All these tests can have false-positive results, so all positive results are confirmed by another test. In most U.S. cities, this involves screening the patient with a nontreponemal test, usually an RPR, and confirming all positives with a specific treponemal test, usually an MHA-TP. If a treponemal test, such as the TPPA or EIA, is used for initial screening, either a nontreponemal test or the other, specific treponemal test should be used to confirm the first test. A nontreponemal RPR/VDRL is also performed on all positives to determine the titer and monitor treatment success. If the initial screening treponemal-specific test is positive, but the nontreponemal test is negative, a history of prior syphilis and treatment should be sought. If prior syphilis and adequate treatment can be documented, and if examination shows no evidence of either primary or late syphilis, the patient is followed and considered serofast after treatment. If the nontreponemal test is negative, but a second treponemal test is positive, and if no prior history of syphilis and its treatment can be found, the patient is considered to have late latent syphilis (less likely, recent infection) and is treated appropriately. This patient is considered noninfectious. If the two treponemal tests are discordant, one positive and the other negative, a third treponemal-specific test can be ordered, or the case can be referred to a public health department for expert consultation. Because the nontreponemal tests are falsely negative in 25% or more of patients with primary syphilis and in up to 40% with late syphilis, in these patients a specific treponemal test should also be performed as a screening test.

In resource-poor countries, serologic testing for syphilis is largely unavailable because reagents require refrigeration or the tests require electrical equipment for processing. In Bangladesh and in some countries in sub-Saharan Africa and South America, more than 75% of women receive prenatal care, but only about 40% receive prenatal syphilis screening. Syphilis is endemic in these regions, with infection rates in pregnant women exceeding 1%, and thus millions of pregnant women with syphilis go undiagnosed. More than half a million babies die of congenital syphilis in sub-Saharan Africa every year. New, rapid treponemal-specific tests that can be used in these resource-poor countries have been developed. They cost only $0.31–$0.41 (U.S.) per test and await available funding to be put into use.

Nontreponemal tests are very valuable in following the efficacy of treatment in syphilis. By diluting the serum serially, the strength of the reaction can be stated in dilutions; the number given is the highest dilution giving a positive test result. In primary infection, the titer may be only 1:2; in secondary syphilis, it is regularly high, 1:32 to 1:256, or higher; in late syphilis, generally much lower, perhaps 1:4 or 1:8. The rise of titer in early infection is of great potential diagnostic value, as is the fall after proper treatment or the rise again if there is reinfection or relapse. Patients with very high antibody titers, as occur in secondary syphilis, may have a false-negative result when undiluted serum is tested. This "prozone" phenomenon will be overcome by diluting the serum.

Biologic False-Positive Test Results

"Biologic false-positive" (BFP) test result is used to denote a positive serologic test for syphilis in persons with no history or clinical evidence of syphilis. The term *BFP* is usually applied to the situation of a positive nontreponemal test and a negative treponemal test. About 90% of BFP test results are of low titer (<1:8). "Acute" BFP reactions are defined as those that revert to negative in less than 6 months; those that persist for more than 6 months are categorized as "chronic." Acute BFP reactions may result from vaccinations, infections (infectious mononucleosis, hepatitis, measles, typhoid, varicella, influenza, lymphogranuloma venereum, malaria), and pregnancy. Chronic BFP reactions are seen in connective tissue diseases, especially systemic lupus erythematosus (SLE) (44%), chronic liver disease, multiple blood transfusions/intravenous drug use, and advancing age.

False-positive results to specific treponemal tests are less common but have been reported to occur in lupus erythematosus, drug-induced lupus, scleroderma, rheumatoid arthritis, smallpox vaccination, pregnancy, other related treponemal infections (see next), and genital herpes simplex infections. A pattern of beaded fluorescence associated with FTA-ABS testing may be found in the sera of patients without treponemal disease who have SLE. The beading phenomenon, however, is not specific for SLE or even for connective tissue diseases.

Cutaneous Syphilis

Chancre (Primary Stage)

The chancre is usually the first cutaneous lesion, appearing 18–21 days after infection. The typical incipient chancre is a small red papule or a crusted superficial erosion. In a few days to weeks, it becomes a round or oval, indurated, slightly elevated papule, with an eroded but not ulcerated surface that exudes a serous fluid (Fig. 18.1). On palpation, it has a cartilage-like consistency. The lesion is usually, but not invariably, painless. This is the uncomplicated or classic hunterian chancre. The regional lymph nodes on one or both sides are usually enlarged, firm, and nontender and do not suppurate. Adenopathy begins 1 or 2 weeks after the

Fig. 18.1 Primary syphilis.

Fig. 18.2 Primary syphilis.

chancre appears. The hunterian chancre leaves no scar when it heals.

Chancres generally occur singly, although they may be multiple, especially on the penis in MSM who are infected through oral intercourse. The lesions vary in diameter from a few millimeters to several centimeters. The genital chancre is less often observed in women because of its location within the vagina or on the cervix (Fig. 18.2). Extensive edema of the labia or cervix may occur. In men, the chancre is commonly located in the coronal sulcus or on either side of the frenum. A chancre in the prepuce, being too hard to bend, will flip over all at once when the prepuce is drawn back, a phenomenon called a "dory flop" (resembling a broad-beamed skiff or dory being turned upside down). Untreated,

Fig. 18.3 Primary syphilis, chancre on shoulder with secondary lesions present.

the chancre tends to heal spontaneously in 1–4 months. About the time it disappears, or slightly before, constitutional symptoms and objective signs of generalized (secondary) syphilis occur (Fig. 18.3).

Extragenital chancres may be larger than those on the genitalia. They affect the lips, tongue, tonsil, female breast, index finger, and, especially in MSM, the anus. Oral chancres form firm, eroded papules on the lip, tongue, uvula, or tonsillar pillar and are associated with a history of oral sex. Unilateral cervical adenopathy can be present. The presenting complaints of an anal chancre include an anal sore or fissure and irritation or bleeding on defecation. Anal chancre must be ruled out in any anal fissure not at the 6 or 12 o'clock positions. When there is a secondary eruption, no visible chancre, and the glands below Poupart ligament are greatly enlarged, anal chancre should be suspected.

Atypical chancres are common. Simultaneous infection by a spirochete and another microbial agent may produce an atypical chancre. The mixed chancre caused by infection with *Haemophilus ducreyi* and *Treponema pallidum* will produce a lesion that runs a course different from either chancroid or primary syphilis alone. Such a sore begins a few days after exposure, because the incubation period for chancroid is short, and later the sore may transform into an indurated syphilitic lesion. A phagedenic chancre results from the combination of a syphilitic chancre and contaminating bacteria that may cause severe tissue destruction and result in scarring. Edema indurativum, or penile venereal edema, is marked solid edema of the labia or the prepuce and glans penis accompanying a chancre. Chancre redux is relapse of a chancre with insufficient treatment, accompanied by enlarged lymph nodes. Pseudochancre redux is a gumma occurring at the site of a previous chancre; it is distinguished from relapsing chancre by the absence of lymphadenopathy and a negative darkfield examination. Syphilitic balanitis of Follmann may occur in the absence of a chancre. The lesions may be exudative, circinate, or erosive.

Histologic evaluation of a syphilitic chancre reveals an ulcer covered by neutrophils and fibrin. Subjacent, there is a dense infiltrate of lymphocytes and plasma cells. Blood vessels are prominent with plump endothelial cells. Spirochetes are numerous in untreated chancres and can be demonstrated with an appropriate silver stain, such as the Warthin-Starry, Levaditi, or Steiner methods, or by immunoperoxidase staining. Spirochetes are best found in the overlying epithelium or adjacent or overlying blood vessels in the upper dermis.

In a patient who presents with an acute genital ulceration, darkfield examination should be performed if available. The finding of typical *T. pallidum* in a sore on the cutaneous surface establishes

a diagnosis of syphilis. *Treponema pertenue*, which causes yaws, and *Treponema carateum*, which causes pinta, are both indistinguishable morphologically from *T. pallidum*, but the diseases that they produce are usually easy to recognize. Commensal spirochetes of the oral mucosa are indistinguishable from *T. pallidum*, making oral darkfield examinations unreliable. If the darkfield examination results are negative, the examination should be repeated daily for several days, especially if the patient has been applying a topical antibacterial agent.

The lesion selected for examination is cleansed with water and dried. It is grasped firmly between the thumb and index finger and abraded sufficiently to cause clear or faintly blood-stained plasma to exude when squeezed. In the case of an eroded chancre, a few vigorous rubs with dry gauze are usually sufficient. If the lesion is made to bleed, it is necessary to wait until free bleeding has stopped to obtain satisfactory plasma. The surface of a clean coverslip is touched to the surface of the lesion so that plasma adheres. Then it is dropped on a slide and pressed down so that the plasma spreads out in as thin a film as possible. Immersion oil forms the interface between the condenser and slide and between the coverslip and objective. The specimen must be examined quickly, before the thin film of plasma dries.

An alternative to darkfield microscopy is the direct fluorescent antibody test (DFAT-TP) for the identification of *T. pallidum* in lesions. Serous exudate from a suspected lesion is collected as just described, placed on a slide, and allowed to dry. Many health departments will examine such specimens with fluorescent antibodies specific to *T. pallidum*. The method, unlike the darkfield examination, can be used for diagnosing oral lesions. Multiplex polymerase chain reaction (PCR) is also an accurate and reproducible method for diagnosing genital ulcerations, with the advantage of being able to diagnose multiple infectious agents simultaneously. In genital ulcer disease outbreaks, PCR should be made available.

The results of serologic tests for syphilis are positive in 75% (nontreponemal tests) to 90% (treponemal tests) of patients with primary syphilis; both these tests should be performed in every patient with suspected primary syphilis. The likelihood of positivity depends on the duration of infection. If the chancre has been present for several weeks, test results are usually positive.

A syphilitic chancre must be differentiated from chancroid. The chancre has an incubation period of 3 weeks; is usually a painless erosion, not an ulcer; has no surrounding inflammatory zone; and is round or oval. The edge is not undermined, and the surface is smooth and at the level of the skin. It has a dark, velvety red, lacquered appearance; it has no overlying membrane; and it is cartilage hard on palpation. Lymphadenopathy may be bilateral and is nontender and nonsuppurative. Chancroid, on the other hand, has a short incubation period of 4–7 days; the ulcer is acutely inflamed, is extremely painful, and has a surrounding inflammatory zone. The ulcer edge is undermined and extends into the dermis. It is covered by a membrane and feels soft. Lymphadenopathy is usually unilateral and tender and may suppurate. Chancroid lesions are usually multiple and extend into each other. Cultures for chancroid on special media confirm the diagnosis. However, because a combination of a syphilitic chancre and chancroid (mixed sores) is indistinguishable from chancroid alone, appropriate direct and serologic testing should be performed to investigate the presence of syphilis. Again, multiplex PCR allows for the simultaneous diagnosis of many infectious agents in genital ulcer diseases.

The primary lesion of granuloma inguinale begins as an indurated nodule that erodes to produce hypertrophic, vegetative granulation tissue. It is soft and beefy-red and bleeds readily. A smear of clean granulation tissue from the lesion stained with Wright or Giemsa reveals Donovan bodies in the cytoplasm of macrophages.

The primary lesion of lymphogranuloma venereum (LGV) is usually a small, painless, transient papule or a superficial nonindurated ulcer. It most often occurs on the coronal sulcus, prepuce, or glans in men or on the fourchette, vagina, or cervix in women. A primary genital lesion is noticed by about 30% of infected heterosexual men, but less frequently in women. Primary lesions are followed in 7–30 days by adenopathy of the regional lymph nodes. LGV is confirmed by serologic tests.

Herpes simplex begins with grouped vesicles, often accompanied or preceded by burning pain. After rupture of the vesicles, irregular, scalloped, tender, soft erosions form.

Secondary Syphilis

Cutaneous Lesions. The skin manifestations of secondary syphilis occur in 80% or more of patients with secondary syphilis. The early eruptions are symmetric, more or less generalized, superficial, nondestructive, exanthematous, transient, and macular; later they are maculopapular or papular eruptions, which are usually polymorphous, and less often, scaly, pustular, or pigmented. The early manifestations tend to be distributed over the face, shoulders, flanks, palms and soles, and anal or genital regions. The severity varies widely. The presence of lesions on the palms and soles is strongly suggestive. However, a generalized syphilid can spare the palms and soles. The individual lesions are generally less than 1 cm in diameter, except in the later secondary or relapsing secondary eruptions.

Macular Eruptions. The earliest form of macular secondary syphilis begins with the appearance of an exanthematous erythema 6–8 weeks after the development of the chancre, which may still be present. The syphilitic exanthem extends rapidly, so that it is usually pronounced a few days after onset. It may be evanescent, lasting only a few hours or days, or it may last several months, or partially recur after having disappeared. This macular eruption appears first on the sides of the trunk, about the navel, and on the inner surfaces of the extremities.

Individual lesions of macular secondary syphilis consist of round, indistinct macules that are nonconfluent and rarely may be slightly elevated or urticarial. The color varies from a light pink or rose to brownish red. The macular eruption may not be noticed on black skin and may be so faint that it is also not recognized on other skin colors. Pain, burning, and itching are usually absent, although pruritus may be present in 10%–40% of patients. Simultaneous with the onset of the eruption, there is a generalized shotty adenopathy, most readily palpable in the posterior cervical, axillary, and epitrochlear areas. Rarely, secondary syphilis may cause livedo reticularis. The macular eruption may disappear spontaneously after a few days or weeks without residua or may result in postinflammatory hyperpigmentation. After a varying interval, macular syphilis may be followed by other eruptions.

Papular Eruptions. Papular eruptions usually arise slightly later than the macular eruption. The fully developed lesions are round and of a raw-ham or coppery shade (Fig. 18.4). Although papules most frequently are 2–5 mm in diameter, nodules coalescing to large plaques can occur. Lesions often are only slightly raised, but a deep, firm infiltration is palpable. The surface is smooth, sometimes shiny, and at other times covered with a thick, adherent scale. When this desquamates, it leaves a characteristic collarette of scales overhanging the border of the papule.

Papules are frequently distributed on the face and flexures of the arms and lower legs and are often distributed all over the trunk (Fig. 18.5). Palmar and plantar involvement characteristically appears as indurated, yellowish red spots (Fig. 18.6). Ollendorf (Buschke-Ollendorff) sign is present; the papule is exquisitely tender to the touch of a blunt probe. Healing lesions frequently leave hyperpigmented spots that, especially on the palms and soles, may persist for weeks or months. Split papules are hypertrophic, fissured papules that form in the creases of the alae nasi and at the oral commissures. These may persist for a long period. The papulosquamous syphilids, in which the adherent scales covering

Fig. 18.4 Secondary syphilis.

Fig. 18.5 Secondary syphilis.

Fig. 18.6 Secondary syphilis.

Fig. 18.7 Annular secondary syphilis.

the lesions more or less dominate the picture, may produce a psoriasiform eruption. Follicular or lichenoid syphilids appear as minute, scale-capped papules. If they are at the ostia of hair follicles, syphilids are likely to be conical; elsewhere on the skin, they are domed. Often, syphilids are grouped to form scaling plaques in which the tiny, coalescing papules are still discernible.

As with the other syphilids, papular eruptions tend to be disseminated but may also be localized, asymmetric, configurate, hypertrophic, or confluent. The arrangement may be corymbose or in patches, rings, or serpiginous patterns.

The annular syphilid, as with sarcoidosis, which it may mimic, is more common in blacks (Fig. 18.7). It is often located on the cheeks, especially close to the angle of the mouth, where it may form annular, arcuate, or gyrate patterns of delicate, slightly raised, infiltrated, finely scaling ridges. These ridges are made up of minute, flat-topped papules, and the boundaries between ridges may be difficult to discern. An old term for annular syphilids was "nickels and dimes."

The corymbose syphilid is another infrequent variant, usually occurring late in the secondary stage, in which a large central papule is surrounded by a group of tiny satellite papules. The pustular syphilids are among the rarer manifestations of secondary syphilis. They occur widely scattered over the trunk and extremities, but they usually involve the face, especially the forehead. The pustule usually arises on a red, infiltrated base. Involution is usually slow, resulting in a small, rather persistent, crust-covered, superficial ulceration. Lesions in which the ulceration is deep are called ecthymatous. Closely related is the rupial syphilid, a lesion in which a relatively superficial ulceration is covered with a pile of terraced crusts resembling an oyster shell. Lues maligna is a rare form of secondary syphilis with severe ulcerations, pustules, or rupioid lesions, accompanied by severe constitutional symptoms. This form of secondary syphilis appears to be more common in HIV-infected men.

Involvement of the palms and soles is a characteristic feature of secondary syphilis. In some cases, instead of discrete lesions, the whole area of the palms and soles can be symmetrically involved, resembling keratoderma blennorrhagicum, hyperkeratotic hand eczema, or even an acquired keratoderma, such as Howel-Evans syndrome. Similarly, cutaneous lesions can be very psoriasiform,

Fig. 18.8 Condylomata lata.

and if they develop in a person with known psoriasis, lesions can be mistaken for a flare of that disease. Anetoderma may occur after treatment of secondary syphilis.

Condylomata lata are papular lesions, relatively broad and flat, located on folds of moist skin, especially around the genitalia and anus, but also at the angles of the mouth, nasolabial fold, and toe webs. They may become hypertrophic and, instead of infiltrating deeply, protrude above the surface, forming a soft, red, often mushroom-like mass 1–3 cm in diameter, usually with a smooth, moist, weeping, gray surface (Fig. 18.8). Condyloma lata may be lobulated but are not covered by the digitate elevations characteristic of venereal warts (condylomata acuminata). Secondary syphilis may initially present with perianal erosions and plaques that may mimic cutaneous Crohn disease.

Syphilitic alopecia is irregularly distributed so that the scalp has a moth-eaten appearance. It is unusual, occurring in about 5% of patients with secondary syphilis. Smooth, circular areas of alopecia mimicking alopecia areata may occur in syphilis, and an ophiasis pattern may rarely be seen.

Mucous membrane lesions are present in one third of patients with secondary syphilis and may be the only manifestation of the infection. The most common mucosal lesion in the early phase is the syphilitic sore throat, a diffuse pharyngitis that may be associated with tonsillitis or laryngitis. Hoarseness and sometimes complete aphonia may be present. On the tongue, smooth, small or large, well-defined patches devoid of papillae may be seen, most frequently on the dorsum near the median raphe (Fig. 18.9). Ulcerations may occur on the tongue and lips during the late secondary period, at times resembling aphthae or major aphthae. A rare variant of syphilis is one presenting with oral and cutaneous erosions that histologically show the features of pemphigus vulgaris, with a suprabasilar acantholytic blister, as well as positive direct and indirect immunofluorescence findings of pemphigus.

Mucous patches are the most characteristic mucous membrane lesions of secondary syphilis. They are macerated, flat, grayish, rounded erosions covered by a delicate, soggy membrane. These highly infectious lesions are about 5 mm in diameter and teem with treponemas. They occur on the tonsils, tongue, pharynx, gums, lips, and buccal areas or on the genitalia, chiefly in women,

Fig. 18.9 Mucous patches of secondary syphilis.

in whom the lesions are most common on the labia minora, vaginal mucosa, and cervix. Such mucous erosions are transitory and change from week to week, or even from day to day. Lesions of the oral mucosa frequently contain plasma cells, so the oral pathologist may not consider syphilis. Because the oral lesions of secondary syphilis are usually teeming with spirochetes, a *T. pallidum*–specific immunoperoxidase stain is useful in confirming the diagnosis.

Relapsing Secondary Syphilis. The early lesions of syphilis undergo involution either spontaneously or with treatment. Relapses occur in about 25% of untreated patients, 90% within the first year. Such relapses may take place at the site of previous lesions, on the skin or in the viscera. Recurrent eruptions tend to be more configurate or annular, larger, and asymmetric.

Systemic Involvement. The lymphatic system in secondary syphilis is characteristically involved. The lymph nodes most frequently affected are the inguinal, posterior cervical, postauricular, and epitrochlear. The nodes are shotty, firm, slightly enlarged, nontender, and discrete.

Acute glomerulonephritis, gastritis or gastric ulceration, proctitis, hepatitis, acute meningitis, unilateral sensorineural hearing loss, iritis, anterior uveitis, optic neuritis, Bell palsy, multiple pulmonary nodular infiltrates, periostitis, osteomyelitis, polyarthritis, and tenosynovitis may all be seen in secondary syphilis.

Histopathology

Lesions of secondary syphilis may demonstrate neutrophils within the stratum corneum, elongation of rete ridges, interface dermatitis with a lymphocyte in every vacuole, an interstitial infiltrate (busy dermis), perivascular plasma cells, lymphocytes with visible amphophilic cytoplasm, and endothelial swelling (plump endothelial cells with absence of a lumen). Plasma cells are absent about 30% of cases, and many cases lack other characteristic features as well. Examples of syphilis with fewer histologic features are more likely to demonstrate effacement of the rete pattern rather than elongation of the rete ridges. A high index of suspicion is required, and any combination of interface dermatitis, interstitial inflammation, endothelial swelling, lymphocytes with visible cytoplasm, or plasma cells should raise the possibility of secondary syphilis. As lesions age, macrophages become more numerous, so that in late secondary lues, granulomatous foci are often present, mimicking sarcoidosis, or less often, a granuloma annulare–like pattern. Condylomata lata show spongiform pustules within areas of papillated epithelial hyperplasia, and spirochetes are numerous.

In early-syphilis skin lesions, spirochetes are most numerous within the epidermis and around superficial vessels. Silver stains

are technically difficult, but because the number of organisms is high in early syphilis, the tests are usually positive. PCR and immunoperoxidase assay may identify *T. pallidum* infection when silver stains are negative. However, immunoperoxidase stains may be negative and silver stains positive; therefore if suspicion of early syphilis is high, both silver stains and immunoperoxidase assays may need to be performed.

Diagnosis and Differential Diagnosis

Syphilis has long been known as the "great imitator," because the various cutaneous manifestations may simulate almost any cutaneous or systemic disease. Pityriasis rosea may be mistaken for secondary syphilis, especially because both begin on the trunk. The herald patch, the oval patches with a fine scale at the edge, patterned in the lines of skin cleavage, the absence of lymphadenopathy, and infrequent mucous membrane lesions help to distinguish pityriasis rosea from secondary syphilis. Drug eruptions may produce a similar picture to secondary syphilis but tend to be morbilliform and also pruritic, whereas secondary syphilis is not. Drug eruptions in pityriasis rosea are often pruritic, whereas those in secondary syphilis usually are not.

Lichen planus may resemble papular syphilid. The characteristic papule of lichen planus is flat topped and polygonal, has Wickham striae, and exhibits Koebner phenomenon. Pruritus is severe in lichen planus but is less common and less severe in syphilis. Psoriasis may be distinguished from papulosquamous secondary syphilis by the presence of adenopathy, mucous patches, and alopecia in the latter. Sarcoidosis may produce lesions morphologically identical to secondary syphilis. Histologically, multisystem involvement, adenopathy, and granulomatous inflammation are common to both diseases. Serologic testing and biopsy specimens will distinguish sarcoidosis from syphilis.

The differential diagnosis of mucous membrane lesions of secondary syphilis is of importance. Infectious mononucleosis may cause a biologic false-positive test for syphilis but is diagnosed by serology. Geographic tongue may be confused with the desquamative patches of syphilis or with mucous patches. Lingua geographica occurs principally near the edges of the tongue in relatively large areas, which are often fused and have lobulated contours. It continues for several months or years and changes in extent and degree of involvement from day to day. Recurrent aphthous ulceration produces one or several painful ulcers, 1–3 mm in diameter, surrounded by hyperemic edges, with a grayish covering membrane, on nonkeratinized mucosal epithelium, especially in the gingival sulcus. A prolonged, recurrent history is characteristic. Syphilis of the lateral tongue may resemble oral hairy leukoplakia.

Latent Syphilis

After the lesions of secondary syphilis have involuted, a latent period occurs. This may last for a few months or continue for the remainder of the infected person's life. Between 60% and 70% of untreated infected patients remain latently asymptomatic for life. During this latent period, there are no clinical signs of syphilis, but the serologic tests for syphilis are reactive. During the early latent period, infectivity persists; for at least 2 years, a woman with early latent syphilis may infect her unborn child. For treatment purposes, it is important to distinguish early latency (<1-year duration) from late latency (>1 year or unknown duration).

Late Syphilis

For treatment purposes, late syphilis is defined by the CDC as infection of more than 1 year in duration and by the WHO as more than 2 years in duration. Only about one third of patients with late syphilis will develop complications of their infection.

Tertiary Cutaneous Syphilis

Tertiary syphilids most often occur 3–5 years after infection. About 16% of untreated patients will develop tertiary lesions of the skin, mucous membrane, bone, or joints. Skin lesions tend to be localized, to occur in groups, to be destructive, and to heal with scarring. Treponemas are usually not found by silver stains or darkfield examination but may be demonstrated by immunoperoxidase techniques.

Two main types of cutaneous tertiary syphilis are recognized, the nodular syphilid and the gumma, although the distinction is sometimes difficult to make. The nodular, noduloulcerative, or tubercular type consists of firm, reddish brown or copper-colored papules or nodules, 2 mm in diameter or larger. The individual lesions are usually covered with adherent scales or crusts (Fig. 18.10). The lesions tend to form rings and to undergo involution as new lesions develop just beyond them, producing characteristic circular or serpiginous patterns. A distinctive type is the kidney-shaped lesion, which typically occurs on the extensor surfaces of the arms and on the back. Individual lesions are composed of nodules in different stages of development, so that scars and pigmentation often are found together with fresh as well as ulcerated lesions. On the face, the nodular eruption closely resembles lupus vulgaris. When the disease is untreated, the process may last for years, slowly marching across large areas of skin. The nodules may enlarge and eventually break down to form painless, rounded, smooth-bottomed ulcers a few millimeters deep. These punched-out ulcers arise side by side and form serpiginous syphilitic ulcers, palm sized in aggregate, enduring for many years (Fig. 18.11).

Fig. 18.10 Tertiary syphilis. (Courtesy Laura de Souza Lima Institute, Brazil.)

Fig. 18.11 Destruction of the central face in tertiary syphilis.

Gummas may occur as unilateral, isolated, single or disseminated lesions, or in serpiginous patterns resembling those of the nodular syphilid. They may be restricted to the skin or, originating in the deeper tissues, break down and secondarily involve the skin. The individual lesions, which begin as small nodules, slowly enlarge to several centimeters. Central necrosis is extensive and may lead to the formation of a deep, punched-out ulcer with steep sides and a gelatinous, necrotic base. Again, progression may take place in one area while healing proceeds in another. Perhaps the most frequent site of isolated gummas is the lower legs, where deep punched-out ulcers are formed, often in large, infiltrated areas. On the lower extremities, gummas are frequently mistaken for erythema induratum.

Lesions may be isolated to the mucous membranes, often the tongue, on which nonindurated punched-out ulcers occur. A superficial glossitis may cause irregular ulcers, atrophy of the papillae, and smooth, shiny scarring, a condition known as smooth atrophy. In interstitial glossitis, there is an underlying induration. In the advanced stages, tertiary syphilis of the tongue may lead to a diffuse enlargement (macroglossia). Perforation of the hard palate from gummatous involvement is a characteristic tertiary manifestation. It generally occurs near the center of the hard palate. Destruction of the nasal septum may also occur.

Histologically, nodular lesions of late syphilis usually have changes that resemble those of secondary lesions, with the addition of tuberculoid granulomas containing varying numbers of multinucleate giant cells. The epidermis is often atrophic rather than hyperplastic. In gummas, necrosis within granulomas and fibrosis occur as lesions resolve. Spirochetes are scant.

For diagnosis of late syphilis, clinicians rely heavily on specific treponemal tests. The nontreponemal tests, such as the VDRL and RPR, are positive in approximately 60% of patients. When there are mucous membrane lesions, for which a diagnosis of carcinoma must also be considered, histologic examination is performed. Darkfield examination is not indicated, because it is always negative. When not ulcerated, lesions of tertiary syphilis must be distinguished from malignant tumors, leukemids, and sarcoidosis. The ulcerated tertiary syphilids must be differentiated from other infections, such as scrofuloderma, atypical mycobacterial infection, and deep fungal infection. Wegener granulomatosis and ulcerated cutaneous malignancies must be considered. Histology and appropriate cultures may be required.

Late Osseous Syphilis

Occasionally, gummatous lesions involve the periosteum and the bone. Skeletal tertiary syphilis most often affects the head and face and the tibia. Late manifestations of syphilis may produce periostitis, osteomyelitis, osteitis, and gummatous osteoarthritis. Osteocope (bone pain), most often at night, is a suggestive symptom.

Syphilitic joint lesions also occur, with the Charcot joint being the most prevalent manifestation. These are often associated with tabes dorsalis and occur most frequently in men. Although any joint may be involved, the knees and ankles are most often affected. There is hydrops, then loss of the contours of the joint, hypermobility, and no pain. Joint lesion is readily diagnosed by x-ray examination.

Neurosyphilis

Central nervous system (CNS) infection can occur at any stage of syphilis, even the primary stage. Up to 100% of patients with syphilis may develop CNS infection, but in 80% it is spontaneously cleared by the immune system. This explains why most persons with CNS involvement have no symptoms. About one third of patients who do not spontaneously clear their CNS infection will develop symptomatic neurosyphilis. Finding cerebrospinal fluid (CSF) pleocytosis or a positive CSF-VDRL test has been used to confirm the diagnosis of CNS infection by *T. pallidum*. Unfortunately, a significant proportion of patients with CSF infection with *T. pallidum* will have a negative CSF-VDRL (46%) and nondiagnostic CSF pleocytosis (<20 white blood cells/μL) (33%). In patients with a negative CSF-VDRL but pleocytosis, FTA test can be performed on CSF, thought by many to be 100% sensitive but not specific for CNS syphilis. Combining this with flow cytometry to look for B cells in the CSF, which is 100% specific but only 40% sensitive, will allow the confirmation or exclusion of neurosyphilis in most patients with CSF pleocytosis. The likelihood of having CNS infection is 10-fold greater in persons with RPR of 1:32 or greater. HIV-negative persons with negative CSF examinations have almost no risk of developing neurosyphilis. However, CSF evaluations are not routinely performed in asymptomatic persons with early syphilis, so identifying those at risk for symptomatic neurosyphilis is problematic. *T. pallidum* CNS infection may also be strain dependent, and eventually, typing the infecting strain may predict those at highest risk for neurosyphilis.

