomycosis in North America. There is a male/female ratio of approximately 6:1, and most patients are over age 60. Often, the cutaneous form occurs in patients without a known history of pulmonary lesions.

Outdoor activity after periods of heavy rain is a risk factor for acute pulmonary disease. Beaver lodges are a common site for the fungus, and some reports have linked outbreaks of disease with outings near a beaver lodge. Blastomycosis has also been reported from the bite of a dog with pulmonary blastomycosis. Transmission has been reported between men with prostatic involvement and their sexual partners.

Risk factors for symptomatic disease include preexisting illness. In one study, one quarter of patients with blastomycosis had underlying immunosuppression, including those with organ transplantation, and 22% had diabetes mellitus. In the southern states, blacks have a higher incidence than whites, and the mortality rate is also higher among African Americans.

Immunology

Serologic tests are performed by immunodiffusion or ELISA. Commercial antigen test kits are available for rapid diagnosis.

Differential Diagnosis

Blastomycosis may closely resemble halogenoderma, blastomycosis-like pyoderma, pemphigus vegetans, tuberculosis verrucosa cutis, syphilis, granuloma inguinale, drug eruptions, and trichophytic granuloma. The diagnosis is established by demonstration of *B. dermatitidis* or serologic testing.

Treatment

In mild to moderate disease itraconazole 200 mg thrice daily for 3 days, then twice daily for 6–12 months is the treatment of choice. Amphotericin B given for 1–2 weeks followed by itraconazole 6–12 months for more severe disease is indicated.

SOUTH AMERICAN BLASTOMYCOSIS

Mucocutaneous involvement in South American blastomycosis, also known as paracoccidioidomycosis, is almost always a sign of disseminated disease, primarily in the lungs. Rare cases may arise from inoculation. In Brazil, the disease causes about 200 deaths per year.

The mucocutaneous type usually begins in the mouth, where small papules and ulcerations appear. Gingival lesions are most common, followed by lesions of the tongue and lips. With time, adjacent tissues are affected, and extensive ulcerations eventually destroy the nose, lips, and face. Skin lesions may show ulcerations (Fig. 15.24), pseudoepitheliomatous hyperplasia, and microabscesses. The lymphangitic type manifests itself by enlargement of the regional lymph nodes soon after the appearance of the initial lesions about the mouth. The adenopathy may extend to the supraclavicular and axillary regions. Nodes may become greatly enlarged and break down with ulcerations that secondarily involve the skin, causing severe pain and dysphagia with progressive cachexia and death. Primary skin lesions are less common. The infection may closely simulate Hodgkin disease, especially when the suprahyoid, preauricular, or retroauricular groups of lymph nodes are involved.

There is a visceral type, caused by hematogenous spread of the disease to the liver, adrenal glands, spleen, intestines, and other organs. There is also a mixed type that has the combined symptomatology of the mucocutaneous, lymphangitic, and visceral types. South American blastomycosis may present as a rapidly progressive

Fig. 15.24 Paracoccidioidomycosis. (Courtesy Lauro de Souza Lima Institute, Brazil.)

acute disease or follow a subacute course, or it may occur as a chronic, slowly advancing form.

Etiology and Pathology

South American blastomycosis is caused by the fungus *Paracoccidioides brasiliensis*. Biopsies may demonstrate pseudoepitheliomatous hyperplasia, abscess formation, or ulceration. A granulomatous inflammatory infiltrate is frequently present, consisting of lymphocytes, epithelioid cells, and Langerhans giant cells. The organism appears as a round cell, 10–60 μm in diameter, with a delicate wall. Multiple buds may be present, creating a resemblance to a mariner's wheel.

This chronic granulomatous disease is endemic in Brazil and also occurs in Argentina and Venezuela. Occasional cases have been reported in the United States, Mexico, Central America, Europe, and Asia. Most of these patients have a travel history to endemic areas. The disease is generally found among laborers, mostly in men. Although the initial infection is usually respiratory, some individuals may become infected by picking their teeth with twigs or from chewing leaves.

South American blastomycosis is 15 times more common in men, which is of particular interest because it has been shown that 17β-estradiol inhibits transition from the mycelial to the tissue-invasive yeast form. *P. brasiliensis* can lodge in periodontal tissues and some cases start after extraction of teeth. Many cases have been reported in patients with AIDS or organ transplant recipients, in whom the course is usually acute and severe.

Immunology

Complement fixation tests are positive in 97% of severe cases, and the titer rises as the blastomycosis becomes more severe. With improvement, the titer decreases. Immunodiffusion tests are often used for diagnosis and posttherapy follow-up. The test is highly specific but only about 90% sensitive.

Treatment

Itraconazole, 200 mg/day for 6–9 months for mild disease and 12–18 months for moderate disease, is indicated. For severe disease initial amphotericin followed by itraconazole as in North American blastomycosis should be given. Ketoconazole and trimethoprim-sulfamethoxazole (TMP-SMX) are alternative treatments. When HIV patients are infected, lifelong therapy with TP-SMX is the rule.

SPOROTRICHOSIS

Sporotrichosis usually results from direct inoculation by a thorn, cat's claw, or other minor penetrating injury. The earliest manifestation may be a small nodule that may heal and disappear before the onset of other lesions. In the course of a few weeks, nodules generally develop along the draining lymphatics (Fig. 15.25). These lesions are at first small, dusky red, painless, and firm. In time, the overlying skin becomes adherent to them and may ulcerate. When the lesions occur on the face, the lymphatic drainage is radial, rather than linear, and secondary nodules occur as rosettes around the primary lesion.

Regional lymphangitic sporotrichosis is the common type, accounting for 75% of cases. Fixed cutaneous sporotrichosis is seen in 20% of cases and is characterized by a solitary ulcer, plaque, or crateriform nodule without regional lymphangitis (Fig. 15.26). It may also present as localized rosacea-like lesions of the face without regional lymphangitis. Increased host resistance, a smaller inoculum, facial location, and variations in strain pathogenicity have all been suggested as triggers for the fixed cutaneous form. The distribution in children is similar to that in adults.

Disseminated sporotrichosis is the least common form. Factors that predispose to extracutaneous disease include oral prednisone therapy, other immunosuppressive drugs (including TNF-α inhibitors), chronic alcoholism, diabetes mellitus, hematologic malignancies, and AIDS. Systemic invasion may produce cutaneous, pulmonary, GI, articular, and brain lesions. Arthritis or bone involvement occurs in most patients. The cutaneous lesions are reddish, tender nodules, which soften, form cold abscesses, and eventually suppurate, leaving chronic ulcers or fistulas. These are usually around arthritic joints and the face and scalp, but may occur anywhere on the skin. At times, only internal involvement is apparent.

Etiology and Pathology

Sporotrichosis is caused by the *Sporothrix schenckii* complex, with more than six species identified by molecular techniques. These

Fig. 15.25 Sporotrichosis. (Courtesy Lauro de Souza Lima Institute, Brazil.)

Fig. 15.26 Fixed cutaneous sporotrichosis. (Courtesy Scott Norton, MD.)

fungi are dimorphic in that they grow in a yeast form at 37°C and in a mycelial form at room temperature. Cutaneous disease typically presents with palisading granulomatous dermatitis surrounding a stellate suppurative abscess. Organisms appear as cigar-shaped yeast in tissue but are rarely seen in North American cases. In Asian cases of sporotrichosis, the organisms are frequently more numerous. Asteroid bodies and mycelial elements are prevalent in regional lymphangitic sporotrichosis. PCR methods of detection are available.

Epidemiology

There seems to be no geographic limitation to the occurrence of sporotrichosis. Most often, the primary invasion is seen as an occupational disease in gardeners, florists, and laborers after injuries by thorns, straw, or sphagnum moss. The pathogen typically lives as a saprophyte on grasses, shrubs, and other plants. Carnations, rose bushes, barberry shrubs, and sphagnum moss are common sources. High humidity and high temperature favor infection. Experimentally, it has been produced in many laboratory animals, and spontaneous cases have been observed in horses, mules, dogs, cats, mice, and rats. In cats, sporotrichosis usually produces disseminated disease. The organism may be found on the claws and may be transmitted to humans through cat scratches. This is becoming the most common mode of transmission in many areas of the world. Multiple family members or veterinary workers may be infected by a single cat.

Immunology

Although skin testing and agglutination tests may be done, the clinical findings, biopsy, and culture remain the most common means of establishing a diagnosis.

Differential Diagnosis

Demonstration by culture establishes the diagnosis, and it is important to differentiate sporotrichosis from other lymphangitic infections. Atypical mycobacteriosis (especially *Mycobacterium marinum*), leishmaniasis, and nocardiosis all produce lymphangitic spread. In contrast, tuberculosis, cat-scratch disease, tularemia, glanders, melioidosis, lymphogranuloma venereum, and anthrax produce ulceroglandular syndromes (ulcer with regional lymphadenopathy rather than ulcer with nodules along lymphatic vessels).

Treatment

Itraconazole is effective for cutaneous and lymphocutaneous sporotrichosis at a dose of 200 mg/day for 2–4 weeks after all lesions have resolved, usually 3–6 months. If there is no response, the dose may be doubled, or terbinafine, 500 mg two times daily, is a further option.

For cutaneous forms, potassium iodide, 3–6 g/day, remains an effective and inexpensive therapeutic option and may be effective when itraconazole therapy fails. Decades of experience demonstrate the effectiveness of potassium iodide despite the absence of published high-level evidence. Iodide therapy usually requires 6–12 weeks of treatment. Generally, it is best to begin with 5 drops of the saturated solution in grapefruit or orange juice three times daily after meals. The drops can also be put in milk, but strong-flavored citrus juices are better at masking the taste. The dose should be gradually increased up to 40–50 drops three times daily. Potassium iodide is not suitable for pregnant women. Adverse effects of iodide therapy include nausea, vomiting, parotid swelling, acneiform rash, coryza, sneezing, swelling of the eyelids, hypothyroidism, a brassy taste, increased lacrimation and salivation, flares of psoriasis, and occasionally depression. Most of the side effects can be controlled by stopping the drug for a few days and reinstituting therapy at a reduced dosage.

Application of local hot compresses, hot packs, or a heating pad twice a day has been advocated as a useful adjunct, because *S. schenckii* is intolerant to temperatures above 38.5°C (101°F).

In adult disseminated sporotrichosis, amphotericin B, given as a lipid formulation at 3–5 mg/kg daily, is recommended, followed by itraconazole 200 mg twice daily for at least 1 year. In immunocompromised patients, treatment with 200 mg/day may need to be lifelong.

CHROMOBLASTOMYCOSIS

Chromoblastomycosis usually affects one of the lower extremities (Fig. 15.27). It occurs as a result of direct inoculation of the organism into the skin. As a rule, lesions begin as a small, pink, scaly papule or warty growth on some part of the foot or lower leg, then slowly spread through direct extension and satellite lesions. With time, they develop a verrucous or nodular border and central atrophy and scarring. Small lesions may resemble common warts. Regional lymphadenitis may result from secondary bacterial infection, and a lymphangitic pattern of infection has been reported. In rare cases, the disease begins on an upper extremity or the face. Rarely, CNS involvement has been reported, both with and without associated skin lesions.

There is a 4:1 male predominance, and farmers account for almost 75% of patients with chromoblastomycosis. The disease is slowly progressive, and the average time between the appearance of lesions and diagnosis is almost 15 years. Lesions occur at sites of minor trauma. Squamous cell carcinoma may occur in long-standing cases.

Etiology and Pathology

Most cases are caused by one of several dematiaceous fungi. *Fonsecaea pedrosoi* is the most common cause and accounts for 90% or more of the cases reported in South America and is also the most common cause in other parts of the world. Other agents include *Phialophora verrucosa*, *Fonsecaea compacta*, *Cladosporium carrionii*, and *Rhinocladiella aquaspersa*. *Exophiala spinifera* and *Exophiala jeanselmei* have been reported in isolated cases. Patients may have more than one organism, and cutaneous lesions caused by both paracoccidioidomycosis and chromoblastomycosis have been reported in the same patient. Patients may also have chromoblastomycosis concurrently with mycetoma or invasive phaeohyphomycosis.

Histopathologically, lesions are characterized by pseudoepitheliomatous hyperplasia with intraepidermal abscess, a dermal granulomatous reaction, and the presence of pigmented fungal sclerotic bodies. The fungi often appear in clusters that reproduce by equatorial septation, rather than by budding. The presence of sclerotic bodies (Medlar bodies, "copper pennies") rather than hyphae distinguishes the infection from invasive phaeohyphomycosis. The organisms are often seen in association with an embedded splinter. Medlar bodies are usually easily identified as they produce melanin and are pigmented, but Ziehl-Neelsen and Wade-Fite stains have also been used to identify the pathogenic organisms, as has duplex PCR.

Fig. 15.27 Chromomycosis. (Courtesy Lauro de Souza Lima Institute, Brazil.)

Epidemiology

Chromoblastomycosis was first recognized in Brazil but has been found in other parts of South America and the Caribbean, Madagascar, South Asia, East Asia, the United States, Russia, and many other countries. Barefooted farm workers bear the largest burden of infection. Trauma from wood products and soil exposure results in implantation of the organism, and dissemination is rare.

Treatment

Treatment is difficult, and chromoblastomycosis often affects those who cannot afford medication. In some series, only about 30% of patients were cured, although almost 60% improved. About 10% fail therapy, and recrudescence of the disease is noted in more than 40% of patients. Smaller lesions are best treated by surgical excision or cryotherapy. In one study of 22 patients, the number of cryosurgeries varied from 1 to 22, and treatment lasted for up to 126 months. Only three patients did not respond. If the lesions are extensive, chronic, or burrowing, itraconazole, 200–400 mg/day, is given for 6–12 months or until there is a response. Terbinafine, 500–1000 mg/day, alone or in combination with itraconazole, 200–400 mg/day, has been effective in some

patients, as has posaconazole, 800 mg/day. Cryotherapy, CO_2 laser vaporization, PDT, and local hyperthermia are adjuncts. Combination amphotericin B and itraconazole has been used in resistant cases, as has isolated limb infusion with melphalan and actinomycin D. Despite these options, some lesions remain resistant, and amputation may be unavoidable in some patients.

PHAEOHYPHOMYCOSIS

This heterogeneous group of mycotic infections is caused by dematiaceous fungi with morphologic characteristics in tissue that include hyphae, yeastlike cells, or a combination of these. This contrasts with chromomycosis, in which the organism forms round, sclerotic bodies.

There are many types of clinical lesions caused by these organisms. Tinea nigra is an example of superficial infection. Alternariosis can also present as a superficial pigmented fungal infection in immunocompetent patients. Subcutaneous disease occurs most frequently as indolent abscesses at the site of minor trauma (so called "phaeomycotic cyst") (Fig. 15.28). *Exophiala jeanselmei* is the most common cause of this presentation in temperate climates. Systemic phaeohyphomycosis is largely a disease of immunocompromised patients, including solid-organ transplant recipients and patients with CARD9 deficiency, although primary cerebral forms occur in immunocompetent patients. Localized forms generally result from primary inoculation of the organism into the skin. Disseminated disease may also begin as a skin infection. The lesions usually appear as dry, black, leathery eschars with a scalloped, erythematous, edematous border. *Bipolaris spicifera* is the most common cause of disseminated disease, although *Scedosporium prolificans* has been reported as the most common organism in some areas. The presence of melanin in the cell wall may be a virulence factor for these fungi. Eosinophilia is noted in about 10% of patients with disseminated disease. Phaeohyphomycosis often disseminates to many organs. In some series, the mortality rate from disseminated disease is about 80%.

Fig. 15.28 Phaeohyphomycosis. (Courtesy Scott Norton, MD.)

Etiology and Pathology

Many black molds are capable of causing phaeohyphomycosis, including *E. jeanselmei*, *B. spicifera*, *Alternaria* spp., *Dactylaria gallopava*, *Phialophora parasitica*, *Cladosporium sphaerospermum*, *Wangiella dermatitidis*, *Exserohilum rostratum*, *Cladophialophora bantiana*, *Wallemia sebi*, and *Chaetomium globosum*. Some fungi, such as *Phialophora verrucosa*, can cause both phaeohyphomycosis and chromoblastomycosis. Some fungi, such as *E. jeanselmei*, may cause mycetoma (characterized by grain formation) in some patients and phaeohyphomycosis or chromoblastomycosis in others.

All these organisms produce pigmented hyphae in tissue and culture, although the pigment may only be visible focally in some histologic sections. Melanin can be stained by the Fontana-Masson method, but many molds produce enough melanin to stain positive, and a positive stain should not be misinterpreted as proof of phaeohyphomycosis. Organisms as diverse as zygomycetes and dermatophytes can stain with Fontana-Masson. When hyphae appear brown in tissue, there is little question as to the diagnosis, but when the organism appears hyaline in tissue, the presence of melanin staining must be interpreted in the context of the fungal morphology. Most organisms of phaeohyphomycosis produce thick, refractile walls and have prominent bubbly cytoplasm. This contrasts with the thin, delicate walls of organisms such as *Aspergillus*, *Fusarium*, and dermatophytes. Zygomycetes are aseptate and usually appear hollow in tissue sections. Their thick, refractile wall usually stains intensely red with H&E, contrasting with the pale wall of a phaeomycotic organism. Some organisms, such as *Bipolaris*, produce round, dilated structures that resemble spores in tissue. The mix of round structures and hyphae is a helpful clue to the presence of a black mold in tissue.

Treatment

Phaeomycotic cysts are best treated with excision. Superficial phaeohyphomycosis may respond to topical antifungal agents and superficial debridement. For invasive and disseminated disease, surgical excision should generally be combined with antifungal therapy. Itraconazole has the best record of treating this group of infections, and doses of 400 mg/day are usually needed for at least 6 months. Case reports indicate success with voriconazole and posaconazole so they are alternatives. In widely disseminated disease, excision of lesions becomes impractical, but debulking of skin disease may be of some value.