Because CNS infection is common and the recommended treatments with benzathine penicillin do not reach treponemicidal levels in the CSF, persistent concern surrounds the failure to diagnose and treat asymptomatic neurosyphilis. Apparently, although treatment does not clear the spirochetes from the CSF, most non–HIV-infected persons are able to clear the CNS infection spontaneously. CSF evaluation is recommended in all patients with syphilis with any neurologic, auditory, or ophthalmic signs or symptoms, possibly resulting from syphilis, independent of stage or HIV status. In borderline cases, those with RPR of 1:32 or greater should have CSF evaluation. The indications for lumbar puncture in patients with coexistent HIV infection and early syphilis (<1 or 2 years' duration) remains unclear. The two factors predicting the likelihood of CNS infection are RPR of 1:32 or more and CD4 count of 350 cells/μL or less. Patients with latent syphilis or syphilis of unknown duration should have CSF evaluation if they are HIV positive or fail initial therapy, or if therapy other than penicillin is planned for syphilis of more than 1 year in duration. Patients with tertiary syphilis should have CSF evaluation before treatment to exclude neurosyphilis. An appropriate fall in the serum RPR after treatment for neurosyphilis predicts clearing of the CNS infection, so a repeat lumbar puncture after therapy is not required in HIV-negative or HIV-positive patients adequately treated for neurosyphilis.

Early Neurosyphilis. Early neurosyphilis is mainly meningeal, occurs in the 2 years of infection, and affects 1.4%–6% of untreated persons with syphilis. Meningeal neurosyphilis manifests as meningitis, with fever, headache, stiff neck, nausea, vomiting, cranial nerve disorders (loss of hearing, often unilateral, and facial weakness), photophobia, blurred vision, seizures, and delirium.

Meningovascular Neurosyphilis. Meningovascular neurosyphilis most frequently occurs 5–12 years after infection, affecting about 3% of untreated syphilis patients. It is caused by thrombosis of vessels in the CNS and presents, as in other CNS ischemic events, with acute onset of symptoms. Hemiplegia, aphasia, hemianopsia, transverse myelitis, and progressive muscular atrophy may occur. Cranial nerve palsies may also occur, such as eighth nerve deafness and eye changes. The eyes may show fixed pupils, Argyll Robertson pupils, or anisocoria.

Late (Parenchymatous) Neurosyphilis. Parenchymatous neurosyphilis tends to occur more than 10 years after infection. There are two classic clinical patterns: tabes dorsalis and general paresis.

Tabes dorsalis is the degeneration of the dorsal roots of the spinal nerves and of the posterior columns of the spinal cord. The symptoms and signs are numerous. Gastric crisis with severe pain and vomiting is the most frequent symptom. Other symptoms are

lancinating pains, urination difficulties, paresthesias (numbness, tingling, burning), spinal ataxia, diplopia, strabismus, vertigo, and deafness. The signs that may be present are Argyll Robertson pupils, absent or reduced reflexes, Romberg sign, deep tendon tenderness, loss of proprioception and vibratory sensation, atonic bladder, trophic changes, malum perforans pedis, Charcot joints, and optic atrophy.

Paresis has prodromal manifestations of headache, fatigability, and inability to concentrate. Later, personality changes occur, along with memory loss and apathy. Grandiose ideas, megalomania, delusions, hallucinations, and finally dementia may occur.

Late Cardiovascular Syphilis

Late cardiovascular syphilis occurs in about 10% of untreated patients. Aortitis is the basic lesion of cardiovascular syphilis, resulting in aortic insufficiency, coronary artery disease, and ultimately aortic aneurysm.

Congenital Syphilis

Congenital syphilis has reappeared with heterosexual syphilis epidemics. There were 195 cases of congenital syphilis reported in New York City from 2000 to 2009. Cases are also reported from Asia and Europe. In sub-Saharan Africa, where prenatal syphilis testing is not available, even for women with prenatal care, congenital syphilis is common. A total of 21% of all perinatal deaths in sub-Saharan Africa are caused by congenital syphilis. Prenatal syphilis is acquired in utero from the mother, who usually has early syphilis. Infection through the placenta usually does not occur before the fourth month, so treatment of the mother within the first two trimesters will almost always prevent negative outcomes. For this reason, prenatal care with syphilis serologies done in the early second trimester and at delivery (and any time in between if there is clinical suspicion of syphilis or high risk of acquisition of syphilis) is recommended. Common causes for failure to prevent congenital syphilis in mothers who received prenatal care are (1) lack of documented treatment of syphilis diagnosed before pregnancy, (2) absence of serologic testing during pregnancy, (3) late or no maternal treatment, and (4) treatment with a nonpenicillin regimen. If any of these is noted in the maternal history, congenital syphilis should still be suspected.

Recent reports from China suggest that preschool children may acquire syphilis by nonsexual close contact. In all cases, a caregiver had infectious syphilis, but sexual abuse was apparently excluded. This report suggests that the diagnosis of syphilis should be considered whenever the clinical manifestations suggest this possibility.

If the mother has early syphilis and prenatal infection occurs soon after the fourth month, fetal death and miscarriage occur in about 40% of pregnancies. During the remainder of the pregnancy, infection is equally likely to produce characteristic physical developmental stigmata or, after the eighth month, active, infectious congenital syphilis. About 40% of pregnant women with untreated early syphilis will have a syphilitic infant. Infant mortality rate from congenital syphilis can exceed 10%. In utero infection of the fetus is rare when the pregnant mother has had syphilis for 2 or more years. Two thirds of neonates with congenital syphilis are normal at birth and only detected by serologic testing. Lesions occurring within the first 2 years of life are called early congenital syphilis, and those developing thereafter, late congenital syphilis. The clinical manifestations of these two syndromes are different.

Early Congenital Syphilis

Early congenital syphilis describes those cases presenting within the first 2 years of life. Cutaneous manifestations usually appear during the third week of life, but sometimes occur as late as 3 months after birth. Neonates born with findings of congenital syphilis are usually severely affected. They may be premature and are often marasmic, fretful, and dehydrated. The face is pinched and drawn, resembling that of an old man or woman. Multisystem disease is characteristic.

Snuffles, a form of rhinitis, is the most frequent and often the first specific finding. The nose is blocked, often with blood-stained mucus, and a copious discharge of mucus runs down over the lips. The nasal obstruction often interferes with the child's nursing. In persistent and progressive snuffles, ulcerations develop that may involve the bones and ultimately cause perforation of the nasal septum or development of saddle nose, which are important stigmata later in the disease.

Cutaneous lesions of congenital syphilis resemble those of acquired secondary syphilis and occur in 30%–60% of infants with syphilis (Fig. 18.12). Annular lesions resembling those of neonatal lupus erythematosus may be present and may contain dermal mucin. The early skin eruptions are usually morbilliform and more rarely, purely papular. The lesions are at first a bright or violaceous red, later fading to a coppery color. The papules may become large and infiltrated; scaling often is pronounced. There is secondary pustule formation with crusting, especially in lesions that appear 1 year or more after birth. The eruption shows a marked predilection for the face, arms, buttocks, legs, palms, and soles.

Syphilitic pemphigus, a bullous eruption, usually on the palms and soles, is a relatively uncommon lesion. Lesions are present at birth or appear in the first week of life. They are teeming with spirochetes. The bullae quickly become purulent and rupture,

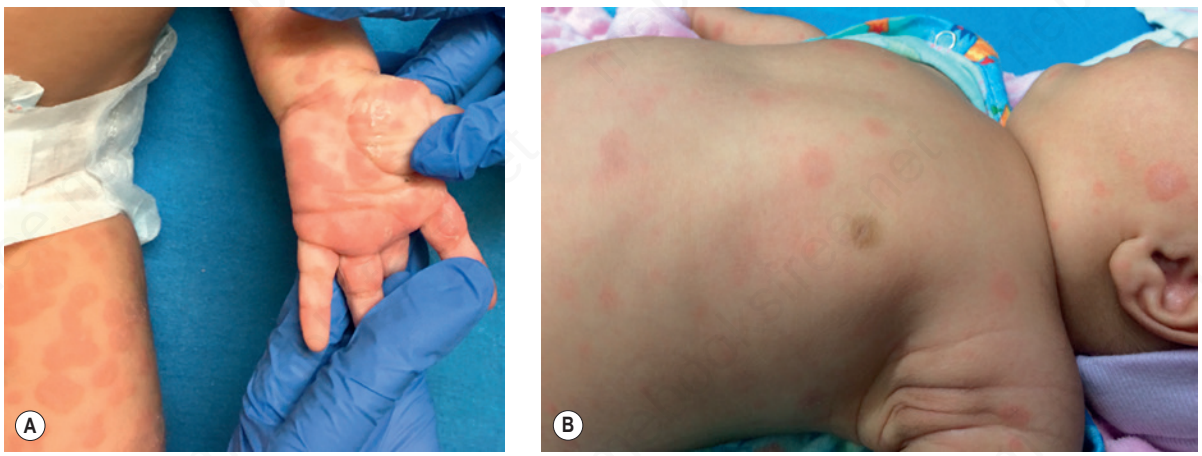

Fig. 18.12 (A and B) Congenital syphilis. (Courtesy Children's Hospital of Philadelphia Dermatology.)

leaving weeping erosions. They are found also on the eponychium, wrists, ankles, and infrequently on other parts of the body. Even in the absence of bullous lesions, desquamation is common, often preceded by edema and erythema, especially on the palms and soles.

Various morphologies of cutaneous lesions occur on the face, perineum, and intertriginous areas. These are usually fissured lesions resembling mucous patches. In these sites, radial scarring often results, leading to rhagades. Condylomata lata, large, moist, hypertrophic papules, are found around the anus and in other folds of the body. They are more common about the first year of life than in the newborn period. In the second or third year, recurrent secondary eruptions are likely to take the papulopustular form. Annular lesions occur, similar to those in adults. Mucous patches in the mouth or on the vulva are seen infrequently.

Bone lesions occur in 70%–80% of infants with early congenital syphilis. Epiphysitis is common and apparently causes pain on motion, leading to the infant refusing to move (Parrot pseudoparalysis). Radiologic features of the bone lesions in congenital syphilis during the first 6 months after birth are quite characteristic, and x-ray films are an important part of the evaluation of a child suspected of having congenital syphilis. Bone lesions occur chiefly at the epiphyseal ends of the long bones. The changes may be classified as osteochondritis, osteomyelitis, and osteoperiostitis.

A general enlargement of the lymph nodes usually occurs, with enlargement of the spleen. Clinical evidence of liver involvement is common, manifested by both hepatomegaly and elevated liver function test results, and interstitial hepatitis is a frequent finding at autopsy. The nephrotic syndrome and less often acute glomerulonephritis have been reported in congenital syphilis.

Symptomatic or asymptomatic neurosyphilis, as demonstrated by a positive CSF serologic test, may be present. Of infants with congenital syphilis diagnosed by clinical and laboratory findings born to mothers with untreated early syphilis, 86% will have CNS involvement, compared with only 8% of those with no clinical or laboratory findings. All infants with early congenital syphilis are treated as if they have neurosyphilis because it is very common, and CSF-VDRL test may be negative, even in documented CNS infection. Clinical manifestations may not appear until the third to sixth month of life and are meningeal or meningovascular in origin. Meningitis, obstructive hydrocephalus, cranial nerve palsies, and cerebrovascular accident (stroke) may all occur.

Late Congenital Syphilis

Although no sharp line can be drawn between early and late congenital syphilis, children who appear normal at birth and develop the first signs of the disease after age 2 years show a different clinical picture. Lesions of late congenital syphilis are of two types: persistent inflammatory foci and malformations of tissue affected at critical growth periods (stigmata).

Inflammatory Lesions. Lesions of the cornea, bones, and CNS are the most important. Interstitial keratitis, which begins with intense pericorneal inflammation and persists to characteristic diffuse clouding of the cornea without surface ulceration, occurs in 20%–50% of children with late congenital syphilis. If persistent, it leads to permanent, partial or complete opacity of the cornea. Syphilitic interstitial keratitis must be differentiated from Cogan syndrome, consisting of nonsyphilitic interstitial keratitis, usually bilateral, associated with vestibuloauditory symptoms, such as deafness, tinnitus, vertigo, nystagmus, and ataxia. It is congenital.

Perisynovitis (Clutton joints), which affects the knees, leads to symmetric, painless swelling. Gummas may also be found in any of the long bones or in the skull. Ulcerating gummas are frequently seen and probably begin more often in the soft parts or in the underlying bone than in the skin itself. When they occur in the nasal septum or palate, ulcerating gummas may lead to painless perforation.

Fig. 18.13 Hutchinson teeth in congenital syphilis.

The CNS lesions in late congenital syphilis are, as in late adult neurosyphilis, usually parenchymatous (tabes dorsalis or generalized paresis). Seizures are a frequent symptom in congenital cases.

Malformations (Stigmata). The destructive effects of syphilis in young children often leave scars or developmental defects called stigmata, which persist throughout life and confirm a diagnosis of congenital syphilis. Hutchinson emphasized the diagnostic importance of changes in the incisor teeth, opacities of the cornea, and eighth cranial nerve deafness, which have since become known as the Hutchinson triad. Hutchinson teeth, corneal scars, saber shins, rhagades of the lips, saddle nose, and mulberry molars are of diagnostic importance.

Hutchinson teeth are a malformation of the central upper incisors that appear in the secondary or permanent teeth. The characteristic teeth are cylindrical rather than flattened, the cutting edge is narrower than the base, and in the center of the cutting edge a notch may develop (Fig. 18.13). The mulberry molar, usually the first molar and appearing about age 6 years, is a hyperplastic tooth; its flat occlusal surface is covered with a group of little knobs representing abortive cusps. Nasal chondritis in infancy results in flattening of the nasal bones, forming a so-called saddle nose. The unilateral thickening of the inner third of one clavicle (Higouménaki sign) is a hyperostosis resulting from syphilitic osteitis in individuals who have had late congenital syphilis. The lesion appears typically on the right side in right-handed persons and on the left side in left-handed persons.

Diagnosis

Infants of women who meet the following criteria should be evaluated for congenital syphilis:

1. Maternal untreated syphilis, inadequate treatment, or no documentation of adequate treatment
2. Treatment of maternal syphilis with nonpenicillin regimen
3. Treatment less than 1 month before delivery
4. Inadequate maternal response to treatment
5. Appropriate treatment before pregnancy, but insufficient serologic follow-up to document adequacy of therapy

The results of serologic tests for syphilis for every woman delivering a baby must be known before the discharge of that baby from the hospital. Serologic testing of the mother and child

at delivery are recommended. Evaluation of the children as just noted might include the following:

1. A complete physical examination for findings of congenital syphilis
2. Nontreponemal serology of the infant's serum (not cord blood)
3. CNS evaluation
4. Pathologic evaluation of the placenta using specific antitreponemal antibody staining

Treatment

Penicillin remains the drug of choice for treatment of all stages of syphilis. Erythromycin is not recommended for treatment of any stage or form of syphilis. HIV testing is recommended in all patients with syphilis. Treatment for HIV-infected patients is discussed later. Patients with primary, secondary, or early latent syphilis known to be of less than 1 year in duration can be treated with a single intramuscular injection of 2.4 million units (megaunits, MU) of benzathine penicillin G. In nonpregnant, penicillin-allergic, HIV-negative patients, tetracycline, 500 mg orally four times daily, or doxycycline, 100 mg orally twice daily for 2 weeks, is recommended. Ceftriaxone, 1 g intramuscularly or intravenously for 8–10 days, is an acceptable alternative if the patient cannot tolerate the previous options. Azithromycin and erythromycin can no longer be recommended as treatment for syphilis because of the worldwide presence of macrolide resistance, caused by a mutation in the gene encoding part of the ribosome responsible for binding macrolides. Close follow-up is recommended for all patients treated with non–penicillin-based regimens. These alternative agents are not recommended for persons with HIV infection and syphilis.

The recommended treatment of late or late latent syphilis of more than 1-year duration in an HIV-negative patient is benzathine penicillin G, 2.4 MU intramuscularly once weekly for 3 weeks. In a penicillin-allergic, nonpregnant, HIV-negative patient, doxycycline, 100 mg orally twice daily, for 14 days (28 days for latent syphilis) is recommended. Persons with a penicillin allergy whose compliance with therapy cannot be ensured should be desensitized and treated with benzathine penicillin. CSF evaluation is recommended if neurologic or ophthalmologic findings are present, if there is evidence of active late (tertiary) syphilis, if treatment has previously failed, if the nontreponemal serum titer is 1:32 or higher, or if any regimen not based on penicillin is planned.

Recommended treatment regimens for neurosyphilis include penicillin G crystalline, 3–4 MU intravenously every 4 hours for 10–14 days, or procaine penicillin, 2.4 MU/day intramuscularly, plus probenecid, 500 mg orally four times daily, both for 10–14 days. These regimens are shorter than those for treatment of late syphilis, so they may be followed by benzathine penicillin G, 2.4 MU intramuscularly, once weekly for 3 weeks. Patients allergic to penicillin should have their allergy confirmed by skin testing. If allergy exists, desensitization and treatment with penicillin are recommended.

Treatment of congenital syphilis in the neonate is complex. Therapy should be undertaken in consultation with a pediatric infectious disease specialist. Management strategies can be found in the CDC *Guidelines for the Management of Sexually Transmitted Diseases.* Older children with congenital syphilis should have a CSF evaluation and may be treated with aqueous crystalline penicillin G, 200,000–300,000 U/kg/day intravenously or intramuscularly (50,000 U every 4–6 hours) for 10–14 days. The CDC also lists benzathine penicillin G 50,000 U/kg intramuscularly, up to the adult dose of 2.4 million units in a single dose.

Pregnant women with syphilis should be treated with penicillin in doses appropriate for the stage of syphilis. A second dose of benzathine penicillin, 2.4 MU intramuscularly, may be administered 1 week after the initial dose in pregnant women with primary, secondary, or early latent syphilis. Sonographic evaluation of the fetus in the second half of pregnancy for signs of congenital infection may facilitate management and counseling. Expert consultation should be sought when evidence of fetal syphilis is found, because fetal treatment failure is increased in this situation. Follow-up quantitative serologic tests should be performed monthly until delivery. Pregnant women who are allergic to penicillin should be skin-tested and desensitized if test results are positive.

Jarisch-Herxheimer or Herxheimer Reaction

A febrile reaction often occurs after the initial dose of antisyphilitic treatment, especially penicillin, is given. Although historically reported to occur in more than 50% of patients treated for early syphilis, a recent report found a rate of only 10%. The reaction generally occurs 6–8 hours after treatment and consists of shaking chills, fever, malaise, sore throat, myalgia, headache, tachycardia, and exacerbation of the inflammatory reaction at sites of localized spirochetal infection. A vesicular Herxheimer reaction can occur. A Herxheimer reaction in pregnancy may induce premature labor and fetal distress. Every effort should be made to avoid this complication. Early in pregnancy, women should rest and take acetaminophen for fever. Women treated after 20 weeks of pregnancy should seek obstetric evaluation if they experience fever, decreased fetal movement, or regular contractions within 24 hours of treatment. Increased inflammation in a vital structure may have serious consequences, as when aneurysm of the aorta or iritis is present. When the CNS is involved, avoiding the Herxheimer reaction is especially important, even though the paralyses that may result are often transitory. It is important to distinguish the Herxheimer reaction from a drug reaction to penicillin or other antibiotics. The reaction has also been described in other spirochetal diseases, such as leptospirosis and louse-borne relapsing fever.

Treatment of Sex Partners

Sexual partners of persons with syphilis should be identified. Persons who are exposed within 90 days of the diagnosis of primary, secondary, or early latent syphilis, even if seronegative, should be treated presumptively. If the exposure occurred before 90 days of diagnosis but follow-up is uncertain, presumptive treatment should be given. If the infectious source has a serologic titer of greater than 1:32, the patient should be presumed to have infectious early syphilis, and sexual partners should be treated. At-risk partners are identified as those exposed within 3 months plus the duration of the primary lesions, for 6 months plus the duration of the secondary lesions, or 1 year for latent syphilis. Treatment of sexual partners is based on their clinical and serologic findings. If they are seronegative but had exposures as previously outlined, treatment would be as for early syphilis, with benzathine penicillin, 2.4 MU intramuscularly as one dose.

Serologic Testing After Treatment

Before therapy and then regularly thereafter, quantitative VDRL or RPR testing should be performed on patients who are to be treated for syphilis to ensure appropriate response.

Clinical and serologic evaluation should be performed at 6 and 12 months after treatment. A fourfold increase in serologic titer clearly indicates treatment failure or reinfection. Failure of nontreponemal test titers to decline fourfold within that time period may also indicate treatment failure, but 15%–20% of persons with primary and secondary syphilis will not achieve the fourfold decline at 1 year after treatment. These persons should receive additional clinical and serologic follow-up and be evaluated for HIV infection and CNS infection.

If it is decided to retreat the patient, injection of benzathine penicillin G 2.4 MU weekly for 3 weeks is recommended.

Patients treated for latent or late syphilis may be serofast, so failure to observe a titer fall in these patients does not in itself indicate a need for retreatment. If the titer is less than 1:32, the possibility of a serofast state exists, and retreatment should be planned on an individual basis.

Seroreversion in specific treponemal tests can occur. By 36 months, 24% of patients treated for early syphilis had a negative FTA-ABS and 13% had a negative MHA-TP.

Syphilis and HIV Disease

Syphilis and other genital or anal sexually transmitted diseases enhance the risk of transmission and acquisition of HIV. This may result from early lesions of syphilis containing mononuclear cells with enhanced expression of CCR5, the coreceptor for HIV-1. HIV testing is recommended in all patients with syphilis. Maternal syphilis increases the risk of HIV transmission to the infant.

Most HIV-infected patients with syphilis exhibit the classic clinical manifestations with appropriate serologic titers for that stage of disease. Responses to treatment, both clinical and serologic in HIV-infected patients with syphilis, generally follow the clinical and serologic patterns seen in patients without coexisting HIV infection. In a large study that compared HIV-positive and HIV-negative patients with syphilis, the former were more likely to present with secondary syphilis (53% vs. 33%) and were more likely to have a chancre that persisted when they had secondary syphilis (43% vs. 15%). Unusual clinical manifestations of syphilis in HIV range from florid skin lesions to few atypical ones, but these are exceptions, not the rule. Because most HIV-infected patients in large urban areas in the United States and Western Europe who acquire syphilis are MSM, chancres may be in atypical locations, such as the lips, tongue, or anus.

In general, the nontreponemal tests are of higher titer in HIV-infected persons. Rarely, the serologic response to infection may be impaired or delayed, and seronegative secondary syphilis has been reported. Biopsy of the skin lesions and histopathologic evaluation with special stains will confirm the diagnosis of syphilis in such patients. This approach, along with darkfield examination of appropriate lesions, should be considered if the clinical eruption is characteristic of syphilis and the serologic tests yield negative results.

Neurosyphilis has been frequently reported in HIV-infected persons, even after appropriate therapy for early syphilis. Manifestations have been those of early neurosyphilis or meningeal or meningovascular syphilis. These have included headache, fever, hemiplegia, and cranial nerve (CN) deficits, especially deafness (CN VIII), decreased vision (CN II), and ocular palsies (CNs III and VI). Whether HIV-infected persons are at increased risk for these complications or whether they occur more quickly is unknown. It is known that spirochetes are no more likely to remain in the CSF after treatment in HIV-infected persons than in HIV-negative persons. Whether the impaired host immunity allows these residual spirochetes to cause clinical relapse more frequently or more quickly in the setting of HIV is unknown.

Patients with HIV infection who have primary or secondary syphilis, who are not allergic to penicillin, and who have no neurologic or psychiatric findings should be treated with benzathine penicillin G, 2.4 MU intramuscularly. There is no evidence that additional treatment will reduce the risk of treatment failure. Patients who are allergic to penicillin should be desensitized and treated with penicillin. Following treatment, the patient should have serologic follow-up with quantitative nontreponemal tests at 3, 6, 9, 12, and 24 months. Failure of the titer to fall is an indication for reevaluation, including lumbar puncture. Factors associated with treatment failure in HIV disease include a low initial serologic titer (RPR <1:16), a history of prior syphilis, and a CD4 count less than 350 cells/mL.

Because of the concerns about neurologic relapse in the syphilitic patient with HIV disease, more careful CNS evaluation is advocated. Lumbar puncture is recommended in HIV-infected patients with latent syphilis (of any duration), with late syphilis (even with a normal neurologic examination), and with any neurologic or psychiatric signs or symptoms. If RPR is 1:32 or greater and CD4 count is less than 350 cells/mL, neurosyphilis is more likely, and lumbar puncture can be considered. Treatment in these patients will be determined by the result of their CSF evaluation. HIV-infected patients with primary or secondary syphilis should be counseled about their possible increased risk of CNS relapse.

Benzathine penicillin, 2.4 MU intramuscularly, should be used to treat all HIV-infected contacts of patients with syphilis who are at risk of acquiring infection.

NONVENEREAL TREPONEMATOSES: YAWS, ENDEMIC SYPHILIS, AND PINTA

This group of diseases is called the endemic or nonvenereal treponematoses. They share many epidemiologic and pathologic features. As with venereal syphilis, the clinical manifestations are divided into early and late stages. Early disease is considered infectious and lasts for approximately 5 years. There are periods of latency. The histology is similar in all the diseases and resembles venereal syphilis. Cutaneous manifestations are prominent. The bones and mucosa may also be involved in some cases (except in pinta). Cardiovascular and nervous system involvement and congenital disease are not seen. Children younger than 15 years are primarily affected. Person-to-person contact or sharing of a drinking vessel is the mode of transmission.

The endemic treponematoses are closely related to poverty and a lack of available health services. They are described as occurring "where the road ends." These diseases tend to occur in the tropics, especially yaws, and the wearing of few clothes and a hot, humid climate are associated with higher prevalence. In endemic areas, as hygiene improves, "attenuated" forms of yaws and endemic syphilis appear. A larger percentage of the population is latently infected, and secondary lesions are fewer in number, drier, and limited to moist skinfolds. Instead of several "crops" of eruptions lasting months to years, infected persons have only a single crop. Transmission is thus reduced, although a large percentage of the population may be infected.

Yaws was nearly eradicated during the 1950s through mass-treatment campaigns, but has undergone a resurgence in Cameroon, Fiji, Indonesia, Timor, Papua New Guinea, the Solomon Islands, and Vanuatu. The discovery of treponemal infection with a high genetic similarity to yaws in monkeys in Africa suggests a possible animal reservoir for this infection, and evidence suggests that necrophagous flies can carry and spread the organism, further complicating eradication efforts.

Yaws (Pian, Frambesia, Bouba)

Yaws is caused by *Treponema pallidum* subsp. *pertenue*. It is transmitted nonsexually, by contact with infectious lesions. Yaws predominantly affects children younger than 15 years. The disease has a disabling course, affecting the skin, bones, and joints, and is divided into early (primary and secondary) and late (tertiary) disease.

Early Yaws

A primary papule or group of papules appears at the site of inoculation after an incubation period of about 3 weeks (10 days to 3 months), during which there may be headache, malaise, and other mild constitutional symptoms. The initial lesion becomes crusted and larger (2–5 cm) and is known as the "mother yaw" (maman pian). The crusts are amber-yellow. They may be knocked off, forming an ulcer with a red, pulpy, granulated surface, but quickly reform, so that the typical yaws lesion is crusted. The lesion is not indurated. There may be some regional adenopathy.

Fig. 18.14 Yaws.

Exposed parts are most frequently involved—the extremities, particularly the lower legs, feet, buttocks, and face—although the mother's breasts and trunk may be infected by her child. The lesion is almost always extragenital, and when genital, is a result of accidental contact rather than intercourse. After being present for about 3–6 months, the mother yaw spontaneously disappears, leaving slight atrophy and depigmentation.

Weeks or months after the primary lesion appears, secondary yaws develops. Secondary lesions resemble the mother yaw, but they are smaller and may appear around the primary lesions or in a generalized pattern. The secondary lesions may clear centrally and coalesce peripherally, forming annular lesions (ringworm yaws or tinea yaws) (Fig. 18.14). The palms and soles may be involved, resembling secondary syphilis. In some sites, especially around the body orifices and in the armpits, groins, and gluteal crease, condylomatous lesions may arise, resembling condyloma latum of secondary syphilis. In drier endemic regions and during drier seasons, lesions tend to be fewer, less papillomatous, and more scaly, and instead of being generalized, favor the folds of the axillae, groin, and oral cavity. Yaws in the dry seasons and dry geographic areas closely resembles endemic syphilis. The palms and soles may develop thick, hyperkeratotic plaques that fissure. They are painful, resulting in a crablike gait (crab yaws). At times there is paronychia. Generalized lymphadenopathy, arthralgias, headaches, and malaise are common. With improved nutrition and hygiene, an "attenuated" form, with only scattered, flat, gray lesions in intertriginous areas, has been described.

Over a few weeks or months, the secondary lesions may undergo spontaneous involution, leaving either no skin changes or hypopigmented macules that later become hyperpigmented. However, the eruption may persist for many months as a result of fresh, recurrent outbreaks. The course is slower in adults than in children, in whom the secondary period rarely lasts longer than 6 months. During latency, skin lesions may relapse for as long as 5 years. Painful osteoperiostitis and polydactylitis may present in early yaws as fusiform swelling of the hands, feet, arms, and legs.

Late Yaws

The disease usually terminates with the secondary stage, but in about 10% of patients, it progresses to the late stage, usually 5–10 years after initial infection. The typical late-yaws skin lesions are gummas that present as indolent ulcers with clean-cut

or undermined edges. They tend to fuse and form configurate and occasionally serpiginous patterns clinically indistinguishable from those of tertiary syphilis. On healing, these lesions scar, leading to contractures and deformities. Hyperkeratotic palmoplantar plaques and keratoderma frequently recur in the late stage.

Similar processes may occur in the skeletal system and other deep structures, leading to painful nodes on the bones, or destruction of the palate and nasal bone (gangosa). There may be periostitis, particularly of the tibia (saber shin, saber tibia), epiphysitis, chronic synovitis, and juxta-articular nodules. Goundou is a rare proliferative osteitis initially affecting the nasal aspects of the maxilla. Two large, hard tumors form on the lateral aspects of the nose. These can significantly obstruct vision. The process may extend into other bones of the central face, affecting the palate and nose, and resulting in protrusion of the whole central face as a mass. Although yaws is classically thought to spare the eye and nervous system, abnormal CSF findings in early yaws and scattered reports of eye and neurologic findings in patients with late yaws suggest that yaws, like syphilis, has the potential to cause neurologic or ophthalmic sequelae, although rarely.