ALTERNARIOSIS

Alternaria is a genus of molds recognized as common plant pathogens but also as a cause of human infection. As a pigmented fungus, it is one cause of phaeohyphomycosis. Most reported cases of invasive infection have occurred in immunocompromised patients, with the most frequent risk factors being solid-organ transplantation and Cushing syndrome. Cutaneous alternariosis usually presents as focal ulcerated papules and plaques or pigmented patches on exposed skin of the face, forearms and hands, or knees of immunocompetent patients. Topical corticosteroids may predispose to local infection. Localized disease in immunocompetent patients may respond to local debridement, hyperthermia, wide surgical excision, or Mohs micrographic surgery. Itraconazole has been successful, although resistance has also been reported. Terbinafine, posaconazole, voriconazole, ketoconazole, caspofungin, and intralesional miconazole have also been used successfully in individual cases.

MYCETOMA

Mycetoma, also known as Madura foot and maduromycosis, is a chronic, granulomatous, subcutaneous, inflammatory disease caused by filamentous bacteria (actinomycetoma) or true fungi (eumycetoma). The organisms enter the skin by traumatic inoculation. Both forms of mycetoma present as a triad of progressive subcutaneous swelling with sinus tracts that discharge grains (Fig. 15.29).

The disease progresses slowly. Mycetomas generally begin on the instep or the toe webs. The lesion usually is relatively painless, nontender, and firm. The overlying skin may be normal or attached to the underlying nodularity. Mature lesions often have draining sinuses. Not only the skin and subcutaneous tissues, but also the underlying fascia and bone are involved. Other parts of the body, such as the hands, arms, chest, jaw, and buttocks, may be involved. Exposed sites are most common, and lesions in covered areas are almost always actinomycetomas.

Etiology and Pathology

Mycetoma is divided into actinomycetoma, produced by bacteria, and eumycetoma, produced by fungi. Actinomycetomas are caused by *Nocardia asteroides*, *N. brasiliensis*, *N. caviae*, *N. otitidiscaviarum*, *Actinomadura madurae*, *Actinomadura pelletieri*, *Actinomyces israelii* (the major cause of lumpy jaw), and *Streptomyces somaliensis*. Eumycetomas are caused by fungi, including pigmented fungi such as *Madurella* spp., and hyaline fungi such as *Pseudallescheria*. Causative dematiaceous organisms include *Madurella grisea*, *M. mycetomatis*, *Leptosphaeria senegalensis*, *L. tompkinsii*, *Exophiala jeanselmei*, *Pyrenochaeta romeri*, *Phialophora verrucosa*, *Curvularia lunata*, and *C. geniculate*. The hyaline or white fungi that cause mycetoma include *Pseudallescheria boydii* (which may occasionally disseminate as the asexual form, *Scedosporium apiospermum*), *Acremonium falciforme*, *A. recifei*, *Fusarium moniliform*, *F. solanii*, *Aspergillus nidulans*, and *Neotestudina rosatii*.

Fig. 15.29 Mycetoma. (Courtesy Debabrata Bandyopadhyay, MD.)

Almost all actinomycetomas produce light-colored grains, as do hyaline fungi. Red grains are usually produced by *A. pelletieri*. Pigmented fungi produce dark grains.

Histologic sections demonstrate stellate abscesses containing grains. Gram stain of an actinomycotic grain shows gram-positive, thin filaments, 1–2 μm thick, embedded in a gram-negative amorphous matrix. Club formation in the periphery of a grain may be seen. In eumycotic grains special stains such as PAS and GMS, will clearly show hyphae of 2–5 μm thickness and other fungal structures. When obtaining a specimen for culture it should be taken from deep tissue, at the base of the biopsy.

Epidemiology

The mycetoma belt stretches between the latitudes of 15° south and 30° north. Relatively arid areas have higher rates of infection than humid areas. In the Western Hemisphere, the incidence is highest in Mexico, followed by Venezuela and Argentina. In Africa, it is found most frequently in Senegal, Sudan, and Somalia. Mycetomas are also reported in large numbers in India. Actinomycetomas outnumber eumycetomas by 3:1, which is fortunate because actinomycetomas are much more responsive to therapy. The male/female ratio varies from 2:1 to 5:1.

Diagnosis

Mycetoma may be diagnosed when the triad of signs, tumefaction, sinuses, and granules, are present. Pus gathered from a deep sinus will show the granules when examined microscopically. The slide containing the specimen should have 1 drop of 10% NaOH added and a coverslip placed on top. A biopsy may be required. Radiographs will show the bone involvement, and magnetic resonance images may show the "dot in a circle" sign, corresponding to grains.

Treatment

Actinomycetomas generally respond to antibiotic therapy, although patients with advanced disease may also need surgery. In *A. israelii* infection, penicillin in large doses is curative. *N. asteroides* or *N. brasiliensis* is usually treated with sulfonamides. Severe refractory disease may respond to imipenem.

Patients in the early stage of eumycetoma may be successfully treated by surgical removal of the area. In the more advanced stages, a combination of antifungal therapy and surgery may be successful. In some patients with eumycetoma, amputation will be necessary. Posaconazole alone or combined with surgical excision is the treatment of choice for cases caused by *P. boydii*.

KELOIDAL BLASTOMYCOSIS (LOBOMYCOSIS OR LACAZIOSIS)

Keloidal blastomycosis was originally described by Jorge Lobo in 1931. Most cases have occurred in countries in Central and South America. One case occurred in an aquarium attendant in Europe who cared for an infected dolphin; and another in an American who had walked under the pounding water of Angel Falls on a trip to South America.

Keloidal blastomycosis may involve any part of the body, and the lesions appear characteristically keloidal (Fig. 15.30). Fistulas may occur. The nodules gradually increase in size by invasion of the surrounding normal skin or through the superficial lymphatics. Long-standing cases may involve the regional lymph nodes. A common location is the ear, which may resemble the cauliflower ear of a boxer. Disseminated disease has also been described.

The fungus is probably acquired from water, soil, or vegetation in forested areas where the disease is prevalent. Agricultural laborers have been most frequently affected, with 90% of cases occurring in men.

The causative organism, *Lacazia loboi*, is an obligate parasite. Culture has not been successful, but the organism can grow in mouse footpads. Histologically, the epidermis is atrophic. The organisms are thick-walled, refractile spherules, larger than those of *P. brasiliensis*. One or two buds may be seen, but never multiple budding as in *P. brasiliensis*. The organisms are typically numerous and appear in chains of spheres connected by short, narrow tubes. The cellular infiltrate is composed of histiocytes, giant cells, and lymphocytes.

Surgical excision of the affected areas may be curative when the lesions are small, but recurrence is common. Complete resolution of keloidal blastomycosis has been reported in a patient treated for 1 year with a combination of itraconazole, 100 mg/day, and clofazimine, 100 mg/day. Posaconazole 400 mg twice daily for 27 days was effective in another report. Cryotherapy may be a useful adjuvant.

RHINOSPORIDIOSIS

Rhinosporidiosis is a polypoid disease usually involving mucosal surfaces, especially the nasal mucosa (Fig. 15.31). Conjunctival, lacrimal, oral, and urethral tissues may also be involved, and genital lesions may resemble condylomata. The lesions begin as small papillomas and develop into pedunculated tumors with fissured and warty surfaces. Grayish white flecks may be noted on the tissue, corresponding to transepithelial elimination of large sporangia. Bleeding occurs easily. Widespread cutaneous lesions are rare. Conjunctival lesions begin as small, pinkish papillary nodules, which later become larger, dark, and lobulated. Rectal and vaginal lesions have been reported. As with penile lesions, they may resemble condylomata or polyps. Dissemination rarely occurs, and bone involvement has been described. The disease is endemic in Sri Lanka and India but also occurs in parts of East Asia, Latin America, the southern United States, the United Kingdom, and Italy.

Rhinosporidium seeberi, a lower aquatic fungus found in stagnant water, is the causative organism. The organisms appear as spherules 7–10 µm in diameter, which are contained within large, cystic sporangia that may be as large as 300 µm in diameter. When the organism does not form endospores, it resembles *Coccidioides immitis* spherules, but differs by the regular presence of a central nucleus

Fig. 15.31 Rhinosporidiosis.

within each organism. The organisms are usually present within a polypoid structure. A granulomatous response is seen in about 50% of patients, and gigantic foreign body giant cells can rarely be noted filled with organisms.

Suppurative inflammation may be observed at the site of rupture of sporangia. Transepithelial elimination of sporangia is common. Destruction of the involved area by excision or electrosurgery is the most common method of treatment. Antifungal agents have been of little value. Dapsone is the only medication to have shown much benefit.

ZYGOMYCOSIS (PHYCOMYCOSIS)

There are a number of important pathogens in the class Zygomycetes. The two orders within this class that cause cutaneous infection most often are the Entomophthorales and Mucorales.

Entomophthoromycosis

Infections caused by the order Entomophthorales have been named entomophthoromycosis, rhinoentomophthoromycosis, conidiobolomycosis, or basidiobolomycosis. Infection occurs usually in healthy individuals, and unlike mucormycosis, often runs an indolent course. The infections may be classified as cutaneous, subcutaneous, visceral, or disseminated. Subcutaneous lesions occur in two basic types, each involving different anatomic sites, either as well-circumscribed subcutaneous masses involving the nose, paranasal tissue, and upper lip, or as nodular, subcutaneous lesions located on the extremities, buttocks, and trunk.

Etiology

Conidiobolus coronatus typically causes the perinasal disease, whereas *Basidiobolus ranarum* causes the type of subcutaneous disease seen on the face.

Epidemiology

Occurrence is worldwide. Entomophthoromycosis was first reported in Indonesia, where it is prevalent. Since then, reports have come from Africa, Asia, and the Americas. Generally, infection occurs in a belt between 15° north and 15° south of the equator.

Diagnosis

Isolation and identification of the causative fungus are fundamental to the diagnosis. Culture on Sabouraud dextrose agar is made of nasal discharge, abscess fluid, or biopsy specimens. Biopsy specimens will show fibroblastic proliferation and an inflammatory reaction with lymphocytes, plasma cells, histiocytes, eosinophils, and giant cells. The organisms appear as broad hyphae that are generally aseptate and may be branched at right angles. The Splendore-Hoeppli phenomenon is common and appears as eosinophilic sleeves around the hyphae. Pythiosis, caused by *Pythium insidiosum*, a primitive aquatic hyphal organism that acts as a zoonotic pathogen, may affect humans and has a similar appearance.

Treatment

Potassium iodide has been the drug of choice for entomophthoromycosis, although amphotericin B, cotrimoxazole, ketoconazole, itraconazole, and fluconazole have also been used successfully. Excision of small lesions is an alternative method of management, but the recurrence rate is significant. Rare human cases of pythiosis have responded to amphotericin B.

Mucormycosis

Mucormycosis refers to infections caused by the order Mucorales of the class Zygomycetes. When invasive, infections characteristically are acute, rapidly developing, and often fatal. In some series the mortality rate is about 80%. Most infections occur in ketoacidotic patients with diabetes, but leukemia, lymphoma, AIDS, iatrogenic immunosuppression in transplant patients, chronic renal failure, and malnourishment all predispose to these infections. Infection has also been associated with methotrexate, prednisone, and infliximab therapy. Healthy individuals may also develop these infections. In them, primary cutaneous disease occurs often after trauma, burns, or as a result of contaminated surgical dressings.

The five major clinical forms of mucormycosis (rhinocerebral, pulmonary, cutaneous, GI, disseminated) all demonstrate vasculotropism of the organisms. This leads to infarction, gangrene, and the formation of black, necrotic, purulent debris. Ulceration, cellulitis, ecthyma gangrenosum–like lesions, and necrotic abscesses may occur. The infection may involve the skin through traumatic implantation or by hematogenous dissemination.

Etiology

The fungi that cause this infection are ubiquitous molds common in the soil, on decomposing plant and animal matter, and in the air. The pathogenic genera include *Rhizopus*, *Absidia*, *Mucor*, *Cunninghamella*, *Apophysomyces*, *Rhizomucor*, *Saksenaea*, *Mortierella*, and *Cokeromyces*.

Diagnosis

Tissue obtained by biopsy or curettage is examined microscopically and cultured. Prompt diagnosis of mucormycosis is essential in this rapidly fatal infection. Histologically, the organism generally appears as eosinophilic, thick-walled hyphae that look hollow in cross section. The organism is quite irregular in outline, and right-angle branching is common. The organisms are highly vasculotropic and dissect along the media of muscular vessels, resulting in infarction of tissue. Fungal stains, such as GMS, have been used, but zygomycetes show variable staining with fungal stains. Often H&E is the optimal stain, and the organisms may stain avidly with a tissue Gram stain.

Treatment

A combination of excision of affected tissue and antifungal therapy, usually with liposomal amphotericin B, is necessary in most patients with mucormycosis. Alternatives include posaconazole, 400 mg twice daily with meals, or isavuconazole. Primary cutaneous disease in an immunocompetent patient may be treated with excision or Mohs surgery alone.

HYALOHYPHOMYCOSIS

The term *hyalohyphomycosis* contrasts with *phaeohyphomycosis* and refers to opportunistic mycotic infections caused by nondematiaceous molds. Most of these organisms are septate, and compared with black molds, most have delicate walls. Organisms include *Penicillium*, *Acremonium*, *Trichoderma*, *Scedosporium*, *Fusarium*, *Aspergillosis*, *Scedosporium apiospermum*, and *Paecilomyces*. The two most important of this group, *Fusariosis* and *Aspergillosis*, will be discussed separately.

These organisms are ubiquitous; they occur as saprophytes in soil or water or on decomposing organic debris. They generally do not cause disease except in immunocompromised patients. *Fusarium solani* (keratomycosis) and *Fusarium oxysporum* (white superficial onychomycosis) are exceptions. Localized hyalohyphomycosis has also occurred in immunocompetent patients after traumatic implantation. There is no classic clinical morphology to the lesions, but keratotic masses, ulcerations, ecthyma gangrenosum–like lesions, erythematous nodules, dark eschars, and disseminated erythema have been described (Fig. 15.32).

Penicillium marneffei infection is an indicator of HIV disease, especially in Southeast Asia. This organism is dimorphic and appears in tissue as small, intracellular organisms within histiocytes. The histologic similarity to histoplasmosis is striking.

Most of these infections are treated with a combination of excision and amphotericin B. *Scedosporium* and *Paecilomyces* respond in some cases to voriconazole or posaconazole. In *Penicillium* infections in HIV patients, itraconazole is used indefinitely after initial therapy with amphotericin B.

Fig. 15.32 Hyalohyphomycosis caused by *Paecilomyces*. (Courtesy Dan Loo, MD.)

PNEUMOCYSTOSIS

Pneumocystis jiroveci (formerly *P. carinii*) is an opportunistic infection, occurring primarily as a pulmonary infection in AIDS patients. Extrapulmonary involvement is uncommon and usually occurs in the reticuloendothelial system. Skin findings may occur. At least half of reported cases are of nodular growths in the auditory canal, with the remainder having nonspecific, pink to skin-colored papules and nodules that may ulcerate. On biopsy, the dermis contains foamy material within which Giemsa-positive organisms are identified. Mixed cutaneous infection with *Cryptococcus* has been reported; the skin lesions appeared xanthomatous. Cutaneous botryomycosis caused by combined *Staphylococcus aureus* and *P. jiroveci* has been reported in patients with HIV infection. A 3-week course of trimethoprim-sulfamethoxazole is the treatment of choice. In combined infections, all pathogens require treatment. Dapsone prophylaxis has been associated with acute generalized exanthematous pustulosis.

Peña ZG, et al: Mixed *Pneumocystis* and *Cryptococcus* cutaneous infection histologically mimicking xanthoma. Am J Dermatopathol 2013; 35: e6.
Vas A, et al: Acute generalised exanthematous pustulosis induced by *Pneumocystis jirovecii* pneumonia prophylaxis with dapsone. Int J STD AIDS 2013; 24: 745.

FUSARIOSIS

Fusarium has emerged as an important pathogen, especially in patients with hematologic malignancy, neutropenia, and T-cell immunodeficiency, particularly those with hematopoietic stem cell transplants and graft-versus-host disease (GVHD). Skin involvement is present in about 70% of patients, and the infection may begin in the skin and then disseminate. Many cases begin in the lungs or sinuses, then disseminate to the skin. Blood cultures usually are positive, but skin biopsies provide the highest diagnostic yield. Contaminated hospital plumbing may be a source of fusariosis. *Fusarium* has been cultured from drains, water tanks, sink faucet aerators, and shower heads. Aerosolization of *Fusarium* spp. by shower heads has been documented.

The mortality rate is high but has improved with the availability of new antifungal agents. Neutropenia, a factor predicting mortality, must be controlled with colony-stimulating factors. Liposomal amphotericin B is the drug of choice; voriconazole and posaconazole

are second-line drugs. Posaconazole can raise calcineurin inhibitor levels in the blood, and these must be closely monitored during therapy.

ASPERGILLOSIS

Aspergillosis is second only to candidiasis in frequency of opportunistic fungal disease in patients with leukemia and other hematologic neoplasia. Neutropenia remains the key risk factor for invasive aspergillosis in this population. Risk factors include prolonged corticosteroid therapy, other immunosuppressive therapy, GVHD, and cytomegalovirus infection. Solid-organ transplant patients are predisposed to *Aspergillus* infections. Pulmonary involvement is usually present in invasive disease; skin lesions are present in only about 10% of patients. Biopsy of a skin lesion may establish the diagnosis when other studies have failed. Blood culture is an insensitive method of diagnosis.