Histopathology

Early yaws shows epidermal edema, acanthosis, papillomatosis, neutrophilic intraepidermal microabscesses, and a moderate to dense perivascular infiltrate of lymphocytes and plasma cells. Treponemas are usually demonstrable in the primary and secondary stages with the use of the same silver stains employed in diagnosing syphilis. Tertiary yaws shows features identical to the gumma of tertiary syphilis.

Diagnosis

The diagnosis should be suspected from the typical clinical appearance in a person living in an endemic region. The presence of keratoderma palmaris et plantaris in such a person is highly suggestive of yaws. Darkfield demonstration of spirochetes in the early lesions and a reactive VDRL or RPR test can be used to confirm primary and secondary yaws.

Endemic Syphilis (Bejel)

Bejel is a Bedouin term for this nonvenereal treponematosis, which occurs primarily in the seminomadic tribes who live in the arid regions of North Africa, Southwest Asia, and the eastern Mediterranean. The etiologic agent of bejel is *Treponema pallidum* subsp. *endemicum*. It occurs primarily in childhood and is spread by skin contact or from mouth to mouth by kissing or use of contaminated drinking vessels. The skin, oral mucosa, and skeletal system are primarily involved.

Primary lesions are rare, probably occurring undetected in the oropharyngeal mucosa. The most common presentation is with secondary oral lesions resembling mucous patches. These are shallow, relatively painless ulcerations, occasionally accompanied by laryngitis. Split papules, angular cheilitis, condylomatous lesions of the moist folds of the axillae and groin, and a nonpruritic generalized papular eruption may be seen. Generalized lymphadenopathy is common. Osteoperiostitis of the long bones may occur, causing nocturnal leg pains.

Untreated secondary bejel heals in 6–9 months. The tertiary stage can occur between 6 months and several years after the early symptoms resolve. In the tertiary stage, leg pain (periostitis) and gummatous ulcerations of the skin, nasopharynx, and bone occur. Gangosa (rhinopharyngitis mutilans) can result. Rarely reported neurologic sequelae seem to be restricted to the eye, including uveitis, choroiditis, chorioretinitis, and optic atrophy. As with yaws, with improved nutrition, an attenuated form of endemic syphilis occurs, often presenting with leg pain from periostitis. The diagnosis of bejel is confirmed by the same means as for venereal syphilis.

Pinta

Pinta is an infectious, nonvenereal, endemic treponematosis caused by *Treponema carateum*. The mode of transmission is unknown, but repeated, direct, lesion-to-skin contact is likely. Only skin lesions occur. By contrast with yaws and bejel, pinta affects persons of all ages, favoring those 14–30 years old. It was once prevalent in the forests and rural areas of Central and South America and Cuba, but it is now rarely reported. The manifestations of pinta may be divided into primary, secondary (early), and tertiary (late) stages. Historically, however, patients may describe continuous evolution from secondary dyspigmented lesions to the characteristic achromic lesions of tertiary pinta.

Primary Stage

It is believed that the initial lesion appears 7–60 days after inoculation. The lesion begins as a tiny red papule that becomes an elevated, poorly defined, erythematous, infiltrated plaque up to 10–12.5 cm in diameter over 2–3 months. Expansion of the primary lesion may occur by fusion with surrounding satellite macules or papules. Ultimately, it becomes impossible to distinguish the primary lesion from the secondary lesions. At no time is there erosion or ulceration such as occurs in the syphilitic chancre. Most initial lesions of pinta develop on the legs and other uncovered parts. The RPR and VDRL tests are nonreactive in the primary stage. Darkfield examination may be positive.

Secondary Stage

The secondary stage of pinta appears 5 months to 1 year or more after infection. It begins with small, scaling papules that may enlarge and coalesce, simulating psoriasis, ringworm, eczema, syphilis, or Hansen disease. The papules are located mostly on the extremities and face and frequently are somewhat circinate. Over time, the initially red to violaceous lesions show postinflammatory hyperpigmentation, in shades of gray, blue, or brown, or hypopigmentation. Secondary lesions are classified as erythematous, desquamative, hypochromic, or hyperchromic. Multiple different morphologies may be present simultaneously, giving a very polymorphous appearance. Nontreponemal tests for syphilis are reactive in the secondary stage in about 60% of pinta patients. Darkfield examination may show spirochetes.

Late Dyschromic Stage

Until the 1940s the late pigmentary changes were the only recognized clinical manifestations of pinta. These have an insidious onset, usually in adolescents or young adults, of widespread depigmented macules resembling vitiligo. The lesions are located chiefly on the face, waistline, wrist flexures, and trochanteric region, although diffuse involvement may occur, so that large areas on the trunk and extremities are affected. The lesions are symmetric in more than one third of patients. Hemipinta is a rare variety of the disease in which the pigmentary disturbances affect only half the body. In the late dyschromic stage of pinta, the serologic test for syphilis is positive in nearly all patients.

Histopathology

Skin lesions in early pinta show moderate acanthosis; occasionally, lichenoid changes with basal layer vacuolization; and an upper dermal perivascular infiltrate of lymphocytes and plasma cells.

Melanophages are prominent in the upper dermis. Spirochetes may be demonstrated in the epidermis by special stains in primary, secondary, and hyperpigmented lesions of tertiary pinta. In tertiary pinta, the depigmented skin shows a loss of basal pigment, pigmentary incontinence, and virtually no dermal inflammatory infiltrate. Spirochetes are rarely found in depigmented tertiary lesions.

Treatment

The treatment of choice for all endemic treponematoses is benzathine penicillin G, 1.2–2.4 MU intramuscularly (0.6–1.2 MU for children under age 10). In penicillin-allergic patients, tetracycline, 500 mg four times daily for adults, or erythromycin, 8–10 mg/kg four times daily for children, for 15 days is recommended. Penicillin-resistant yaws has been reported from New Guinea, and a single oral dose of azithromycin (30 mg/kg) has been shown to be noninferior to benzathine penicillin for the treatment of early yaws, supporting the WHO policy for use of oral azithromycin in resource-poor settings. The dose recommended for trachoma is lower than that for yaws, but also lowers the prevalence of yaws infection. In tertiary pinta, the blue color gradually disappears, as do the areas of partial depigmentation. The vitiliginous areas, if present for more than 5 years, are permanent.

Eradication of the endemic treponematoses is possible with persistent and effective treatment strategies, including the following:

1. Screening of the whole population in endemic areas
2. Diagnosis of patients seen at health services and by community outreach
3. Health education
4. Improved hygiene (soap and water)

If more than 10% of the population is affected, the whole population is treated (mass treatment). If 5%–10% of the population is affected, treat all active cases, all children younger than 15, and all contacts (juvenile mass treatment). If less than 5% of the population is infected, treat all active cases and all household and close personal contacts (selective mass treatment). Unfortunately, with the areas affected by the endemic treponematoses also struggling with epidemics of HIV, tuberculosis, and malaria, eradication programs have been largely discontinued.

19 Viral Diseases

Bonus images for this chapter can be found online at expertconsult.inkling.com

Viruses are obligatory intracellular parasites. The structural components of a viral particle (virion) consist of a central core of nucleic acid, a protective protein coat (capsid), and (in certain groups of viruses only) an outermost membrane or envelope. The capsid of the simplest viruses consists of many identical polypeptides (structural units) that fold and interact with one another to form morphologic units (capsomeres). The number of capsomeres is believed to be constant for each virus with cubic symmetry, and it is an important criterion in the classification of viruses. The protein coat determines serologic specificity, protects the nucleic acid from enzymatic degradation in biologic environments, controls host specificity, and increases the efficiency of infection. The outermost membrane of the enveloped viruses is essential for the attachment to, and penetration of, host cells. The envelope also contains important viral antigens.

Two main groups of viruses are distinguished: deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). The DNA virus types are parvovirus, papovavirus, adenovirus, herpesvirus, and poxvirus. RNA viruses are picornavirus, togavirus, reovirus, coronavirus, orthomyxovirus, retrovirus, arenavirus, rhabdovirus, and paramyxovirus. Some viruses are distinguished by their mode of transmission: arthropod-borne viruses, respiratory viruses, fecal-oral or intestinal viruses, venereal viruses, and penetrating-wound viruses.

HERPESVIRUS GROUP

The herpes viruses are medium-sized viruses that contain double-stranded (ds) DNA and replicate in the cell nucleus. They are characterized by the ability to produce latent but lifelong infection by infecting immunologically protected cells (immune cells and nerves). Intermittently, they have replicative episodes with amplification of the viral numbers in anatomic sites conducive to transmission from one host to the next (genital skin, orolabial region). The vast majority of infected persons remain asymptomatic. Viruses in this group are varicella-zoster virus (VZV; human herpesvirus type 3 [HHV-3]); herpes simplex virus types 1 and 2 (HSV-1 and HSV-2); cytomegalovirus (CMV); Epstein-Barr virus (EBV); human herpesviruses types 6, 7, and 8 (HHV-6, HHV-7, and HHV-8); *Herpesvirus simiae* (B virus); and other viruses of animals.

Herpes Simplex Virus (Human Herpesvirus Types 1 and 2)

Infection with HSV is one of the most prevalent infections worldwide. HSV-1 infection, the cause of most cases of orolabial herpes, is more common than infection with HSV-2, the classical cause of most cases of genital herpes, though rates of HSV-1 in genital herpes has been rising, particularly in younger patients. Between 30% and 95% of adults (depending on the country and group tested) are seropositive for HSV-1, although seroprevalence of HSV-1 has decreased in the United States among adolescents (age 14–19 years) more recently. Seroprevalence for HSV-2 is lower, and it appears at the age of onset of sexual activity. About 2.4% of adults become infected annually with HSV-2 in their third decade of life. In the United States about 25% of adults are infected with HSV-2, with black men and women twice as likely to be HSV-2 infected as whites. In sexually transmitted disease (STD) clinic patients, the infection rate is 30%–50%. In sub-Saharan Africa, infection rates are 60%–95%. Worldwide, the seroprevalence is higher in persons infected with human immunodeficiency virus (HIV). Serologic data show that many more people are infected than give a history of clinical disease. For HSV-1, about 50% of infected persons give a history of orolabial lesions. For HSV-2, 20% of infected persons are completely asymptomatic (latent infection), 20% have recurrent genital herpes they recognize, and 60% have clinical lesions that they do not recognize as genital herpes (subclinical or unrecognized infection). Most persons with HSV-2 infection are symptomatic, but the majority do not recognize that their symptoms are caused by HSV. All persons infected with HSV-1 and HSV-2 are potentially infectious even if they have no clinical signs or symptoms. Routine screening for HSV in asymptomatic patients, including those who are pregnant, is not currently recommended; testing is appropriate in patients with signs or symptoms of the disease.

Herpes simplex infections are classified as either "first episode" or "recurrent." Most patients have no lesions or findings when they are initially infected with HSV. When patients have their first clinical lesion, this is usually a recurrence. Because the initial clinical presentation is not associated with a new infection, the previous terminology of "primary" infection has been abandoned. Instead, the initial clinical presentation is called a first episode and may represent a true primary infection or a recurrence. Persons with chronic or acute immunosuppression may have prolonged and atypical clinical courses.

Infections with HSV-1 or HSV-2 are diagnosed by specific and nonspecific methods. Bedside, in-office diagnosis can be made using the Tzanck smear. It is nonspecific because both HSV and VZV infections result in the formation of multinucleate epidermal giant cells. Although the technique is rapid, its success depends heavily on the skill of the interpreter. The accuracy rate is 60%–90%, with a false-positive rate of 3%–13%. The direct fluorescent antibody (DFA) test is more accurate and will identify virus type; results can be available in hours if a virology laboratory is nearby. Both Tzanck, which is neither sensitive nor specific, and DFA, which is nonspecific, are less useful than viral culture or polymerase chain reaction (PCR) testing. Viral culture is very specific and relatively rapid, compared with serologic tests, because HSV is stable in transport and grows readily and rapidly in culture, and can be used for antiviral sensitivity testing if necessary, though it can be expensive to culture virus. Results are often available in 48–72 hours. PCR is as specific as viral culture but four times more sensitive and can be performed on dried or fixed tissue, and is becoming increasingly viewed as the test of choice. Skin biopsies of lesions can detect viropathic changes caused by HSV, and with specific HSV antibodies, immunoperoxidase (IP) techniques can accurately diagnose infection. The accuracy of various tests depends on lesion morphology. Only acute, vesicular lesions are likely to be positive with Tzanck smears. Crusted, eroded, or ulcerative lesions are best diagnosed by viral culture, DFA, histologic methods, or PCR.

Serologic tests are generally not used in determining whether a skin lesion is caused by HSV infection. A positive serologic test indicates only that the individual is infected with that virus, not that the viral infection is the cause of the current lesion. In addition to determining the infection rate in various populations, serologic tests are most useful in evaluating couples in which only one partner gives a history of genital herpes (discordant couples), in

Fig. 19.1 Herpetic gingivostomatitis, extensive erosions of the oral mucosa.

Fig. 19.2 Recurrent herpes simplex infection.

couples (if childbearing) at risk for neonatal herpes infection, and for possible HSV vaccination (when available).

Orolabial Herpes

Orolabial herpes is virtually always caused by HSV-1. In 1% or less of newly infected persons, herpetic gingivostomatitis develops, mainly in children and young adults (Fig. 19.1). The onset is often accompanied by high fever, regional lymphadenopathy, and malaise. The herpetic lesions in the mouth are usually broken vesicles that appear as erosions or ulcers covered with a white membrane. The erosions may become widespread on the oral mucosa, tongue, and tonsils, and the gingival margin is usually eroded. Herpetic gingivostomatitis produces pain, foul breath, and dysphagia. In young children, dehydration may occur. It may cause pharyngitis, with ulcerative or exudative lesions of the posterior pharynx. The duration, untreated, is 1–2 weeks. If the initial episode of herpetic gingivostomatitis or herpes labialis is so severe that intravenous (IV) administration is required, IV acyclovir, 5 mg/kg three times daily, is recommended. Oral therapeutic options include acyclovir suspension, 15 mg/kg five times daily for 7 days; valacyclovir, 1 g twice daily for 7 days; or famciclovir, 500 mg twice daily for 7 days. This therapy reduces the duration of the illness by more than 50%.

The most frequent clinical manifestation of orolabial herpes is the "cold sore" or "fever blister." Recurrent HSV-1 is the cause of 95% or more of cases and typically presents as grouped blisters on an erythematous base. The lips near the vermilion are most frequently involved (Fig. 19.2), although lesions may occur wherever the virus was inoculated or proliferated during the initial episode (Fig. 19.3). Recurrences may be seen on the cheeks, eyelids, and earlobes. Oral recurrent HSV usually affects the keratinized surfaces of the hard palate and attached gingiva. Outbreaks are variable in severity, partly related to the trigger of the outbreak. Some outbreaks are small and resolve rapidly, whereas others may be severe, involving both the upper and the lower lip. In severe outbreaks, lip swelling is often present. Patient symptomatology is variable. A prodrome of up to 24 hours of tingling, itching, or burning may precede the outbreak. Local discomfort, as well as headache, nasal congestion, or mild flulike symptoms, may occur. Ultraviolet (UV) exposure, especially UVB, is a frequent trigger of recurrent orolabial HSV, and severity of the outbreak may correlate with intensity of the sun exposure. Surgical and dental procedures of the lips (or other areas previously affected with HSV) may trigger recurrences, and a history of prior HSV should be solicited in all patients in whom such procedures are recommended (see next section).

Fig. 19.3 Recurrent herpes simplex infection. (Courtesy Steven Binnick, MD.)

In most patients, recurrent orolabial herpes represents more of a nuisance than a disease. Because UVB radiation is a common trigger, use of a sunblock daily on the lips and facial skin may reduce recurrences. All topical therapies for the acute treatment of recurrent orolabial herpes have limited efficacy, reducing disease duration and pain by 1 day or less. Tetracaine cream, penciclovir cream, and acyclovir cream (not ointment) have some limited efficacy. Topical acyclovir ointment and docosanol cream provide minimal to no reduction in healing time or discomfort. The minimal benefit from these topical agents suggests that they should not be recommended for significant symptomatic orolabial herpes outbreaks. If oral therapy is contemplated for patients with severely symptomatic recurrences of orolabial HSV, it must be remembered that much higher doses of oral antivirals are required than for treatment of genital herpes. Intermittent treatment with valacyclovir, 2 g twice daily for 1 day, or famciclovir, 1.5 g as a single dose, starting at the onset of the prodrome, are simple and effective oral, 1-day regimens. Because the patient's own inflammatory reaction against the virus contributes substantially to the severity of lesions of orolabial herpes simplex, topical therapy with a high-potency topical corticosteroid (fluocinonide gel 0.05%, three times daily) in combination with an oral antiviral agent more rapidly reduces pain and reduces maximum lesion area and time to healing. In nonimmunosuppressed patients, if episodic treatment for orolabial HSV is recommended and an oral agent is used, the

addition of a high-potency topical corticosteroid should be considered. In patients with six or more outbreaks per year, chronic suppressive daily antiviral therapy can be used. Squaric acid dibutyl ester has been used as an immunosensitizer in one small study to reduce recurrent outbreaks.

Although most patients with orolabial herpes simplex do not require treatment, certain medical and dental procedures may trigger outbreaks of HSV. If the cutaneous surface has been damaged by the surgical procedure (e.g., dermabrasion, chemical peel, laser resurfacing), the surgical site can be infected by the virus and may result in prolonged healing and possible scarring. Prophylaxis is regularly used before such surgeries in patients with a history of orolabial herpes simplex. Famciclovir, 250 mg twice daily, and valacyclovir, 500 mg twice daily, or oral acyclovir 400 mg three times daily, are prophylactic options, to be begun 24 hours before the procedure. Duration of treatment in part depends on severity of the skin insult and rate of healing but should be at least 1 week and could be as long as 14 days. For routine surgeries at sites of HSV recurrences (upper or lower lip), acyclovir, 200 mg five times daily; famciclovir, 250 mg three times daily; or valacyclovir, 1 g twice daily, starting 2–5 days before the procedure and continuing for 5 days, can be considered. Prophylaxis could also be considered before skiing or tropical vacations and before extensive dental procedures, at the same dosages. Reactivation of orolabial herpes has also been associated with hyaluronic acid filler injections in about 1.5% of patients; and extensive facial HSV-1 infection has followed intense inhaled corticosteroid therapy. Kissing of the penis during circumcision can lead to penile HSV-1 infection, which can present acutely, or even years after the initial exposure. Some of these infants have died of disseminated or central nervous system HSV infection.

Herpetic Sycosis

Recurrent or initial herpes simplex infections (usually from HSV-1) may primarily affect the hair follicle. The clinical appearance may vary from a few eroded follicular papules (resembling acne excoriée) to extensive lesions involving the whole beard area in men (Fig. 19.4). Close razor blade shaving immediately before initial exposure or in the presence of an acute orolabial lesion may be associated with a more extensive eruption. The onset may be acute (over days) or more subacute or chronic. Diagnostic clues include the tendency for erosions, a self-limited course of 2–3 weeks, and an appropriate risk behavior. The diagnosis may be confirmed by biopsy. Although the herpes infection is primarily in the follicle, surface cultures of eroded lesions will usually be positive in the first 5–7 days of the eruption.

Fig. 19.4 Herpetic sycosis.

Herpes Gladiatorum

Infection with HSV-1 is highly contagious to susceptible persons who wrestle with an infected individual with an active lesion. One third of susceptible wrestlers will become infected after a single match. In tournaments and wrestling camps, outbreaks can be epidemic, affecting up to 20% of all participants. Lesions usually occur on the lateral side of the neck, the side of the face, and the forearm, all areas in direct contact with the face of the infected wrestler (Fig. 19.5). Vesicles appear 4–11 days after exposure, often preceded by 24 hours of malaise, sore throat, and fever. Ocular symptoms may occur. Lesions are frequently misdiagnosed as a bacterial folliculitis. Any wrestler with a confirmed history of orolabial herpes should be taking suppressive antiviral therapy during all periods of training and competition. Rugby players (especially forwards who participate in scrums), mixed–martial arts fighters, and even boxers are also at risk.

Herpetic Whitlow

Herpes simplex infection may occur infrequently on the fingers or periungually. Lesions begin with tenderness and erythema, usually of the lateral nailfold or on the palm. Deep-seated blisters develop 24–48 hours after symptoms begin (Fig. 19.6). The blisters may be tiny, under the thick epidermis, and require careful inspection to detect them. Deep-seated lesions that appear unilocular may be mistaken for a paronychia or other inflammatory process. Lesions may progress to erosions or may heal without ever impairing epidermal integrity because of the thick stratum corneum in this location. Herpetic whitlow may simulate a felon. Swelling of the affected hand can occur. Lymphatic streaking and swelling of the epitrochlear or axillary lymph nodes may occur, mimicking a bacterial cellulitis. Repeated episodes of herpetic lymphangitis may lead to persistent lymphedema of the affected hand. Herpetic whitlow has become much less common among health care workers since the institution of universal precautions and glove use during contact with the oral mucosa. Currently, most cases are seen in persons with herpes elsewhere. Children may be infected while

Fig. 19.5 Herpes gladiatorum.

Fig. 19.6 Herpetic whitlow, classic grouped vesicles.

thumb sucking or nail biting during their initial herpes outbreak or by touching an infectious lesion of an adult. Herpetic whitlow is bimodal in distribution, with about 20% of cases occurring in children younger than 10 years and 55% of cases in adults between ages 20 and 40. Virtually all cases in children are caused by HSV-1, and there is often a coexisting herpetic gingivostomatitis. In adults, up to three quarters of cases are caused by HSV-2. Among adults, herpetic whitlow is twice as common in women. Herpetic whitlow in health care workers can be transmitted to patients. In patients whose oropharynx is exposed to the ungloved hands of health care workers with herpetic whitlow, 37% develop herpetic pharyngitis.

Herpetic Keratoconjunctivitis

Herpes simplex infection of the eye is a common cause of blindness in the United States. It occurs as a punctate or marginal keratitis or as a dendritic corneal ulcer, which may cause disciform keratitis and leave scars that impair vision. Topical corticosteroids in this situation may induce perforation of the cornea. Vesicles may appear on the lids, and preauricular nodes may be enlarged and tender. Recurrences are common. Ocular symptoms in any person with an initial outbreak of HSV could represent ocular HSV, and an ophthalmologic evaluation should be performed to exclude this possibility.

Genital Herpes

Genital herpes infection is usually caused by HSV-2. In the mid-1980s the prevalence of genital herpes caused by HSV-1 began to increase because of changes in sexual habits and decreasing prevalence of orolabial HSV-1 infection in developed nations. In women under age 25, HSV-1 represents more than 50% of cases of genital herpes, whereas in women over 25 and in men of all ages, HSV-2 remains the most common cause of genital herpes. HSV-1 in the genital area is much less likely to recur. Only 20%–50% of patients have a recurrence; when it does recur, the average patient experiences only about one outbreak per year.

Genital herpes is spread by skin-to-skin contact, usually during sexual activity. The incubation period averages 5 days. Active lesions of HSV-2 contain live virus and are infectious. Persons with recurrent genital herpes shed virus asymptomatically between outbreaks (asymptomatic shedding). Even persons who are HSV-2 infected but have never had a clinical lesion (or symptoms) shed virus, so everyone who is HSV-2 infected is potentially infectious to a sexual partner. Asymptomatic shedding occurs simultaneously from several anatomic sites (penis, vagina, cervix, rectum) and can occur through normally appearing intact skin and mucosae. In addition, persons with HSV-2 infection may have lesions they do not recognize as being caused by HSV (unrecognized outbreak) or have recurrent lesions that do not cause symptoms (subclinical outbreak). Most transmission of genital herpes occurs during subclinical or unrecognized outbreaks, or while the infected person is shedding asymptomatically.

The risk of transmission in monogamous couples, in which only one partner is infected, is about 5%–10% annually, with women being at much greater risk than men for acquiring HSV-2 from their infected partner. Prior HSV-1 infection does not reduce the risk of being infected with HSV-2 but does make it more likely that initial infection will be asymptomatic. There is no strategy that absolutely prevents herpes transmission. All prevention strategies are more effective in reducing the risk of male-to-female transmission than female-to-male transmission. Condom use for all sexual exposures and avoiding sexual exposure when active lesions are present have been shown to be effective strategies, as has chronic suppressive therapy of the infected partner with valacyclovir.

The symptomatology during acquisition of infection with HSV-2 has a broad clinical spectrum, from totally asymptomatic to severe genital ulcer disease (erosive vulvovaginitis or proctitis). Only 57% of new HSV-2 infections are symptomatic. Clinically, the majority of symptomatic initial herpes lesions are classic, grouped blisters on an erythematous base. At times, the initial clinical episode is that of typical grouped blisters, but with a longer duration of 10–14 days. Although uncommon and representing 1% or fewer of new infections, severe first-episode genital herpes can be a significant systemic illness. Grouped blisters and erosions appear in the vagina, in the rectum, or on the penis, with continued development of new blisters over 7–14 days. Lesions are bilaterally symmetric and often extensive, and the inguinal lymph nodes can be enlarged bilaterally. Fever and flulike symptoms may be present, but in women the major complaint is vaginal pain and dysuria (herpetic vulvovaginitis). The whole illness may last 3 weeks or more. If the inoculation occurs in the rectal area, severe proctitis may occur from extensive erosions in the anal canal and on the rectal mucosa. The initial clinical episode of genital herpes is treated with oral acyclovir, 200 mg five times or 400 mg three times daily; famciclovir, 250 mg three times daily; or valacyclovir, 1000 mg twice daily, all for 7–10 days. It is clinically difficult to distinguish true initial (or primary) HSV-2 infection from a recurrence, so all patients with their initial clinical episode receive the same therapy. Only serology can determine whether the person is totally HSV naïve and experiencing a true primary episode, is partially immune from prior HSV-1 infection, or is already HSV-2 infected with first clinical presentation actually a recurrence. In fact, 25% of "initial" clinical episodes of genital herpes are actually recurrences.

Virtually all persons infected with HSV-2 will have recurrences, even if the initial infection was subclinical or asymptomatic. HSV-2 infection results in recurrences in the genital area six times more frequently than HSV-1. Twenty percent of persons with HSV-2 infection are truly asymptomatic, never having had either an initial lesion or a recurrence. Twenty percent of patients have lesions they recognize as recurrent genital herpes, and 60% have clinical lesions that are culture positive for HSV-2, but that are unrecognized by the patient as being caused by genital herpes. This large group of persons with subclinical or unrecognized genital herpes are infectious, at least intermittently, and represent one factor in the increasing number of new HSV-2 infections.

Typical recurrent genital herpes begins with a prodrome of burning, itching, or tingling. Usually within 24 hours, red papules appear at the site, progress to blisters filled with clear fluid over 24 hours, form erosions over the next 24–36 hours, and heal in another 2–3 days (Fig. 19.7). The average total duration of a typical outbreak of genital herpes is 7 days. Lesions are usually grouped blisters and evolve into coalescent grouped erosions, which characteristically have a scalloped border. Erosions or ulcerations

Fig. 19.7 Herpes genitalis. (Courtesy Steven Binnick, MD.)

from genital herpes are usually very tender and not indurated (unlike chancre of primary syphilis). Lesions tend to recur in the same anatomic region, although not at exactly the same site (unlike fixed drug eruption). Less classic clinical manifestations are tiny erosions or linear fissures on the genital skin. Lesions occur on the vulva, vagina, and cervical mucosa, as well as on the penile and vulval skin. The upper buttock is a common site for recurrent genital herpes in both men and women. Intraurethral genital herpes may present with dysuria and a clear penile discharge and is usually misdiagnosed as a more common, nongonococcal urethritis such as *Chlamydia* or *Ureaplasma* infection. Inguinal adenopathy may be present. Looking into the urethra and culturing any erosions will establish the diagnosis. Recurrent genital herpes usually heals without scarring.

The natural history of untreated recurrent genital herpes is not well studied. Over the first few years of infection, the frequency of recurrences usually stays the same. Over periods longer than 3–5 years, the frequency of outbreaks decreases in at least two thirds of patients treated with suppressive antiviral therapy.

Recurrent genital herpes is a problematic disease because of the associated social stigma. Because it is not curable, patients frequently have a significant emotional response when first diagnosed, including anger (at presumed source of infection), depression, guilt, and feelings of unworthiness. During the visit, the health care worker should ask about the patient's feelings and any psychological complications. This psychological component of genital herpes must be recognized, addressed directly with the patient, and managed properly for the therapy of recurrent genital herpes to be successful. Education regarding timing of outbreak and exposure, including potential for initial asymptomatic infection, is important.

Management of recurrent genital herpes should be individualized. A careful history, including a sexual history, should be obtained. Examination should include seeing the patient during an active recurrence so that the infection can be confirmed. The diagnosis of recurrent genital herpes should not be made on clinical appearance alone because of the psychological impact of the diagnosis. The diagnosis is best confirmed by viral culture, PCR, or DFA, allowing for typing of the causative virus. Genital HSV is a risk factor for HIV infection, and patients with genital HSV should be evaluated for and counseled about other STDs.

Treatment depends on several factors, including the frequency of recurrences, severity of recurrences, infection status of the sexual partner, and psychological impact of the infection on the patient. For patients with few or mildly symptomatic recurrences, treatment is often unnecessary. Counseling regarding transmission risk is required. In patients with severe but infrequent recurrences and in those with severe psychological complications, intermittent therapy may be useful. To be effective, intermittent therapy must be initiated at the earliest sign of an outbreak. The patient must be given the medication before the recurrence so that treatment can be started by the patient when the first symptoms appear. Intermittent therapy only reduces the duration of the average recurrence by about 1 day. However, it is a powerful tool in the patient who is totally overwhelmed by each outbreak. The treatment of recurrent genital herpes is acyclovir, 200 mg five times daily or 800 mg twice daily, or famciclovir, 125 mg twice daily, for 5 days. Shorter regimens that are equally effective include valacyclovir, 500 mg twice daily for 3 days; acyclovir, 800 mg three times daily for 2 days; or famciclovir, 1 g twice daily for 1 day.

For patients with frequent recurrences (>6–12 yearly), suppressive therapy may be more reasonable. Acyclovir, 400 mg twice daily, 200 mg three times daily, or 800 mg once daily, will suppress 85% of recurrences, and 20% of patients will be recurrence free during suppressive therapy. Valacyclovir, 500 mg/day (or 1000 mg/day for those with >10 recurrences/year), or famciclovir, 250 mg twice daily, is an equally effective alternative. Up to 5% of immunocompetent patients will have significant recurrences on these doses, and the dose of the antiviral may need to be increased. Chronic suppressive therapy reduces asymptomatic shedding by almost 95%. After 10 years of suppressive therapy, many patients can stop treatment, with substantial reduction in frequency of recurrences. Chronic suppressive therapy is safe, and laboratory monitoring is not required.