Aspergillus fumigatus is the most common cause of disseminated aspergillosis with cutaneous involvement. The organism grows on media without cycloheximide in 24 hours or longer. In tissue, the organisms appear as slender hyphae with delicate walls and bubbly cytoplasm. The appearance is identical to that of *Fusarium*, except for the lack of vesicular swellings along hyphae. The hyphae in both are septate with 45-degree branching. Both tend to be vasculotropic and are associated with cutaneous necrosis. *Aspergillus flavus* rarely causes fungus balls in the lungs but is a common cause of fungal sinusitis and skin lesions. *Aspergillus niger* is a rare cause of disseminated infection with skin lesions. In third-degree burns, *Aspergillus* often colonizes the eschar. Deep incisional biopsies are required to distinguish invasive disease from colonization.

Primary Cutaneous Aspergillosis

Primary cutaneous aspergillosis is a rare disease. Most cases occur at the site of IV cannulas in immunosuppressed patients. Hemorrhagic bullae and necrotic ulcers may be present (Fig. 15.33). *A. flavus* is most frequently associated with this form of infection. Patients must be treated aggressively because the fungus may disseminate from the skin lesion.

Aspergillus is a frequent contaminant in cultures from thickened, friable, dystrophic nails, and various *Aspergillus* spp. have been implicated as true etiologic agents of onychomycosis. Nail infection may respond to itraconazole.

Otomycosis

The ear canal may be infected by *Aspergillus fumigatus*, *A. flavus*, and *A. niger*. Pathogenic bacteria, especially *Pseudomonas aeruginosa*, are often found concurrently. The colonization may be benign, but malignant otitis may occasionally occur, especially in diabetic or iatrogenically immunosuppressed patients. Invasive disease must be treated with systemic agents. Topical clotrimazole ear drops are effective in immunocompetent patients.

Treatment

Voriconazole is the treatment of choice for invasive aspergillosis, although visual disturbances, photosensitivity, skin cancer, and skin eruptions can be a problem with this drug. Liposomal amphotericin B, caspofungin, micafungin, posaconazole, and isavuconazole are alternate therapies.

DISEASE CAUSED BY ALGAE (PROTOTHECOSIS)

Protothecosis is caused by the *Prototheca* genus of saprophytic, achloric (nonpigmented) algae. These organisms reproduce asexually by internal septation or morulation. This reproductive method, along with the absence of glucosamine and muramic acid in the cell wall, separates the genus from the bacteria and fungi. Two *Prototheca* species cause disease in humans, *Prototheca wickerhamii* and *Prototheca zopfii*. Stagnant water, tree slime, and soil appear to be the source of infection in most cases.

Skin lesions may present as verrucous lesions, ulcers, papulonodular lesions, or crusted papules with umbilication. Protothecosis of the olecranon bursa is usually seen in healthy individuals, but cutaneous infections have been most often reported in patients receiving immunosuppressive therapy and in those with renal failure, liver disease, AIDS, hematologic malignancy, or diabetes mellitus. Neutropenia is not a common risk factor.

Prototheca spp. are easily recognized in PAS-stained tissue specimens when the characteristic morulating cells are visible.

These are more common in *P. wickerhamii*. The organism also appears with a single, black nucleus and a thick, slightly asymmetric, refractile wall. It grows on most routine mycologic media, but cycloheximide will suppress growth of *Prototheca* spp. The use of fluorescent antibody reagents permits the rapid and reliable identification of *Prototheca* spp. in culture and tissue.

IV amphotericin B remains the most effective agent for disseminated *Prototheca* infections. Voriconazole, posaconazole, itraconazole, and fluconazole have been successful in individual cases. Surgery and topical amphotericin B have been used for isolated cutaneous disease.

16 Mycobacterial Diseases

Bonus images for this chapter can be found online at expertconsult.inkling.com

TUBERCULOSIS

No ideal classification scheme exists for cutaneous tuberculosis (TB), but the system listed here is logical and takes into account the mechanism of disease acquisition. Unfortunately, unlike in Hansen disease, these categories do not correlate perfectly to host immunity. The four major categories of cutaneous TB are as follows:

1. Inoculation from an exogenous source (primary inoculation TB, TB verrucosa cutis)
2. Endogenous cutaneous spread contiguously or by autoinoculation (scrofuloderma, TB cutis orificialis)
3. Hematogenous spread to the skin (lupus vulgaris; acute miliary TB; TB ulcer, gumma, or abscess; tuberculous cellulitis) (Lupus vulgaris can also occur adjacent to lesions of scrofuloderma, suggesting that both hematogenous spread and local spread are capable of triggering this reaction pattern.)
4. Tuberculids (erythema induratum [Bazin disease], papulonecrotic tuberculid, lichen scrofulosorum)

The finding of mycobacterial deoxyribonucleic acid (DNA) by polymerase chain reaction (PCR) in tuberculids suggests that tuberculids also represent hematogenous dissemination of TB, which is quickly controlled by the host, usually resulting in the absence of detectable organisms by culture and histologic methods. Miliary TB is the form with least effective host immunity. Tuberculous ulcer/abscess/cellulitis and TB cutis orificialis are conditions of poor host immunity against *Mycobacterium tuberculosis*. Bacilli are prominent in these forms of cutaneous TB, and histologic and microbiologic confirmation is usually straightforward. This is fortunate, because cellular-based diagnostic modalities (purified protein derivative [PPD], interferon-γ release assay [IGRA]) may be negative. TB verrucosa cutis and lupus vulgaris are conditions of high host immunity to TB, and tuberculin skin tests and IGRA for TB will usually be positive. Scrofuloderma is usually associated with a positive PPD, and identification by culture and histologic methods is positive in only 20% and 40% of cases, respectively. In its initial stage, primary inoculation TB will be multibacillary and culture positive. As host immunity develops, the skin test becomes positive, and the number of organisms on biopsy diminishes. The tuberculids also represent high host immune response manifestations of TB, and bacilli are rarely found.

Epidemiology

The increase in the numbers of cases of TB that started in the mid-1980s in the United States was associated with three phenomena: large numbers of immigrants from high-prevalence countries, the human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) epidemic, and an increasing number of persons in congregative facilities (shelters for homeless persons, prisons). Asians, African Americans, and Hispanics have the greatest risk for developing TB in the United States. Aggressive diagnosis and treatment programs have led to a reduction in new U.S. cases of TB. The infection rate in the U.S.-born population of adults is now 3 cases per 100,000 population. However, local pockets of TB are still found in U.S. regions of otherwise very low incidence. This is partly attributable to the persistently high infection rate in the foreign-born U.S. population, which has also fallen dramatically over the years, but is still at 15 cases per 100,000.

In the developing world, TB is the number one cause of death resulting from a single infectious agent. The increasing number of infections has been driven largely by the HIV/AIDS epidemic. One third or more of HIV-infected persons in Africa are also infected with *M. tuberculosis*. Latent TB is 100 times more likely to reactivate in persons with HIV infection, and HIV-infected persons are much more likely to acquire new tuberculous infection. Countries such as India still account for a quarter of the total global TB burden, although great progress has been made. Hematopoietic stem cell transplantation and solid organ transplant recipients are particularly prone to TB, at a rate of 10 to 70 times the general population.

TB has increasingly become resistant to first-line treatments. Strains classified as *multidrug-resistant tuberculosis* (MDR-TB) are resistant to at least isoniazid and rifampin. *Extensively drug-resistant tuberculosis* (XDR-TB) is, in addition, resistant to any fluoroquinolone and at least one of the following: capreomycin, kanamycin, or amikacin. The emergence of these resistant strains of TB has made treatment more costly and more difficult. However, aggressive treatment protocols using multiple drugs for up to 2 years and, when indicated, surgical techniques can cure up to 60% of even XDR-TB patients.

Cutaneous TB is an uncommon complication of tuberculous infection, with less than 2% of TB patients having skin lesions, even in highly endemic areas. The types of cutaneous lesion that the patient will develop depend on the following host factors:

1. *Age:* About 25% of scrofuloderma cases and most cases of lichen scrofulosorum occur in children.
2. *Gender:* Women are 10 times more likely to develop erythema induratum, but men are two to three times more likely to have other forms of cutaneous TB.
3. *Anatomic location:* Lupus vulgaris occurs on the face and extremities, whereas TB verrucosa cutis occurs predominantly on the hands.
4. *Nutritional status:* Tuberculous abscesses and scrofuloderma are associated with malnutrition.

The pattern of cutaneous TB has been changing over the last few decades and is different in developed than in developing nations. The average age of patients with cutaneous TB has increased in developed countries, and tuberculids, especially erythema induratum, represent a larger proportion of cases. In Hong Kong 85% of cases of cutaneous TB are tuberculids. This suggests that most cutaneous TB in adults will be found in patients infected in the distant past who are reactivating their disease, not recently infected persons. Cutaneous TB is uncommon in immunosuppressed hosts; when they acquire new TB or reactivate their TB, it usually reactivates at a noncutaneous site and is diagnosed before skin disease occurs. Miliary TB is the most frequently reported form of cutaneous TB in the HIV-infected patient. In areas of high TB endemicity in the developing world, cutaneous TB is still common. More than 50% of cases will occur before age 19. The likelihood of finding associated systemic TB is higher in children than adults. Nonetheless, unlike in all other forms of extrapulmonary TB, failure to find an underlying focus of TB in patients with cutaneous TB can occur. Between 3% and 12% of patients with cutaneous TB will have an abnormal chest radiograph. Most often, TB of the lymph nodes will be found.

Tuberculin Testing

The tuberculin skin test (TST) is designed to detect a memory cell–mediated immune response to *M. tuberculosis*. The test becomes positive 2–10 weeks after infection and remains positive for many years, although it may wane with age. PPD preparations are currently used for testing in the United States and Canada at a dose of 5 tuberculin units (TU). The intradermal, or Mantoux, test is the standard and offers the highest degree of consistency and reliability. The test is read 48–72 hours after intradermal injection. Induration measuring 5 mm or more is considered positive in HIV-infected patients, in solid organ transplantation patients, in those with risk factors for developing TB (e.g., patients who will receive or are receiving anti–tumor necrosis factor [TNF] therapy), in those on greater than 15 mg/day of prednisone for over 1 month, in patients on current cancer chemotherapy, in recent close contacts, or in those with chest x-ray findings consistent with healed TB. Because children are at increased risk of developing active TB after exposure, a 5-mm or larger reaction in contact investigations is considered positive. If the PPD measures more than 10 mm, it is considered positive in injection (intravenous) drug users (IDUs), HIV-negative IDUs, those born in foreign countries of high TB prevalence, health care workers, residents and employees in high-risk congregate facilities, and those with medical conditions that predispose to TB. If induration is more than 15 mm, it is positive in all others; 0- to 4-mm induration is negative.

The lower the threshold for positivity for the TST, the less this represents true positivity (the higher number of false positives). This is why a TST of less than 15 mm is considered positive only in patients at higher risk for having latent TB. Conversely, as the cutoff for true positivity is raised, the number of infected persons the TST detects will decrease (the number of false negatives increases). A TST of over 6 mm will detect 89% of persons with latent TB, over 10 mm will detect 75%, and over 15 mm will detect only 47% of latently infected patients. At least 7% of patients with latent TB will have a completely negative TST. Many intermediate TST responses may represent cross-reaction with atypical mycobacteria. Bacillus (bacille) Calmette-Guérin (BCG) immunization leads to a positive tuberculin result in immunized children, but this reaction usually does not persist beyond 10 years. Repeated BCG immunization or BCG administration after age 2 years is more likely to result in a persistently positive TST on this basis. However, positive reactions in adults should not automatically be attributed to childhood BCG administration.

Reactivity to the tuberculin protein is impaired in certain conditions in which cellular immunity is impaired. Lymphoproliferative disorders, sarcoidosis, corticosteroid and immunosuppressive drugs (including TNF inhibitors), severe protein deficiency, chronic renal failure, and numerous infectious illnesses, including HIV infection, are capable of diminishing tuberculin reactivity. In overwhelming TB (miliary disease), more than 50% of patients have a negative skin test before beginning therapy. A negative or doubtful reaction to a PPD preparation does not rule out TB infection, particularly in the patient with suggestive symptoms and signs.

TST then has significant limitations, which also include negative tests in a substantial number of patients with active TB (sensitivity only 77%), repeat visits to interpret, technical competence of person applying the test, booster effect of repeat testing creating potential false-positive results, and false-positive tests in persons with prior BCG vaccination. To overcome these obstacles, antigen-specific in vitro assays have been developed. These assays measure the amount of interferon (IFN)–γ released by peripheral blood T cells (IGRAs; e.g., QuantiFERON-TB Gold, ELISpot^{PLUS}, T-SPOT). Results are variable with respect to the sensitivity and specificity of these assays, but they are valuable in certain settings. They are considerably more specific in the BCG-vaccinated population, in whom the TST is only 60% specific, whereas IGRAs are 93% specific. In addition, in HIV-infected patients and those receiving corticosteroids, IGRAs are much more likely to be positive than a TST in those with *M. tuberculosis* infection. In children under age 5 the TST is preferred, as it is in those requiring serial testing. In other settings either TST or IGRAs may be used. If the TST is combined with an IGRA and the tests are concordant, false-negative results are 2% and false-positive tests only 1%. Therefore a combination of TST and IGRA may be used to clarify a TST result. In such cases the two tests should be done simultaneously, as the IGRA results may be boosted in a patient who has had a TST within the prior 3 months.

Appropriate screening before initiating anti-TNF therapy or immunosuppression in a dermatology patient would include the following:

1. Screen for active TB by history and physical examination (and chest x-ray where suspicion for TB is elevated).
2. Administer a TST or an IGRA.
3. Interpret the test results with caution in patients already on significant iatrogenic immunosuppressive or anti-TNF treatments.
4. Regularly monitor patients on anti-TNF agents for the development of TB with appropriate history, physical examination, and laboratory testing; and suspect and screen for TB if clinical symptoms may indicate infection.
5. Rescreen with a TST or IGRA annually.

Bacille Calmette-Guérin Vaccination

BCG is a live attenuated strain of *Mycobacterium bovis* used in most parts of the world (except North America and Western Europe) to immunize infants. It enhances immunity to TB and is effective in reducing childhood TB, especially if given to neonates. Once the patient has been vaccinated, the TST becomes positive and remains so for a period of less than 10 years (unless the person is BCG immunized after age 2 or repeatedly immunized). In an adult who was vaccinated as a child in a foreign country with a high prevalence of TB and whose TST measures more than 10 mm, active TB should be assumed. The use of BCG instillation in the bladder to treat bladder cancer has been associated with disseminated disease, usually pneumonitis, hepatitis, prostatitis, and abdominal aneurysms.

Dermatologic complications of BCG vaccination are rarely seen. Localized abscesses and regional suppurative adenitis occur at a rate of about 0.4 per 1000 vaccines. Excessive ulceration may occur if the BCG is inoculated too deeply. Scrofuloderma is rare. Disseminated infection is seen in 1–4 cases per 1 million infants vaccinated and is associated with high mortality. Disseminated BCG develops only in the setting of immunodeficiency. Lupus vulgaris can occur rarely at the vaccination site or at a distant site and will respond to appropriate antituberculous treatment. Papular and papulonecrotic tuberculids, as well as erythema induratum, can occur after BCG immunization, appearing 10 days to several months after vaccination. Treatment may not be necessary for the BCG-induced tuberculids; they frequently heal in a few months with no treatment.

Inoculation Cutaneous Tuberculosis From Exogenous Source

Primary Inoculation Tuberculosis (Primary Tuberculous Complex, Tuberculous Chancre)

Primary inoculation TB develops at the site of inoculation of tubercle bacilli into a TB-free individual (Fig. 16.1). Regional lymphadenopathy usually occurs, completing the "complex." It

Fig. 16.1 Primary inoculation tuberculosis.

Fig. 16.2 Tuberculosis verrucosa cutis. (Courtesy Debabrata Bandyopadhyay, MD.)

occurs chiefly in children and affects the face or extremities. The inoculation can occur during tattooing, medical injections, nose piercing, or external physical trauma. The earliest lesion, appearing 2–4 weeks after inoculation, is a painless brown-red papule that develops into an indurated nodule or plaque that may ulcerate. This is the tuberculous chancre. Prominent regional lymphadenopathy appears 3–8 weeks after infection and, occasionally, suppurative and draining lesions may appear over involved lymph nodes. Primary tuberculous complex occurs on the mucous membranes in about one third of patients. Spontaneous healing usually occurs within 1 year, with the skin lesion healing first, then the lymph node, which is often persistently enlarged and calcified. Delayed suppuration of the affected lymph node, lupus vulgaris overlying the involved node, and occasionally dissemination may follow this form of cutaneous TB.

Histologically, there is a marked inflammatory response during the first 2 weeks, with many polymorphonuclear leukocyte neutrophils (PMNs) and tubercle bacilli. During the next 2 weeks, the picture changes. Lymphocytes and epithelioid cells appear and replace the PMNs. Distinct tubercles develop within 3 or 4 weeks of inoculation. Simultaneously, with the appearance of epithelioid cells, the number of tubercle bacilli decreases rapidly.

The differential diagnosis of primary inoculation TB extends over the spectrum of chancriform conditions of deep fungal or bacterial origin, such as sporotrichosis, blastomycosis, histoplasmosis, coccidioidomycosis, nocardiosis, syphilis, leishmaniasis, yaws, tularemia, and atypical mycobacterial disease. Pyogenic granuloma and cat-scratch disease must also be considered.

Paucibacillary Cutaneous Tuberculosis From Exogenous or Endogenous Source in Persons With High Immunity

Tuberculosis Verrucosa Cutis. TB verrucosa cutis occurs from exogenous inoculation of bacilli into the skin of a previously sensitized person with strong immunity against *M. tuberculosis.* The tuberculin test is strongly positive. The prosecutor's wart resulting from inoculation during an autopsy is the prototype of TB verrucosa cutis.

Clinically, the lesion begins as a small papule, which becomes hyperkeratotic, resembling a wart. The lesion enlarges by peripheral expansion, with or without central clearing, sometimes reaching several centimeters or more in diameter (Fig. 16.2). Fissuring of the surface may occur, discharging purulent exudate. Lesions are almost always solitary, and regional adenopathy is usually present only if secondary bacterial infection occurs. Frequent locations for TB verrucosa cutis are on the dorsa of the fingers and hands in adults and the ankles and buttocks in children. The lesions are persistent but usually superficial and limited in extent. Local scarring, as seen in lupus vulgaris, can occur. Although sometimes separated by exudative or suppurative areas, the lesions seldom ulcerate and may heal spontaneously.

Histologically, there is pseudoepitheliomatous hyperplasia of the epidermis and hyperkeratosis. Suppurative and granulomatous inflammation is seen in the upper and middle dermis, sometimes perforating through the epidermis. Caseation is rare. The number of acid-fast bacilli (AFB) is usually scant, and failure to find AFB should not be used to exclude the diagnosis. Culture will be positive in slightly more than 50% of cases.

TB verrucosa cutis is differentiated only by culture from atypical mycobacteriosis caused by *Mycobacterium marinum.* It must also be distinguished from North American blastomycosis, chromoblastomycosis, verrucous epidermal nevus, hypertrophic lichen planus, halogenoderma, and verruca vulgaris.

Lupus Vulgaris. Lupus vulgaris may appear at sites of inoculation, in scrofuloderma scars, or most frequently at distant sites from the initial infectious focus, probably by hematogenous dissemination. Approximately half of such cases will have evidence of TB elsewhere, so a complete evaluation is mandatory. Because lupus vulgaris is associated with moderately high immunity to TB, most patients will have a positive tuberculin test.

Lupus vulgaris typically is a single plaque composed of grouped red-brown papules, which, when blanched by diascopic pressure, have a pale, brownish yellow or "apple jelly" color. On dermoscopy a yellowish-orange patch may indicate the presence of dermal granulomas secondary to lupus vulgaris, sarcoidosis, a foreign body reaction, or cutaneous leishmaniasis. The papules, called lupomas, tend to heal slowly in one area and progress in another. They are minute, translucent, and embedded deeply and diffusely in the infiltrated dermis, expanding by the development of new papules at the periphery, which coalesce with the main

Fig. 16.3 Lupus vulgaris. (Courtesy Dr. Tavares-Bello, MD.)

Fig. 16.4 Lupus vulgaris. (Courtesy Debabrata Bandyopadhyay, MD.)

plaque (Figs. 16.3 and 16.4). The plaques are slightly elevated. The disease is destructive, frequently causes ulceration, and on involution leaves deforming scars as it slowly spreads peripherally over the years. Lupus vulgaris lesions of the head and neck can be associated with lymphangitis or lymphadenitis in some cases. If lesions involve the nose or the earlobes, these structures are shrunken and scarred, as if nibbled away. Atrophy is prominent, and ectropion and eclabion may occur. The tip of the nose may be sharply pointed and beaklike, or the whole nose may be destroyed, with only the orifices and the posterior parts of the septum and turbinates visible. The upper lip, a site of predilection, may become diffusely swollen and thickened, with fissures, adherent thin crusts, and ulcers. On the trunk and extremities, lesions may be annular or serpiginous or may form gyrate patterns. On the hands and feet and around the genitals or buttocks, lesions may cause mutilation by destruction, scar formation, warty thickenings, and elephantiasic enlargement.

An unusual form of lupus vulgaris may follow measles or another significant febrile illness. The window of immune deficiency caused by the acute illness results in dissemination of the TB hematogenously from a single focus of lupus vulgaris. Multiple erythematous papules in a generalized distribution appear a month or more after the illness. These lesions evolve to small papules and plaques, clinically and histologically resembling lupus vulgaris. The TST is negative during the immediate period after the febrile illness, then rapidly reverts to strongly positive. This is called "lupus vulgaris postexanthematicus."

Although classically considered a scarring and atrophying process, lesions of the lips and ears may be quite hyperplastic. The lips may resemble cheilitis granulomatosis clinically and histologically. Uniform hyperplasia of the ear pinna and lobe may closely mimic "turkey ear," as described in sarcoidosis. When the mucous membranes are involved, the lesions become papillomatous or ulcerative. They may appear as circumscribed, grayish, macerated, or granulating plaques. On the tongue, irregular, deep, painful fissures occur, sometimes associated with microglossia to the degree that nutrition is compromised.

The rate of progression of lupus vulgaris is slow, and a lesion may remain limited to a small area for several decades. The onset may be in childhood and persist throughout life. It may slowly spread, and new lesions may develop in other regions. In some patients, the lesions become papillomatous, vegetative, or thickly crusted, with a rupioid appearance. Squamous cell carcinoma may develop in long-standing lesions.

Histologically, classic tubercles are the hallmark of lupus vulgaris. Caseation within the tubercles is seen in about half the cases and is rarely marked. Sarcoidosis may be simulated. The epidermis is affected secondarily, sometimes flattened and at other times hypertrophic. AFB are found in 10% or less of cases with standard acid-fast stains. PCR may only be positive in the minority of cases of paucibacillary forms of cutaneous TB. Cultures of the skin lesions grow *M. tuberculosis* in about half the cases.

Colloid milia, acne vulgaris, sarcoidosis, and rosacea may simulate lupus vulgaris. Differentiation from tertiary syphilis, chronic discoid lupus erythematosus, Hansen disease, systemic mycoses, and leishmaniasis may be more difficult, and biopsy and tissue cultures may be required.

Cutaneous Tuberculosis From Endogenous Source by Direct Extension (Scrofuloderma and Periorificial Tuberculosis)

Scrofuloderma is tuberculous involvement of the skin by direct extension from an underlying focus of infection. It occurs most frequently over the cervical lymph nodes but also may occur over bone or around joints if these are involved. Clinically, the lesions begin as subcutaneous masses, which enlarge to form nodules. Suppuration occurs centrally. They may be erythematous or skin colored, and usually the skin temperature is not increased over the mass. Lesions may drain, forming sinuses, or they may ulcerate with reddish granulation at the base (Figs. 16.5 and 16.6). Surgical procedures may incite lesions of scrofuloderma over joints or the abdominal cavity, apparently by releasing the loculated focus and contaminating the track along which instruments are inserted. Scrofuloderma heals with characteristic cordlike scars, frequently allowing the diagnosis to be made many years later.

Perianal TB is characterized by a chronic anal fistula characteristically in men age 30–60. The intestinal tract, especially the rectum, is involved in most of these cases. Anal strictures and involvement of the scrotum may occur if disease is untreated.

Histologically, in scrofuloderma, the tuberculous process begins in the underlying lymph node or bone and extends through the deep dermis. Necrosis occurs with formation of a cavity filled with liquefied debris and PMNs. At the periphery, more typical

Fig. 16.5 Scrofuloderma. (Courtesy Debabrata Bandyopadhyay, MD.)

Fig. 16.6 Scrofuloderma. (Courtesy Scott Norton, MD.)

granulomatous inflammation is seen, along with AFB observed in slightly less than half of cases.

Scrofuloderma should be differentiated from atypical mycobacterial infection, sporotrichosis, actinomycosis, coccidioidomycosis, and hidradenitis suppurativa. Lymphogranuloma venereum (LGV) favors the inguinal and perineal areas, with positive serologic tests for LGV.

TB cutis orificialis is a form of cutaneous TB that occurs at the mucocutaneous borders of the nose, mouth, anus, urinary meatus, and vagina and on the mucous membrane of the mouth or tongue. It is caused by autoinoculation from underlying active visceral TB, particularly of the larynx, lungs, intestines, and genitourinary tract. It indicates failing resistance to the disease. Consequently, tuberculin positivity is variable but usually positive. Lesions ulcerate from the beginning and extend rapidly, with no tendency to spontaneous healing. The ulcers are usually soft and punched out and have undermined edges. Histologically, the ulcer base is usually composed largely of granulation tissue infiltrated with PMNs. Deep and lateral to the ulcer, granulomatous inflammation may be found, and AFB are numerous.

Fig. 16.7 Metastatic tuberculosis. (Courtesy Debabrata Bandyopadhyay, MD.)

Cutaneous Tuberculosis From Hematogenous Spread

Miliary (Disseminated) Tuberculosis

Miliary TB appears in the setting of fulminant TB of the lung or meninges. Generally, patients have other unmistakable signs of severe disseminated TB. It is most common in children but may occur in adults. Most reported cases of cutaneous TB seen in patients with AIDS are of this type. Miliary TB may also follow infectious illnesses that reduce immunity, especially measles. Because this represents uncontrolled hematogenous infection, the TST is negative. Lesions are generalized and may appear as erythematous macules or papules, pustules, subcutaneous nodules, and purpuric "vasculitic" lesions. Ulceration may occur, and the pain in the infarcted lesions may be substantial. The prognosis is guarded.

Skin biopsies show diffuse suppurative inflammation of the dermis or subcutis with predominantly PMNs, at times forming abscesses. Caseating granulomas may be seen. AFB are abundant.

Metastatic Tuberculous Abscess, Ulceration, or Cellulitis

The hematogenous dissemination of mycobacteria from a primary focus may result in firm, nontender, erythematous plaques (resembling cellulitis) or nodules (Fig. 16.7). The nodules can evolve to form abscesses, ulcers, or draining sinus tracts. This form of cutaneous TB is usually seen in children, and most patients have decreased immunity from malnutrition, infection, or an immunodeficiency state. Patients presenting with tuberculous skin ulcers may or may not have other foci of TB identified. Aerosolization of mycobacteria may occur during incision and drainage and during dressing changes, leading to secondary cases among surgical and nursing staff treating these ulcers. Histologically, abscess formation and numerous AFB are seen.

Sporotrichoid Tuberculosis

Although TB is usually thought to be spread either by direct extension or hematogenously, in about 3% of patients with cutaneous TB, the lesions occur in a sporotrichoid pattern, suggesting lymphatic spread (Fig. 16.8). Classically, this begins with a distal lesion, and new lesions appearing more proximally. Less often, a proximal lesion is present initially, and new lesions appear distally (retrograde lymphatic spread). The draining proximal lymph nodes may be enlarged. The individual lesions have the same morphology

Fig. 16.8 Sporotrichoid tuberculosis. (Courtesy Dr. Juliana Kauge.)

in any given patient, but different patients can have different morphologies. A string of lupus vulgaris–like lesions is most common. Less often, a string of deep nodules may become fluctuant, drain to the surface, or ulcerate, forming linear scrofuloderma-like lesions. The draining lymph node may be enlarged (more often than in sporotrichoid atypical mycobacterial infection). The TST is positive. Underlying foci of systemic TB are often not found. Biopsy of the lesions (and affected lymph nodes) typically shows granulomatous inflammation, but AFB stains are usually negative. Culture may be positive.

This form of TB presents significant diagnostic problems, because sporotrichoid lesions would more often result from atypical mycobacteria or sporotrichosis. Because atypical mycobacteria, especially *M. marinum*, may result in a positive TST, confirming the diagnosis is difficult, even if AFB are found on biopsy. Culture and PCR used to speciate the infecting organism from the biopsy is definitive.

Tuberculous Mastitis

Rarely, TB will present as subcutaneous nodules on the breast. The lesions can suppurate, forming abscesses, or break down, forming sinus tracts. The condition favors women of childbearing age but can also affect men. Tuberculous mastitis may closely resemble breast cancer, so biopsies are frequently done. Abscesses may be incised and drained. The consequence of the ongoing inflammation, destroying the fat of the breast, and the surgical procedures can be a severely disfigured breast. An underlying focus of TB may be present in the underlying bone or at a distant site in some cases. TST is positive. Histology shows granulomatous inflammation with negative AFB stains. Culture is usually negative. The diagnosis of tuberculous mastitis should be considered in all patients with granulomatous mastitis from endemic areas of TB.

Tuberculids

Tuberculids are a group of skin eruptions associated with an underlying or silent focus of TB. They are diagnosed by their characteristic clinical features, histologic findings, a positive TST or IGRA, sometimes by the finding of TB at a distant site, and resolution of the eruption with antituberculous therapy. Tuberculids represent cutaneous lesions induced by hematogenous dissemination of tubercle bacilli to the skin. Lupus vulgaris may develop at the sites of tuberculids, and *M. tuberculosis* DNA may be found in tuberculid lesions by PCR. Tuberculids usually occur in persons with a strong immunity to TB (and thus a positive PPD). This results in rapid destruction of the bacilli and autoinvolution of individual lesions in many cases. New lesions continue to appear, however, because hematogenous dissemination from the underlying focus continues. Tuberculids tend to be bilaterally symmetric eruptions because they result from hematogenous dissemination.

Papulonecrotic Tuberculid

Papulonecrotic tuberculid is usually an asymptomatic, chronic disorder, presenting in successive crops. Lesions are symmetrically distributed on the extensor extremities, especially on the tips of the elbows and on the knees; dorsal surfaces of the hands and feet; buttocks; face and ears; and glans penis. Lesions may favor pernio-prone sites and may be worse during winter months. Two thirds of cases occur before age 30, and females are affected 3 : 1 over males. Evidence of prior or active TB is found in one third to two thirds of patients, especially in the lymph nodes. The TST is positive and may generate a necrotic reaction.

Typical lesions vary in size from 2–8 mm and are firm, inflammatory papules that become pustular or necrotic (Fig. 16.9). Lesions resolve slowly over several weeks, but occasional ulcers persist longer. Varioliform scarring follows the lesions. Crops recur over months to years.

Papulonecrotic tuberculids may appear in association with other cutaneous manifestations of TB, particularly erythema induratum or scrofuloderma. Associated clinical phenomena have included tuberculous arteritis with gangrene in young adult Africans and development of lupus vulgaris from the lesions. HIV-infected persons may develop papulonecrotic tuberculid.

Histologically, the epidermis is ulcerated in well-developed lesions. A palisaded collection of histiocytes surrounds an ovoid or wedge-shaped area of dermal necrosis. Well-formed tubercles are not seen, except in nonhealing lesions evolving into lupus vulgaris. Vascular changes are prominent, ranging from a mild lymphocytic vasculitis to fibrinoid necrosis and thrombotic occlusion of vessels. This is not a neutrophilic leukocytoclastic vasculitis, but rather a chronic granulomatous, small-vessel vasculitis. Capillaries, venules, and arterioles may be involved. AFB stains are negative, but PCR may detect mycobacterial DNA in up to half of patients with papulonecrotic tuberculid.

Fig. 16.9 Papulonecrtotic tuberculid. (Courtesy James Steger, MD.)

Fig. 16.10 Erythema induratum.

Papulopustular secondary syphilis, pityriasis lichenoides et varioliformis acuta, Churg-Strauss granuloma, lymphomatoid papulosis, perforating granuloma annulare, perforating collagenosis, and necrotizing or septic vasculitis share clinical and histologic features with papulonecrotic tuberculid.

Lichen Scrofulosorum

Lichen scrofulosorum consists of groups of indolent, minute, keratotic discrete papules scattered over the trunk. The lesions are 2–4 mm, follicular or parafollicular, and yellow-pink to reddish brown. They are firm and flat topped or surmounted by a tiny pustule or thin scale. The lesions are arranged in nummular or discoid groups, where they persist unchanged for months and cause no symptoms. They may slowly undergo spontaneous involution, followed at times by recurrence. About 95% of cases of lichen scrofulosorum occur in children and adolescents under age 20. Active TB at a distant site, usually the bones or lymph nodes, is present in about three quarters of patients. The tuberculin test is always positive.

Histologically, lichen scrofulosorum shows noncaseating tuberculoid granulomas just beneath the epidermis, between and surrounding hair follicles. Normally, tubercle bacilli are not seen in the pathologic specimens and cannot be cultured from biopsy material.

Lichen nitidus, lichen planus, secondary syphilis, and sarcoidosis should be considered in the differential diagnosis.

Erythema Induratum and Vascular Reactions Caused by Tuberculosis (Nodular Tuberculid and Nodular Granulomatous Phlebitis)

Erythema induratum (Bazin disease) is chronic and occurs predominantly (80%) in women of middle age. Lesions favor the posterior lower calf, which may also show acrocyanosis. Individual lesions are tender, erythematous or violaceous, 1–2 cm subcutaneous nodules (Fig. 16.10). They resolve spontaneously, with or without ulceration, over several months and can heal with scarring. A clinically similar but less common condition called nodular granulomatous phlebitis also affects women primarily but involves both the lower legs and the thighs, usually along the course of the saphenous vein. Individual lesions evolve over weeks to months but may recur for years in a seasonal pattern. They do not ulcerate or heal with scarring. The TST is positive. Idiopathic nodular vasculitis unassociated with TB may have identical clinical and histologic features, and this diagnosis is made when the PPD is negative.

The primary pathologic changes occur in the subcutaneous fat, which shows lobular panniculitis with fat necrosis. Granulomatous inflammation occurs in two thirds of cases and is noncaseating. In addition, a granulomatous vasculitis of arterioles can be present in the fat and is the apparent cause of the fat necrosis. Biopsies of nodular granulomatous phlebitis show thrombosis of and granulomatous inflammation centered around veins in the deep dermis. AFB are not found on special stains or cultures of the biopsy. PCR may help to confirm these diagnoses; however, the positive PPD obviates the need for it. At times, necrotizing vasculitis is present at the dermohypodermal junction. This reaction has been termed nodular tuberculid. The histology of nodular tuberculid may be identical or very similar to polyarteritis nodosa. More rarely, small-vessel vasculitis (leukocytoclastic vasculitis) or Sweet syndrome–like lesions may be seen as a "reaction" to an underlying focus of TB.