Intrauterine and Neonatal Herpes Simplex

Neonatal herpes infection occurs in 1:3000 to 1:20,000 live births, with an estimate of 14,000 cases annually worldwide and 1500–2200 cases of neonatal herpes annually in the United States. Eighty-five percent of neonatal herpes simplex infections occur at delivery; 5% occur in utero with intact membranes; and 10%–15% occur from nonmaternal sources after delivery. In utero infection may result in fetal anomalies, including skin lesions and scars, limb hypoplasia, microcephaly, microphthalmos, encephalitis, chorioretinitis, and intracerebral calcifications. It is either fatal or complicated by permanent neurologic sequelae.

Seventy percent of neonatal herpes simplex infections are caused by HSV-2 worldwide; however, in the United States recently HSV-1 was reported more frequently than HSV-2. Neonatal HSV-1 infections are usually acquired postnatally through contact with a person with orolabial disease, but can also occur intrapartum if the mother is genitally infected with HSV-1. The clinical spectrum of perinatally acquired neonatal herpes can be divided into the following three forms:

1. Localized infection of the skin, eyes, and/or mouth (SEM)
2. Central nervous system (CNS) disease
3. Disseminated disease (encephalitis, hepatitis, pneumonia, and coagulopathy)

The pattern of involvement at presentation is important prognostically. With treatment, localized disease (skin, eyes, or mouth) is rarely fatal, whereas brain or disseminated disease is fatal in 15%–50% of neonates so affected. In treated neonates, long-term sequelae occur in 10% of infants with localized disease. More than 50% of patients with CNS or disseminated neonatal herpes have neurologic disability.

In 68% of infected babies, skin vesicles are the presenting sign and are a good source for virus recovery. However, 39% of neonates with disseminated disease, 32% with CNS disease, and 17% with SEM disease never develop vesicular skin lesions. Because the incubation period may be as long as 3 weeks and averages about 1 week, skin lesions and symptoms may not appear until the child has been discharged from the hospital.

The diagnosis of neonatal herpes is confirmed by viral culture or preferably immediate DFA staining of material from skin or ocular lesions. CNS involvement is detected by PCR of the cerebrospinal fluid (CSF). PCR of the CSF is negative in 24% of neonatal CNS herpes infections, so pending other testing, empiric therapy may be required. Neonatal herpes infections are treated with IV acyclovir for 14 days for SEM disease and for 21 days for CNS and disseminated disease.

Seventy percent of mothers of infants with neonatal herpes simplex are asymptomatic at delivery and have no history of genital herpes. Thus extended history taking is of no value in predicting which pregnancies may be complicated by neonatal herpes. The most important predictors of infection appear to be the nature of the mother's infection at delivery (first episode vs. recurrent) and the presence of active lesions on the cervix, vagina, or vulvar area. The risk of infection for an infant delivered vaginally when the mother has active recurrent genital herpes infection is 2%–5%, whereas it is 26%–56% if the maternal infection at delivery is a first episode. One strategy to prevent neonatal HSV would be to prevent transmission of HSV to at-risk women during pregnancy, eliminating initial HSV episodes during pregnancy. To accomplish this, pregnant women and their partners would be tested to identify discordant couples for HSV-1 and HSV-2. If the woman is HSV-1 negative and the man is HSV-1 positive, orogenital contact during pregnancy should be avoided and a condom used for all episodes of sexual contact. Valacyclovir suppression of the infected male could also be considered but might have limited efficacy. If the woman is HSV-2 seronegative and her partner is HSV-2 seropositive, barrier protection for sexual contact during gestation is recommended, and valacyclovir suppression of the man could be considered. Abstinence from intercourse during the third trimester would also reduce the chances of an at-risk mother acquiring genital herpes that might first present perinatally. These strategies have not been tested and could not be guaranteed to prevent all cases of neonatal HSV. At a minimum, discordant couples should be informed of the increased risk to the fetus from the mother's acquisition of HSV during pregnancy.

The appropriate management of pregnancies complicated by genital herpes is complex and still controversial. Routine prenatal cultures are not recommended for women with recurrent genital herpes because they do not predict shedding at delivery. Such cultures may be of value in women with primary genital herpes during pregnancy. Scalp electrodes should be avoided in deliveries where cervical shedding of HSV is possible; they can increase the risk of neonatal infection by up to sevenfold (Fig. 19.8). Vacuum-assisted delivery also increases the relative risk of neonatal transmission of HSV 2–27 times. Genital HSV-1 infection appears to be much more frequently transmitted intrapartum than HSV-2. The current recommendation is still to perform cesarean section in the mother with active genital lesions or prodromal symptoms. This will reduce the risk of transmission of HSV to the infant from 8% to 1% for women who are culture positive from the cervix at delivery. However, this approach will not prevent all cases of neonatal herpes, is expensive, and has a high maternal morbidity. Because the risk of neonatal herpes is much greater in mothers who experience their initial episode during pregnancy, antiviral treatment of all initial episodes of genital HSV in pregnancy is recommended (except in the first month of gestation, when there may be an increased risk of spontaneous abortion). Standard acyclovir doses for initial episodes, 400 mg three times daily for 10 days, are recommended. This is especially true for all initial episodes in the third trimester. Chronic suppressive therapy with acyclovir has been used from 36 weeks of gestation to delivery in women with an initial episode of genital HSV during pregnancy, to reduce outbreaks and prevent the need for cesarean section. This approach has been recommended by the American College of Obstetrics and Gynecology and may also be considered for women with recurrent genital herpes.

The condition of extensive congenital erosions and vesicles healing with reticulate scarring may represent intrauterine neonatal herpes simplex. The condition is rare because intrauterine HSV infection is rare and usually fatal. Probably only a few children survive to present later in life with the characteristic widespread reticulate scarring of the whole body. This may explain the associated CNS manifestations seen in many affected children. One author treated a child with this condition who developed infrequent widespread cutaneous blisters from which HSV could be cultured. Modern obstetric practices, which screen for herpes in pregnant women, and prophylactic treatment with acyclovir in the third trimester may prevent the condition, explaining the lack of recent cases.

Eczema Herpeticum (Kaposi Varicelliform Eruption)

Infection with herpesvirus in patients with atopic dermatitis (AD) may result in spread of herpes simplex throughout the eczematous areas, called eczema herpeticum (EH) (Fig. 19.9) or Kaposi varicelliform eruption (KVE). In a large series, development of EH was associated with more severe AD, higher IgE levels, elevated eosinophil count, food and environmental allergies (as defined by radioallergosorbent testing [RAST]), and onset of AD before age 5 years. EH patients are also more likely to have *Staphylococcus aureus* and molluscum contagiosum infections. All these features identify AD patients who have significant T-helper type 2 cell (Th2) shift of their immune system. The use of topical calcineurin inhibitors (TCIs) has been repeatedly associated with EH

Fig. 19.8 Neonatal herpes; a scalp monitor was associated with infection of this infant.

Fig. 19.9 Eczema herpeticum.

Fig. 19.10 Eczema herpeticum, sudden appearance of uniform erosions, accentuated in areas of active dermatitis.

development. Bath or hot tub exposure has been reported as a risk factor. The Th2 shift of the immune system and TCIs are both associated with a decrease in antimicrobial peptides in the epidermis, an important defense against cutaneous HSV infection. Increased interleukin-10 (IL-10)–producing proinflammatory monocytes lead to local expansion of regulatory T cells and may contribute to the development of EH. HLA-B7 and local IL-25 expression are also associated with EH. In Japan, polymorphisms in the gene for IL-19 are associated with EH complicating TCI treatment. The repair of the epidermal lipid barrier with physiologic lipid mixtures reverses some of the negative effects of the TCIs and may reduce the risk of EH. One sequencing study suggested that *IFNGR1* variants may confer susceptibility.

Cutaneous dissemination of HSV-1 or HSV-2 may also occur in severe seborrheic dermatitis, scabies, Darier disease, benign familial pemphigus, pemphigus (foliaceus or vulgaris), pemphigoid, cutaneous T-cell lymphoma, Wiskott-Aldrich syndrome, allergic and photoallergic contact dermatitis, burns, and other states with widespread damage to the epidermis. In its severest form, hundreds of umbilicated vesicles may be present at the onset, with fever and regional adenopathy. Although the cutaneous eruption is alarming, the disease is often self-limited in healthy individuals. Much milder cases are considerably more common and probably go unrecognized and untreated. They present as a few superficial erosions or even small papules (Fig. 19.10). In patients with systemic immunosuppression in addition to an impaired barrier, such as patients with pemphigus and cutaneous T-cell lymphoma, KVE can be fatal, usually from *S. aureus* septicemia, but also from visceral dissemination of herpes simplex.

Psoriasis patients treated with immunosuppressants may develop KVE as well, although this is less common. It usually occurs in the setting of worsening disease or erythroderma. Patients present with erosive lesions in the axilla and erosions of the psoriatic plaques. Lesions extend cephalad to caudad, and the development of large, ulcerated, painful plaques can occur. The lesions are often coinfected with bacteria and yeast. Cultures positive for other pathogens do *not* exclude the diagnosis of KVE, and specific viral culture, DFA, and biopsy should be done if diagnosis of KVE is suspected. Given the limited toxicity of systemic antiviral therapy, treatment should be started immediately, pending the return of laboratory confirmation. Depending on the severity of the disease, either IV or oral antiviral therapy should be given for KVE patients. In children with EH, bacterial superinfection is not uncommon, and early antibiotics in patients with bacteremia are important, though empiric antibiotics are not indicated. Systemic steroids should be avoided, but topical corticosteroids during an eruption do not appear to prolong hospital stay and in some cases may be helpful, though further study is necessary.

Fig. 19.11 Ulcerative herpes simplex in an HIV-infected patient.

Immunocompromised Patients

In patients with suppression of the cell-mediated immune system by cytotoxic agents, corticosteroids, or congenital or acquired immunodeficiency, primary and recurrent cases of herpes simplex are more severe, persistent, and symptomatic and more resistant to therapy. In some settings, such as in bone marrow transplant recipients, the risk of severe reactivation is so high that prophylactic systemic antivirals are administered. In immunosuppressed patients, any erosive mucocutaneous lesion should be considered to be herpes simplex until proved otherwise, especially lesions in the genital and orolabial regions. Atypical morphologies are also seen. HSV reactivation is common with institution of effective antiretroviral therapy (ART) and can be part of the immune reconstitution inflammatory syndrome (IRIS). Oral antivirals prevent this reactivation and can be considered in the HIV-infected patient who will receive ART.

Typically, lesions appear as erosions or crusts (Fig. 19.11). The early vesicular lesions may be transient or never seen. The three clinical hallmarks of HSV infection are pain, an active vesicular border, and a scalloped periphery. Untreated erosive lesions may gradually expand, but they may also remain fixed and even become papular or vegetative, mimicking a wart or granulation tissue. In the oral mucosa, numerous erosions may be seen, involving all surfaces, unlike the hard, keratinized surfaces usually involved by recurrent oral herpes simplex in the immunocompetent host. The tongue may be affected with geometric fissures on the central dorsal surface (Fig. 19.12). Symptomatic stomatitis associated with cancer chemotherapy may be caused or exacerbated by HSV infection. Herpetic whitlow presents as a painful paronychia that is initially vesicular and involves the lateral or proximal nailfolds. Untreated, it may lead to loss of the nail plate and ulceration of a large portion of the digit.

Despite the frequent and severe skin infections caused by HSV in the immunosuppressed patient, visceral dissemination is unusual. Extension of oral HSV into the esophagus or trachea may develop spontaneously or as a complication of intubation through an infected

Fig. 19.12 Immunocompromised patient with tongue ulcer and fissures secondary to HSV.

oropharynx. Ocular involvement can occur from direct inoculation, and if lesions are present around the eye, careful ophthalmologic evaluation is required.

In an immunosuppressed host, most herpetic lesions are ulcerative and not vesicular. Viral cultures or PCR from the ulcer margin are positive. At times, these tests are negative, but a skin biopsy will show typical herpetic changes in the epithelium adjacent to the ulceration. If an ulceration does not respond to treatment in 48 hours and cultures are negative, a biopsy is recommended, because it may be the only technique that demonstrates the associated herpesvirus infection.

Therapy often can be instituted on clinical grounds pending confirmatory tests. Acyclovir, 400 mg orally three times daily; famciclovir, 500 mg twice daily; or valacyclovir, 1 g twice daily, all for a minimum of 5–10 days, is used. Therapy should continue until lesions are essentially healed. In severe infection, or in the hospitalized patient with moderate disease, IV acyclovir (5 mg/kg) can be given initially to control the disease. In patients with acquired immunodeficiency syndrome (AIDS) and those with persistent immunosuppression, consideration should be given to chronic suppressive therapy with acyclovir, 400–800 mg two or three times daily, or valacyclovir or famciclovir, 500 mg twice daily.

In the immunosuppressed host (but not in the immunocompetent host), long-term treatment with acyclovir and its analogs, or treatment of large herpetic ulcerations, may be complicated by the development of acyclovir resistance. This resistance may be caused by selection of acyclovir-resistant wild-type virus, which is present in large numbers on the surface of such large herpes lesions. In the immunocompetent host, these acyclovir-resistant mutants are few in number and eradicated by the host's immune system. The immunosuppressed host has much more HSV in the lesions, and the host's immune system is ineffective in killing the virus. These acyclovir-resistant viral strains may be difficult to culture and may be identified only by skin biopsy or PCR of the ulceration. Antiviral resistance is suspected if maximum oral doses of acyclovir, valacyclovir, or famciclovir do not lead to improvement. IV acyclovir, except if given by constant infusion, will also invariably fail in such patients. Resistance to one drug is associated with resistance to all three of these drugs, usually from loss of the viral thymidine kinase. HSV isolates can be tested for sensitivity to acyclovir and some other antivirals. The standard treatment of acyclovir-resistant herpes simplex is IV foscarnet. In patients intolerant of or resistant to foscarnet, IV cidofovir may be used; brincidofovir is being investigated and may be an option in the future. Smaller lesions can sometimes be treated with topical trifluorothymidine (Viroptic) with or without topical or intralesional interferon (IFN) alpha, or topical or intralesional cidofovir. Imiquimod may sometimes be of benefit in healing these lesions, perhaps through activation of cystatin A. Destruction of small lesions by desiccation, followed by the previous therapies, may also be curative. If an HIV-infected patient with previous acyclovir-resistant genital herpes has a recurrence, at least half will be acyclovir sensitive, as the latent virus within the nerve that is reactivating is usually the initial virus from first infection, so a trial of standard antivirals is acceptable. If an AIDS patient has a nonhealing genital ulcer that harbors HSV, there may be dual infection with cytomegalovirus, and only treatment with an agent active against both HSV and CMV will lead to improvement in those cases.

Histopathology

The vesicles of herpes simplex are intraepidermal. The affected epidermis and adjacent inflamed dermis are infiltrated with leukocytes. Ballooning degeneration of the epidermal cells produces acantholysis. The most characteristic feature is the presence of multinucleated giant cells, which tend to mold together, forming a crude jigsaw puzzle appearance. The steel-gray color of the nucleus and peripheral condensation of the nucleoplasm may be clues to HSV infection, even if multinucleate cells are not seen. IP stains can detect HSV and differentiate from VZV even in paraffin-fixed tissue, allowing the diagnosis to be absolutely confirmed from histologic material.

Differential Diagnosis

Herpes labialis most often must be differentiated from impetigo. Herpetic lesions are composed of groups of tense, small vesicles, whereas in bullous impetigo, the blisters are unilocular, occur at the periphery of a crust, and are flaccid. A mixed infection is not unusual and should especially be suspected in immunosuppressed hosts and when lesions are present in the typical herpetic regions around the mouth. Herpes zoster presents with clusters of lesions along a dermatome, but early on, if the number of zoster lesions is limited, it can be relatively indistinguishable from herpes simplex. In general, herpes zoster will be more painful and over 24 hours will progress to involve more of the affected dermatome.

A genital herpes lesion, especially on the glans or corona, can be mistaken for a syphilitic chancre or chancroid. Darkfield examination, multiplex PCR, and cultures for *Haemophilus ducreyi* on selective media will aid in making the diagnosis, as will diagnostic tests for HSV (Tzanck, culture, or DFA). Combined infections occur in up to 20% of patients, so finding a single pathogen may not complete the diagnostic evaluation, and patients are often empirically treated for multiple ulcer-forming STDs and screened for other STDs when one is diagnosed.

Herpetic gingivostomatitis is often difficult to differentiate from aphthosis, streptococcal infections, diphtheria, coxsackievirus infections, and oral erythema multiforme. Aphthae tend to occur mostly on the buccal and labial mucosae. They usually form shallow, grayish erosions, generally surrounded by a prominent ring of hyperemia. Aphthae typically occur on nonattached mucosa, whereas recurrent herpes of the oral cavity primarily affects the attached gingiva and palate.

Varicella

Varicella, commonly known as chickenpox, is the primary infection with the VZV. In temperate regions, 90% of cases occur in children younger than 10 years, with the highest age-specific incidence in ages 1–4 in unvaccinated children. More than 90% of adults in temperate countries have evidence of prior infection and are "immune" to varicella by age 15. In tropical countries, however, varicella tends to be a disease of teenagers, and only 60% of adults are "immune" serologically. Outbreaks among non–U.S.-born crew members have occurred on cruise ships.

The incubation period of VZV is 10–21 days, usually 14–15 days. Transmission is by the respiratory route and less often by direct contact with the lesions. A susceptible person may develop varicella after exposure to the lesions of herpes zoster. Infected persons are infectious from 5 days before the eruption appears and are most infectious 1–2 days before the rash appears. Infectivity usually ceases 5–6 days after the eruption appears. There is an initial viral replication in the nasopharynx and conjunctiva, followed by viremia and infection of the reticuloendothelial system (liver, spleen) between days 4 and 6. A secondary viremia occurs at days 11–20, resulting in infection of the epidermis and the appearance of the characteristic skin lesions. Low-grade fever, malaise, and headache are usually present but slight. The severity

Fig. 19.13 Varicella.

Fig. 19.14 Varicella with bullous impetigo as a complication.

of the disease is age dependent, with adults having more severe disease and a greater risk of visceral disease. In healthy children, mortality from varicella is 1.4 in 100,000 cases; in adults, 30.9 in 100,000 cases. Pregnant women have five times greater risk of an adverse outcome. As with most viral infections, immunosuppression may worsen the course of the disease. Lifelong immunity follows varicella, and second episodes of "varicella" indicate either immunosuppression or another viral infection such as coxsackievirus.

Varicella is characterized by a vesicular eruption consisting of delicate "teardrop" vesicles on an erythematous base (Fig. 19.13). The eruption starts with faint macules that develop rapidly into vesicles within 24 hours. Successive fresh crops of vesicles appear for a few days, mainly on the trunk, face, and oral mucosa. Initially, the exanthem may be limited to sun-exposed areas, the diaper area of infants, or sites of inflammation. The vesicles quickly become pustular and umbilicated, then crusted. Because the lesions appear in crops, lesions of various stages are present at the same time, a useful clue to the diagnosis. Lesions tend not to scar, but larger lesions and those that become secondarily infected may heal with a characteristic round, depressed scar.

Secondary bacterial infection with *S. aureus* or a streptococcus is the most common complication of varicella (Fig. 19.14). Rarely, it may be complicated by osteomyelitis, other deep-seated infections, or septicemia. Other complications are rarer. Pneumonia is uncommon in normal children but is seen in 1 in 400 adults with varicella. It may be bacterial or caused by VZV, a difficult differential diagnosis. Cerebellar ataxia and encephalitis are the most common neurologic complications. VZV can rarely infect cerebral arteries and cause a vasculopathy leading to stroke, sinus thromboses, and giant cell arteritis. VZV may cause stroke in both children and adults. Asymptomatic myocarditis and hepatitis may occur in children with varicella, but rarely are significant and resolve spontaneously with no treatment. Reye syndrome, with hepatitis and acute encephalopathy, is associated with the use of aspirin to treat the symptoms of varicella. Aspirin is absolutely contraindicated in patients with varicella. Any child with varicella and severe vomiting should be referred immediately to exclude Reye syndrome. Symptomatic thrombocytopenia is a rare manifestation of varicella, which can occur either with the exanthem or several weeks after. Purpura fulminans, a form of disseminated intravascular coagulation associated with low levels of proteins C and S, may complicate varicella.

The diagnosis of varicella is easily made clinically. Tzanck smear from a vesicle will usually show characteristic multinucleate giant cells, and DFA can confirm the infection and type the virus. PCR is increasingly used due to high sensitivity and specificity. VZV grows poorly and slowly in the laboratory, so viral culture is rarely indicated.

Treatment

Both immunocompetent children and adults with varicella benefit from acyclovir therapy if started early, within 24 hours of the eruption's appearance. Therapy does not seem to alter the development of adequate immunity to reinfection. Because the complications of varicella are infrequent in children, routine treatment is not recommended; therapeutic decisions are made on a case-by-case basis. Acyclovir therapy appears mainly to benefit secondary cases within a household, which tend to be more severe than the index case. In this setting, therapy can be instituted earlier. Therapy does not return children to school sooner, however, and the impact on parental workdays missed is not known. The dose of acyclovir is 20 mg/kg, maximum 800 mg per dose, four times daily for 5 days. Aspirin and other salicylates should not be used as antipyretics in varicella because their use increases the risk of Reye syndrome. Topical antipruritic lotions, oatmeal baths, dressing the patient in light, cool clothing, and keeping the environment cool may all relieve some of the symptomatology. Children living in warm homes and kept very warm with clothing have anecdotally been observed to have more numerous skin lesions. Children with AD, Darier disease, congenital ichthyosiform erythroderma, diabetes, cystic fibrosis, conditions requiring chronic salicylate or steroid therapy, and inborn errors of metabolism should be treated with acyclovir, because they may have more complications or exacerbations of their underlying illness with varicella.

Varicella is more severe and complications are more common in adults. Between 5% and 14% of adults will have pulmonary involvement. Smokers and those with preexisting lung disease (but not asthma) are at increased risk. The pneumonitis can progress rapidly and be fatal. Adults with varicella and at least one other risk factor should be evaluated with physical examination, pulse oximetry, and chest radiography. Antiviral treatment is recommended in all adolescents and adults (13 and older) with varicella. The dose is 800 mg four or five times daily for 5 days. Severe, fulminant cutaneous disease and visceral complications are treated with IV acyclovir, 10 mg/kg every 8 hours, adjusted for creatinine clearance. If the patient is hospitalized for therapy, strict isolation is required. Patients with varicella should not be admitted to wards with immunocompromised hosts or to pediatric wards, but rather are best placed on wards with healthy patients recovering from acute trauma.

Pregnant Women and Neonates

Maternal VZV infection may result in severe illness in the mother, and if the infection occurs before 28 weeks of gestation, and especially before 20 weeks, a small but significant risk of infection of the fetus (congenital varicella syndrome). In one study, 4 of 31 women with varicella in pregnancy developed varicella pneumonia. The risk for spontaneous abortion by 20 weeks is 3%; in an additional 0.7% of pregnancies, fetal death occurs after 20 weeks. The risk of preterm labor, as reported in various studies, has varied from no increased risk to a threefold increase. Severe varicella and varicella pneumonia or disseminated disease in pregnancy should be treated with IV acyclovir. All varicella in pregnancy should be treated with oral acyclovir, 800 mg five times daily for 7 days, (adjusted for renal function) except perhaps during the first month, when a specialist should be consulted. In all women past 35 weeks of gestation or with increased risk of premature labor, admission and IV acyclovir, 10 mg/kg three times daily, ("adjusted for renal function") should be recommended. The patient should be evaluated for pneumonia, renal function should be carefully monitored, and the patient should be switched to oral therapy once lesions stop appearing (usually in 48–72 hours).

Varicella-zoster immune globulin (VZIG) should not be given once the pregnant woman has developed varicella. VZIG should be given for significant exposures (see next section) within the first 72–96 hours to ameliorate maternal varicella and prevent complications. Its use should be limited to seronegative women because of its cost and the high rate of asymptomatic infection in U.S. patients. The lack of a history of prior varicella is associated with seronegativity in only 20% or fewer of the U.S. population.

Congenital varicella syndrome is characterized by a series of anomalies, including hypoplastic limbs (usually unilateral and lower extremity), cutaneous scars, and ocular and CNS disease. This may not be identified until months after infection. Repeated sonographic examination can be used to monitor at-risk pregnancies. Female fetuses are affected more often than males. The overall risk for this syndrome is about 0.4%; the highest risk, about 2%, is from maternal varicella between weeks 13 and 20. Infection of the fetus in utero may result in zoster occurring postnatally, often in the first 2 years of life. This occurs in about 1% of varicella-complicated pregnancies, and the risk for this complication is greatest in varicella occurring in weeks 25–36 of gestation. The value of VZIG in preventing or modifying fetal complications of maternal varicella is unknown. In one study, however, of 97 patients with varicella in pregnancy treated with VZIG, none had complications of congenital varicella syndrome or infantile zoster, suggesting some efficacy for VZIG. Although apparently safe in pregnancy, acyclovir's efficacy in preventing fetal complications of maternal varicella is unknown.

If the mother develops varicella between 5 days before and 2 days after delivery, neonatal varicella can occur and may be severe because of inadequate transplacental delivery of antivaricella antibody. These neonates develop varicella at 5–10 days of age. In such cases, administration of VZIG is warranted, and IV acyclovir therapy should be considered.

Varicella Vaccine

Live attenuated viral vaccine for varicella is a currently recommended childhood immunization. Two doses are now recommended, one between age 12 and 15 months and the second at 4–6 years. This double-vaccination schedule is recommended because epidemics of varicella still occurred in children ages 9–11 in well-immunized communities, suggesting a waning of immunity by this age. The introduction of widespread vaccination has led to a dramatic decrease in varicella-related hospitalizations. Complications of varicella vaccination are uncommon, and severe complications are rare. A systematic literature review suggested that there were approximately 50–60 breakthrough varicella cases with disseminated infection associated with over 30 million doses of virus. A mild skin eruption from which virus usually cannot be isolated, occurring locally at the injection site within 2 days or generalized 1–3 weeks after immunization, occurs in 6% of children. Many of the breakthrough cases in vaccinated children are mild, and many reported skin lesions were not vesicular (see next section, Modified Varicella-like Syndrome). Prevention of severe varicella is virtually 100%, even when the vaccine is given within 36 hours of exposure. Immunized children with no detectable antibody also have reduced severity of varicella after exposure. Secondary complications of varicella, including scarring, are virtually eliminated by vaccination. One theoretical population-based consequence of widespread vaccination and reduced rates of infection is whether there will be an observed loss of natural "booster" exposures to the virus, and perhaps a changing epidemiology of the disease and increased incidence of zoster (shingles).

Household exposure of immunosuppressed children to recently immunized siblings does not appear to pose a great risk. Children whose leukemia is in remission are also protected by the vaccine but may require three doses. Leukemic children still receiving chemotherapy have a complication rate from vaccination (usually a varicella-like eruption) approaching 50%. They may require acyclovir therapy. Unprotected close contacts develop varicella 15% of the time. In leukemic children, adequate immunization results in complete immunity in some and partial immunity in the others, protecting them from severe varicella. Immunization also reduces the attack rate for zoster in leukemic children. As a live vaccine, administration is contraindicated during pregnancy and in immunosuppressed patients.

Modified Varicella-Like Syndrome. Children immunized with live attenuated varicella vaccine may develop varicella of reduced severity on exposure to natural varicella. This has been called modified varicella-like syndrome (MVLS). The frequency of MVLS is between 0% and 2.7% per year, and children with lower antibody titers are more likely to develop the illness. MVLS occurs an average of 15 days after exposure to varicella and consists primarily of macules and papules with relatively few vesicles. The average number of lesions is about 35–50, compared with natural varicella, which usually has about 300 lesions. The majority of patients are afebrile and the illness is mild, lasting fewer than 5 days on average.

Immunocompromised Patients

Varicella cases can be extremely severe and even fatal in immunosuppressed patients, especially in individuals with impaired cell-mediated immunity. Before effective antiviral therapy, almost one third of children with cancer developed complications of varicella and 7% died. In this setting, varicella pneumonia, hepatitis, and encephalitis are common. Prior varicella does not always protect the immunosuppressed host from multiple episodes. The skin lesions in the immunosuppressed host are usually identical to varicella in the healthy host; however, the number of lesions may be numerous (Fig. 19.15). In an immunosuppressed patient, the lesions more frequently become necrotic, and ulceration may occur. Even if the lesions are few, the size of the lesion may be large, up to several centimeters, and necrosis of the full thickness of the dermis may occur. In patients with HIV infection, varicella may be severe and fatal. Atypical cases of a few scattered lesions without a dermatomal distribution usually represent reactivation disease with dissemination. Chronic varicella may complicate HIV infection, resulting in ulcerative (ecthymatous) or hyperkeratotic (verrucous) lesions. These patterns of infection may be associated with acyclovir resistance.

The degree of immunosuppression likely to result in severe varicella has been debated. There are case reports of severe

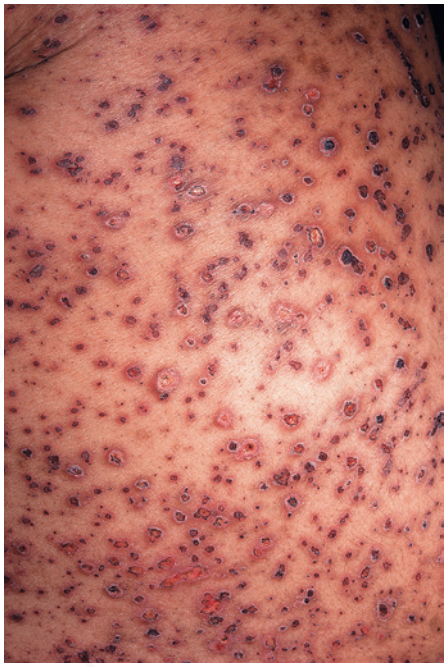

Fig. 19.15 Varicella in a patient with advanced Hodgkin disease.

and even fatal varicella in otherwise healthy children given short courses of oral corticosteroids or even using only inhaled corticosteroids. In a case-control study, however, corticosteroid use did not appear to be a risk factor for development of severe varicella. In the United Kingdom, any patient receiving or having received systemic corticosteroids in the prior 3 months, regardless of dose, is considered at increased risk for severe varicella. Inhaled steroids are not considered an indication for prophylactic antiviral treatment. A "high-risk" or significant exposure is defined as follows:

1. Household contact (i.e., living in same house as a patient with chickenpox or zoster)
2. Face-to-face contact for at least 5 minutes with a patient who has chickenpox
3. Contact indoors for more than 1 hour with a patient who has chickenpox or herpes zoster or, in a hospital setting, a patient with chickenpox or herpes zoster in an adjacent bed or the same open ward

Immunosuppressed children with no prior history of varicella and a high-risk exposure should be treated with VZIG as soon as possible after exposure (within 96 hours). Preengraftment bone marrow transplant patients should receive the same therapy. VZIG treatment does not reduce the frequency of infection, but it does reduce the severity of infection and complications. The value of prophylactic antivirals is unknown. Parents of immunosuppressed children and their physicians should be aware that severe disease can occur and counseled to return immediately after significant exposure or if varicella develops.