Erythema induratum must be distinguished from erythema nodosum, nodular vasculitis, polyarteritis nodosa, tertiary syphilis, and other infectious and inflammatory panniculitides. Erythema nodosum is of relatively short duration, develops rapidly, and chiefly affects the anterior rather than the posterior calves. It produces tender, painful, scarlet or contusiform nodules that appear simultaneously and do not ulcerate. Histology demonstrates a septal panniculitis. In erythema induratum patients, the pain is less severe, and the lesions tend to evolve serially or in crops. A syphilitic gumma is usually unilateral and single or may appear as a small, distinct group of lesions.

Diagnosis of Cutaneous Tuberculosis

Biopsy with acid-fast staining should be done when the history and physical examination suggest cutaneous TB. PCR is increasingly used to identify mycobacterial DNA in tissue specimens and other

biologic samples. It may be positive when both stains and cultures are negative; in paucibacillary disease, however, PCR is not reliably positive. Culture remains the gold standard and provides the means to determine antibiotic sensitivity and response to treatment.

Treatment

Testing for HIV is recommended for all patients diagnosed with TB because HIV-infected patients may require longer courses of therapy, even when antiretroviral therapy is given. In addition, every effort should be made to culture the organism for sensitivity testing because MDR-TB is common in some communities. For all forms of cutaneous TB, multidrug chemotherapy is recommended. The recommendations of the local health clinics that manage other forms of TB should be followed. Three-drug or four-drug regimens are usually recommended for initial empiric treatment. Directly observed therapy is a strategy designed to ensure cure. "Priority patients" are those with prior treatment failure, pulmonary TB with a positive smear, HIV coinfection, current or prior drug use, drug-resistant disease, psychiatric illness, memory impairment, or previous nonadherence to therapy. Surgical excision is useful for the treatment of isolated lesions of lupus vulgaris and TB verrucosa cutis, and surgical intervention also may benefit some patients with scrofuloderma. In many cases of cutaneous TB, the organism has not been identified by either histology or culture, so treatment is inherently empiric. Virtually all forms of cutaneous TB will have begun to respond to treatment by 6 weeks. Failure to respond within this period should result in reconsideration of the diagnosis, assessment for compliance, and concern about drug resistance.

NONTUBERCULOUS MYCOBACTERIOSIS

Many facultative pathogens and saprophytes, which are acid-fast mycobacteria but do not cause TB, are grouped under the designation "nontuberculous mycobacteria." The number of new species has been growing dramatically, with now at least 190 known species. Many of these organisms do not often cause infection and are simply commensals or saprophytes. They exist in a wide variety of natural sources, such as soil, water, and animals; most human disease is acquired from the environment. The number of cases of human infection with these organisms is increasing. This is a result of improved culture and identification techniques, the rising number of cosmetic procedures which may be complicated by infection with rapid growing mycobacteria, and the large immunocompromised population. An increasing number of patients receiving biologic therapy, those with solid-organ or stem cell transplants, and other causes of immunocompromise have been reported with infections. Only select organisms that most frequently affect the skin are discussed in detail here. *M. leprae* and Hansen disease are discussed in Chapter 17.

Classification of Mycobacteria

The clinical care of the patient with nontuberculous mycobacterial infection depends on culturing and identifying the responsible agent from tissue specimens. Identification of specific *Mycobacterium* species is now made using molecular techniques; however, the growth rates have some utility in considering a practical classification. Rapidly growing mycobacteria of the *Mycobacterium fortuitum*, *chelonae*, and *abscessus* group are usually associated with previous surgery, injection, or trauma. The laboratory should be familiar with the special media, necessary incubation times and temperature, and identification characteristics of these organisms. Even with modern techniques, recovery of these organisms from infections is not universal. Granuloma formation may not occur in histologic sections, and AFB stains may be negative. For this reason, if nontuberculous mycobacterial infection is suspected, a biopsy should be done, part of which should be cultured at high and low temperatures and on special media; AFB stains of the tissue should be performed; and in select patients, PCR for specific species from fresh tissue or the paraffin-fixed material should be considered. In some patients, a clinical diagnosis must be made and empiric therapy given.

Fish Tank Granuloma

Mycobacterium marinum is found in fresh and salt water and can infect fish, often killing home aquarium fish. It grows optimally at 30°C. Many infections in the United States and Europe are associated with home aquariums. Fishermen, fish sellers, and persons involved in aquaculture are also at risk. Skin lesions favor males (60%). History of an injury preceding or simultaneous with exposure to contaminated water is usually present. Exposure can be indirect, such as contact with a bucket used to empty an aquarium.

Fig. 16.11 *Mycobacterium marinum* infection. (Courtesy Steven Binnick, MD.)

An indolent lesion usually starts about 3 weeks after exposure as a small papule or nodule located on the hands (Fig. 16.11), knees, elbows, or feet. It often has a keratotic or warty surface. A sporotrichoid pattern with a succession of nodules ascending the arm is common. Less often, ulcers and abscesses may be the presentation, especially in immunosuppressed hosts. Tenosynovitis, bursitis, arthritis, and osteitis are the most frequent forms of deep structure involvement. There may be involvement of the tendon sheaths of the dorsal hands and less frequently the palms. This may limit range of motion and result in significant thickening and induration. Such patients may require surgical as well as medical management. The natural history is for slow progression, and lesions may be relatively indolent for years. Spontaneous resolution may occur in 10%–20% of patients with skin lesions after many months. Patients on TNF-α inhibitor therapy and immunosuppressed patients such as those on prednisone may develop widely disseminated lesions that are progressive.

Histopathologically, there is a suppurative and granulomatous reaction with overlying hyperkeratosis and acanthosis. Acid-fast organisms are found in only about 20% of cases. Tissue culture will be positive in about three quarters of cases. The TST and IGRA to *M. tuberculosis* usually become positive in those who have had *M. marinum* infection.

Treatment is determined by the extent of the infection and the patient's immune status. Optimal treatment has not yet been established. Single-agent therapy is often adequate for immunocompetent patients with infections limited to skin and soft tissue, clarithromycin (500 mg twice daily) seems to be the best single agent; minocycline, 100 mg twice daily, doxycycline (100 mg twice daily), or trimethoprim-sulfamethoxazole (TMP-SMX, 160/800 mg twice daily) are alternative choices. In more severe disease or deep tissue involvement, or in an immunocompromised patient combinations of double or triple therapy, including rifampin, is necessary. The sensitivities of the organism isolated can be used in cases failing initial empiric treatment. For localized lesions in the immunocompetent host, treatment is recommended for at least 1–2 months after resolution of lesions, which is usually 3–4 months in total. More than 90% of such patients will be cured. Only about 75% of patients with deep structure infections will be cured with antibiotics, with or without supplemental surgery. In this situation, treatment is often prolonged—many months to years. The wearing of gloves during and personal disinfectant methods after fish tank cleaning are helpful preventative strategies.

Fig. 16.12 Buruli ulcer.

Buruli Ulcer

Buruli ulcer is the third most common type of mycobacterial skin infection in immunocompetent people. In Africa, 75% of cases occur in children, and elderly persons are disproportionately affected. In endemic areas in Australia, elderly people are seven times more likely to be infected. The lesion usually begins on an extremity as a solitary, hard, painless, subcutaneous nodule called the "preulcerative stage." There can be significant local edema at this point. If untreated, some lesions ulcerate and expand by undermining the surrounding skin (Fig. 16.12). They may become very large, exposing muscle and tendon over a large portion of an affected extremity. Despite their appearance, the lesions are remarkably painless. Persons with hemoglobin SS or SC are as much as five times more likely to develop osteomyelitis from *M. ulcerans*. Histologically, there is extensive coagulative necrosis, minimal cellular infiltrate, and numerous clumps of AFB in the center of the necrotic area.

Mycobacterium ulcerans is the cause of Buruli ulcer. This organism occurs in Australia, numerous African nations (especially in Central and West Africa), Asia, French Guyana, Peru, Suriname, Mexico, and Brazil. The pathogenesis of this infection is now well defined. *M. ulcerans* produces a toxin, mycolactone, responsible for the extensive necrosis and ulceration. In addition to having cellular toxicity, mycolactone is also locally immunosuppressive. Tissue necrosis creates a microaerophilic environment that favors the growth of *M. ulcerans*. Strains of *M. ulcerans* lacking mycolactone are not capable of producing disease. This toxin is also critical in maintaining the life cycle of the organism.

Mycobacterium ulcerans grows under a biofilm on aquatic plants. Snails and other water animals eat the contaminated plants, and carnivorous insects eat the plant-consuming molluscs. *M. ulcerans* moves from the gut of the carnivorous insects to their salivary glands. Only *M. ulcerans* species producing mycolactone are capable of establishing a reservoir in the insect salivary gland. *M. ulcerans* is found in no other tissue in the biting insects and produces no biofilm in the insect salivary gland. When these insects bite a human, they inoculate the mycobacteria into the host and begin the infection. Infection in the human is again associated with the production of the biofilm, which makes treatment difficult. This explains the association between infection and exposure to water, especially swampy water. Interestingly, being repeatedly bitten by these carnivorous insects results in the production of antibodies against the insect salivary contents. This immune response to the insect saliva is protective against *M. ulcerans* infection, explaining why persons working regularly in swampy water are at lower risk for infection than those visiting the area. In Australia, mosquito bites are associated with the development of *M. ulcerans* infection. Whether the mosquitoes carry the infection by the same mechanism as the carnivorous water insects is unknown.

The diagnosis of Buruli ulcer is often made clinically in areas of endemicity. AFB smears of the edge of ulcerative lesions or of aspirates from the center of preulcerative lesions, culture of the lesion, PCR, and histologic examination all can confirm the diagnosis. AFB stains are positive in up to 80% of lesions. Culture has a similar positivity rate. PCR may be slightly less sensitive. When AFB smears, culture, and PCR were all done on the same lesion, at least one test was positive in 94% of cases. Preulcerative lesions give the highest culture results, because ulcerative lesions contain fewer organisms and are contaminated.

Treatment of Buruli ulcer is daily observed treatment for 8 weeks with streptomycin and rifampin. Healing is slow, with half of lesions healing by 24 weeks (with only 8 weeks of antibiotic treatment) and some requiring more than 9 months to heal. Ciprofloxacin may be substituted for streptomycin therapy as an alternative. Surgical excision with delayed grafting is the standard treatment offered to those refusing or intolerant to antibiotic treatment.

Severe scarring can result from untreated and large lesions, leading to contracture deformity or amputation. If the periocular tissues are affected, enucleation of the eye may be required. Multiple metastatic skin lesions can occur. Bone lesions are uncommon and in three quarters of patients, occur at a site distant from the primary ulcer. Rarely, death may result.

Other Nontuberculous Mycobacterial Infections

Mycobacterium Haemophilum

Mycobacterium haemophilum most often infects immunosuppressed patients with HIV infection, with an organ transplant, those receiving biologic agents, or with leukemia or lymphoma. The reservoir for the organism is unknown but thought to be water. Because *M. haemophilum* grows preferentially at 30°C–32°C, skin lesions at acral sites predominate. Papules, plaques (at times cellulitis-like), and dermal or subcutaneous nodules are the primary lesions. These initial lesions break down in many cases, forming painful, draining ulcers. Cutaneous infections after acupuncture, following application of permanent eyebrow makeup, and within tattoos have been reported in immunocompetent and immunosuppressed patients. Septic arthritis, osteomyelitis, and pulmonary nodules may occur. *M. haemophilum* has specific growth requirements, so isolation is not possible using routine laboratory culture techniques. If *M. haemophilum* infection is suspected, the laboratory should be notified so that it can prepare the special media necessary to isolate it. *M. haemophilum* is sensitive to ciprofloxacin, clarithromycin, and rifabutin. Combination therapy with all three medications has been reported to be effective. Treatment is for 1 year. Adjunctive surgery may be required.

Rapidly Growing Mycobacteria

Mycobacterium fortuitum, *M. chelonae*, and *M. abscessus* usually cause subcutaneous abscesses or cellulitis. These rapidly growing mycobacteria (RGM) are frequently resistant to standard antituberculosis medications. Infections usually occur after trauma in immunocompetent patients. Infections may follow a variety of cosmetic surgery procedures (e.g., laser resurfacing, laser hair removal, injection with dermal fillers or botulinum toxin, mesotherapy, liposuction), skin piercing, injection with biologics, skin biopsy, Mohs surgery, acupuncture, catheterization or within tattoos. Outbreaks of leg abscesses caused by *M. fortuitum* have been acquired in nail salon whirlpool footbaths. Most RGM cases are restricted to the skin and start as small erythematous papules,

Fig. 16.13 *Mycobacterium fortuitum* infection.

many of which spontaneously heal. Others progress to large, fluctuant abscesses, which are quite painful and can ulcerate (Fig. 16.13). Sporotrichoid or disseminated disease may occur in immunocompromised patients, but proximal adenopathy is rarely found. Shaving of the legs before visiting the nail salon appears to be a risk factor for acquiring infection with RGM. In renal transplant patients, tender, nodular lesions of the legs are most common. Deep extension into bone underlying a chronic ulcer can occur. Because these infections on the skin are indolent and the organisms grow rapidly, waiting for susceptibilities can be considered.

Treatment is determined by extent of disease and immune status of the patient. For *M. chelonae* and *abscessus* infections, clarithromycin, 500 mg twice daily for 6 months or more, is effective and well tolerated in many patients with disseminated cutaneous infection. Monotherapy may allow resistance to occur, but this rarely happens in immunocompetent patients with simple skin infections. In severe cases and in the setting of immunosuppression, combination treatment with moxifloxacin and surgical debridement should be used. The optimal regimen for treatment of *M. fortuitum* has not been defined, and combination treatment is recommended. Amikacin plus cefoxitin and probenecid can be recommended for initial therapy for 6 weeks, followed by doxycycline or TMP-SMX for up to 1 year. Surgical excision, debridement, and drainage may reduce duration of therapy.

Mycobacterium Avium-Intracellulare Complex

The *M. avium-intracellulare* complex was an uncommon cause of skin infection before the AIDS epidemic. In patients with AIDS who develop disseminated *M. avium-intracellulare* infections, the skin can be involved by hematogenous dissemination and may present as nodules, ulcers, or pustules or have a cellulitis-like appearance. Immunocompromised children with chronic pulmonary infections are also at risk. Only occasional reports of immunocompetent patients with inoculation-type lesions have been reported (Fig. 16.14). Therapy for disseminated infection is undertaken with at least three agents, most often clarithromycin or azithromycin plus ethambutol, and rifabutin. Adequate antiretroviral therapy should be assured in HIV-infected persons.

Fig. 16.14 *Mycobacterium avium-intracellulare* complex, primary inoculation in a healthy woman.

Mycobacterium Kansasii

Mycobacterium kansasii rarely causes skin infection, usually after minor trauma. Three quarters of cases occur in immunosuppressed persons. Lesions can be papules, nodules, pustules, cellulitis, or sporotrichoid. Initial treatment with isoniazid, rifampin, and ethambutol until 12 months after clearing, 15 months for HIV patients, is recommended. Surgical removal can be beneficial if practical. In immunosuppressed patients, cutaneous lesions can occur through hematogenous dissemination, and a visceral source, especially pulmonary, should be sought.

17 Hansen Disease

Bonus images for this chapter can be found online at expertconsult.inkling.com

EPIDEMIOLOGY

The World Health Organization (WHO) has committed itself to eliminating Hansen disease as a public health problem, but the disease remains endemic in certain regions, with 95% of cases reported from 16 countries. Brazil, India, and Indonesia account for 80% of all cases worldwide. Although 90% of diagnosed U.S. cases are imported, Hansen disease is endemic in the coastal southeastern United States and in Hawaii. In the southeastern states, cases may be related to exposure to armadillos, a natural host for the infectious agent.

It is believed that more than 90% of persons exposed to *Mycobacterium leprae* are able to resist infection. In endemic areas, between 1.7% and 31% of the population is seropositive for antibodies to leprosy-specific antigens, suggesting widespread exposure to the bacillus. About 17% of household contacts of multibacillary patients have *M. leprae*, which is detectable by polymerase chain reaction (PCR) on skin swabs, with 4% detectable in nasal swabs. This clears after the multibacillary patient has been treated with multidrug therapy (MDT) for 2 months. Thus although many persons can be transiently infected, they apparently are able to resist overt clinical infection.

There appears to be a genetic basis for susceptibility to acquire Hansen disease. Monozygotic twins have concordant disease in 60%–85% of cases, and dizygotic twins in only 15%–25%. Numerous genes have been identified as possibly conferring susceptibility to infection with *M. leprae*. Different genes have been identified in different populations, suggesting that multiple genetic causes of susceptibility to infection are possible with *M. leprae*. Tight genetic linkage with the PARK2/PACRG regulatory region, HLA-DRB1, and lymphotoxin A (LTA+80) has been detected. *PARK2* is a gene involved in the development of Parkinson disease, and LTA+80 is a low-production lymphotoxin A allele associated with malaria parasitemia. Interleukin (IL)–17F single nucleotide polymorphism (SNP) is associated with an increased susceptibility to Hansen disease, and type 1 reactions in paucibacillary patients. In Chinese patients, susceptibility was linked to multiple genes, including *CCDC12*, *C13orf31*, and a series of genes known to be associated with susceptibility to other mycobacterial diseases, including *NOD2*, *IL12B*, *RIP2K*, and *TNFSF15*.

In adult cases, men outnumber women 1.5:1. Although Hansen disease occurs at all ages, most cases appearing or acquired in endemic areas present before age 35. Patients exposed to armadillos present on average at age 50. The latency period between exposure and overt signs of disease is usually 5 years for paucibacillary cases and an average of 10 years in multibacillary cases. Infected women are likely to present during or immediately after pregnancy.

The mode of transmission remains controversial. Except for cases associated with armadillo exposure, other patients with Hansen disease are thought to be the only possible source of infection. Rarely, tattooing or other penetrating injury to the skin can be the route of infection. Multibacillary cases are much more infectious than paucibacillary cases, so the nature of the source case is the most important factor in transmission. Contact is associated with acquiring infection. Household contacts represent 28% of new Hansen disease patients; there is an 8–10 times greater risk of acquiring disease if the household contact has lepromatous disease, versus only 2–4 times if the contact has tuberculoid leprosy. In 80% of all new cases of Hansen disease, there is a clear history of social contact with an untreated patient with Hansen disease. PCR can detect *M. leprae* on the intact skin by saline washings in up to 90% of multibacillary patients with a high bacterial load (bacterial index [BI] >3). Up to 70% of nasal swabs are similarly positive. Whereas the swabs from the patients remain positive after 3 months of MDT, the swabs of household contacts become negative, suggesting that the bacilli seen in patients are nonviable, and that the risk of transmission is substantially reduced after the index patient is treated. Unfortunately, persons may be infectious from their skin or nasal secretions, with no clinical evidence of Hansen disease (multibacillary patients who are not yet symptomatic and without identifiable skin lesions). This may make strategies relying on treatment of contacts of known Hansen disease patients ineffective in eradicating the disease. In nonendemic areas, transmission to contacts is rare, a reassuring fact for the families of patients diagnosed in areas where Hansen disease is uncommon. The last case of secondary transmission of Hansen disease in the United Kingdom was in 1923.

THE INFECTIOUS AGENT

Until recently, it had been thought that all cases of human and animal leprosy are caused by the same organism, *Mycobacterium leprae.* This is a weakly acid-fast organism that has not been successfully cultured in vitro. *M. leprae* grows best at temperatures (30°C) below the core body temperature of humans. This explains the localization of Hansen disease lesions to cooler areas of the body and the sparing of the midline and scalp. The organism may be cultivated in mouse footpads and most effectively in armadillos, whose lower body temperature is more optimal for growth of *M. leprae.* Phenolic glycolipid 1 (PGL-1) is a surface glycolipid unique to the leprosy bacillus. In infected tissues, the leprosy bacillus favors intracellular locations, within macrophages and nerves. The genome of the leprosy bacillus has been sequenced and compared with its close relative, the tuberculous bacillus. The genome of *M. leprae* contains only 50% functional genes, apparently the result of significant reductive evolution. As with other intracellular parasites, and in the absence of the ability to share DNA with other bacteria, *M. leprae* has lost many nonessential genes, including those involved in energy metabolism, making it dependent on the intracellular environment for essential nutrients. This may explain the extremely long generation time, 12–14 days, and the inability to culture *M. leprae* in vitro.

A second organism, *Mycobacterium lepromatosis*, has been isolated from Hansen disease patients in Mexico and reported as the major cause of leprosy in some regions. Some patients are infected with both *M. leprae* and *M. lepromatosis.* This second mycobacterium is specifically associated with the diffuse type of lepromatous leprosy (DLL), also known as "Lucio leprosy." These are the patients who develop Lucio phenomenon. Invasion of the endothelial cells characterizes infection with the new organism. Although not all researchers accept *M. lepromatosis* as a second, separate species capable of causing Hansen disease, it does suggest more than one causative organism for leprosy.

DIAGNOSIS

A diagnosis of Hansen disease must be considered in any patient with neurologic and cutaneous lesions. The diagnosis is frequently

TABLE 17.1 Spectrum of Host-Parasite Relationship in Hansen Disease

	High Resistance		Unstable Resistance		No Resistance
	Tuberculoid (TT)	**Borderline Tuberculoid (BT)**	**Borderline (BB)**	**Borderline Lepromatous (BL)**	**Lepromatous (LL)**
Lesions	1–3	Few	Few or many asymmetric	Many	Numerous and symmetric
Smear for bacilli	0	1+	2+	3+	4+

Histology	Epithelioid cells decreasing → Nerve destruction, sarcoid-like granuloma			Increasing histiocytes, foam cells, granuloma, xanthoma-like	

Modified from Dr. J. H. Petit.

delayed in the developed world; clinicians do not readily think of Hansen disease because they may never have seen it. In the United States this diagnostic delay averages 1½–2 years. In the United Kingdom, in more than 80% of patients with Hansen disease, the correct diagnosis was not suspected during the initial medical evaluation.

Hansen disease is diagnosed, as with other infectious diseases, by identifying the infectious organism in affected tissue. Because the organism cannot be cultured, this may be very difficult. Biopsies from skin or nerve lesions, stained for the bacillus with Fite-Faraco stain, are usually performed in the developed world. In some Hansen disease clinics, and in the developing world where the disease is endemic, organisms are identified in slit smears of the skin. Smears are very specific, but 70% of all patients with Hansen disease have negative smears. Smears are taken from lesions and cooler areas of the skin, such as the earlobes, elbows, and knees. If organisms are found on skin smears, the patient is said to be multibacillary. If the results of skin smears are negative (and there are five or fewer lesions), the patient is called paucibacillary.

Nerve involvement is detected by enlargement of peripheral nerves and lesional loss of sensation. Enlarged nerves are found in more than 90% of patients with multibacillary Hansen disease and in 75%–85% of patients with paucibacillary disease. About 70% of lesions have reduced sensation, but lesional dysesthesia is not detected in patients with multibacillary Hansen disease, the most infectious form.

Serologic tests to detect antibodies against *M. leprae*–unique antigens have limitations in the diagnosis of leprosy and reactional states. They are universally positive in patients with multibacillary disease, in whom the diagnosis is not difficult. In paucibacillary patients, these tests are often negative, and in endemic areas there is a high background rate of positivity of serologic tests. In pure neural Hansen disease, however, about 50% of patients are seropositive, and serologic testing might be of use. Based on the technology of the T-cell interferon-γ (IFN-γ) production–based assays for *M. tuberculosis* infection, researchers have identified unique peptides of *M. leprae* and developed a research IFN-γ release assay (IGRA). This was able to detect all paucibacillary cases in a Hansen disease cohort. In addition, 13 of 14 household contacts of Hansen disease patients were positive with IGRA. Ideally, in endemic areas, both serologic and cell-based assays can be used to detect all patients with Hansen disease.

In endemic areas, active surveillance of contacts is recommended. In Brazil, about 2% of both in-domicile and extradomiciliary contacts are found to have Hansen disease. Most cases are associated with patients who have multibacillary Hansen disease.

CLASSIFICATION

Hansen disease may present with a broad spectrum of clinical diseases. The Ridley and Jopling scale classifies cases based on clinical, bacteriologic, immunologic, and histopathologic features (Table 17.1). In many exposed patients, the infection apparently clears spontaneously, and no clinical lesions develop. Patients who do develop clinical disease are broadly classified into two groups for the purposes of treatment and for trials that compare treatment strategies. Paucibacillary patients have few or no organisms in their lesions and usually have three to five lesions or fewer (for treatment purposes, the finding of acid-fast bacilli by stains or smears classifies a patient as having multibacillary Hansen disease). Multibacillary patients have multiple, symmetric lesions and organisms detectable by biopsy or smears. The individual's cell-mediated immune response to the organism determines the form that Hansen disease will take in the individual. If the cell-mediated immune response against *M. leprae* is strong, the number of organisms will be low (paucibacillary), and conversely, if this response is inadequate, the number of organisms will be high (multibacillary).

The most common outcome after exposure is probably spontaneous cure. If skin disease does appear, the initial clinical lesion may be a single, hypopigmented patch, perhaps with slight anesthesia. This is called indeterminate disease, because the course of the disease cannot be predicted at this stage. The lesion may clear spontaneously or may progress to any other form of Hansen disease.

The spectrum of Hansen disease has two stable poles, the tuberculoid and lepromatous forms (see Table 17.1). These so-called polar forms do not change; the patient remains in one or the other form throughout the course of the disease. The polar tuberculoid form (called TT), the type with high cell-mediated immunity, is characterized by less than five lesions (often only one) and very few organisms (paucibacillary disease). The patient has strong cell-mediated immunity against the organism. The natural history of many TT leprosy patients is for spontaneous cure over several years. The polar lepromatous form (LL) has very limited cell-mediated immunity against the organism; lesions are numerous and contain many organisms (multibacillary). Between these two poles is every possible degree of infection, forming the borderline spectrum. Cases near the tuberculoid pole are called borderline tuberculoid (BT), those near the lepromatous pole are called borderline lepromatous (BL), and those in the middle are called borderline borderline (BB). Borderline Hansen disease is characteristically unstable, and with time, cases move from the TT to the LL pole, a process called downgrading.

Hansen disease may involve only the nerves. This pure neural disease may be indeterminate, tuberculoid, or lepromatous (paucibacillary or multibacillary) and is so classified. In Nepal and India, pure neural Hansen disease may represent as much as 5% of all new cases.

Early and Indeterminate Hansen Disease

Usually, the onset of Hansen disease is insidious. Prodromal symptoms are generally so slight that the disease is not recognized until the appearance of a cutaneous eruption. Actually, the first

clinical manifestation in 90% of patients is numbness, and years may elapse before skin lesions or other signs are identified. The earliest sensory changes are loss of the senses of temperature and light touch, most often in the feet or hands. The inability to discriminate hot from cold may be lost before pinprick sensibility. Such dissociation of sensibility is especially suspicious. The distribution of these neural signs and their intensity will depend on the type of disease that is evolving.

Often, the first lesion noted is a solitary, poorly defined, hypopigmented macule that merges into the surrounding normal skin. Less often, erythematous macules may be present. Such lesions are most likely to occur on the cheeks, upper arms, thighs, and buttocks. Examination reveals that sensory functions are either normal or minimally altered. Peripheral nerves are not enlarged, and plaques and nodules do not occur. Histologically, a variable lymphocytic infiltrate (without granulomas) is seen, sometimes with involvement of the cutaneous nerves. Usually, no bacilli, or only a few, are seen on biopsy of this indeterminate form. It is the classification, not the diagnosis, that is indeterminate. Few cases remain in this state; they evolve into lepromatous, tuberculoid, or borderline types, or (if cell-mediated immunity is good) often spontaneously resolve and never develop other signs or symptoms of Hansen disease.

Tuberculoid Leprosy

Tuberculoid lesions are solitary or few in number (five or less) and asymmetrically distributed. Lesions may be hypopigmented or erythematous and are usually dry, scaly, and hairless (Fig. 17.1). The typical lesion of tuberculoid leprosy is the large, erythematous plaque with a sharply defined and elevated border that slopes down to a flattened atrophic center. This has been described as having the appearance of "a saucer right side up." Lesions may also be macular and hypopigmented or erythematous, resembling clinically indeterminate lesions. The presence of palpable induration and neurologic findings distinguish tuberculoid lesions from indeterminate lesions clinically. The most common locations are the face, limbs, or trunk; the scalp, axillae, groin, and perineum are not involved.

A tuberculoid lesion is anesthetic or hypesthetic and anhidrotic, and superficial peripheral nerves serving or proximal to the lesion are enlarged, tender, or both. The greater auricular nerve and the superficial peroneal nerve may be visibly enlarged. Nerve involvement is early and prominent in tuberculoid leprosy, leading to characteristic changes in the muscle groups served. There may be atrophy of the interosseous muscles of the hand, with wasting of the thenar and hypothenar eminences, contracture of the fingers, paralysis of the facial muscles, and footdrop. Facial nerve damage dramatically increases the risk for ocular involvement and vision loss.

The evolution of the lesions is generally slow. There is often spontaneous remission of the lesions in about 3 years, or remission may result sooner with treatment. Spontaneous involution may leave pigmentary disturbances.

Borderline Tuberculoid (BT) Leprosy

BT lesions are similar to tuberculoid lesions, except that they are smaller and more numerous (Fig. 17.2). Satellite lesions around large macules or plaques are characteristic.

Borderline Borderline (BB) Leprosy

In BB leprosy, the skin lesions are numerous (but countable) and consist of red, irregularly shaped plaques. Small satellite lesions may surround larger plaques. Lesions are generalized but asymmetric. The edges of lesions are not as well defined as the ones seen at the tuberculoid pole. Nerves may be thickened and tender, but anesthesia is only moderate in the lesions.

Borderline Lepromatous (BL) Leprosy

In BL leprosy, the lesions are symmetric and numerous (too many to count) and may include macules, papules, plaques, and nodules (Fig. 17.3). The number of small, lepromatous lesions outnumbers the larger, borderline-type lesions. Nerve involvement appears later; nerves are enlarged, tender, or both, and it is important to note that involvement is symmetric. Sensation and sweating over individual lesions are normal. Patients usually do not show the features of full-blown lepromatous leprosy, such as madarosis (loss of the eyebrows), keratitis, nasal ulceration, and leonine facies.

Fig. 17.1 Tuberculoid leprosy.

Fig. 17.2 Borderline tuberculoid leprosy.

Fig. 17.3 Borderline lepromatous leprosy.

Fig. 17.4 Lepromatous leprosy.

Lepromatous Leprosy

Lepromatous leprosy may begin as such or develop after indeterminate leprosy or from downgrading of borderline leprosy. The cutaneous lesions of lepromatous leprosy consist mainly of pale macules (Fig. 17.4) or diffuse infiltration of the skin. There is a tendency for the disease to become progressively worse without treatment. Lepromatous leprosy may be divided into a polar form (LLp) and a subpolar form (LLs); these forms may behave differently.

Macular lepromatous lesions are diffusely and symmetrically distributed over the body. Tuberculoid macules are large and few in number, whereas lepromatous macules are small and numerous. Lepromatous macules are poorly defined, show no change in skin texture, and blend imperceptibly into the surrounding skin. There is minimal or no loss of sensation over the lesions, no nerve thickening, and no change in sweating. A slow, progressive loss of hair takes place from the outer third of the eyebrows, then the eyelashes, and finally the body; however, the scalp hair usually remains unchanged.

Fig. 17.5 Diffuse leprosy of Lucio. Note loss of eyebrows.

Lepromatous infiltrations may be divided into the diffuse, plaque, and nodular types. The diffuse type is characterized by the development of a diffuse infiltration of the face, especially the forehead, madarosis, and a waxy, shiny appearance of the skin, sometimes described as "varnished." Diffuse leprosy of Lucio (DLL) is a striking form, uncommon except in western Mexico and certain other Latin American areas, where almost one third of lepromatous cases may be of this type. This form of lepromatous leprosy is characterized by diffuse lepromatous infiltration of the skin (Fig. 17.5); localized lepromas do not form. A unique complication of this subtype is the reactional state referred to as Lucio phenomenon (erythema necroticans).

The infiltrations may be manifested by the development of nodules called lepromas (Fig. 17.6). The early nodules are poorly defined and occur most often in acral parts: ears, brows, nose, chin, elbows, hands, buttocks, or knees.

Nerve involvement invariably occurs in lepromatous leprosy but develops very slowly. As with the skin lesions, nerve disease is bilaterally symmetric, usually in a stocking-glove pattern. This is frequently misdiagnosed as diabetic neuropathy in the United States if it is the presenting manifestation.

Histoid Leprosy

Histoid leprosy is an uncommon form of multibacillary Hansen disease in which skin lesions appear as large, yellow-red, shiny papules and nodules in the dermis or subcutaneous tissue. Lesions appear on a background of normal skin. They vary in size from 1–15 mm in diameter, and may appear anywhere on the body but favor the buttocks, lower back, face, and bony prominences. They may closely resemble molluscum contagiosum. This pattern may appear de novo but has mostly been described in patients with resistance to dapsone.

NERVE INVOLVEMENT

Nerve involvement is characteristic and unique to Hansen disease. This neural predilection or neurotropism is a histopathologic hallmark of Hansen disease. Nerve involvement is responsible for

Fig. 17.6 Lepromatous leprosy. (Courtesy Michelle Weir, MD.)

the clinical findings of anesthesia within lesions (paucibacillary and borderline leprosy) and of a progressive stocking-glove peripheral neuropathy (lepromatous leprosy). The neuropathy is termed *primary impairments* (WHO grade 1). Secondary (or visible) impairments (WHO grade 2) are a consequence of the neuropathy and include skin fissures, wounds, clawing of digits, contractures, shortening of digits, and blindness. Neural damage leads to deformities and in endemic regions results in Hansen disease being a major cause of "limitations of activity" (formerly called disability) and "restrictions in social participation" (formerly called handicap). Neuropathy is present in 1.3%–3.5% of paucibacillary patients and 7.5%–24% of multibacillary patients undergoing MDT. Secondary impairments occur in 33%–56% of multibacillary patients. Neuropathy may progress, even after effective MDT, and secondary impairments may continue to appear for years as a consequence of the neuropathy. This requires patients with neuropathy to be constantly monitored, even though they are "cured" of their infection.

Nerve enlargement is rare in other skin diseases, so the finding of skin lesions with enlarged nerves should suggest Hansen disease. Nerve involvement tends to occur with skin lesions, and the pattern of nerve involvement parallels the skin disease. Tuberculoid leprosy is characterized by asymmetric nerve involvement localized to the skin lesions. Lepromatous nerve involvement is symmetric and not associated with skin lesions. Nerve involvement without skin lesions, called pure neural leprosy, can occur and may be either tuberculoid (paucibacillary) or lepromatous (multibacillary). Nerve disease can be symptomatic or asymptomatic.