An unusual variant of recurrent varicella is seen in elderly patients with a history of varicella in childhood, who have a malignancy of the bone marrow and are receiving chemotherapy. They develop a mild illness with 10–40 widespread lesions and usually no systemic findings. This type of recurrent varicella tends to relapse. It is different from typical varicella because all the lesions are in a single stage of development, and thus it could be easily confused with smallpox.

Ideally, management of varicella in the immunocompromised patient would involve prevention through varicella vaccination before immunosuppression. Vaccination is safe if the person is more than 1 year from induction chemotherapy, if chemotherapy is halted about the time of vaccination, and if lymphocyte count is higher than 700/mm^3. IV acyclovir, 10 mg/kg three times daily (or 500 mg/m^2 in children) is given as soon as the diagnosis of varicella is suspected. IV therapy is continued until 2 days after all new vesicles have stopped. Oral antivirals are continued for a minimum of 10 days of treatment. VZIG is of no proven benefit once clinical disease has developed, but may be given if the patient has life-threatening disease and is not responding to IV acyclovir.

In HIV-infected adults, treatment is individualized. Persons with typical varicella should be evaluated for the presence of pneumonia or hepatitis. Valacyclovir, 1 g three times daily; famciclovir, 500 mg three times daily; or acyclovir, 800 mg 5 times daily, may be used if no visceral complications are present. Valacyclovir and famciclovir may be preferable to acyclovir because of their enhanced oral bioavailability. Visceral disease mandates IV therapy. If the response to oral antiviral agents is not rapid, IV acyclovir therapy should be instituted. The optimal duration of oral antiviral treatment is unknown but must be at least until all lesions are crusted and have no elevated or active borders. Given the safety and efficacy of oral antivirals, treatment duration of at least 10 days and perhaps longer should be considered. Most cases of chronic or acyclovir-resistant VZV infection are associated with initial inadequate oral doses of acyclovir (too short in duration, too low a dose, or in patients with gastrointestinal [GI] disease, in whom reduced GI absorption may be associated with inadequate blood levels of acyclovir). Patients with atypical disseminated disease must be treated aggressively until all lesions resolve. The diagnosis of acyclovir-resistant VZV infection may be difficult. Acyclovir-resistant VZV strains may be difficult to culture, and sensitivity testing is still not standardized or readily available for VZV. Acyclovir-resistant varicella is treated with foscarnet or, in nonresponsive patients, with cidofovir.

Varicella-Zoster Virus (Zoster, Shingles, Herpes Zoster), Human Herpesvirus Type 3

Zoster is caused by reactivation of VZV. Following primary infection or vaccination, VZV remains latent in the sensory dorsal root ganglion cells. The virus begins to replicate at some later time, traveling down the sensory nerve into the skin. Immunosuppression, including use of tumor necrosis factor (TNF) inhibitors, Janus kinase Janus kinase (JAK)-inhibitors, and some cancer therapies, HIV, and age-related deficiency of cell-mediated immunity are some of the most common causes of zoster. A family history of zoster is associated with an increased risk of developing zoster, suggesting a genetic risk component. Patients on hemodialysis and those with comorbidities have increased risk of zoster, possibly related to the association between zoster risk and cholesterol level. Statin use also slightly increases the risk for zoster. Zoster patients are more likely to be subsequently diagnosed with a malignancy, especially a hematologic malignancy, with an absolute risk of any cancer of 0.7%–1.8% at 1 year after zoster.

The incidence of zoster increases with age. Under age 45, the annual incidence is less than 1 in 1000 persons. Among patients older than 75, the rate is more than four times greater. For white persons older than 80, the lifetime risk of developing zoster is 10%–30%. Women appear to have higher risk than men. Overall, about one in three unvaccinated persons will develop herpes zoster. For unknown reasons, being nonwhite reduces the risk for herpes zoster, with African Americans one half to one fourth less likely to develop zoster. Autoimmune diseases, asthma, diabetes, and chronic obstructive pulmonary disease are also associated with increased risk. Immunosuppression, especially hematologic malignancy and HIV infection, dramatically increases the risk for zoster. In HIV-infected patients, annual incidence is 30 in 1000 persons, or an annual risk of 3%. With the universal use of varicella vaccination and decrease in pediatric and adolescent varicella cases, older persons will no longer have periodic boosts of the anti-VZV immune activity. Theoretically this could result in an increase in the incidence of zoster.

Herpes zoster classically occurs unilaterally within the distribution of a cranial or spinal sensory nerve, often with some overflow into the dermatomes above and below. The dermatomes most frequently affected are the thoracic (55%), cranial (20%, with the trigeminal nerve being the most common single nerve involved), lumbar (15%), and sacral (5%). The cutaneous eruption is frequently preceded by one to several days of pain in the affected area, although the pain may appear simultaneously or even after the skin eruption, or the eruption may be painless. The eruption initially presents as papules and plaques of erythema in the dermatome (Fig. 19.16). Within hours the plaques develop blisters. Lesions continue to appear for several days. The eruption may have few lesions or reach total confluence in the dermatome. Lesions may become hemorrhagic, necrotic, or bullous. Rarely, the patient may have pain, but no skin lesions (zoster sine herpete). Pain severity correlates with extent of the skin lesions, and elderly persons tend to have more severe pain. In patients under age 30, the pain may be minimal. Scattered lesions can occur outside the dermatome, usually fewer than 20. In the typical case, new vesicles appear for 1–5 days, become pustular, crust, and heal. The total duration of the eruption depends on three factors: patient age, severity of eruption, and presence of underlying immunosuppression. In younger patients, the total duration is 2–3 weeks, whereas in elderly patients, the cutaneous lesions of zoster may require 6 weeks or more to heal. Scarring is more common in elderly and immunosuppressed patients. Scarring also correlates with the severity of the initial eruption. Lesions may develop on the mucous membranes within the mouth in zoster of the maxillary division (Fig. 19.17) or mandibular division of the facial nerve, or in the vagina with zoster in the S2 or S3 dermatome. Zoster may appear in recent surgical scars and may follow injections of botulinum toxin.

Fig. 19.16 Herpes zoster.

Fig. 19.17 Oral zoster.

Zoster may rarely be seen in children under age 1 year. This can result from intrauterine exposure to VZV or exposure to VZV during the first few months of life. The maternal antibodies still present result in muted expression of varicella—subclinical or very mild disease. The immaturity of the infant's immune system results in poor immune response to the infection, allowing for early relapse in the form of zoster.

Disseminated Herpes Zoster

Disseminated herpes zoster is defined as more than 20 lesions outside the affected dermatome. It occurs chiefly in older or debilitated individuals, especially in patients with lymphoreticular malignancy or AIDS. Low levels of serum antibody against VZV are a highly significant risk factor in predicting dissemination of disease. The dermatomal lesions are sometimes hemorrhagic or gangrenous. The outlying vesicles or bullae, which are usually not grouped, resemble varicella and are often umbilicated and may be hemorrhagic. Visceral dissemination to the lungs, liver, and/or CNS may occur in the patient with disseminated zoster.

Fig. 19.18 Herpes zoster.

Disseminated zoster requires careful evaluation and systemic antiviral therapy. Initially, IV acyclovir is given, which may be changed to an oral antiviral agent once visceral involvement has been excluded and the patient has received at least 2–3 days of IV therapy.

Ophthalmic Zoster

In herpes zoster ophthalmicus, the ophthalmic division of the fifth cranial nerve is involved. If the external division of the nasociliary branch is affected, with vesicles on the side and tip of the nose (Hutchinson sign), the eye is involved 76% of the time, compared with 34% when it is not involved (Fig. 19.18). Vesicles on the lid margin are virtually always associated with ocular involvement. In any case, the patient with ophthalmic zoster should be seen by an ophthalmologist. Systemic antiviral therapy should be started immediately, pending ophthalmologic evaluation. Ocular involvement is most often in the form of uveitis (92%) and keratitis (50%). Less common but more severe complications include glaucoma, optic neuritis, encephalitis, hemiplegia, and acute retinal necrosis. These complications are reduced from 50% of patients to 20%–30% with effective antiviral therapy. Unlike the cutaneous lesions, ocular lesions of zoster and their complications tend to recur, sometimes as long as 10 years after the zoster episode.

Other Complications

Motor nerve neuropathy occurs in about 3% of patients with zoster and is three times more common if zoster is associated with underlying malignancy. About 75% of patients slowly recover, leaving 25% with some residual motor deficit. Thoracic zoster may be associated with motor neuropathy of the abdominal muscles resulting in a bulge on the flank or abdomen, called a "postherpetic pseudotumor." If the sacral dermatome S3, or less often S2 or S4, is involved, urinary hesitancy or actual urinary retention may occur. Hematuria and pyuria may also be present. The prognosis is good for complete recovery. Similarly, pseudoobstruction, colonic spasm, dilation, obstipation, constipation, and reduced anal sphincter tone can occur with thoracic (T6–T12), lumbar, or sacral zoster. Recovery is complete. Maxillary and mandibular alveolar bone necrosis may occur an average of 30 days after zoster of the maxillary or mandibular branches of the trigeminal nerve. Limited or widespread loss of teeth may result.

Ramsay Hunt syndrome (herpes zoster oticus) results from involvement of the facial and auditory nerves by VZV. Herpetic inflammation of the geniculate ganglion is thought to be the cause of this syndrome. The presenting features include zoster of the external ear or tympanic membrane; herpes auricularis with ipsilateral facial paralysis; or herpes auricularis, facial paralysis, and auditory symptoms. Auditory symptoms include mild to severe tinnitus, deafness, vertigo, nausea and vomiting, and nystagmus.

Herpes zoster can be associated with delayed complications, many of which are caused by vasculopathies affecting the CNS or even the peripheral arteries. There appears to be an increased risk of both ischemic and hemorrhagic stroke within the first 3 months after zoster, which fades by 1 year. Delayed contralateral hemiparesis, simulating cerebrovascular accident (stroke), is a rare but serious complication of herpes zoster that occurs weeks to months (mean 7 weeks) after an episode of zoster affecting the first branch of the trigeminal nerve. By direct extension along the intracranial branches of the trigeminal nerve, VZV gains access to the CNS and infects the cerebral arteries. Patients present with headache and hemiplegia. Arteriography is diagnostic, demonstrating thrombosis of the anterior or middle cerebral artery. This form of vasculopathy can also occur after varicella and may be the cause of up to one third of ischemic strokes in children. The recognized vasculopathic complications of VZV have been expanded to include changes in mental status, aphasia, ataxia, hemisensory loss, and both hemianopia and monocular visual loss. Monocular vision loss can occur up to 6 months after zoster. Aneurysm, subarachnoid or cerebral hemorrhage, carotid dissection, and even peripheral vascular disease are other recognized forms of VZV vasculopathy. The vasculopathy may be multifocal and involve both large and small arteries. In more than one third of cases, VZV vasculopathy occurs without a rash. Magnetic resonance imaging (MRI) is virtually always abnormal. The diagnosis is confirmed by VZV PCR and anti-VZV IgG antibody testing of the CSF. Because this is caused by active viral replication in the vessels, the treatment is IV acyclovir, 10–15 mg/kg three times daily for a minimum of 14 days. In some patients, months of oral antivirals are given if symptoms are slow to resolve. A short burst of systemic corticosteroids is also given in some cases. VZV has been linked to giant-cell arteritis as well, theoretically through similar mechanisms. One recent meta-analysis has also suggested an increased risk of cardiac events associated with herpes zoster as well.

Treatment

Middle-age and elderly patients with herpes zoster are urged to restrict their physical activities or even stay home in bed for a few days. Bed rest may be of paramount importance in the prevention of neuralgia. Younger patients may usually continue with their customary activities. Local applications of heat, as with an electric heating pad or a hot water bottle, are recommended. Simple local application of gentle pressure with the hand or with an abdominal binder often gives great relief.

Antiviral therapy is the cornerstone in the management of herpes zoster. Because antiviral therapy does not reduce the rate of zoster-associated pain (ZAP), clinicians may underappreciate the tremendous benefit that antivirals provide. The main benefit of therapy is reduction of the duration and severity of ZAP. Therefore treatment in immunocompetent patients is indicated for those at highest risk for persistent pain—those over age 50. It is also recommended to treat all patients with painful or severe zoster, ophthalmic zoster, Ramsay Hunt syndrome, immunosuppression, cutaneous or visceral dissemination, and motor nerve involvement. In the most severe cases, especially in ophthalmic zoster and disseminated zoster, initial IV therapy may be considered. Therapy should be started as soon as the diagnosis is suspected, pending laboratory confirmation. It is preferable for treatment to be instituted within the first 3 or 4 days. In immunocompetent patients, the efficacy of starting treatment beyond this time is unknown. Treatment leads to more rapid resolution of the skin

lesions and, most importantly, substantially decreases the duration of ZAP. Valacyclovir, 1000 mg, and famciclovir, 500 mg, may be given three times daily. These agents are as effective as or superior to acyclovir, 800 mg five times daily, probably because of better absorption or medication compliance with simpler regimens. Side-by-side trials have demonstrated valacyclovir and famciclovir to be of similar efficacy, but one study from Japan showed famciclovir to result in more rapid reduction in acute zoster pain.

In the immunocompetent host, a total of 7 days of treatment has been as effective as 21 days. These antivirals must be dose-adjusted in patients with renal impairment. In an elderly patient, if the renal status is unknown, the valacyclovir and famciclovir may be started at twice-daily dosing (which is almost as effective), pending evaluation of renal function, or acyclovir can be used. For patients with renal failure (creatinine clearance <25 mL/min), acyclovir is preferable. In the patient with known or acquired renal failure, acyclovir neurotoxicity can occur from IV acyclovir or oral valacyclovir therapy. This can present in the acute setting as hallucinations or with prolonged elevated blood levels, disorientation, dizziness, loss of decorum, incoherence, photophobia, difficulty speaking, delirium, confusion, agitation, and death delusion. Because acyclovir can reduce renal function, the patient's baseline renal function may have been normal, but high doses of acyclovir may have reduced renal function, leading to neurotoxic acyclovir levels.

In the immunosuppressed patient, an antiviral agent should always be given because of the increased risk of dissemination and zoster-associated complications. The doses are identical to those used in immunocompetent hosts. Immunosuppressed patients with ophthalmic zoster, disseminated zoster, or Ramsay Hunt syndrome and those failing oral therapy should receive IV acyclovir, 10 mg/kg three times daily, adjusted for renal function.

Because some of the pain during acute zoster (acute zoster neuritis) may have an inflammatory component, corticosteroids have been used during the acute episode. The use of corticosteroids in this setting is controversial. In selected older patients, corticosteroid use is associated with better quality-of-life measures, reduction in time to uninterrupted sleep, quicker return to usual activities, and reduced analgesic use. A tapering dose of systemic corticosteroids, starting at about 1 mg/kg and lasting 10–14 days, is adequate to achieve these benefits. Systemic corticosteroids should not be used in immunosuppressed patients or when there is a contraindication. All factors considered, the benefits of corticosteroid therapy during acute zoster appear to outweigh the risks in treatment-eligible patients. Reduction in postherpetic neuralgia (PHN) by corticosteroids has never been documented despite multiple studies, but this is also true of antiviral therapy, which reduces the severity and duration but not the prevalence of postherpetic neuralgia.

Zoster-Associated Pain (Postherpetic Neuralgia)

Pain is the most troublesome symptom of zoster; 84% of patients over age 50 will have pain preceding the eruption, and 89% will have pain with the eruption. Various terminologies are used to classify the pain. The simplest approach is to refer to all pain occurring immediately before or after zoster as "zoster-associated pain" (ZAP). Another classification system separates acute pain (within first 30 days), subacute pain (30–120 days), and chronic pain (>120 days).

Two different mechanisms are proposed to cause ZAP: sensitization and deafferentation. Nociceptors (sensory nerves mediating pain) become sensitized after injury, resulting in ongoing discharge and hyperexcitability (peripheral sensitization). Prolonged discharge of the nociceptor enhances the dorsal horn neurons to afferent stimuli and expands the dorsal horn neuron's receptive field (central sensitization), leading to allodynia and hyperalgesia. In addition, neural destruction causes spontaneous activity in deafferented central neurons, generating constant pain. The spinal terminals of mechanoreceptors may contact receptors formerly occupied by C fibers, leading to hyperalgesia and allodynia. The loss of function or death of dorsal horn neurons, which have an inhibitory effect on adjacent neurons, contributes to increased activity transmitted up the spinal cord. The central sensitization is initially temporary (self-limited) but may become permanent.

The quality of the pain associated with herpes zoster varies, but three basic types have been described: the constant, monotonous, usually burning or deep, aching pain; the shooting, lancinating (neuritic) pain; and triggered pain. The last is usually allodynia (pain with normal nonpainful stimuli such as light touch) or hyperalgesia (severe pain produced by a stimulus normally producing mild pain). The character and quality of acute zoster pain are identical to the pain that persists after the skin lesions have healed, although these may be mediated by different mechanisms.

The rate of resolution of pain after herpes zoster is reported over a wide range. The following data are from a prospective study and do not represent selected patients, as are recruited in drug trials for herpes zoster. The tendency to have persistent pain is age dependent, occurring for longer than 1 month in only 2% of persons under age 40. Fifty percent of persons over age 60 and 75% of those over 70 continue to have pain beyond 1 month. Although the natural history is for gradual improvement in persons over age 70, 25% have some pain at 3 months and 10% have pain at 1 year. Severe pain lasting longer than 1 year is uncommon, but 8% of persons over 60 have mild pain and 2% still have moderate pain at 1 year.

The ZAP, especially that of long duration, is very difficult to manage. Adequate medication should be provided to control the pain from the first visit. Once established, neuropathic pain is difficult to control. Every effort should be made to prevent neuronal damage. In addition, chronic pain may lead to depression, complicating pain management. Patients with persistent, moderate to severe pain may benefit from referral to a pain clinic. With this background, the importance of early and adequate antiviral therapy and pain control cannot be overemphasized.

Oral antiviral agents are recommended in all patients over age 50 with pain who still have blisters, even if the drugs are not given within the first 96 hours of the eruption. Oral analgesia should be maximized using acetaminophen, nonsteroidal antiinflammatory drugs (NSAIDs), and opiate analgesia as required. The combination of oral gabapentin and valacyclovir was reported to reduce PHN in one study criticized due to the lack of a control group, but gabapentin alone has not been shown to be highly effective in other zoster trials. Capsaicin applied topically every few hours may reduce pain, but the application itself may cause burning, and the benefits are modest. Local anesthetics, such as 10% lidocaine in gel form, 5% lidocaine-prilocaine, or lidocaine patches (Lidoderm), may acutely reduce pain. Combined topical amitriptyline 4% and ketamine 2% has been reported for PHN and other neuropathic pain conditions. These topical measures may provide some short-term analgesic effect, but do not appear to have any long-term benefit in reducing the severity or prevalence of ZAP. Patients with PHN have lower vitamin C levels than controls, and vitamin C supplementation intravenously (not orally) has been associated with PHN reduction. Sublesional anesthesia, epidural blocks (with or without ketamine), and sympathetic blocks with and without corticosteroids are reported in large series (but rarely studied in controlled trials) to provide acute relief of pain. Although the benefit of nerve blocks in preventing or treating persistent ZAP remains to be proved, these are a reasonable consideration in the acute setting if the patient is having severe pain (unable to eat or sleep) and if oral therapy has yet to be effective. Nerve blocks may also be used in patients who have failed the standard therapies. A transcutaneous electrical nerve stimulation (TENS) unit may be beneficial for persistent neuralgia. Ultrasound-guided spinal nerve radiofrequency treatment has been utilized as well. Botulinum toxin, 100 U, spread out over the affected area in a

checkerboard or fanlike pattern with 5 U per route, has dramatically improved PHN in anecdotal reports.

Despite this vast array of medication options, PHN is typically difficult to treat for two reasons. First, the recommended medications are simply often not effective. Second, in elderly patients, who are most severely affected by PHN, these medications have significant and often intolerable side effects, limiting the dose that can be prescribed. If multiple agents are combined to reduce the toxicity of any one agent, their side effects overlap (sedation, depression, constipation) and drug-drug interactions may occur, limiting combination treatment options.

Three classes of medication are used as standard therapies to manage ZAP and PHN: tricyclic antidepressants (TCAs), antiseizure medications, and long-acting opiates. If opiate analgesia is required, it should be provided by a long-acting agent, and the duration of treatment should be limited and the patient transitioned to another class of agent. Constipation is a major side effect in elderly persons. During painful zoster, these patients ingest less fluid and fiber, enhancing the constipating effects of the opiates. Bulk laxatives should be recommended. Tramadol is an option for acute pain control, but drug interactions with the TCAs must be monitored. TCAs such as amitriptyline (or nortriptyline) and desipramine are well tested and documented as effective for the management of PHN and are considered first-line agents. The TCAs are dosed at 25 mg/night (or 10 mg for those over age 65–70). The dose is increased by the same amount nightly until pain control is achieved or the maximum dose is reached. The ultimate dose is between 25 and 100 mg in a single nightly dose. The early use of amitriptyline was able to reduce the pain prevalence at 6 months, suggesting that early intervention is optimal. Venlafaxine (Effexor) may be used in patients who do not tolerate TCAs, at a starting dose of 25 mg/night, gradually titrated upward as required. Gabapentin (Neurontin) and pregabalin (Lyrica) have been documented as helping to reduce ZAP. The starting dose of gabapentin is usually 300 mg three times daily, escalating up to 1800mg/day. A minimum total dose of 600 mg or more is needed to obtain optimal benefit. One meta-analysis suggests that higher-dose gabapentin (1800 mg/day) can reduce PHN pain, though somnolence, dizziness, and other side effects were common. Pregabalin has improved pharmacokinetics and is given at 300 mg or 600 mg daily, depending on renal function, with better absorption and steadier blood levels. The anticonvulsants diphenylhydantoin, carbamazepine, and valproate; neuroleptics such as chlorprothixene and phenothiazines; and H_2 blockers such as cimetidine cannot be recommended because they have been not been studied critically, many are poorly tolerated by elderly patients, and some are associated with significant side effects. If the patient fails to respond to local measures, oral analgesics (including opiates), TCAs, gabapentin, and venlafaxine, referral to a pain center is recommended.

Immunosuppressed Patients

Immunosuppression increases the risk of zoster, though studies vary as to the impact. The use of TNF inhibitors was initially reported to increase the risk of development of zoster by 1.6 times (or 60%), though a large cohort study suggested no increased risk with monotherapy, only an elevated risk with combination TNF-I and methotrexate. The risk is significant enough that prophylactic immunization should be considered, if not contraindicated, before a patient starts a TNF inhibitor. VZV immunization of patients already receiving TNF inhibition who have had prior varicella has not led to increased zoster or adverse events, and it has reduced the rate of zoster with anti-TNF therapy. This strategy should be considered on a case-by-case basis, perhaps in consultation with an infectious disease specialist. This may be more of a risk with newer classes of drugs, particularly the JAK inhibitors, which appear to carry an elevated risk for zoster.

Patients with malignancy, especially Hodgkin disease and leukemia, are five times more likely to develop zoster than their age-matched counterparts. Patients who also have a higher incidence of zoster include those with deficient immune systems, such as individuals who are immunosuppressed for organ transplantation or by connective tissue disease, or by the agents used to treat these conditions, especially corticosteroids, chemotherapeutic agents, cyclosporine, sirolimus, and tacrolimus. After stem cell transplantation for leukemia, up to 68% of patients will develop herpes zoster in the first 12 months (median 5 months). The cumulative incidence of VZV reactivation in this group may exceed 80% in the first 3 years. Antiviral prophylaxis has been shown to reduce zoster in this population. Because zoster is 30 times more common in HIV-infected persons, the zoster patient under age 50 should be questioned about HIV risk factors. In pediatric patients with HIV infection and in other immunosuppressed children, zoster may rapidly follow primary varicella.

The clinical appearance of zoster in the immunosuppressed patient is usually identical to typical zoster, but the lesions may be more ulcerative and necrotic and may scar more severely. Dermatomal zoster may appear, progress to involve the dermatome, and persist without resolution. Multidermatomal zoster is more common in immunosuppressed patients, including the rare variant "herpes zoster duplex bilateralis," with involvement of two different contralateral dermatomes. Visceral dissemination and fatal outcome are extremely rare in immunosuppressed patients (about 0.3%), but cutaneous dissemination is possible, occurring in 12% of cancer patients, especially those with hematologic malignancies. In bone marrow transplant patients with zoster, 25% develop disseminated zoster and 10%–15%, visceral dissemination. Disseminated zoster may be associated with the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and present with hyponatremia, abdominal pain, and ileus. This later presentation has been reported in stem cell transplant patients. Despite treatment with IV acyclovir, the SIADH can be fatal. In this patient, the number of skin lesions may be small, and the lesions resemble "papules" rather than vesicles. The mortality rate in patients with zoster who have undergone bone marrow transplantation is 5%. VZV IgG serostatus is determined before transplant, and all seropositive patients receive prophylaxis with either acyclovir, 800 mg twice daily, or valacyclovir, 500 mg twice daily, for 1 year or longer if the patient is receiving immunosuppressive therapy. In AIDS patients, ocular and neurologic complications of herpes zoster are increased. Immunosuppressed patients often have recurrences of zoster, up to 25% in patients with AIDS (Fig. 19.19).

Two atypical patterns of zoster have been described in AIDS patients: ecthymatous lesions, which are punched-out ulcerations with a central crust, and verrucous lesions (Fig. 19.20). These patterns were not reported before the AIDS epidemic. Atypical clinical patterns, especially the verrucous pattern, may correlate with acyclovir resistance.

Diagnosis

The same techniques used for the diagnosis of varicella are used to diagnose herpes zoster. The clinical appearance is often adequate to suggest the diagnosis, and an in-office Tzanck smear can rapidly confirm the clinical suspicion. Zosteriform herpes simplex can also have a positive Tzanck smear, but the number of lesions is usually more limited and the degree of pain substantially less than with zoster. Beyond Tzanck preparation, PCR or DFA testing is preferred to a viral culture because it is rapid, types the virus, and has a higher yield than culture. Compared with documented VZV infections, Tzanck smear was 75% positive (with up to 10% false-positives and high variability, depending on skill of examiner), and culture only 44% positive. PCR testing is 97% positive and is generally the test of choice. In atypical lesions, biopsy may be necessary to demonstrate the typical herpes virus cytopathic effects.

Fig. 19.20 Verrucous zoster in AIDS patient.

IP stain tests can then be performed on paraffin-fixed tissue to identify VZV specifically. When acyclovir fails clinically, viral culture may be attempted and acyclovir sensitivity testing performed. It is not as standardized for VZV as it is for HSV, and availability is limited.

Histopathology

As with herpes simplex, the vesicles in zoster are intraepidermal. Within and at the sides of the vesicle are large, swollen cells called balloon cells, which are degenerated cells of the spinous layer. Acidophilic inclusion bodies similar to those seen in HSV are present in the nuclei of the cells of the vesicle epithelium. Multinucleated keratinocytes, nuclear molding, and peripheral condensation of the nucleoplasm are characteristic and confirmatory of an infection with either HSV or VZV. In the vicinity of the vesicle, there is marked intercellular and intracellular edema. In the upper part of the dermis, vascular dilation, edema, and perivascular infiltration of lymphocytes and polymorphonuclear leukocytes (PMNs) are present. Atypical lymphocytes may also be found. An underlying leukocytoclastic vasculitis suggests VZV infection over HSV. Inflammatory and degenerative changes are also noted in the posterior root ganglia and in the dorsal nerve roots of the affected nerve. The lesions correspond to the areas of innervation of the affected nerve ganglion, with necrosis of the nerve cells.

Differential Diagnosis

The distinctive clinical picture of zoster permits a diagnosis with little difficulty. A unilateral, painful eruption of grouped vesicles along a dermatome, with hyperesthesia and on occasion regional lymph node enlargement, is typical. Occasionally, segmental cutaneous paresthesias or pain may precede the eruption by 4 or 5 days. In such patients, prodromal symptoms are easily confused with the pain of angina pectoris, duodenal ulcer, biliary or renal colic, appendicitis, pleurodynia, or early glaucoma. The diagnosis becomes obvious once the cutaneous eruption appears. Herpes simplex and herpes zoster are confused if the lesions of HSV are linear (zosteriform HSV), or if the number of zoster lesions is small and localized to one site (not involving whole dermatome). DFA testing or viral culture will distinguish them; DFA is generally preferred because it is rapid and sensitive.

Prevention of Zoster

A vaccine using the same attenuated virus as in the varicella vaccination, but at much higher titers, was licensed for the prevention of herpes zoster (Zostavax), and initially recommended in all persons 60 years or older. This vaccination reduced the incidence of zoster by 50%. In addition, PHN was 67% lower in the vaccine recipients, and duration of ZAP was shortened. Those vaccinated between ages 60 and 69 had a greater reduction in zoster incidence than those over 70, but in both groups, PHN and burden of illness were reduced similarly. Vaccination has led to a reduced rate of ED visits and costs associated with zoster in populations recommended for vaccination. Because it is a live virus vaccine, persons taking antiviral medications must stop them 24 hours before immunization and not take them for 14 days after immunization. Immunosuppressed patients can be safely immunized following specific guidelines. A second zoster vaccine has been developed (Shingrix), which is now recommended for healthy adults 50 years and older, including adults who previously received the first generation shingles vaccine (Zostavax), and is now the preferred vaccine for shingles. This vaccine demonstrated a moderately high rate of side effects, including 81% of subjects with injection-site reactions (pain, myalgia) and 66% with systemic reaction (myalgias), in clinical trials.