Leprosy bacilli may be delivered to the nerves through the perineural and endoneural blood vessels. Once the bacilli transgress the endothelial basal lamina and are in the endoneurium, they enter resident macrophages or selectively enter Schwann cells. Damage to the nerves could then occur by the following mechanisms:

1. Obstruction of neural vessels
2. Vasculitis of neural vessels
3. Interference with metabolism of the Schwann cell, making it unable to support the neuron
4. Immunologic attack on endothelium or nerves
5. Infiltration and proliferation of *M. leprae* in the closed and relatively nonexpandable endoneural and perineural spaces

Different and multiple mechanisms may occur in different forms of Hansen disease and in the same patient over time. The selective ability of *M. leprae* to enter Schwann cells is unique among bacteria. *M. leprae*–unique PGL-1, expressed abundantly on the surface of leprosy bacilli, binds selectively to the α2 G module of laminin 2. This α2 chain is tissue restricted and specifically expressed on peripheral nerve Schwann cells. Other accessory binding molecules may facilitate the binding and endocytosis. The nerves become immunologic targets when they present *M. leprae* antigens on their surface in the context of major histocompatibility complex (MHC) class II molecules. Schwann cells and thus nerves are usually protected from immunologic attack mediated by the adaptive immune system because they rarely present MHC class II antigens on their surface. In Hansen disease, expression of these immunologic molecules occurs on the surface of Schwann cells, making them potential targets for CD4+ cytotoxic T cells. This mechanism may be important in the nerve damage that occurs in type 1 (reversal) reactions.

Schwann cells have been infected with *M. leprae* in vitro. Infected Schwann cells with high bacterial load are reprogrammed into mesenchymal stem cell–like cells. In association with Schwann cells, these dedifferentiated cells attract histiocytes and form granulomas. The attracted histiocytes are infected by the mycobacteria-containing Schwann cells and are released from the granulomas. If this process also occurs in vivo, it may be the mechanism by which multibacillary disease is spread throughout the body from a reservoir of infected nerves.

The neural signs in Hansen disease are dysesthesia, nerve enlargement, muscular weakness and wasting, and trophic changes. The lesions of the vasomotor nerves accompany the sensory disturbances or may precede them. Dysesthesia develops in a progressive manner. The first symptom is usually an inability to distinguish hot and cold. Subsequently, the perception of light touch is lost, then that of pain, and last the sense of deep touch. At times, the sensory changes in large Hansen disease lesions are not uniform because of the variation in the involvement of the individual neural filaments supplying the area. Therefore the areas of dysesthesia may not conform to the distribution of any particular nerve and, except in lepromatous cases, are not symmetric.

Nerve involvement mainly affects (and is most easily observed in) the more superficial nerve trunks, such as the ulnar, median, radial, peroneal, posterior tibial, fifth and seventh cranial, and especially the great auricular nerve. Beaded enlargements, nodules, or spindle-shaped swellings may be found, which at first may be tender. Neural abscesses may form. The ulnar nerve near the internal condyle of the humerus may be as thick as the little finger, round, and stiff and is often easily felt several centimeters above the elbow.

Because the presentation of neural involvement in Hansen disease is variable, the diagnosis is often not suspected, especially in nonendemic areas. Even in endemic areas, the diagnosis may be delayed. Between one half and one third of patients with pure neural Hansen disease, a biopsy of hypesthetic skin can show specific leprotic skin changes, and if nonspecific inflammation is considered confirmatory, the positivity of such biopsies is greater than 50%. Therefore skin biopsy of a hypesthetic skin site should

Fig. 17.7 Claw hand of Hansen disease.

be considered before nerve biopsy when pure neural Hansen disease is a possibility.

As a result of the nerve damage, areas of anesthesia, paralysis, and trophic disorders in the peripheral parts of the extremities gradually develop. Muscular paralysis and atrophy generally affect the small muscles of the hands and feet or some of the facial muscles, producing weakness and progressive atrophy. Deeper motor nerves are only rarely involved. The fingers develop contractures, with the formation of a clawhand (Fig. 17.7). Also, as the result of resorption of phalangeal bones, fingers and toes become shorter. Ptosis, ectropion, and a masklike appearance occur from damage to the fifth and seventh cranial nerves.

Subsequent to nerve damage, ulceration, hyperkeratosis, bullae, alopecia, anhidrosis, and mal perforans pedis can develop. Trophic ulceration usually manifests as a perforating ulcer on the ball or heel of the foot.

OCULAR INVOLVEMENT

Corneal erosions, exposure keratitis, and ulcerations may result from involvement of the seventh cranial nerve in Hansen disease patients. Specific changes may include corneal opacity, avascular keratitis, pannus formation, interstitial keratitis, and corneal lepromas. The corneal opacities enlarge and finally form visible white flecks called "pearls." When (in BL or lepromatous cases only) the iris and the ciliary body become involved, miliary lepromas (iris pearls), nodular lepromas, chronic granulomatous iritis, and acute diffuse iridocyclitis may result. Of multibacillary patients, 2.8%–4.6% are blind at diagnosis, and 11% will have a potentially blinding process.

MUCOUS MEMBRANE INVOLVEMENT

The mucous membranes may also be affected, especially in the nose, mouth, and larynx. The nasal mucosa is most frequently involved, and lepromatous patients frequently complain of chronic nasal congestion. By far the most common lesions in the nose are infiltrations and nodules. Perforation of the nasal septum may occur in patients with advanced Hansen disease, with collapse of the nasal bridge (Fig. 17.8). Saddle-nose deformities and loss of the upper incisor teeth can occur.

Nodules occurring on the vocal cords will produce hoarseness.

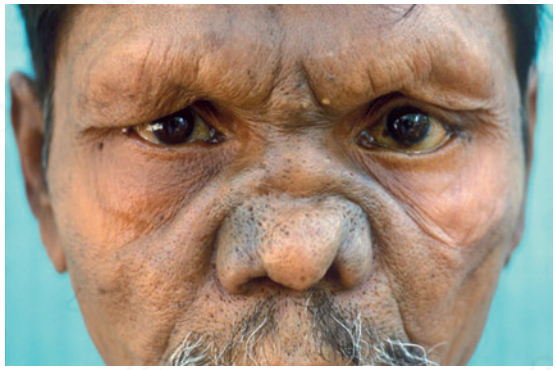

Fig. 17.8 Lepromatous leprosy. (Courtesy Shyam Verma, MBBS, DVD.)

VISCERAL INVOLVEMENT

In lepromatous leprosy, the body is diffusely involved and bacteremia occurs. Except for the gastrointestinal tract, lungs, and brain, virtually every organ can contain leprosy bacilli. The lymph nodes, bone marrow, liver, spleen, and testicles are most heavily infected. Visceral infection is restricted mostly to the reticuloendothelial system, which despite extensive involvement rarely produces symptoms or findings. Testicular atrophy with loss of androgens can result in gynecothelia (hypertrophy of nipple) and/or gynecomastia, or premature osteoporosis. Secondary amyloidosis with renal impairment may complicate multibacillary leprosy. Glomerulonephritis occurs in more than 5% and perhaps as many as 50% of Hansen disease patients and is not correlated with bacillary load or the presence of erythema nodosum leprosum.

SPECIAL CLINICAL CONSIDERATIONS AND HANSEN DISEASE

Pregnancy

Hansen disease may be complicated in several ways by pregnancy. As a state of relative immunosuppression, pregnancy may lead to an exacerbation or reactivation after apparent cure. In addition, pregnancy or, more often, the period immediately after delivery may be associated with the appearance of reactional states in patients with Hansen disease. Pregnant patients with Hansen disease cannot be given certain medications used to treat the disease, such as thalidomide, ofloxacin, and minocycline. MDT is tolerated by pregnant women if these restricted agents are avoided.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) infection, although a cause of profound immunosuppression of the cell-mediated immune system, does not seem to have an adverse effect on the course of Hansen disease. Patients are treated with the same agents and can be expected to have similar outcomes in general. Duration of treatment with MDT may need to be extended in patients with HIV infection. Treatment of HIV-infected patients with Hansen disease using effective antiretroviral drugs may be associated with the appearance of reactional states (usually type 1) as part of the immune reconstitution syndrome. This virtually always occurs in the first 6 months of antiviral therapy.

Organ Transplantation

Hansen disease has been reported in organ transplant recipients (renal, liver, heart, and bone marrow). If the disease has been

treated and the patient is then given a transplant, Hansen disease can recur, apparently as a result of the immunosuppressive regimen. In addition, transplant patients may present with new Hansen disease, most frequently toward the lepromatous pole (BL or LL). Erythema nodosum leprosum (ENL) may occur. The correct management of the organ transplant recipient with Hansen disease is not known, but MDT with highly active agents is usually given.

Patients with Hansen disease may also acquire a second cutaneous mycobacterial infection. This may occur as a complication of corticosteroid treatment for reactional states. *Mycobacterium fortuitum* has been reported in one case, and one of the authors has seen coinfection with *M. haemophilum*. In these patients, the MDT plan should include agents effective against both Hansen disease and the second mycobacterial infection.

IMMUNOPATHOGENESIS

The patient's immune reaction to the leprosy bacillus and ongoing exposure are critical elements in determining the outcome of infection. Continuous exposure downregulates the cellular immune response against the pathogen and favors lepromatous disease. Tuberculoid patients make well-formed granulomas that contain helper T cells, whereas lepromatous patients have poorly formed granulomas, and suppressor T cells predominate. The cytokine profile in tuberculoid lesions is good cell-mediated immunity, with IFN-γ and interleukin-2 (IL-2) present. In lepromatous patients, these cytokines are reduced, and IL-4, IL-5, and IL-10, cytokines that downregulate cell-mediated immunity and enhance suppressor function and antibody production, are prominent. Lepromatous leprosy thus represents a classic T-helper cell type 2 (Th2) response to *M. leprae.* Lepromatous patients have polyclonal hypergammaglobulinemia and high antibody titers to *M. leprae*–unique antigens and may have false-positive syphilis serology, rheumatoid factor, and antinuclear antibodies. Although the cell-mediated immune response of lepromatous patients to *M. leprae* is reduced, these patients are not immunosuppressed for other infectious agents. Tuberculosis behaves normally in patients with lepromatous leprosy.

HISTOPATHOLOGY

Ideally, biopsies should be performed from the active border of typical lesions and should extend into the subcutaneous tissue. Punch biopsies are usually adequate. Fite-Faraco stain is optimal for demonstrating *M. leprae*. Because the diagnosis of Hansen disease is associated with significant social implications, evaluation must be complete, including evaluation of multiple sections in paucibacillary cases. Consultation with a pathologist experienced in the diagnosis of Hansen disease can be helpful if the diagnosis is suspected, but organisms cannot be identified in the affected tissue, especially in paucibacillary disease and reactional states. PCR has not been very useful; it is positive in only 50% of paucibacillary cases. The histologic features of Hansen disease correlate with the clinical pattern of disease. Nerve involvement is characteristic, and histologic perineural and neural involvement should suggest Hansen disease.

Tuberculoid Leprosy

Dermal tuberculoid granulomas, consisting of groups of epithelioid cells with giant cells, are found in tuberculoid leprosy. The granulomas are elongated and generally run parallel to the surface, following neurovascular bundles. The epithelioid cells are not vacuolated or lipidized. The granulomas extend up to the epidermis, with no grenz zone. Lymphocytes are found at the periphery of the granulomas. Acid-fast bacilli are rare. The most important specific diagnostic feature, besides finding bacilli, is selective destruction of nerve trunks and the finding of perineural concentric fibrosis. An S-100 stain may show this selective neural destruction by demonstrating unrecognizable nerve remnants in the inflammatory foci. Bacilli are most frequently found in nerves, but the subepidermal zone and arrector pili muscles are other fruitful areas.

Borderline Tuberculoid Leprosy

The histopathology of BT leprosy is similar to that seen in the tuberculoid variety. However, epithelioid cells may show some vacuolation, bacilli are more abundant, and a grenz zone separates the inflammatory infiltrate from the overlying epidermis in BT leprosy.

Borderline Leprosy

In borderline leprosy, granulomas are less well organized, giant cells are not seen, the macrophages have some foamy cytoplasm, and organisms are abundant.

Borderline Lepromatous Leprosy

In BL lesions, foamy histiocytes, rather than epithelioid cells, make up the majority of the granuloma. Lymphocytes are still present and may be numerous in the granulomas but are dispersed diffusely within them, not organized at the periphery. Perineural involvement with lymphocyte infiltration may be present. Organisms are abundant and may be found in clumps.

Lepromatous Leprosy

In lepromatous leprosy, granulomas are composed primarily of bacilli-laden and lipid-laden histocytes. These are the so-called lepra cells or foam cells of Virchow. The infiltrate is localized in the dermis and may be purely perivascular or sheetlike and separated from the epidermis by a well-defined grenz zone. Acid-fast bacilli are typically abundant and appear as round clumps (globi). Pure polar lepromatous leprosy differs from the subpolar type primarily in the paucity of lymphocytes in the pure polar form.

REACTIONAL STATES

Reactions are a characteristic and clinically important aspect of Hansen disease. The majority of reactions occur after initiation of therapy, with an incidence of about 50% in patients starting MDT. In addition to antibiotic therapy, intercurrent infections, vaccination, pregnancy, vitamin A, iodides, and bromide may trigger reactions. Reactions can be severe and are an important cause of permanent nerve damage in borderline patients. Reactional states frequently appear abruptly, unlike Hansen disease itself, which changes slowly. A reaction is therefore a common reason why patients seek consultation. In addition, if a patient believes that the chemotherapy is triggering the reaction, the patient will tend to discontinue the treatment, leading to treatment failure.

Reactional states are divided into two forms, called type 1 and type 2 reactions. Type 1 reactions are caused by cell-mediated immune inflammation within existing skin lesions. These generally occur in patients with borderline leprosy (BT, BB, BL). Type 2 reactions are mediated by immune complexes and occur in lepromatous patients (BL, LL).

Type 1 Reactions (Reversal, Lepra, and Downgrading Reactions)

Type 1 reactions represent an enhanced cell-mediated immune response to *M. leprae* and usually occur after treatment is initiated. If the reactions occur with antibiotic chemotherapy, they are called reversal reactions, and if they occur as borderline disease shifts

Fig. 17.9 Type 1 reactional leprosy. (Courtesy Laura de Souza Lima Institute, Brazil.)

toward the lepromatous pole (downgrading), they are called downgrading reactions. These two reaction types are clinically identical. Patients in all parts of the borderline spectrum may be affected by type 1 reactions, but these are most severe in patients with BL leprosy who have a large amount of *M. leprae* antigen and therefore have prolonged and repeated reactions during treatment.

Type 1 reactions clinically present with inflammation of existing lesions (Fig. 17.9). The patient has no systemic symptoms, such as fever, chills, or arthralgias. Lesions swell, become erythematous, and are sometimes tender, simulating cellulitis. In severe cases, ulceration can occur.

Patients may state that new lesions appeared with the reaction, but these probably represent subclinical lesions that were highlighted by the reaction. The major complication of type 1 reactions is nerve damage. As the cell-mediated inflammation attacks *M. leprae* antigen, any infected tissue compartment can be damaged. Because bacilli are preferentially in nerves, neural symptoms and findings are often present. Reversal reaction occurring within a nerve may lead to sudden loss of nerve function and permanent damage to that nerve. This makes type 1 reactions an emergency. In this setting, affected nerves are enlarged and tender. In other patients, the neuritis may be subacute or chronic and of limited acute symptomatology, but may still result in severe nerve damage. Histologically, skin lesions show perivascular and perineural edema and large numbers of lymphocytes. Severe reactions may demonstrate tissue necrosis. Bacilli are reduced.

Type 2 Reactions (Erythema Nodosum Leprosum)

ENL occurs in half of patients with BL or lepromatous leprosy, 90% of the time within a few years of institution of antibiotic treatment for Hansen disease or during pregnancy. ENL represents immune complex–mediated vasculitis, with most of the complexes forming locally rather than circulating. Nerve damage in leprosy is related to in situ generation of the membrane attack complex, and higher levels are found in ENL. Increased levels of tumor necrosis factor–α (TNF-α) and other proinflammatory cytokines are found along with an increased CD4(+)/CD8(+) ratio in both skin and peripheral blood.

In contrast to type 1 reactions, type 2 (ENL) can result in multisystem involvement and is usually accompanied by systemic symptoms (fever, myalgias, arthralgias, anorexia). Skin lesions are characteristically erythematous, subcutaneous, and dermal nodules that are widely distributed (Fig. 17.10). They do not occur at the sites of existing skin lesions. Severe skin lesions can ulcerate. Unlike

Fig. 17.10 Type 2 reactional leprosy. (Courtesy Aileen Chang, MD.)

classic erythema nodosum, lesions of ENL are generalized and favor the extensor arms and medial thighs.

A multisystem disease, ENL can produce conjunctivitis, neuritis, keratitis, iritis, synovitis, nephritis, hepatosplenomegaly, orchitis, and lymphadenopathy. The intensity of the reaction may vary from mild to severe and may last from a few days to weeks, months, or even years. Histologically, ENL demonstrates a leukocytoclastic vasculitis. Laboratory evaluation will reveal an elevated sedimentation rate, increased C-reactive protein, and a neutrophilia.

Lucio Phenomenon

Lucio phenomenon is an uncommon and unusual reaction that occurs in patients with diffuse lepromatous leprosy (DLL) of the "la bonita" type, most often found in western Mexico. Some consider it a subset of ENL, but Lucio's reaction differs in that it lacks neutrophilia and systemic symptoms. It is not associated with institution of antibiotic treatment as is ENL, and Lucio phenomenon is frequently the reason for initial presentation in affected patients. Purpuric macules evolve to bullous lesions that rapidly ulcerate, especially below the knees (Fig. 17.11). These may be painful but may also be relatively asymptomatic. Histologically, bacilli are numerous and, in addition to being in the dermis, are seen within blood vessel walls with thrombosis of middermal vessels, resulting in cutaneous infarction. Fever, splenomegaly, lymphadenopathy, glomerulonephritis, anemia, hypoalbuminemia, polyclonal gammopathy, and hypocalcemia may be associated conditions. If the patient is diagnosed early, before significant metabolic and infectious complications occur, the outcome is favorable.

TREATMENT

Dapsone monotherapy promotes resistance. MDT is now standard. Treatment recommendations are summarized in Tables 17.2 and 17.3.

TABLE 17.2 U.S. Department of Health and Human Services Treatment Guidelines

ADULTS		
Tuberculoid (TT and BT) (WHO Classification Paucibacillary, "Pb")		
Agent	**Dose**	**Duration**
Dapsone	100 mg daily	12 months
Rifampicin	600 mg daily	
ADULTS		
Lepromatous (LL, BL, BB) (WHO Classification Multibacillary, "Mb")		
Agent	**Dose**	**Duration[a]**
Dapsone	100 mg daily	24 months
Rifampicin	600 mg daily	
Clofazimine	50 mg daily	
ALTERNATIVE ANTIMICROBIAL AGENTS		
Minocycline, 100 mg daily, substituted for dapsone in individuals who do not tolerate this drug. It can also be used instead of clofazimine, although evidence of antiinflammatory activity against type 2 reactions is not as substantial.		
Clarithromycin, 500 mg daily, can be used as a substitute for any of the other drugs in a multiple-drug regimen.		
Ofloxacin, 400 mg daily, may be used in place of clofazimine, for adults. This is not recommended for children.		

RECOMMENDED LABORATORY TESTS AND FREQUENCY

	Initial visit	Second visit (1–2 Months)	3 Months	6 Months	12 Months	18 Months	24 Months
CBC + platelets	X	X	X	X	X	X	X
AST	X		X	X	X	X	X
ALT	X		X	X	X	X	X
Ca	X						
BUN	X						
Creatinine	X						
Bilirubin	X						
G6PD	X						
Hepatitis B							
Hepatitis C							

ALT, Alanine transaminase; *AST,* aspartate transaminase; *BUN,* blood urea nitrogen; *Ca,* calcium; *CBC,* complete blood count; G6PD, glucose-6-phosphate dehydrogenase; *WHO,* World Health Organization.

TABLE 17.3 World Health Organization Treatment Guidelines

ADULTS		
Single Skin Lesion Paucibacillary Leprosy		
Agent	**Dose**	**Duration**
Rifampicin Ofloxacin Minocycline	600 mg 400 mg 100 mg	Single dose
ADULTS		
Tuberculoid (TT and BT) (WHO Classification Paucibacillary, "Pb")		
Agent	**Dose**	**Duration**
Dapsone	100 mg daily	6 months
Rifampicin	600 mg monthly	
ADULTS		
Lepromatous (LL, BL, BB) (WHO Classification Multibacillary, "Mb")		
Agent	**Dose**	**Duration**
Dapsone	100 mg daily	12 months
Rifampicin	600 mg monthly	
Clofazimine	300 mg monthly and 50 mg daily	

WHO, World Health Organization.

The WHO defines paucibacillary disease as the presence of no bacilli on smears or biopsy and ≤5 lesions. Alternative regimens have been suggested for patients with compromised immunity and in those with multibacillary disease with a very high bacterial load. Therapies consist of an intensive regimen for 6–12 months that can be followed by a continuous phase for another 18 months. Rifapentine, 900 mg, appears superior to rifampin in these combinations. Proposed newer "intensive" drug regimens for rifampin-sensitive multibacillary patients include rifapentine, 900 mg; moxifloxacin, 400 mg; and clarithromycin, 1000 mg (or minocycline, 200 mg), all once monthly for 12 months. For rifampin-resistant patients, moxifloxacin, 400 mg; clofazimine, 50 mg; clarithromycin, 500 mg; and minocycline, 100 mg, are given daily, supervised for 6 months. The continuous phase of treatment could comprise moxifloxacin, 400 mg; clarithromycin, 1000 mg; and minocycline, 200 mg, once monthly, supervised for an additional 18 months.

Drug resistance is widespread and has even recently been reported in the United States. It should be suspected if the patient fails to respond to treatment. There are currently available PCR techniques to detect drug resistance from biopsy specimens based on known mutations such as those DNA gyrase responsible for quinolone resistance.

At the end of treatment, visible skin lesions are often still present, especially with the WHO short-duration treatments. Paucibacillary lesions tend to clear 1–2 years after the 6-month treatment course. In the United States treatment could be continued until skin lesions are clear, even if the recommended duration of treatment has been passed. With short-duration MDT, it is very difficult to distinguish clinical relapse (failure of treatment) from late type 1 reactions causing skin lesions to reappear. Pathologic examination (biopsy) or an empiric trial of prednisone for several months may be considered in these patients.

Significant disagreement surrounds the effectiveness of the 1-year or 2-year WHO-recommended MDT regimens. Relapse rates for multibacillary patients treated with MDT for 1 or 2 years have been reported to be as high as 7%–20% overall, and 13%–39% with BI of 4 or greater at diagnosis. Based on this information, patients with BL/LL disease with a BI of 4 or greater are at highest risk for relapse and should be treated beyond the 1-year recommended period, with treatment continued until smear negativity.

Treatment of Hansen disease patients with effective antibiotic regimens usually does not result in regaining of neurologic deficits. When deficits do recover, it appears to be mostly from elimination of the perineural inflammation, rather than regeneration of the affected nerves. Therefore early treatment of patients when neurologic defects are minimal and aggressive treatment of type 1 reactions are the key to limiting neural damage in Hansen disease.

Adjunctive Treatments

Once neurologic complications have occurred, patients with Hansen disease should be offered occupational therapy. This should include training on how to avoid injury to insensitive skin of the hands and feet. Special shoes may be required. Ocular complications are common, and an ophthalmologist with specific skill in treating patients with Hansen disease is an invaluable member of the treatment team.

MANAGEMENT OF REACTIONS

Even though reactions may appear after drug treatment is instituted, it is not advisable to discontinue or reduce antileprosy medication because of these. In mild reactions—those without neurologic complications or severe systemic symptoms or findings—treatment may be supportive. Bed rest and administration of aspirin or nonsteroidal antiinflammatory drugs may be used.

Type 1 reactions are usually managed with systemic corticosteroids. Prednisone is given orally, starting at a dose of 40–60 mg/day. Neuritis and eye lesions are urgent indications for systemic steroid therapy. Nerve abscesses may also need to be surgically drained immediately to preserve and recover nerve function. The corticosteroid dose and duration are determined by the clinical course of the reaction. Once the reaction is controlled, the prednisone may need to be tapered slowly, over months to years. The minimum dose required and alternate-day treatment should be used in corticosteroid courses more than 1 month in duration. Clofazimine appears to have some activity against type 1 reactions and may be added to the treatment in doses of up to 300 mg/day if tolerated. Cyclosporine can be used if steroids fail or as a steroid-sparing agent. The starting dose would be 5–10 mg/kg. If during treatment the function of some nerves fails to improve while the function of others normalizes, the possibility of mechanical compression should be evaluated by surgical exploration. Transposition of the ulnar nerve does not seem to be more effective than immunosuppressive treatment for ulnar nerve dysfunction.

Thalidomide has been demonstrated to be uniquely effective against ENL and is the treatment of choice. The initial recommended dosage is up to 400 mg/day in patients weighing more than 50 kg. This dose is highly sedating in some patients, and patients may complain of central nervous system side effects, even at doses of 100 mg/day. For this reason, such a high dose should be used for only a brief period, or in milder cases, treatment may be started at a much lower dose, such as 100–200 mg/day. In patients with an acute episode of ENL, the drug may be discontinued after a few weeks to months. In chronic type 2 reactions, an attempt to discontinue the drug should be made every 6 months. Thalidomide is a potent teratogen and should not be given to women of childbearing age. Long-term use is associated with predominantly sensory neuropathy, and even short-term use is associated with a risk of thromboembolic phenomena, as well as constipation. Systemic corticosteroids are also effective in type 2 reactions, but long-term use may lead to complications. Clofazimine in higher doses, up to 300 mg/day, is effective in ENL and may be used alone or to reduce corticosteroid or thalidomide doses. The combination of pentoxifylline, 400–800 mg twice daily, and clofazimine, 300 mg/day, can be given to patients with ENL when thalidomide cannot be used or to avoid the use of systemic steroids to manage severe ENL. Pentoxifylline alone is inferior to steroids and thalidomide but can be considered in milder cases. TNF inhibitors have been reported to be effective in treating recurrent ENL.

Lucio phenomenon is poorly responsive to both corticosteroids and thalidomide. Effective antimicrobial chemotherapy for lepromatous leprosy is the only recommended treatment, combined with wound management for leg ulcers.

PREVENTION

Because a defect in cell-mediated immunity is inherent in the development of Hansen disease, vaccine therapies are being tested. Bacille Calmette-Guérin (BCG) vaccination alone provides about 34%–80% protection against *M. leprae* infection, Other vaccines have been produced, but it is unclear if vaccine will be needed except in the areas of highest endemicity, because MDT has been effective in reducing the prevalence of Hansen disease. Because 80% of patients have contact with multibacillary patients, prevention depends on treating active multibacillary patients and examining exposed persons on an annual basis to detect early evidence of infection. Prophylactic antibiotic regimens have been used in such exposed patients and demonstrate a reduction in new Hansen disease cases by more than 50% in the first 2 years. Patients who had less contact with the source patient benefited more. In the United Kingdom, close contacts under age 12 whose source case was lepromatous are given rifampin, 15 mg/kg once monthly for

6 months. Several trials of chemoprophylaxis in whole endemic regions (once-yearly MDT with single-dose rifampin, minocycline, and clofazimine) have shown early promise and may be useful in hyperendemic regions.

18 Syphilis, Yaws, Bejel, and Pinta

Bonus images for this chapter can be found online at expertconsult.inkling.com.

SYPHILIS

Syphilis, also known as lues, is a contagious, sexually transmitted disease caused by the spirochete *Treponema pallidum* subspecies *pallidum*. The only known host is the human. The spirochete enters through the skin or mucous membranes, where the primary manifestations are seen. In congenital syphilis, the treponeme crosses the placenta and infects the fetus. The risk of acquiring infection from sexual contact with an infected partner in the previous 30 days is 16%–30%. Syphilis results in multiple patterns of skin and visceral disease and can be lifelong.

Syphilis, yaws, pinta, and endemic syphilis are closely related infectious conditions caused by "genetically monomorphic bacteria," with less than 2% difference in the genomes of the treponemes (treponemas) that cause these infections. Historically, yaws first arose with humans in Africa and spread with human migrations to Europe and Asia. Endemic syphilis evolved from yaws and became endemic in the Middle East and the Balkans at some later date. Yaws moved with human migration to the New World and became endemic in South America. Syphilis, *T. pallidum pallidum*, may have originated in the New World from *T. pallidum pertenue*, the organism causing yaws, much as human immunodeficiency virus (HIV) evolved in Africa from simian immunodeficiency virus (SIV). A tribe in Guyana with a spirochetal infection with features of both yaws and syphilis was identified. Sequencing the genome of this spirochete suggested that it was the ancestor of *T. pallidum pallidum*. This lends support to the theory that syphilis originated more recently in the New World and was brought back to Europe by sailors who went to the New World with Christopher Columbus. Exactly how and when it became primarily a venereally transmitted disease is unclear, but apparently this happened toward the end of the 15th century.

Treponema pallidum is a delicate, spiral spirochete that is actively motile. The number of spirals varies from 4 to 14, and the entire length is 5–20 µm. It can be demonstrated in preparations from fresh primary or secondary lesions by darkfield microscopy or by fluorescent antibody techniques. The motility is characteristic, consisting of three movements: a projection in the direction of the long axis, a rotation on its long axis, and a bending or twisting from side to side. The precise uniformity of the spiral coils is not distorted during these movements. Microscopic characteristics of *T. pallidum* cannot be distinguished from commensal oral treponemes, so darkfield examination of oral lesions is unreliable. Direct fluorescent antibody testing can be used for confirmation.

The genome of *T. pallidum* has been sequenced and contains about one quarter of the number of genes of most bacteria. It lacks significant metabolic capacity. It is very sensitive to temperature, with some enzymes working poorly at typical body temperature (perhaps explaining why fever therapy was effective). These two factors may contribute to the inability to culture the organism in vitro. *T. pallidum* is an effective pathogen because it disseminates widely and rapidly after infection. It is in the bloodstream within hours of intratesticular injection and in numerous organs, including the brain, within 18 hours after inoculation. Once the organisms reach a tissue, they are able to persist for decades. In each tissue, the number of organisms is very low, perhaps below a "critical antigenic mass." In addition, *T. pallidum* expresses very few antigenic targets on its surface (only about 1% as many as *Escherichia coli*). The outer membrane proteins of *T. pallidum* also undergo rapid mutation, so that during an infection, the host accumulates numerous subpopulations of organisms with different surface antigens. This low infection load, widespread dissemination, poor surface antigen expression, and rapid evolution of antigenically distinct subpopulations may allow the infection to persist despite the development by the host of antigen-specific antibodies and immune cells.

Syphilis remains a major health problem worldwide, despite a highly effective and economical treatment for more than 50 years. The story of the U.S. and world epidemiology of syphilis illustrates a movement of infection from one population to another due to changing social conditions and behaviors. Just as the health systems respond to one epidemic, another appears. Using serologic testing, contact tracing, and penicillin treatment, U.S. health departments reduced the incidence of syphilis dramatically from the turn of the 20th century through the mid-1950s. The incidence then gradually increased through the next two decades and into the 1980s. In the early 1980s half the cases of syphilis diagnosed were in men who have sex with men (MSM). Changes in sexual behavior patterns among gay men in response to the acquired immunodeficiency syndrome (AIDS) epidemic reduced the number of these cases, but in the late 1980s syphilis again began to increase dramatically, associated with drug use, especially crack cocaine. The incidence of syphilis increased disproportionately among socioeconomically disadvantaged minority populations, especially in major cities. Throughout the 1990s the rate of syphilis fell in the United States, so that by 1999 the national rate of 2.6 cases in 100,000 population was the lowest level ever recorded. In addition, half of new cases were concentrated in 28 counties, mainly in the southeastern United States and in select urban areas. With the advent of effective antiretroviral therapy for HIV, there was a change in sexual behavior in MSM, including those with HIV infection. Epidemics of syphilis in this group have now occurred in many major North American, European, and Asian cities. This epidemic is characterized by an older average age, anonymous sex partners (often met on the Internet), use of amphetamines and sildenafil citrate (Viagra), HIV-positive status, and oral sex as the sole sexual exposure. In addition, there was a syphilis epidemic in Russia and the newly independent states starting in the late 1990s, with rates of syphilis 34 times that of Western Europe. Beginning in the mid-1990s, China had a syphilis epidemic affecting primarily unmarried men, female sex workers, and MSM, so that in 2008 one province in China (Guangdong) had more syphilis cases than the whole European Union.

Worldwide, an estimated 12 million persons are infected annually with syphilis, 2 million of whom are pregnant women. The U.S. Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have undertaken campaigns to eradicate syphilis. The shifting epidemiology of syphilis over more than five decades suggests it will not be an easy task without an effective vaccine. Until then, reporting of all cases to public health departments for tracing and treatment of contacts should be continued, along with widespread screening of persons at risk, including all pregnant women, female sex workers, MSM, and men with HIV infection.

Serologic Tests

Serologic testing for infection with *T. pallidum*, as in tuberculosis, is undergoing changes that incorporate newer technologies into establishing the diagnosis. Tests are considered either "treponemal" or "nontreponemal." Treponemal tests detect specific antitreponemal antibodies by enzyme immunoassay (EIA) or *T. pallidum* particle assay (TPPA). These new treponemal tests have specificity and sensitivity exceeding 95%, even in patients with primary syphilis. These generate more positive tests that require further testing than do older strategies. Nontreponemal tests are based on the fact that serum of persons with syphilis aggregates a cardiolipin-cholesterol-lecithin antigen. This aggregation can be viewed directly in tubes or on cards or slides, or it can be examined in an autoanalyzer. Because these tests use lipoidal antigens rather than *T. pallidum* or its components, they are called nontreponemal antigen tests. The most widely used nontreponemal tests are the rapid plasma reagin (RPR) and Venereal Disease Research Laboratories (VDRL) tests. These nontreponemal tests are the standard tests used in the United States and generally become positive within 5–6 weeks of infection, shortly before the chancre heals. Tests are usually strongly positive throughout the secondary phase, except in rare patients with AIDS, whose response is less predictable, and usually become negative during therapy, especially if therapy is begun within the first year of infection. Results may also become negative after a few decades, even without treatment. EIA tests are available that detect both immunoglobulin G (IgG)– and immunoglobulin M (IgM)–specific antibodies against *T. pallidum*. The IgM becomes detectable 2–3 weeks after infection, about the time the chancre appears. The IgG test becomes positive at 4–5 weeks; thus the IgM test is much more useful in diagnosing primary syphilis. The "treponemal" tests used in the United States are the microhemagglutination assay for *T. pallidum* (MHA-TP) or the fluorescent treponemal antibody absorption (FTA-ABS) test. These specific treponemal tests are also positive earlier than the nontreponemal tests and may be used to confirm the diagnosis of primary syphilis in a patient with a negative RPR/VDRL. The EIA, TPPA, FTA-ABS, and MHA-TP remain positive for life in the majority of patients, although in 13%–24% of patients these tests will become negative with treatment, regardless of stage and HIV status. The IgM EIA test, however, becomes negative after treatment in early syphilis, so that at 1 year 92% of these patients are negative on the IgM EIA.