Institutionalized patients who develop herpes zoster are infectious to other patients and the health care team. Prior immunization with varicella vaccine and "adequate serologic titers" may not prevent acquiring infection, especially in immunosuppressed patients. Covering the cutaneous lesions specifically with semipermeable dressings (not just gauze bandages) appears to reduce transmission. Patients with active disease should avoid unvaccinated, nonimmunized, immunosuppressed, or pregnant patients if possible.

Inflammatory Skin Lesions after Zoster Infection (Isotopic Response)

Following zoster, inflammatory skin lesions may rarely occur within the affected dermatome. Lesions usually appear within 1 month, or rarely, longer than 3 months, after the zoster. Clinically, the lesions are usually flat-topped or annular papules in the dermatome. Histologically, such papules most frequently demonstrate various patterns of granulomatous inflammation from typical granuloma annulare to sarcoidal reactions or even granulomatous vasculitis

Fig. 19.21 Dermatome previously affected by zoster developed a granulomatous dermatitis histologically consistent with granuloma annulare.

(Fig. 19.21). Persistent viral genome has not been detected in these lesions, suggesting that continued antiviral therapy is not indicated. Persistent VZV glycoproteins may be the triggering antigens. Topical and intralesional therapy with corticosteroids is beneficial, but the natural history of these lesions is generally spontaneous resolution. Less often, other inflammatory skin diseases have been reported in areas of prior zoster, including lichen planus, lichen sclerosus, vitiligo, Kaposi sarcoma (KS), graft-versus-host disease (GVHD), morphea, and benign or even atypical lymphoid infiltrates. Leukemic infiltrates and lymphomas may affect zoster scars, as can metastatic carcinomas (inflammatory oncotaxis) or nonmelanoma skin cancers (NMSCs).

Epstein-Barr Virus (Human Herpesvirus Type 4)

Epstein-Barr virus (EBV) is a γ-herpesvirus. It infects human mucosal epithelial cells and B lymphocytes, and infection persists for the life of the host. EBV infection may be latent—not producing virions, but simply spread from mother cell to both daughter cells

by copying the viral DNA with each host cell replication. Intermittently, infection may be productive, resulting in production and release of infectious virions. EBV infection may transit between latent and productive infection many times. The ability of EBV to maintain persistent infection is aided by the expression of the EBV nuclear antigen 1 (EBNA-1) viral gene product, which prevents cytotoxic T-lymphocyte response to the virus.

Initial infection with EBV occurs in childhood or early adulthood, so that by their early twenties, 95% of the population has been infected. The virus is shed into the saliva, so contact with oral secretions is the most common route of transmission. Primary infection may be asymptomatic or may produce only a mild, nonspecific febrile illness, especially in younger children. In young adults, primary infection is more likely to be symptomatic and in 50% of cases produces a syndrome termed *infectious mononucleosis* (IM). The incubation period is 3–7 weeks. IM is characterized by a constellation of findings: fever (up to 40°C), headache, lymphadenopathy, splenomegaly, and pharyngitis (sore throat).

Cutaneous and mucous membrane lesions are present in about 10% of IM patients. Exanthems occur in less than 5%, more often in children. Edema of the eyelids and a macular or morbilliform eruption are most common. The eruption is usually on the trunk and upper extremities. Other, less common eruptions are urticarial, vesicular, bullous, petechial, erythema multiforme, and purpuric types. Cold urticaria transiently occurs in 5% of patients with IM. Leukocytoclastic vasculitis and large-vessel arteritis have been seen in chronic EBV infection, often in the setting of immunodeficiency. The mucous membrane lesions consist of distinctive pinhead-sized petechiae, 5–20 in number, at the junction of the soft and hard palate (Forchheimer spots). Gianotti-Crosti syndrome (GCS) and the papular-purpuric glove-and-stocking (or gloves-and-socks) syndrome are two specific viral exanthem patterns that may occur in the patient with asymptomatic primary EBV infection. EBV is now the leading cause of GCS worldwide. EBV reactivation has been infrequently associated with drug-induced hypersensitivity syndrome. EBV is also associated with enhanced insect bite reactions.

Painful genital ulcerations may precede the symptomatic phase of IM, especially in premenarcheal girls. The ulcerations are up to 2 cm in diameter, single or multiple, and may be accompanied by marked swelling of the labia. Lesions last several weeks and heal spontaneously, often as the patient is developing symptoms of IM. Transmission to patients through orogenital sex has been proposed, but the virus may also reach the vulvar mucosa hematogenously. EBV may be the cause of some nonsexually related genital ulcers (Lipschutz ulcers). The lesions closely resemble herpetic ulcerations and fixed drug eruption, which must be considered in the differential diagnosis.

Laboratory evaluation in patients with IM frequently shows an absolute lymphocytosis of greater than 50% and monocytosis with abnormally large, "atypical" lymphocytes. The white blood cell (WBC) count ranges from 10,000–40,000 cells/mm^3. Liver function tests (LFTs) may be elevated. Heterophile antibodies will be present in 95% or more of cases. In acute primary EBV infection, immunoglobulin M (IgM) antibodies to early antigen (EA) and viral capsid antigen (VCA) are found in high titer and decrease during recovery. Antibodies to VCA and EBNA appear in the recovering phase and persist for years after primary infection. There is no specific therapy, and in most IM patients, no treatment is required. Acyclovir is not effective in altering the length or severity of IM, although it is active against EBV in doses used for VZV. A recent Cochrane review concluded there is a lack of quality evidence to support antiviral therapy, and treatment decisions depend on the clinical scenario. If patients have severe pharyngeal involvement with encroachment on the airway, or cytopenias or liver failure, oral corticosteroid therapy (40–60 mg/day of prednisone) is useful to induce a prompt response, but are not generally indicated for symptom control in more mild cases. Most patients recover completely. Patients who participate in contact sports should have abdominal ultrasonography to rule out splenomegaly if planning to participate within 1 month of IM diagnosis.

Almost all patients with IM treated with ampicillin, amoxicillin, or other semisynthetic penicillins typically develop a generalized, pruritic, erythematous to copper-colored macular exanthem on the 7th–10th day of therapy. The eruption starts on the pressure points and extensor surfaces, generalizes, and becomes confluent. The eruption lasts about 1 week and resolves with desquamation. The eruption often does not recur when these medications are given after the acute mononucleosis has resolved, and this is not a true drug allergy.

Oral hairy leukoplakia (OHL) is a distinctive condition initially reported in strong association with HIV, though now has been recognized in patients with other forms of immunocompromise. It appears as poorly demarcated, corrugated white plaques seen on the lateral aspects of the tongue (Fig. 19.22). Lesions on the other areas of the oral mucosa are simply white plaques without the typical corrugations. OHL can be distinguished from thrush by the fact that OHL cannot be removed by firm scraping with a tongue blade. More than one third of patients with AIDS have OHL, but is not restricted to patients with HIV infection; it also occurs in other immunosuppressed hosts, especially renal and bone marrow transplant recipients, and those using inhaled steroids for chronic obstructive pulmonary disease. OHL can be a part of the IRIS. EBV does not establish infection in the basal cell layer of the oral epithelium but is maintained by repeated direct infection of the epithelium by EBV in the oral cavity. Only chronically immunosuppressed patients continuously shed EBV in their oral secretions, thus explaining the restriction of OHL to immunosuppressed hosts. In normal persons, a similar morphologic and histologic picture can be seen (pseudo-OHL), but EBV is not found in these patients' lesions. Thus the finding of OHL warrants immunologic evaluation. A biopsy of the OHL lesions searching for EBV in the epithelium can be useful in this setting. OHL is usually asymptomatic and requires no treatment. If treatment is requested in immunosuppressed patients, podophyllin, applied for 30 seconds to 1 minute to the lesions once each month, is the simplest approach. Tretinoin gel, applied topically twice daily, or oral acyclovir, 400 mg five times daily, is also effective. Lesions recur when treatment is discontinued.

In immunosuppressed and immunocompetent hosts, EBV may be responsible for benign and malignant disorders, some of which can be fatal. These include Kikuchi disease (histiocytic necrotizing lymphadenitis), hydroa vacciniforme (HV) and HV-like lymphoma, hypereosinophilic syndrome, leiomyomas and leiomyosarcomas, lymphomatoid granulomatosis, erythema multiforme, and multiple

Fig. 19.22 Oral hairy leukoplakia.

types of lymphoma and lymphoproliferative disorders, especially in organ transplant recipients (posttransplant lymphoproliferative disorders, immunosuppression-associated lymphoproliferative disorders). Richter syndrome (development of lymphoma in the patient with chronic lymphocytic leukemia) can present in the skin and may be associated with fludarabine treatment of EBV infection. EBV and other HHV reactivation has been demonstrated in drug reaction with eosinophilia and systemic symptoms (DRESS), and viral replication and host-antiviral response is felt to play a role in the pathophysiology. Ongoing studies are exploring whether there is a connection between EBV and autoimmune disorders, including multiple sclerosis and systemic lupus erythematosus.

Cytomegalovirus (Cytomegalic Inclusion Disease); Human Herpesvirus Type 5

Congenital cytomegalovirus (CMV) infection, as documented by CMV excretion, is found in 1% of newborns, 90% of whom are asymptomatic. Clinical manifestations in infants may include jaundice, hepatosplenomegaly, cerebral calcifications, chorioretinitis, microcephaly, mental retardation, and deafness. Cutaneous manifestations may result from thrombocytopenia, with resultant petechiae, purpura, and ecchymoses. Purpuric lesions, which may be macular, papular, or nodular, may show extramedullary hematopoiesis (dermal erythropoiesis), producing the "blueberry muffin baby." A generalized vesicular eruption may rarely occur. Most symptomatic cases occur within the first 2 months of life. Neonatal disease is more severe and sequelae are more frequent in neonates of mothers with primary rather than recurrent CMV disease in pregnancy.

Between 50% and 80% of immunocompetent adults and up to 100% of HIV-infected men who have sex with men (MSM) are infected with CMV. Infection in adults may be acquired by exposure to infected children, sexual transmission, and transfusion of CMV-infected blood. Symptomatic primary infection in adults is unusual and is identical to IM caused by EBV. An urticarial or morbilliform eruption or erythema nodosum may occur in primary CMV infection in immunocompetent adults. Ampicillin and amoxicillin administration will often result in a morbilliform eruption in acute CMV infection, similar to that seen in acute EBV infection.

Infection with CMV is common in AIDS patients, most frequently causing retinitis (20% of patients), colitis (15%), cholangitis, encephalitis, polyradiculomyopathy, and adrenalitis. It occurs in the setting of very advanced HIV infection, usually with CD4 counts below 50, and has become much less common in the era of highly active antiretroviral therapy (HAART).

CMV infection can manifest in other immunosuppressed hosts. CMV viremia is routinely monitored after stem cell transplant depending on host/donor CMV serostatus, and some cases are treated with prophylactic antivirals or preemptive therapy based on serial CMV PCR testing. Infection will usually affect the GI tract or lungs. Skin disease is rare but may have a wide range of manifestations, from nonspecific morbilliform exanthems that can easily be mistaken for drug reactions, to ulcerated plaques.

Cytomegalovirus infection in tissues is usually identified by the histologic finding of a typical CMV cytopathic effect. In a very small percentage of AIDS patients with CMV infection, skin lesions may occur that contain such cytopathic changes. In most cases, CMV is found in association with another infectious process, and the treatment of that other infection will lead to resolution of the CMV in the skin without its treatment. This is especially true of perianal HSV ulcerations. CMV may even be found in totally normal skin in CMV-viremic AIDS patients, suggesting that finding the CMV cytopathic effect is insufficient alone to imply a causal relationship of the CMV to any cutaneous lesion. Only in the case of perianal and oral ulcerations has the pathogenic role of CMV been documented. In unusual cases of extremely painful genital ulcerations, only CMV infection is found histologically, or the ulceration persists after effectively treating HSV, with CMV identified histologically. The CMV cytopathic changes may be noted in the nerves at the base of these ulcerations, suggesting that CMV neuritis may be producing the severe pain that characterizes these cases. The diagnosis of CMV ulceration is one of exclusion. CMV cytopathic changes must be seen in the lesion and cultures, and histologic evidence of any other infectious agent must be negative. In these ulcerations, clinically suggested by their location (genital or oral) and painful nature, specific treatment with valganciclovir, foscarnet, or cidofovir will lead to healing of the ulceration and dramatic resolution of the pain.

The CMV infecting endothelial cells may produce a vasculopathy in CMV-viremic or partially reactivating patients. This can lead to prominent vasculopathic changes, including Raynaud phenomenon, deep venous thrombosis, digital gangrene, and reticulated purpura. Anticardiolipin antibodies may be positive. Anti-CMV therapy can reverse the syndrome and clear the anticardiolipin antibodies.

Human Herpesviruses 6 and 7

Infection with HHV-6 is almost universal in adults, with seropositivity in the 80%–85% range in the United States, and seroprevalence almost 100% in children. There are intermittent periods of viral reactivation throughout life; persistent infection occurs in several organs, particularly in the CNS. Acute seroconversion to HHV-6 and to HHV-7 each appears to be responsible for about one third of roseola cases, and in the remaining third, neither is found. HHV-6 infection occurs earlier than HHV-7, and second episodes of roseola in HHV-6–seropositive children may be caused by HHV-7. Primary infection with HHV-6 is associated with roseola in only 9% of cases, and 18% of children with seroconversion have a rash. Primary infection may occur with only fever and no rash, or rash without fever. Other common findings include otitis media, diarrhea, and bulging fontanelles, sometimes with findings of meningoencephalitis and seizures. Infrequently, hepatitis, intussusception, and even fatal multisystem disease may occur. In adults, acute HHV-6 infection resembles acute mononucleosis. Some have suggested that HHV-6 and HHV-7 may be involved in the development of pityriasis rosea. HHV-6 and HHV-7 reactivation has been demonstrated during DRESS syndrome (along with less commonly EBV and CMV), with many feeling that the drug trigger then allows latent virus replication followed by a host-antiviral response leading to the clinical phenotype observed, which explains the long time course and prolonged treatment required, and the potential for delayed autoimmune sequelae.

As with other herpesviruses, the pattern of disease in HHV-6 may be different in immunosuppressed hosts. HHV-6 reactivation is common after transplantation: 32% after solid-organ and 48% after bone marrow transplantation, peaking on day 21. These patients can be quite ill, with fever, diarrhea, and elevated LFTs, simulating GVHD, with some developing pneumonitis and CNS manifestations as well. Engraftment can be delayed. HHV-6 viremia, detected by PCR, can confirm the diagnosis. Chronic macular erythema has been reported in several cases. Careful histologic evaluation has identified HHV-6–infected lymphocytes and histiocytes in the macular erythema, confirming the diagnosis. Antiviral therapy with ganciclovir, foscarnet, or valganciclovir can lead to improvement, with broad-acting antiviral T cells under investigation.

Roseola Infantum (Exanthem Subitum, Sixth Disease)

Roseola infantum is a common cause of sudden, unexplained high fever in young children between 6 and 36 months of age. Prodromal fever is usually high and may be accompanied by convulsions and lymphadenopathy. Suddenly, on about the fourth day, the fever drops. Coincident with the decrease in temperature, a morbilliform erythema of discrete, rose-colored macules appears on the neck, trunk, and buttocks and sometimes on the face and extremities. Often, there is a blanched halo around the lesions. The eruption may also be papular or rarely even vesicular. The mucous membranes are spared. Complete resolution of the eruption occurs in 1–2 days. A case of spontaneously healing, generalized eruptive histiocytosis has been reported after exanthem subitum.

Human Herpesvirus 8

A γ-herpesvirus, HHV-8 is most closely related to EBV. HHV-8 has been found in all patients with KS, including those who have AIDS (Fig. 19.23), in African cases; in elderly men from the Mediterranean basin; and in transplant patients. In addition, the seropositivity rate (infection rate) for this virus correlates with the prevalence of KS in a given population.

The background seroprevalence rate of HHV-8 in North America and Northern Europe is near zero. Seroprevalence is highest in KS-endemic areas in sub-Saharan Africa (50%–100%). In the general population in Italy, the seroprevalence is 10%–15% (6%–10% in children under age 16, 22% after age 50). In south-central Italy and in Sardinia, seroprevalence rates are higher, 20%–25% for the general population. In Italy, high rates of HHV-8 seropositivity are also seen in HIV-infected MSM (up to 60%), in female prostitutes (40%), and in heterosexual men who have had sex with prostitutes (40%). Infection with HHV-8 precedes and predicts subsequent development of KS in HIV-infected men. In addition to KS lesions, HHV-8 can be found in saliva and in circulating blood cells in HHV-8–infected patients. HHV-8 is also found in the semen of up to 20% of KS patients. Heterosexual partners of patients with classic KS have high rates of HHV-8 seropositivity (>40%). These epidemiologic features all strongly support sexual transmission as an important mechanism of the spread of HHV-8. The finding of a significant number of infections in prepubertal children, however, suggests that nonsexual methods of transmission also exist. HHV-8 seroprevalence rate in heterosexual IV drug users and persons with HIV infection acquired

Fig. 19.23 Kaposi sarcoma in an HIV-infected patient; the palate is commonly involved.

through blood transfusion are not increased above that in the general population, suggesting that HHV-8 is poorly transmitted by blood and blood products.

Human herpesvirus 8 is present in a rare type of B-cell lymphoma called body cavity–based B-cell lymphoma or primary effusion lymphoma (PEL), which presents with pleural, pericardial, and peritoneal malignant effusions. Rarely, this form of lymphoma may be associated with skin lesions or may present as an intravascular lymphoma. The cutaneous lesions can resemble a CD30-positive, anaplastic, large T-cell lymphoma. HHV-8 is also found in all patients with multicentric Castleman disease (MCD) associated with HIV infection and in 10%–50% of HIV-negative patients with MCD. Cytokine production, specifically IL-6 from Kaposi syndrome herpesvirus (KSHV)–infected cells (vIL-6) and host inflammatory cells (hIL-6), along with VEGF, appears causal. Exanthems and cutaneous nodules may accompany MCD, and HHV-8 has been identified in the skin lesions. KSHV inflammatory cytokine syndrome (KICS) is an inflammatory syndrome analogous to MCD but lacking the prominent lymphadenopathy. It is also mediated by IL-6 and other cytokines. In HHV-8–associated MCD and KICS, HHV-8 viral loads are much higher than in patients with KS, perhaps aiding in the diagnosis. Kikuchi disease has been linked primarily to EBV, but one study suggests potential association with HHV-8 instead.

B Virus

B virus *(Herpesvirus simiae)* is endemic in Asiatic Old World monkeys (macaques) and may infect other monkeys housed in close quarters with infected monkeys. In macaques, *H. simiae* disease is a recurrent vesicular eruption analogous to HSV in humans, with virus shed from conjunctiva, oral mucosa, and urogenital area. Humans become infected after being bitten, scratched, or contaminated by an animal shedding B virus. Usually, patients are animal handlers or researchers. Rare cases of respiratory or human-to-human contact spread have been reported. Within a few days of the bite, vesicles, erythema, necrosis, or edema appear at the site of inoculation. Regional lymph nodes are enlarged and tender. Fever is typically present. In a substantial number of human infections, rapid progression to neurologic disease occurs. This is initially manifested by peripheral nerve involvement (dysesthesia, paresthesia), then progresses to spinal cord involvement (myelitis and ascending paralysis with hyporeflexia), and finally to brain disease (decreased consciousness, seizures, respiratory depression). Of 22 reported patients, 15 have died, and all survivors of encephalitis had severe neurologic sequelae. Treatment with acyclovir or ganciclovir has been successful in some, but other patients similarly treated have died.

INFECTIOUS HEPATITIS

Hepatitis B Virus

Hepatitis B virus (HBV) is a dsDNA virus that is spread by blood and blood products, and sexually in Europe and the Western Hemisphere. In Africa and Asia, infection often occurs perinatally. HBV and hepatitis C virus (HCV) are the primary cause of hepatocellular carcinoma and may also cause liver failure and cirrhosis. Acute infection with HBV is associated with anorexia, nausea, right upper quadrant pain, and malaise. Between 10% and 30% of patients with acute HBV infection have a serum sickness–like illness with urticaria, arthralgias, and occasionally arthritis, glomerulonephritis, or vasculitis. These symptoms appear 1–6 weeks before onset of clinically apparent liver disease and fade as jaundice starts. Immune complexes containing hepatitis B surface antigen (HBsAg) and hypocomplementemia are found in serum and joint fluid. The process spontaneously resolves as antigen is cleared from the blood.

Hepatitis B is associated with polyarteritis nodosa (PAN), with some studies suggesting that more than 30% PAN cases are secondary to HBV. PAN usually occurs within the first 6 months of infection, even during the acute phase, but may occur as long as 12 years after infection. Unlike the urticarial reaction, which is usually associated eventually with development of clinical hepatitis, HBV infection associated with PAN may be silent.

Immunosuppressive treatments can lead to reactivation of silent HBV infection. Before initiating treatment with an immunosuppressive agent (including TNF inhibitors), the patient should be screened for HBV infection by checking hepatitis B antibodies. Only two thirds of patients who receive immunomodulators will be HBsAg positive. Although 75% of HBV-infected patients will remain asymptomatic during immunomodulator treatment, a third will develop severe hepatitis, and more than 10% will die or develop fulminant hepatitis. Rituximab and cyclophosphamide cause reactivation early. Most of these patients would be candidates for preemptive antiviral therapy, so all patients with serologic evidence of HBV infection in whom immunosuppressive treatment or TNF inhibitor therapy is being considered should be referred to a hepatologist before initiating immunosuppressive therapy.

A highly effective vaccine is available to prevent HBV infection. It is recommended as a part of standard childhood immunizations,

and all health care workers should be immunized. Patients who will receive TNF inhibitor treatment and who are not immunized may be considered for immunization.

Hepatitis C Virus

Hepatitis C virus (HCV) is a single-stranded (ss) RNA virus that causes most cases of non-A, non-B viral hepatitis. Now that a serologic test is available to screen blood products for HCV infection, the vast majority of new cases of HCV infection are parenterally transmitted by IV drug use. Compared with hepatitis B, sexual transmission is uncommon (<1% transmission/year of exposure). Mother-to-infant spread occurs in 5% of cases. Only about one third of patients are symptomatic during acute infection. Between 55% and 85% of patients will have chronic infection. Although most patients have minimal symptoms for the first one to two decades of infection, cirrhosis and liver failure, as well as hepatocellular carcinoma, are common sequelae. Chronic HCV infection is associated with various skin disorders, either by direct effect or from the associated hepatic damage.

Cutaneous necrotizing vasculitis, which is usually associated with a circulating mixed cryoglobulin, occurs in approximately 1% of patients with chronic HCV infection. In 84%–90% of patients with type II or type III cryoglobulinemia, HCV infection is present. The most common clinical presentation is palpable purpura of the lower extremities (90% of cases). Livedo reticularis, retiform purpura, urticaria, and subcutaneous nodules showing a granulomatous vasculitis may also occur. Arthropathy, glomerulonephritis, and neuropathy frequently accompany the skin eruption. Leg ulcers can occur in 10%–20%. Rheumatoid factor, a type II cryoglobulin, and hypocomplementemia (often isolated low C4 and normal C3) are found in the majority of cases. Histologically, a leukocytoclastic vasculitis is seen in all patients, though some may also show small fibrin thrombi and vasculopathy. In some, the vasculitis may involve small arteries, giving a histologic pattern similar to that seen in PAN. In various studies, 5%–20% of patients with PAN were HCV positive, suggesting that both HBV and HCV can cause PAN. The presence of anti-HCV antibodies should not be used as the sole diagnostic test in patients with PAN, because PAN may cause a false-positive enzyme-linked immunosorbent assay (ELISA) test for HCV. HCV-infected patients with mixed cryoglobulinemia are 35 times more likely to develop non-Hodgkin lymphoma, usually of the B-cell type. In virus-associated vasculitis, treating the underlying virus is essential.

Patients with porphyria cutanea tarda (PCT) often have hepatocellular abnormalities. Depending on the prevalence of HCV infection in the population studied, 10%–95% of sporadic (not familial) PCT cases are HCV associated. Treatment of the HCV infection may lead to improvement of the PCT.

Hepatitis C infection has been associated with lichen planus, with about a fourfold increased risk for its development in the HCV-positive patient. The likelihood of identifying HCV infection in a patient with lichen planus is greatest in geographic regions with high rates of HCV infection. Patients with oral lichen planus are also more likely to be HCV infected. Serologic testing in a patient should be considered if the patient has HCV risk factors or abnormal LFTs or is from a geographic region where, or from population in whom, HCV infection is common. HCV may also be associated with cutaneous B-cell lymphoma. In studies from Japan and Israel, patients with HCV infection were almost twice as likely to develop psoriasis, especially men over 40 years. They were less obese but had higher rates of hypertension and diabetes mellitus. Approximately 15% of patients with HCV infection have pruritus. Pruritus virtually always is associated with advanced liver disease and abnormal LFTs. Patients with pruritus and normal LFTs and no history of hepatitis rarely will be infected with HCV.

Fig. 19.24 Necrolytic acral erythema. (Courtesy Carrie Kovarik, MD.)

Necrolytic acral erythema (NAE) is a rare condition associated with HCV infection. It affects persons of African origin and occurs in less than 2% of HCV-infected patients in the United States. It resembles the nutritional deficiency dermatoses, except that it has an acral distribution. The clinical lesions are painful or pruritic, keratotic, well-defined plaques with raised red scaly borders or diffuse hyperkeratosis (Fig. 19.24). Erosion and flaccid blisters may occur, contributing to the discomfort. The dorsal feet (less often the dorsal hands) as well as the lower extremities may be involved. Histologically, there is necrosis of the superficial portion of the epidermis, along with hyperkeratosis, papillomatosis, loss of the granular cell layer, and parakeratosis. Intraepidermal spongiotic foci are present, which may be macroscopic at times, with the cleavage plane between the necrotic and viable epidermis. Generally zinc, essential fatty acid, and glucagon levels are normal, unlikely in other "deficiency" dermatoses, but the patients may be hypoalbuminemic and have low serum amino acids because of their liver disease. Some cases of NAE have been described with zinc deficiency, and as responsive to zinc supplementation. Treatment of the associated HCV infection with IFN and ribavirin, IFN plus zinc, and liver transplantation has resulted in resolution. Hyperalimentation was also partially effective in some patients, as was amino acid supplementation with zinc.

The treatment of HCV infection is rapidly evolving. A combination of IFN alpha and ribavirin is the historical treatment for patients with chronic HCV infection, with sustained responses in slightly over 50% of patients. Combined IFN and ribavirin therapy may be complicated by an eczematous eruption with pruritus in about 8% of patients and severe pruritus in about 1%. Eczema typically affects the distal extremities, dorsal hands, face, neck, and less frequently the trunk, axillae, and buttocks. The eruption may be photodistributed and photoexacerbated. These eczematous eruptions typically begin 2–4 months after initiation of treatment. In affected patients, prior treatment with IFN alone was usually not associated with an eczematous eruption. Histologically, the eruptions show a spongiotic dermatitis. The eruption resolves completely if treatment is stopped for 2–3 weeks but will recur when treatment is restarted. Aggressive therapy with antihistamines, emollients, and potent topical corticosteroids will usually control the eczema, allowing uninterrupted continuation of treatment. IFN has also been reported to induce granulomatous reactions,

including cutaneous and systemic sarcoidosis, both at injection sites and remotely.

Telaprevir, an HCV protease inhibitor, was introduced as an agent to enhance response of HCV to treatment. This agent, however, was associated with a high rate of adverse skin reactions (60%–80% of patients). Most occurred in the first 10 days of telaprevir administration. More than 90% of telaprevir-associated drug reactions are graded as mild (localized, grade 1) or moderate (diffuse, grade 2) and could be treated with topical agents and oral antipruritics. Over time, numerous severe cutaneous reactions, including high rates of DRESS and Stevens-Johnson syndrome, were observed. Newer agents are available with both better efficacy and substantially reduced adverse event rates, and telaprevir is no longer available in the United States.

Newer "direct-acting antiviral" (DAA) agents include elbasvir-grazoprevir, combination regiments with paritaprevir-ritonavir-ombitasvir, and other novel antiviral agents. Generally regimens are tailored to the patient based on the level of cirrhosis, prior treatment history, and HCV-genotype status.

Fig. 19.25 Gianotti-Crosti syndrome.

Gianotti-Crosti Syndrome (Papular Acrodermatitis of Childhood, Papulovesicular Acrolocated Syndrome)

Gianotti-Crosti syndrome (GCS) is a characteristic viral exanthem. It was initially associated with the early anicteric phase of HBV infection. With universal HBV immunization, HBV is now a rare cause of GCS. EBV is now the most common cause of GCS worldwide. Other implicated infectious agents have included adenovirus, CMV, enteroviruses (coxsackie A16, B4, and B5), vaccinia virus, rotavirus, hepatitis A and C, respiratory syncytial virus, parainfluenza virus, parvovirus B19, rubella virus, HHV-6, streptococcus, and *Mycobacterium avium*. Immunizations against poliovirus, diphtheria, tetanus, pertussis, Japanese encephalitis, influenza, and hepatitis B and measles (together) have also caused GCS.

The clinical features are identical, independent of the cause. GCS typically affects children 6 months to 14 years of age (median age 2 years, 90% of cases occurring before the age of 4), more commonly in those with atopy, and may rarely be seen in adults (women primarily, men very rarely). Proposed diagnostic criteria involve the following positive clinical features of GCS:

1. Monomorphous, flat-topped, pink-brown papules or papulovesicles of 1–10 mm in diameter (Figs. 19.25 and 19.26)
2. Any three or all four sites involved—face, buttocks, forearms, and extensor legs
3. Symmetry
4. Duration of at least 10 days

Negative clinical features include the following:

1. Extensive truncal lesions
2. Scaly lesions

The lesions develop over a few days but last longer than most viral exanthems (>10 days and up to many weeks). Lesion numbers may vary from a few to a generalized eruption coalescing to form plaques covering the face, trunk, and upper extremities. Early in the course of the eruption, the lesions will demonstrate a Koebner phenomenon. Pruritus is variable, and the mucous membranes are spared, except when inflamed by the associated infectious agent. Depending on the cause, the lymph nodes, mainly inguinal and axillary, are moderately enlarged for 2–3 months. No treatment appears to shorten the course of GCS, which is self-limited.

POXVIRUS GROUP

The poxviruses are DNA viruses of a high molecular weight. The viruses are 200–300 nm in diameter and thus can be seen in routine histologic material. Molluscum contagiosum virus and the now-eliminated variola virus are the only poxviruses for which humans represent the primary host and reservoir. The other poxviruses are primarily infections of animals, from whom humans accidentally become infected. The orthopoxviruses that have infected humans include vaccinia, monkeypox, cowpox, buffalopox, and camelpox. The parapoxviruses causing human disease include orf, bovine papular stomatitis, and sealpox. Many other genera of poxviruses have recently been discovered but are primarily pathogens in wild animals, so human disease is extremely rare or is not yet identified.

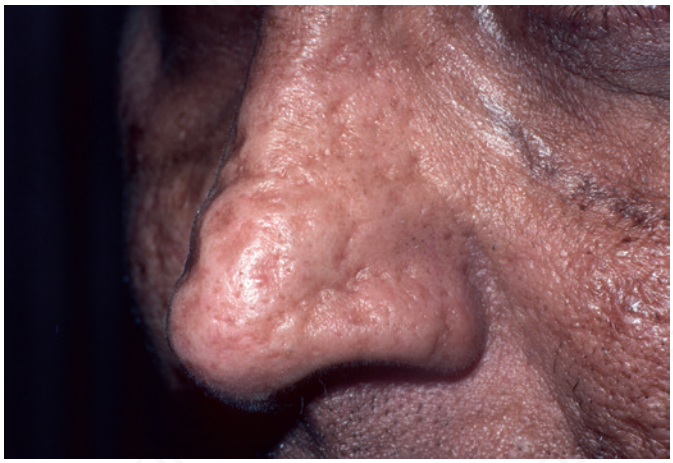

Fig. 19.27 Smallpox scarring. (Courtesy Steven Binnick, MD.)

Variola Major (Smallpox)

Smallpox was eradicated worldwide in 1977. It continues to be of interest to dermatologists as a potential biologic warfare agent, and some have suggested that wild smallpox may have the potential to reemerge as climate change and global warming thaw previously frozen mass graves from the era when smallpox was rampant. Variola is spread by the respiratory route, with 37%–88% of unvaccinated contacts becoming infected. The incubation period for smallpox is 7–17 days (average 10–12 days). The prodromal phase consists of 2–3 days of high fever (>40°C), severe headache, and backache. The fever subsides, and an exanthem covers the tongue, mouth, and oropharynx. This is followed in 1 day by the appearance of skin lesions, distributed in a centrifugal pattern, with the face, arms, and legs more heavily involved than the trunk. Lesions appear first on the palms and soles and feel like firm "BBs" under the skin. Beginning as erythematous macules (days 1–2), the lesions all in synchrony become 2–3 mm papules (days 2–4) and evolve to 2–5 mm vesicles (days 4–7) and 4–6 mm pustules (days 5–15). The pustules umbilicate, collapse, and form crusts beginning in the second week. The total evolution averages 2 weeks. Lesions on the palms and soles persist the longest. The crusts separate after about 1 more week, leaving scars (Fig. 19.27), which are permanent in 65%–80% of the survivors. Patients are infectious from the onset of the exanthem through the first 7–10 days of the eruption. A variety of complications occur, including pneumonitis, blindness caused by viral keratitis or secondary infection (1% of patients), encephalitis (<1% of patients), arthritis (2% of children), and osteitis. Immunity is lifelong. The mortality rate was 5%–40% in undeveloped countries (and before current intensive care and antiviral management).

Diagnosis is made by electron microscopy, viral culture, and PCR. Special laboratories, usually associated with city and state health departments in the United States, can process these specimens and confirm the diagnosis. The differential diagnosis is primarily varicella, especially the more severe form seen in adults. In varicella, the prodrome lasts for 1–2 days; fever begins with onset of the eruption (not preceding it by 1–3 days, as in variola); the eruption is concentrated on the torso (not centrifugally); and individual lesions of different stages are present and evolve from vesicles to crust within 24 hours. The diagnostic test of choice in these patients is a Tzanck smear, which can rapidly confirm the multinucleated cells of varicella, followed by confirmatory testing with PCR or DFA.

Treatment of smallpox includes strict isolation and protection of health care workers. Only vaccinated persons should treat the patient, and any of those exposed should immediately be vaccinated because this modifies the disease, with ring vaccination of contacts. Cidofovir modifies infections by other orthopoxviruses and may be indicated.

Vaccinia

The vaccinia virus (VACV) has been propagated in laboratories for immunization against smallpox. There are multiple strains used in vaccines, and the rates of complications vary somewhat, depending on the strain used. The available antiviral agents with activity against vaccinia are limited. If a case of vaccinia is encountered, the state health department or the U.S. Centers for Disease Control and Prevention (CDC) should be contacted immediately for optimal management. VACV appears to have been initially isolated by Jenner from horse hooves and is closely related to horsepoxvirus. There have been epidemics of VACV infections on the teats of dairy cattle, the mouths of their calves, and the hands of dairy farmers in Brazil since the 1990s. VACV has also been isolated from wild rodents in Brazil.

Vaccination

Vaccination is inoculation of live VACV into the epidermis and upper dermis by the multiple puncture technique. Between 3 and 5 days after inoculation, a papule forms, which becomes vesicular at days 5–8, then pustular, reaching a maximum size at days 8–10. The pustule dries from the center outward, revealing the pathognomonic umbilicated pustule, and forms a scab that separates 14–21 days after vaccination, resulting in a pitted scar. Formation by days 6–8 of a papule, vesicle, ulcer, or crusted lesion, surrounded by a rim of erythema and induration, is termed a "major reaction" or "take." The rim of erythema averages 3.5–4 cm in diameter in new vaccinees and peaks on days 9–11. Repeat vaccinees have reactions of a similar time course, but the maximum diameter of the erythema is only 1–2 cm. Reactions that do not match this description are considered equivocal, and such persons cannot be considered immune; revaccination should be considered. A large vaccination reaction, or "robust take," is the development of a plaque of erythema and induration greater than 10 cm at the site of inoculation. This occurs in 10% of initial vaccinees. It peaks at days 8–10 and resolves without treatment within 72 hours. Cellulitis secondary to vaccination occurs on days 1–5 after vaccination or after several weeks and progresses without treatment. Management should be expectant, but a bacterial culture may be taken. Vaccinated patients may have fever on days 8–10 after vaccination, so culture is not helpful in separating cellulitis from a "robust take." Rarely, patients will develop lesions at the site of vaccination an average of 2 months later. Their nature is unknown, but these lesions have not been identified as containing live virus and are self-limited.

Vaccination involves the inoculation of a live virus. Complications result from an abnormal response to the vaccination by the host or from inadvertent transmission to another person. Persons with eczema or systemic immunity are at particular risk for adverse outcomes from vaccination. Because some complications may be fatal, extremely careful steps must be taken to avoid complications.

Fig. 19.28 Vaccinia vaccination with autoinoculation.

Inadvertent Inoculation and Autoinoculation

Inadvertent inoculation of vaccinia may occur by transmission of virus by hands or fomites from the vaccination site to another skin area or the eye, or to another person. Accidental autoinoculation occurs in about 1 in 1000 vaccinees (Fig. 19.28). Autoinoculation most often occurs around the eyes and elsewhere on the face, but the groin and other sites may be involved. These lesions evolve in parallel with the primary vaccination site and, except for ocular lesions, cause no sequelae, except scarring at times. Any evidence of ocular inflammation in a recently vaccinated individual could represent ocular vaccinia infection and requires immediate ophthalmologic evaluation. Transmission to others (secondary transfer) is rare if the vaccination site is kept covered until it heals (7.4 in 100,000 primary vaccinees). It usually occurs within a household or through intimate contact. Serial transmission can occur among male sports partners and has been reported in serial sexual partners. Correct bandaging of the vaccination site using foam or occlusive dressings, not gauze bandages, and treating the inoculation site with povidone-iodine ointment beginning 7 days after immunization both can reduce viral shedding and might reduce autoinoculation and secondary cases.

Generalized Vaccinia

From 6–9 days after vaccination, a generalized vaccinia eruption may occur, in about 81 per 1 million new vaccinees or 32 per 1 million repeat vaccinees. The lesions are papulovesicles that become pustules and involute in 3 weeks, although successive crops may occur within that time. Generalized vaccinia may be accompanied by fever, but patients do not appear ill. Lesions may be generalized or limited to one anatomic region and can number from a few to hundreds. They can be confused with multisite autoinoculation, as well as erythema multiforme. The diagnosis is confirmed by biopsy, viral culture, or PCR. Generalized vaccinia is self-limited and does not require treatment in the immunocompetent host. In the patient with underlying immunodeficiency, early intervention

with vaccinia immune globulin intravenous (VIGIV) may be beneficial.

Eczema Vaccinatum

Eczema vaccinatum is analogous to EH, representing VACV infection superimposed on a chronic dermatitis, especially AD. Patients with Darier disease, Netherton syndrome, and other disorders of cornification may also be at risk. Because patients with AD or any past history of AD should not be vaccinated, most cases of eczema vaccinatum represent secondary transfer to an at-risk individual from a recent vaccinee, usually a family member. The vesicles appear suddenly, mostly in areas of active dermatitis. The lesions are sometimes umbilicated and appear in crops, resembling smallpox or chickenpox. The onset is sudden, and fresh vesicles appear for several days. Scarring is common. Often, cervical adenopathy and fever occur, and affected persons are systemically ill (unlike those with generalized vaccinia). Secondary bacterial infection can complicate eczema vaccinatum. The mortality rate for eczema vaccinatum is 30%–40% if untreated. VIGIV reduces the mortality rate to 7%. Multiple doses of VIGIV and perhaps treatment with effective antivirals may be required.

Progressive Vaccinia (Vaccinia Necrosum, Vaccinia Gangrenosum)

Progressive vaccinia is a rare, severe, and often fatal complication of vaccination that occurs in immunodeficient persons. Most cases occur when infants with undiagnosed immunodeficiency are immunized. The initial vaccination site continues to progress and fails to heal after more than 15 days. The vaccination site is characterized by a painless but progressive necrosis and ulceration (Fig. 19.29), with or without metastatic lesions to distant sites (skin, bones, viscera). No inflammation is present at the sites of infection, even histologically. Untreated progressive vaccinia is virtually always fatal. Progressive vaccinia is diagnosed by skin biopsy, viral culture, or PCR. VIGIV should be given, and antiviral antibiotics available from the CDC have been effective in this rare condition.

Cutaneous Immunologic Complications

A spectrum of erythematous eruptions follows vaccination. These eruptions are more common than generalized vaccinia, with which they are often confused. Cases of Stevens-Johnson syndrome after vaccination have been seen in the past, primarily in children, but apparently are rare in adult vaccinees.

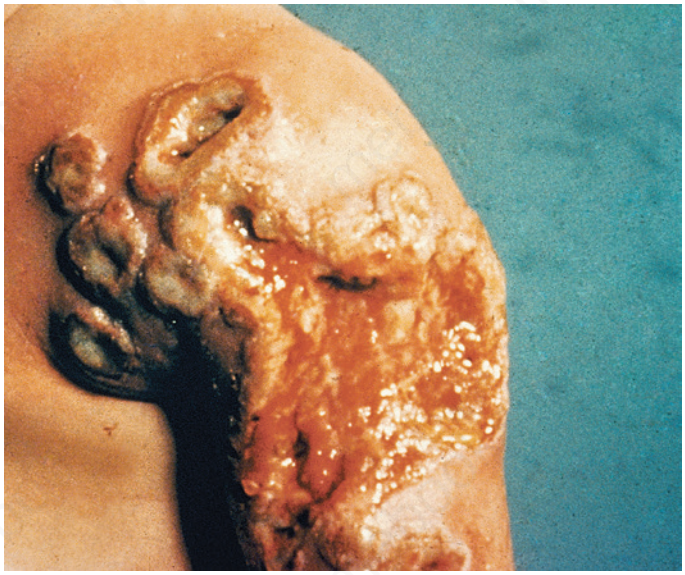

Fig. 19.29 Vaccinia necrosum.

Benign Hypersensitivity Reactions to Vaccinia. About 0.08% of vaccinees will develop a diffuse cutaneous eruption during the second week after vaccination, around the peak of the immunization site reaction. These reactions have been classified as exanthematous (by far the most common), urticaria, and erythema multiforme (EM)–like (the most rare). A follicular eruption has also been reported (see next section). All these reaction patterns evolve over 1–2 days and resolve over days. Patients may have mild symptoms but are afebrile. At times, the eruption may evolve from around the inoculation site and generalize, called "roseola vaccinia" in the past. Primary vaccinees are more likely to develop these reactions. Histology is nonspecific, showing features of a viral exanthem (mild spongiotic dermatitis). These reactions are distinguished from generalized vaccinia by a later onset (end of second week vs. days 6–9 after vaccination), prominent erythema, lack of vesicles and pustules, and negative laboratory testing for vaccinia virus. The eruptions described as EM-like lack mucosal involvement and blistering and more closely resemble urticaria multiforme (see Chapter 7). They are distinguished from EM/Stevens-Johnson syndrome by the absence of atypical purpuric or typical targetoid lesions, lack of mucosal involvement, and histologic evaluation.

Postvaccination Follicular Eruption. A generalized variant of the eruption occurred in 2.7% of new vaccinees and a localized variant in 7.4% during a trial of Aventis Pasteur smallpox vaccine. In the second week, 9–11 days after vaccination, multiple follicular, erythematous papules appeared, primarily on the face, trunk, and proximal extremities. Lesions were mildly pruritic. Over several days, the lesions evolved to pustules, which resolved without scarring. Lesions were simultaneously at different stages of development. The number of lesions was usually limited and rarely exceeded 50. Lesions spontaneously resolved over a few days. Histologic evaluation revealed a suppurative folliculitis. No virus was detected in the lesions by PCR or viral culture.

Other Skin Lesions at Vaccination Scars. Melanomas, basal cell carcinomas (BCCs), and squamous cell carcinomas (SCCs) have all occurred in vaccination scars. Benign lesions with a tendency to occur in scars, such as dermatofibromas, sarcoidosis, and granuloma annulare, also can occur in vaccination scars.

Human Monkeypox

Human monkeypox (virus, MPXV), caused by an orthopoxvirus, is a sporadic zoonosis that occurs in remote areas of the tropical rainforests in central and western Africa, primarily the Democratic Republic of Congo. The mortality rate is 1%–8%. The number of cases has dramatically increased since the 1980s. The main vector for monkeypox is wild African rodents and monkeys. Humans are accidental hosts. Direct contact with an infected animal or person appears to be required to acquire the infection. In Africa, more than 90% of cases occur in children under 15 years of age, in whom the fatality rate is 11%. The secondary attack rate in African households is 10%–12%. An outbreak of 81 cases of monkeypox occurred in the United States. Prairie dogs became infected when housed with infected African rodents. Persons who purchased the prairie dogs became infected, most frequently through bites or scratches or areas of damaged skin. The pattern of monkeypox seen in the U.S. cases was different from that of African cases; transmission was believed to be by inoculation, and many of the affected persons were previously immunized with vaccinia. Primary skin lesions occurred at sites of inoculation and limited spread occurred thereafter, with the appearance of 1–50 additional satellite and disseminated lesions over several days. Patients often had fever, respiratory symptoms, and characteristic lymphadenopathy (67%). About one quarter required hospitalization, and only two children had serious clinical illness, one with encephalitis and one with severe oropharyngeal lesions.

In Africa, monkeypox is clinically similar to smallpox, with an incubation period of 10–14 days. Patients develop headache (100%); fever, sweats, and chills (82%); and lymphadenopathy (90%). Lymphadenopathy is not a feature of smallpox. The prodrome lasts 2 days, followed by the appearance of 2–5 mm papules. The lesions spread centrifugally and progress from papules to vesicles, then pustules all in 14–21 days. In 80% of patients, the lesions are largely monomorphic but are more pleomorphic than smallpox. The distribution is generalized, and the buccal mucosa can be affected. Lesions resolve with hemorrhagic crusts. The disease is self-limited. It is less severe in persons previously vaccinated against smallpox.

Buffalopoxvirus

Buffalopoxvirus (BPXV) is an orthopoxvirus closely related to VACV. It affects buffalo, cows, and humans, and multiple outbreaks have occurred in India. Wild rodents are probably the natural reservoir. Lesions occur on the hands and arms of animal handlers and resemble a milder form of cowpox. Family members may be affected, and children have developed lesions resembling eczema vaccinatum.

Zoonotic Poxvirus Infections

The diagnosis of zoonotic poxvirus infection is usually by epidemiologic history, clinical features, and electron microscopy, which can separate the various poxvirus genera. Laboratory culture is slow, and PCR analysis of the viral DNA allows for speciation. Rarely is antiviral therapy indicated; most diseases are self-limited. Cidofovir would be thought to have activity against the zoonotic poxviruses.

Cowpox

Cowpox (virus, CPXV) is an orthopoxvirus that is geographically restricted to the United Kingdom, Europe, Russia, and adjacent states. It is largely a zoonosis that rarely affects cattle. The domestic cat is the usual source of human infection. Cats acquire infection from wild animal reservoirs (small wild rodents such as mice and voles). Lesions first appear on the head and then on the paws and ears. Feline infection may be asymptomatic, or the cat may be very ill. Most human cases occur in the late summer and in fall. The recent popularity of pet rats in Europe has led to several cases of rat-to-human transmission of CPXV, especially in children too young to have received smallpox vaccination.

The incubation period of CPXV is about 7 days. There is then an abrupt onset of fever, malaise, headache, and muscle pain. Lesions are usually solitary (72%), with coprimary lesions in 25% of cases. Lesions occur on the hands and fingers in half the cases and the face in another third. Pet rats seem to infect children usually on the neck. Secondary lesions are uncommon and generalized disease is rare, usually occurring in patients with AD and Darier disease. The lesion progresses from a macule through a vesicular stage, then a pustule that becomes blue-purple and hemorrhagic. A hard, painful, 1–3 cm, indurated eschar develops after 2–3 weeks and may resemble cutaneous anthrax. In anthrax, however, the eschar forms by day 6. Lesions are always painful, and there is local lymphadenopathy, which is usually tender. The amount of surrounding edema and induration is much more marked than in orf. Patients are systemically ill until the eschar stage. Healing usually takes 6–8 weeks. Scarring is common after cowpox.

Farmyard Pox

Because closely related parapoxviruses of sheep and cattle cause similar disease in humans, orf and milker's nodules have been collectively called farmyard pox. The epidemiologic features are discussed separately, but the clinical and histologic features, which are identical, are discussed jointly. The diagnosis of these infections is based on taking an accurate history and can virtually always be confirmed by routine histologic evaluation.

Bovine-Associated Parapoxvirus Infections: Milker's Nodules, Bovine Papular Stomatitis (BPSV), and Pseudocowpox (PCPV). Bovine-associated parapoxvirus infections cause worldwide occupational disease of milkers or veterinarians, most often transmitted directly from the udders (milker's nodules) or muzzles (bovine papular stomatitis) of infected cows. Lesions are usually solitary or few in number and are confined to the hands or forearms (Fig. 19.30). Numerous lesions have been reported in healing first-degree and second-degree burns in milker's nodules. These cases occurred on farms with infected cattle, but the patients had not had direct contact with the cattle, suggesting indirect viral transmission.

Orf. Also known as ecthyma contagiosum, orf is a common disease in goat-farming and sheep-farming regions throughout the world. Direct transmission from active lesions on lambs is most common,

Fig. 19.30 Milker's nodule.

Fig. 19.31 Orf.

but infection from fomites also frequently occurs because the virus is resistant to heat and dryness. Slaughtering of animals for religious feasts can spread the disease, and in Australia, deer was the vector for one case. Once patients are infected, autoinoculation (particularly to the genital area) can occur, but human-to-human transmission is rare. One report detailed orf occurring in skin-graft donor and recipient sites. One patient receiving etanercept developed a giant lesion and progressive disease. He was successfully treated with surgical removal, cryotherapy, and topical imiquimod, with discontinuation of the etanercept.

Clinical Features. The incubation period for farmyard pox is about 1 week. Lesions are usually solitary and occur on the hands, fingers (Fig. 19.31), or face. Lesions evolve through the following six stages:

1. A papule forms, which then becomes a target lesion with a red center surrounded by a white ring and then a red halo.
2. In the acute stage, a red, weeping nodule appears, resembling pyogenic granuloma.
3. In a hairy area, temporary alopecia ensues.
4. In the regenerative stage, the lesion becomes dry with black dots on the surface.
5. The nodule then becomes papillomatous.
6. The nodule finally flattens to form a dry crust, eventually healing.

Lesions are usually about 1 cm in diameter, except in immunosuppressed patients, in whom giant lesions may occur. Dermoscopy likely varies by stage, but a nodule with central crust, white structureless areas, white streaks, surrounded by vessels and peripheral scale has been described. Spontaneous resolution occurs in about 6 weeks, leaving minimal scarring. Mild swelling, fever, pain, and lymphadenitis may accompany the lesions, but these symptoms are milder than those seen in cowpox. Orf may be associated with an EM-like eruption in about 5% of patients. Treatment is supportive, although shave excision may accelerate healing. Topical cidofovir and imiquimod have been effective.

Histologic Features. Histologic features of farmyard pox correlate with the clinical stage. Nodules show a characteristic pseudoepitheliomatous hyperplasia covered by a parakeratotic crust. Keratinocytes always demonstrate viropathic changes of nuclear vacuolization and cytoplasmic, 3–5 μm, eosinophilic inclusions surrounded by a pale halo. The papillary dermis is severely edematous. The dermal infiltrate, which is dense and extends from the interface to the deep dermis, consists of lymphocytes, histiocytes, neutrophils, and eosinophils. Massive capillary proliferation and dilation are present in the upper dermis. Electron microscopy has been used to identify the viral particles.

Human Tanapox

Tanapox infection is a yatapoxvirus infection endemic to equatorial Africa. It is spread from its natural hosts, nonhuman primates, through minor trauma. Human-to-human transmission is rare. Tanapox infection is manifested by mild fever of abrupt onset lasting 3–4 days, followed by the appearance of one or two pock lesions. Lesions are firm and cheesy, resembling cysts. The disease is self-limited, and smallpox vaccination would not be expected to be protective. Rare cases have been imported into Europe and the United States.

Molluscum Contagiosum

Molluscum contagiosum (MC) is caused by up to four closely related types of poxvirus, MCV-1 to MCV-4, and their variants. Although the proportion of infection caused by the various types varies geographically, MCV-1 infections are most common worldwide. In small children, virtually all infections are caused by MCV-1. In contrast to HSV, there is no difference in the anatomic region of isolation with regard to infecting type. In patients infected with HIV, however, MCV-2 causes the majority of infections (60%).

Infection with MCV is worldwide and increasing. Three groups are primarily affected: young children (highest in ages 1–4 years), sexually active young adults (ages 20–29), and immunosuppressed

Fig. 19.32 Molluscum contagiosum. (Courtesy Steven Binnick, MD.)

Fig. 19.33 Molluscum contagiosum. (Courtesy Shyam Verma, MBBS, DVD.)

persons, especially those with HIV infection. MC is most easily transmitted by direct skin-to-skin contact, especially if the skin is wet. Bathing and swimming pools have been associated with infection although it is not clear how much of this is because of sharing wet towels, kickboards and other swim equipment. Even plantar lesions can be seen.

In all forms of MC infection, the lesions can vary in size and presentation although the most typical is a small smooth-surfaced, firm, dome-shaped, pearly papule, averaging 3–5 mm in diameter (Fig. 19.32 and 19.33). Early lesions can be less than 1 mm and larger "giant" cystic lesions can be over 1 cm. A central umbilication or central white core is characteristic but may not be notable until the lesions get to a certain size. Side lighting can help highlight the opening in the top of the lesion and when the lesions are frozen, often a small circular area is highlighted on top. Irritated lesions may become crusted and even pustular, simulating secondary bacterial infection. The inflammatory response can result in warmth,

Fig. 19.34 Molluscum contagiosum in child with atopic dermatitis.

surrounding redness and pain that closely simulates and may be indistinguishable from cellulitis. Lesions that rupture into the dermis may elicit a marked suppurative inflammatory reaction that resembles an abscess.

The clinical pattern depends on the risk group affected. In young children, even with normal immunity, the lesions are usually generalized and number from a few to more than 100. Lesions tend to be on the axillae, inguinal areas, popliteal or antecubital fossae and face. Genital lesions, as part of a wider distribution, occur in 10% of childhood cases. When MC is restricted to the genital area in a child, inappropriate sexual contact must be considered but even in this scenario, the infection is usually not from this type of contact. Children with AD, either active or inactive, are four times more likely than nonatopic children to have more than 50 lesions and the course may last longer. Exuberant infection especially in association with other viral infections should raise the possibility of immunodeficiency such as a DOCK-8 mutation. Transmission from the mother's skin can occur during vaginal delivery and may be associated with presentation in the first few months of life especially on the scalp. Immunosuppression, either systemic T-cell immunosuppression (usually HIV, immunosuppressive medications, and malignancies) or abnormal cutaneous immunity (as in AD or topical steroid use), predisposes to infection. In AD patients, lesions tend to be confined to dermatitic skin (Fig. 19.34). The MC virus itself has been shown to cause inhibit NF Kappa B possibly explaining how it avoids the immune system for so long.

Several forms of inflammation occur in children with MC. The most common inflammatory response, seen in 40% of affected children, is "molluscum dermatitis." More common in atopic children, it is a mild, eczematous eruption surrounding the individual lesions. An asymmetric, new dermatitis in an axilla or antecubital or popliteal fossa of a young child should alert the clinician to evaluate for very small molluscum causing the dermatitis. The dermatitis is not associated with more rapid resolution of the MC, and treatment of this dermatitis with low potency topical corticosteroids does not appear to lead to increased MC. Inflamed MC is characterized by erythema and swelling of the individual lesions, sometimes with pustulation or fluctuance. It occurs in 20% of children with MC and usually heralds the resolution of disease. This has been named the "BOTE" sign (beginning of the end) and can be helpful for parents who are concerned about the redness and pain to understand that the infection may be close to resolution. Secondary infection may occur, but most inflamed MC are not infected, but rather undergoing spontaneous involution by the immune response. Rarely, erythema annulare centrifugum

may be associated with MC. A Giannotti-Crosti type reaction characterized by minimally pruritic symmetric monomorphic papules on the extensor surfaces including the elbows and knees sparing the trunk can occur as the lesions are starting to resolve occurring in up to 5% of children with MC. The lesions closely resemble individual lesions of molluscum causing parents and clinician to mistakenly think the molluscum is suddenly rapidly spreading.

In adults, MC can be sexually transmitted, and other STDs may coexist. The lesions favor the lower abdomen, upper thighs, and perineum including the penile shaft in men. Pubic hair removal by shaving, clipping, or waxing is a risk factor for acquiring MC by sexual contact or spreading it once the infection has occurred. Mucosal involvement is very uncommon.

Lesions on the eyelid margin or conjunctiva may be associated with a conjunctivitis or keratitis. Rarely, the molluscum lesions may present as a cutaneous horn. Between 10% and 30% of AIDS patients not receiving ART have MC. Virtually all HIV-infected patients with MC already have an AIDS diagnosis and a helper T-cell (Th) count of less than 100. In untreated HIV disease, lesions favor the face (especially the cheeks, neck, and eyelids) and genitalia. Lesions may form confluent plaques and facial disfigurement can occur. Giant lesions can occur and may be confused with a skin cancer. Involvement of the oral and genital mucosa may occur, virtually always indicative of advanced AIDS (Th count <50).

MC has a characteristic histopathology. Lesions primarily affect the follicular epithelium. The lesion is acanthotic and cup shaped. In the cytoplasm of the prickle cells, numerous small, eosinophilic and later basophilic inclusion bodies form, called molluscum bodies or Henderson-Paterson bodies. Eventually, their bulk compresses the nucleus to the side of the cell. In the fully developed lesion, each lobule empties into a central crater. Inflammatory changes are slight or absent. Latent infection has not been found, except in untreated AIDS patients, in whom even normal-appearing skin may contain viral particles. Therefore new appearance of previously undetectable MC may be seen in AIDS patients starting ART as a part of IRIS. Resolving and inflamed lesions may contain a dense inflammatory infiltrate of lymphocytes and neutrophils. Some of the lymphocytes may be large and CD30 positive. MCV contains an IL-18–binding protein. This blocks the host's initial effective Th1 immune response against the virus by reducing local IFN-γ production.

The diagnosis of MC is easily established in most cases because of the distinctive central umbilication of the dome-shaped lesion. Other papules that can also umbilicate and simulate molluscum include the infections *Cryptococcus*, *Histoplasmosis*, *coccidioidiomycosis* and *Penicillium marnefii* and the skin tumors keratoacanthoma and desmoplastic trichilemmoma. Lesions that cluster and coalesce in the intergluteal cleft can mimic condyloma accuminatum and especially in a young child, it is vital to differentiate these diagnosis because condyloma is more likely to be transmitted due to inappropriate sexual contact. The central umbilication of molluscum may be enhanced by light cryotherapy, which highlights the round opening of the umbilication. For confirmation, the pasty core of a lesion can be expressed, squashed firmly between two microscope slides (or slide and coverslip with caution not to break the coverslip), and stained with Wright, Giemsa, or Gram, the oval Henderson Patterson bodies can be seen.

Treatment is determined by the clinical setting. In young immunocompetent children, especially those with numerous lesions, because the lesions spontaneously resolve, it is reasonable not to treat. Aggressive treatment may be emotionally traumatic and may lead to scarring. Individual lesions last 2–4 months each; duration of infection is 12–18 months. Because the MC lesions often induce an eczematous reaction around them, just treating this with low-potency topic steroid is reasonable to decrease itch while awaiting resolution.

Simple at home therapies include pressing tape against a lesion and picking it up multiple times per day for a few weeks or continuous application of surgical tape to each lesion daily after bathing for 16 weeks. Topical cantharidin is often used to lesions on the body and extremities though typically the face is avoided as is the perineum in children due to risk of exuberant blisters in these areas. The more that is applied and longer the therapy is left on prior washing, the more vesiculation that occurs. Cantharone mixed with podophyllin should be avoided in molluscum as it is unnecessarily strong. Cantharone is applied by the wooden end of a cotton swab only to the lesion and left on for 1–6 hours before washing. Approximately 20 lesions can be treated per setting. This therapy is well tolerated, has a very high satisfaction rate for patients and their parents, and complications are rare.

If lesions are limited and the child is cooperative, slightly nicking the opening of the lesions with a blade or needle to allow for comedone extraction, squeezing the lesion with a tissue forceps, light cryotherapy, application of trichloroacetic acid (TCA, 35%–100%), and removal by curettage are all alternatives. The application of lidocaine-prilocaine cream for 1 hour before any painful treatments has made the management of MC in children easier but there are reports of systemic toxicity so caution is advised. No controlled trials have confirmed the efficacy of imiquimod, and two large trials have shown that it is no more effective than placebo. Topical tretinoin applied with a toothpick or Q tip in very small amounts to the individual lesions can be used with some benefit especially for lesions on the face to induce some slight irritation and activate the immune system. Intralesional immunotherapy with candidal antigen injections in up to three lesions led to complete resolution of all lesions in 55% of children in one study. Hydrogen peroxide 1% cream, ingenol mebutate, pulse dye laser, povidone iodine, aloe vera and potassium hydroxide 10% are other reported therapies.

Oral cimetidine has been similarly used for its immunomodulatory effects and may have benefit mostly in some patients with atopic patients. In patients with AD, curettage or cryotherapy is most effective while least likely to exacerbate the AD. If cantharone is used, the AD in the area should be treated before therapy to decrease the risk of exuberant response.

In adults with genital molluscum, removal by cryotherapy or curettage is very effective. Neither imiquimod nor podophyllotoxin has been demonstrated to be effective. In fact, the failure of these agents to improve "genital warts" suggests the diagnosis of genital MC. Sexual partners should be examined; screening for coexistent STDs is mandatory.

In immunosuppressed patients, especially those with AIDS, management of MC can be difficult. Treatment of the HIV infection, is predictably associated with a dramatic resolution of the lesions. This response is delayed 6–8 months from the institution of treatment, so reports of resolution with certain agents in the HIV patient is confounded by the coexistent therapy. MC occurs frequently in the beard area, so shaving with a blade razor should be discontinued to prevent its spread. If lesions are few, curettage or core removal with a blade and comedo extractor is most effective. Cantharone or TCA may be applied to individual lesions. Temporary dyspigmentation and slight surface irregularities may occur. Cryotherapy may be effective but must be used with caution in persons of color due to risk of dyspigmentation. When lesions are numerous or confluent, treatment of the whole affected area may be required because of possible latent infection. TCA peels above 35% concentration (medium depth) or daily applications of 5-fluorouracil (5-FU) to the point of skin erosion may eradicate lesions, at least temporarily. In patients with HIV infection, continuous application of tretinoin cream once nightly at the highest concentration tolerated may reduce the rate of appearance of new lesions. Topical 1%–3% cidofovir application and systemic infusion of this agent have been reported to lead to dramatic resolution of molluscum in patients with AIDS.

PICORNAVIRUS GROUP

Picornavirus designates viruses that were originally called enteroviruses (polioviruses, coxsackieviruses, and echoviruses), plus the rhinoviruses. The picornaviruses are small, ssRNA, icosahedral viruses varying in size from 24–30 nm. Only the enterovirus types 70, 71 coxsackieviruses (A16, and A6) and echoviruses, and are significant causes of skin disease.

Enterovirus Infections

Person-to-person transmission occurs by the intestinal-oral route, oral-oral or respiratory routes or by direct inoculation from active lesions to broken skin. Enteroviruses are identified by type-specific antigens. Viral cultures obtained from the rectum, pharynx, eye, and nose may isolate the infecting agent and stool will carry the virus for weeks after the cutaneous infection resolves Usually, the diagnosis is by clinical characteristics although with the more exuberant A6 infections, differentiation from HSV is sometimes necessary. Enteroviral infections most frequently occur in children between ages 6 months and 6 years.

Many nonspecific exanthems and enanthems that occur during the summer and early fall are caused by coxsackievirus or echovirus. The exanthemata most typically are diffuse macular or morbilliform erythemas, which sometimes also contain vesicular lesions or petechial or purpuric areas. Each type of exanthem has been associated with many subtypes of coxsackievirus or echovirus (one exanthem, many possible viral causes). Echovirus 9, the most prevalent enterovirus, causes a morbilliform exanthem, initially on the face and neck, then the trunk and extremities. Only occasionally is there an eruption on the palms and soles. Small, red or white lesions on the soft palate may occur. Rarely, Echovirus 9 has caused an eruption resembling acute meningococcemia. The most common specific eruptions caused by enteroviruses are hand-foot-and-mouth disease, herpangina, enterovirus superinfecting AD (eczema coxackium) and a roseola-like illness. Rare reported presentations of enterovirus infection include a unilateral vesicular eruption simulating herpes zoster, caused by echovirus 6; a fatal dermatomyositis-like illness in a patient with hypogammaglobulinemia, caused by echovirus 24. Pleconaril and other antienteroviral agents may be useful in severe enteroviral infections.

Although the cutaneous eruptions caused by these viruses are quite benign, infections with enterovirus 71 can be severe, with the development of brainstem encephalitis and fatal neurogenic pulmonary edema, as well as ascending flaccid paralysis resembling

Fig. 19.35 Herpangina.

poliomyelitis. Epidemics with severe disease have been reported in Bulgaria, Hungary, Hong Kong, Japan, Australia, Malaysia, and Singapore. Taiwan had the worst epidemic, affecting more than 1 million people with 78 deaths in 1998.

Herpangina

Herpangina, a disease of children worldwide, is caused by multiple types of coxsackievirus (most frequently A8, A10, and A16), echoviruses, and enterovirus 71. In the severe outbreaks in Taiwan, 10% of patients with fatal cases had herpangina. It begins with acute onset of fever, headache, sore throat, dysphagia, anorexia, and sometimes, stiff neck. The most significant finding, which is present in all patients, is one or more yellowish white, slightly raised, 2-mm vesicles in the throat, usually surrounded by an intense areola (Fig. 19.35). The lesions are found most frequently on the anterior faucial pillars, tonsils, uvula, or soft palate. The lesions can cluster, ranging in number from one to having the entire visible pharynx may be studded with them. Usually, the individual or coalescent vesicles ulcerate, leaving a shallow, punched-out, grayish yellow crater 2–4 mm in diameter. The lesions disappear in 5–10 days. Coxsackievirus A10 causes acute lymphonodular pharyngitis, a variant of herpangina, characterized by discrete, yellow-white papules in the same distribution as herpangina. Herpangina is differentiated from aphthosis and primary herpetic gingivostomatitis by the location of the lesions in the posterior oropharynx and by isolation of an enterovirus. Treatment of herpangina is supportive, consisting of topical anesthetics and maintain hydration.

Hand-Foot-and-Mouth Disease

Hand-foot-and-mouth disease (HFMD) is usually a mild illness caused primarily by coxsackievirus A16, but also other cocksackie A and B viruses, as well as enterovirus 71. It primarily affects children age 6 months to 10 years, but exposed adults may also develop disease. Infection begins with a fever and sore mouth. In 90% of patients, oral lesions develop; these consist of small (4–8 mm), rapidly ulcerating vesicles surrounded by a red areola on the buccal mucosa, tongue, soft palate, and gingiva. Lesions on the hands and feet are asymptomatic red papules that quickly become small, gray, 3–7 mm vesicles surrounded by a red halo. They are often oval, linear, or crescentic and run parallel to the skin lines on the fingers and toes (Fig. 19.36). They are distributed sparsely on the dorsa of the fingers and toes and more frequently on the palms and soles. Especially in children who wear diapers, vesicles and erythematous, edematous papules may occur on the buttocks. The infection is usually mild and seldom lasts more than 1 week. In the severe Taiwanese enterovirus 71 outbreak, 80% of cases with CNS disease had the skin lesions of HFMD.

Fig. 19.36 Hand-foot-and-mouth disease.

Fig. 19.37 Coxsackie A6 hand-foot-and-mouth disease.

Cocksackievirus A6 (CVA6) has become a common cause of "atypical HFMD" in Europe, the United States, and Asia. CVA6 can cause typical HFMD but also a more widespread eruption with numerous lesions on the trunk in addition to the characteristic locations. Perioral lesions suggest CVA6 HFMD, and when severe, can suggest severe impetigo or Stevens-Johnson syndrome. Hospitalization may be required for severe dehydration and pain management. Child-to-adult transmission can occur because most adults are not immune to CVA6 (Fig. 19.37). In adults, numerous widespread purpuric lesions can occur, simulating a vasculitis or the atypical targets of EM major. In children with AD, CVA6 causes a vesicular and erosive eruption concentrated in the areas of dermatitis, similar to EH, called "eczema coxsackium." Treatment is supportive, although therapy for the AD to prevent pruritis can be helpful. Monitoring for secondary bacterial infection is important. Onychomadesis often follows HFMD (especially CVA6), about 1 month after the acute viral syndrome.

The virus may be recovered by PCR from the skin vesicles. Histopathologic findings are those of an intraepidermal blister formed by vacuolar and reticular degeneration of keratinocytes, similar to other viral blisters. Inclusion bodies and multinucleated

giant cells are absent. HFMD is distinguished from herpangina by the distribution of the oral lesions and the presence of skin lesions. HFMD usually requires no treatment.

Eruptive Pseudoangiomatosis

Eruptive pseudoangiomatosis has been described in summer in the Mediterranean region and in South Korea. The disorder is characterized by the sudden appearance of 2–4 mm, blanchable red papules that resemble angiomas. The red papules blanch on pressure and are often surrounded by a 1–2 mm pale halo. Lesions often number about 10 but may be much more numerous. Most lesions appear on the exposed surfaces of the face and extremities, but the trunk may also be affected. In children, lesions are short-lived, virtually always resolving within 10 days. Lesions may last slightly longer in adults. Annual recrudescences may occur. Epidemics have been described in adults, and even health care workers caring for patients with eruptive pseudoangiomatosis have developed lesions. Echoviruses 25 and 32 had been implicated in the initial reports. The occurrence in young children and the presence of miniepidemic outbreaks suggest an infectious trigger. This disorder closely resembles "erythema punctatum Higuchi," which is common in Japan and known to be caused by *Culex pipiens pallens* bites. It appears that mosquito bites, viral infection, or enhanced insect bite reaction due to intercurrent viral infection are possible pathogenic causes of eruptive pseudoangiomatosis. In children, it is usually associated with a viral syndrome, but most affected adults have no viral symptoms. In adults, females outnumber males 2:1. Histologically, dilated upper dermal vessels, but not increased numbers of blood vessels, with prominent endothelial cells are seen. There is no known treatment.

FILOVIRUS

The viruses in the *Filovirus* genus are single-stranded and on electron micrographs they appear filamentous, hence the name. Filoviruses are among the most virulent and hazardous pathogens for humans and nonhuman primates and are most closely related to the human viruses that cause measles and rabies. There are two genera, *Marburg virus* (MARV) and *Ebola virus* (EBOV). The incubation period is 1–21 days. The initial symptomatic phase (phase I) is characterized by abrupt onset of fever, headache (usually occipital), myalgias, and arthralgias. Phase II starts 2–4 days after symptom onset and lasts for 7–10 days. Abdominal pain, watery diarrhea, and violent sore throat occur. In phase II a nonpruritic morbilliform eruption resembling measles appears 4–5 days after symptom onset in more than half of patients. The onset of the eruption begins as pinpoint dark red follicular papules. The exanthema may begin acrally and spread centripetally to the trunk or vice versa, beginning proximally and extending centrifugally. By day 8 the skin has a generalized, dark, livid erythema. The eruption resolves over a few days in the survivors, followed by desquamation of the affected skin, especially of the palms and soles. Mucosal lesions are also seen in half of patients with bilateral conjunctival congestion, aphthous-like oral lesions, gingivitis, glossitis, and with extension down the throat, dysphagia. The oral lesions can have a gray exudate or small (tapioca granule) white lesions on the soft palate. Phase III is the terminal phase with shock and multiorgan failure. In this stage, supportive care can maintain the patient until the spontaneous eradication of the virus. Convalescence is prolonged with intense fatigue and migratory arthralgias.

In the nonepidemic setting the initial presentation of the symptoms and skin findings are not specific and can be mistaken for viral or bacterial gastroenteritis, Lassa fever, Dengue, Chikungunya, and even measles, which have overlapping signs and symptoms. In the epidemic setting rapid recognition, establishment of high-quality isolation facilities to treat victims, and absolutely rigid infection control measures to handle infected persons, corpses, and EBOV-infected material are essential.

The animal reservoir for these viruses is four fruit bat species found in Africa. Transmission occurs in humans through contact with female bat blood, infected nonhuman primates and by contact with the bodily fluids of infected humans (including but not limited to blood, urine, sweat, semen, and breast milk). Infected humans can transmit the virus from the time they become febrile. The diagnoses of these agents is by PCR.

The case fatality rate approaches 90% in African outbreaks but appears to be much lower if aggressive supportive medical care is available. Due to the highly contagious nature of these viruses, health care workers are particularly at risk of becoming infected, and special precautions must be taken when managing infected patients.

Neutralizing antibodies from survivors and experimental antivirals are being tested as therapies.

PARAMYXOVIRUS GROUP

The most important dermatologic diseases caused by paramyxoviruses are measles (rubeola) and German measles (rubella). Other viruses of this group are mumps virus, parainfluenza virus, Newcastle disease virus, and respiratory syncytial virus.

Measles

Measles is a highly infectious and potentially fatal viral infection. Highly effective two-dose vaccines are available, and when countries

reach a rate of 95% vaccination, measles elimination has been achieved. However, measles remains a major health problem in many nations, including developed countries that provide immunizations to their population. Numerous hospitalizations and even deaths from measles are still occurring in developed nations. The majority of cases are in unvaccinated persons, supporting the concept that vaccination (specifically two doses) is protective, and that these measles epidemics and deaths are preventable. Because the children in unvaccinated groups may share common schools, camps, and social networks, they provide a prime breeding ground for epidemics. Some developed European and Asian countries (notably Japan, with 200,000 cases annually) have not been able to achieve high immunization levels, meaning that their populations are still at risk. The lack of "herd" immunity in these nations leaves at particular risk those infants and susceptible children who cannot be immunized because of other medical conditions. Cases of measles continue to be imported into the United States, which have resulted in numerous "outbreaks." Dermatologists and pediatricians in the Americas need to be alert for cases of measles when seeing persons from these countries or unvaccinated persons from the Americas especially if they have traveled to nations known to have ongoing measles outbreaks. In the current epidemics, however, older children, adolescents, and adults can be affected. Measles is spread by respiratory droplets and has an incubation period of 9–12 days.

The prodrome consists of fever, malaise, conjunctivitis, and prominent upper respiratory symptoms (nasal congestion, sneezing, coryza, cough). Koplik spots, which are pathognomonic, appear during the prodrome (Fig. 19.38). The spots appear first on the buccal mucosa nearest to the lower molars as 1-mm white papules on an erythematous base. They may spread to involve other areas of the buccal mucosa and pharynx. They have been less frequently reported in recent outbreaks. After 1–7 days, the exanthem appears, usually as macular or morbilliform lesions on the anterior scalp line and behind the ears. Lesions begin as discrete erythematous papules that gradually coalesce. The rash spreads quickly over the face (Fig. 19.39), then by the second or third day (unlike the more rapid spread of rubella) extends down the trunk to the extremities. By the third day, the whole body is involved. Lesions are most prominent and confluent in the initially involved areas and may be more discrete on the extremities. Purpura may be present, especially on the extremities, and should not be confused with "black measles," a rare, disseminated intravascular coagulation–like complication of measles. After 6–7 days, the exanthem clears, with simultaneous subsidence of the fever. Rubella, scarlet fever, secondary syphilis, enterovirus infections, and drug eruptions are in the differential diagnosis.

Complications include otitis media, pneumonia, encephalitis, and thrombocytopenic purpura. Encephalitis, although rare (<1% of cases), can be fatal. Infection in pregnant patients is associated with fetal death. Complications and fatalities are more common in children who are undernourished or have T-cell deficiencies. In HIV-infected children, the exanthem may be less prominent.

Modified measles occurs in a partially immune host as a result of prior infection, persistent maternal antibodies, or immunization, and this is a milder disease that may be difficult to differentiate from other exanthems. Patients may have only fever, or fever and a rash. The course is shorter, the exanthem less confluent, and Koplik spots may be absent.

A diagnosis of measles is established by the presence of a high fever, Koplik spots, the characteristic conjunctivitis, upper respiratory symptoms, and typical exanthem. Lymphopenia is common, with a decreased WBC count. Biopsies of skin lesions may show syncytial keratinocytic giant cells, similar to those seen in respiratory secretions. Laboratory confirmation can be with acute and convalescent serologic tests or PCR. PCR-based technologies can rapidly detect the measles virus genome in urine, oropharyngeal secretions, and blood and are highly useful in modified and previously vaccinated patients. Identification of virus-specific IgM (5 days after the rash presents) is highly suggestive of infection in an unimmunized individual. If done too early, however, a serum IgM assay may lead to a false-negative result, and the test should be repeated.

Administration of high doses of vitamin A may reduce the morbidity and mortality rates of hospitalized children with measles. Two doses of retinyl palmitate, 200,000 IU 24 hours apart, are recommended for all children 6–24 months of age, immunodeficient children, children with malnutrition or evidence of vitamin A deficiency, and recent immigrants from areas of high measles mortality. Otherwise, treatment is symptomatic, with bed rest, analgesics, and antipyretics.

Live virus vaccination is recommended at age 12 months, with a booster before entering school (age 4–5 years). A faint maculopapular exanthem may occur 7–10 days after immunization. Prophylaxis with vaccination and immune globulin should be offered to exposed susceptible persons. It must be provided within

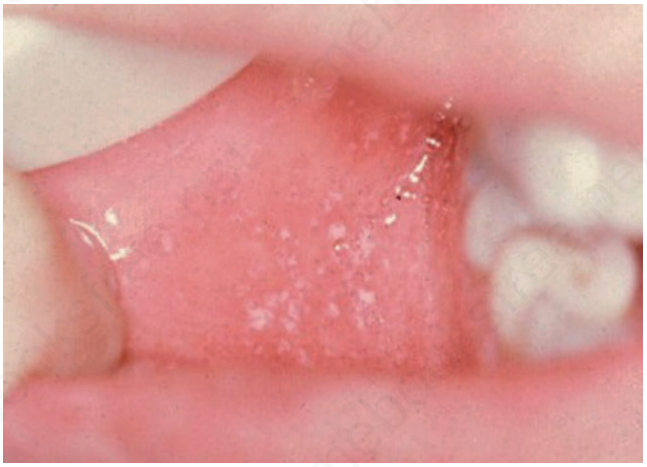

Fig. 19.38 Koplik spots.

Fig. 19.39 Rubeola (measles).

the first few days after exposure, so identification of susceptible persons is critical. In an Australian outbreak, these strategies prevented 80% of possible secondary cases.

Rubella

Rubella, commonly known as German measles, is caused by a togavirus and probably spreads by respiratory secretions. The incubation period is 12–23 days (usually 15–21). Live virus vaccination is highly effective, providing lifelong immunity.

There is a prodrome of 1–5 days consisting of fever, malaise, sore throat, eye pain, headache, red eyes, runny nose, and adenopathy. Pain on lateral and upward eye movement is characteristic. The exanthem begins on the face and progresses caudad, covering the entire body in 24 hours and resolving by the third day. The lesions are typically pale-pink, morbilliform macules, smaller than those of rubeola. The eruption may resemble roseola or erythema infectiosum. An exanthem of pinhead-sized red macules or petechiae on the soft palate and uvula (Forchheimer sign) may be seen. Posterior cervical, suboccipital, and postauricular lymphadenitis occurs in more than half of cases. Rubella is in general a much milder disease than rubeola. Arthritis and arthralgias are common complications, especially in adult women, lasting 1 month or longer. The diagnosis is confirmed by finding rubella-specific IgM in oral fluids or the serum. This IgM develops rapidly, but 50% of sera drawn on the first day of the rash are negative. The virus is rapidly cleared from the blood, being absent by day 2 of the rash. However, the virus is found in oral secretions for 5–7 days after the rash has appeared. PCR-based techniques to identify virus in oral secretions may detect infection more effectively in earlier samples. The combination of PCR-based virus detection tests and identification of rubella virus–specific IgM will result in rapid confirmation of most cases of rubella within the first few days of appearance of disease symptoms.

Congenital Rubella Syndrome

Infants born to mothers who had rubella during the first trimester of pregnancy may have congenital cataracts, cardiac defects, and deafness. Numerous other manifestations, such as glaucoma, microcephaly, and various visceral abnormalities, may emerge. Among the cutaneous expressions are thrombocytopenic purpura; hyperpigmentation of the navel, forehead, and cheeks; bluish red, infiltrated, 2–8 mm lesions ("blueberry muffin" type), which represent dermal erythropoiesis; chronic urticaria; and reticulated erythema of the face and extremities.

Asymmetric Periflexural Exanthem of Childhood (APEC)

This clinical syndrome, also known as unilateral laterothoracic exanthem, or superimposed lateralized exanthema, occurs primarily in the late winter and early spring and appears to be most common in Europe. It affects girls more often than boys (1.2 : 1 to 2 : 1). It occurs in children 8 months to 10 years of age, but most cases are between 2 and 3 years. Multiple cases have been reported in adults. The cause is unknown, but a viral origin has been proposed because it occurs in young children and is seasonal, and secondary cases in families have been reported. No reproducible viral etiology has been implicated; however, at least three cases attributed to parvovirus B19 have been reported. Adenovirus, parainfluenza virus, HHV-6, HHV-7, and EBV have also been described in association with "superimposed lateralized exanthema." Clinically, two thirds to three quarters of affected children have symptoms of a mild upper respiratory or GI infection, usually preceding the eruption. The lesions are usually discrete, 1-mm erythematous papules that coalesce to poorly marginated morbilliform plaques. Pruritus is usually present but is mild. Lesions begin unilaterally close to a flexural area, usually the axilla (75% of cases). Spread is centrifugal, with new lesions appearing on the adjacent trunk and proximal extremity. Normal skin may intervene between lesions. The contralateral side is involved in 70% of cases after 5–15 days, but the asymmetric nature is maintained throughout the illness. Lymphadenopathy of the nodes on the initially affected side occurs in about 70% of patients. The APEC syndrome lasts 2–6 weeks on average, but may last more than 2 months, and resolves spontaneously. Topical corticosteroids and oral antibiotics are of no benefit, but oral antihistamines may help associated pruritus. Histologically, a mild to moderate lymphocytic (CD8+ T-cell) infiltrate surrounds and involves the eccrine ducts but not the secretory coils. There may be an accompanying interface dermatitis of the upper eccrine duct and adjacent epidermis.

PARVOVIRUS GROUP

Parvovirus B19 is the most common agent in this *Erythrovirus* genus to cause human disease. Infection is worldwide, occurring in 50% of persons by age 15. The vast majority of elderly adults are

Fig. 19.40 (A and B) Erythema infectiosum.

seropositive. Infections are more common in the spring in temperate climates. Epidemics in communities occur about every 6 years. The virus is spread by the respiratory route, and infection rates are very high within households. Most infections are asymptomatic. The propensity for parvovirus B19 to affect the bone marrow is reflected by the presence of thrombocytopenia or leukopenias during the acute infection. Parvovirus DNA has been found in a wide variety of dermatologic conditions, suggesting the virus may persist in skin but not be pathogenic, casting some doubt on the true association between the virus and some dermatologic diseases. Regardless, parvovirus B19 is the prototype for the concept of "one virus, many exanthems." The patient may have multiple types of exanthems simultaneously or sequentially. Erythema infectiosum and papular-purpuric gloves-and-socks syndrome are both strongly associated with parvovirus B19 infection. Parvovirus B19 may also play a role in some cases of GCS and APEC. Parvovirus B19 has been reported to present with acute generalized exanthematous pustulosis, flagellate erythema, cellulitis-like lesions, microvesicular eruptions, reticulated and annular erythema, and more. Acral, periflexural eruptions with purpuric, annular, or reticulate lesions have been suggested as signs of parvovirus infection. Parvovirus was demonstrated in two pediatric cases of DRESS. Other known complications of this viral infection include arthropathy (especially in middle-age females), aplastic crisis in hereditary spherocytosis and sickle cell disease, and chronic anemia in immunosuppressed patients. Infection of a pregnant woman leads to transplacental infection in 30% of cases and a fetal loss rate of 5%–9%. Acute viral myocarditis and pericarditis are frequently secondary to parvovirus B19 infection.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum is a worldwide benign infectious exanthem that occurs in epidemics in the late winter and early spring. In normal hosts (but not immunosuppressed or sickle cell patients in crisis), viral shedding has stopped by the time the exanthem appears, making isolation unnecessary. The incubation period is 4–14 days (average 7 days). Infrequently, a mild prodrome of headache, runny nose, and low-grade fever may precede the rash by 1 or 2 days.

Erythema infectiosum has three phases. It begins abruptly with an asymptomatic erythema of the cheeks (Fig. 19.40A), referred to as "slapped cheek." The erythema is typically diffuse and macular, but tiny translucent papules may be present. It is most intense beneath the eyes and may extend over the cheeks in a butterfly-wing pattern. The perioral area, lids, and chin are usually unaffected. After 1–4 days, the second phase begins, consisting of discrete erythematous macules and papules on the proximal extremities and later the trunk. This evolves into a reticulate or lacy pattern (Fig. 19.40B). These two phases typically last 5–9 days. A characteristic third phase is the recurring stage. The eruption is greatly reduced or invisible, only to recur after the patient is exposed to heat (especially when bathing) or sunlight, or in response to crying or exercise. About 7% of children with erythema infectiosum have arthralgias. However, 80% of adults, especially women, have joint involvement, often with little to no rash. Necrotizing lymphadenitis may also occur in the cervical, epitrochlear, supraclavicular, and intraabdominal lymph nodes. Children with aplastic crisis caused by parvovirus B19 usually do not have a rash. However, even healthy children can develop significant bone marrow complications, although transient and self-limited.

Papular-Purpuric Gloves-and-Socks Syndrome

The papular-purpuric gloves-and-socks (or glove-and-stocking) syndrome (PPGSS), which is less common than erythema infectiosum, occurs primarily in teenagers and young adults. Pruritus, edema, and erythema of the hands and feet appear, and a fever is present. The lesions are sharply cut off at the wrists and ankles (Fig. 19.41). Over a few days, they become purpuric. There is a mild erythema of the cheeks, elbows, knees, and groin folds. Oral erosions, shallow ulcerations, aphthous ulcers on the labial mucosa, erythema of the pharynx, Koplik spots, or petechial lesions may be seen on the buccal or labial mucosa. The lips may be red and swollen. Vulvar edema and erythema accompanied by dysuria may be seen. An unusual variant is a unilateral petechial and erythematous eruption of the axilla. The acral erythema may rarely move proximally along lymphatics, simulating a lymphangitis. Transient lymphocytopenia, decreased platelet count, and elevated LFTs may be seen. PPGSS resolves within 2 weeks. Evidence of

Fig. 19.41 Purpuric glove-sock syndrome.

seroconversion for parvovirus B19 has been found in most reported patients. Histologically, a dermal infiltrate of CD30+ T lymphocytes surrounds the upper dermal vessels. There is an interface component and prominent extravasation of red blood cells in petechial lesions. Parvovirus B19 antigen has been found in the endothelial cells, sweat glands and ducts, and epidermis. Because the antigen is located in the endothelial cells, a leukocytoclastic vasculitis picture both clinically and histologically may be seen. Similarly, a Degos disease–like morphology can occur. In HIV-infected patients who develop PPGSS, the eruption is more persistent, lasting 3 weeks to 4 months, and is associated with anemia.

Not all cases of PPGSS are caused by parvovirus B19. In adults, it may be associated with HBV infection. In children, the syndrome occurs at an average age of 23 months. The eruption lasts an average of 5 weeks. Also in children, CMV and EBV are the most common documented causes in Taiwan, where PPGSS appears to be very common in the last quarter of the year.

Other Skin Findings Attributed to Parvovirus B19

In some patients, the exanthem of parvovirus B19 affects primarily the flexural areas, especially the groin. This may present as APEC (see earlier), petechiae in the groin, or an erythema studded with pustules in the groin and to a lesser degree in the axillae, resembling baboon syndrome. The petechial eruption of PPGSS may also involve the perioral area and has been called the "acropetechial syndrome." An outbreak in Kerala, India, described 50 children, mostly under age 2 years, who presented with high fever and a diffuse, intensely erythematous, tender skin eruption. The children were very irritable and cried when held. Their skin was extremely swollen, and whole-body edema was present. The acute exanthem was followed by diffuse desquamation. There were no secondary cases. IgM for parvovirus B19 was detected in 15 of 24 cases tested. The authors called this "red baby syndrome."

Infection with parvovirus B19 may trigger a hemophagocytic (or macrophage activation) syndrome. This presents with progressive cytopenias, liver dysfunction, coagulopathy, high ferritin level, and hemophagocytosis. Numerous nonspecific eruptions have been described with hemophagocytic syndrome, including nodules, ulcers, purpura, and panniculitis. The diagnostic hemophagocytic cells may occasionally be identified in skin biopsies. Infection with parvovirus B19 may lead to cutaneous necrosis in persons with a hypercoagulable state, such as paroxysmal nocturnal hemoglobinuria. The presence of edema, purpuric lesions, facial erythema, fever, cytopenias, and hypocomplementemia, even with positive antinuclear antibodies, allows for severe cases of parvovirus B19 infection to be confused with systemic lupus erythematosus. Parvovirus has been associated with the development of autoimmune diseases, potentially through molecular mimicry.

ARBOVIRUS GROUP (TOGAVIRIDAE)

The arboviruses comprise the numerous arthropod-borne RNA viruses. These viruses multiply in vertebrates, as well as in arthropods. The vertebrates usually act as reservoirs and the arthropods as vectors of the various diseases.

West Nile Fever

West Nile virus (WNV) is a flavivirus that is endemic in East Africa. It first appeared in eastern North America in 1999 and reached California by 2004. It is primarily an infection of the crow family (crows, ravens, magpies, and bluejays). It is spread by *Culex* mosquitoes, though very rarely via transfusion,

transplantation, and one report exists of possible sexual transmission. Approximately 80% of infected persons will have no symptoms. After an incubation period of 3–15 days, a febrile illness of sudden onset occurs. Headache, myalgia, arthralgia, conjunctivitis, pharyngitis, cough, adenopathy, abdominal pain, hepatitis, pancreatitis, and myocarditis are recognized clinical manifestations. The primary complications, however, are neurologic disease, including seizures (10% of symptomatic adults), ascending flaccid paralysis (as in poliomyelitis), ataxia, meningitis, encephalitis, myelitis, cranial neuropathies, optic neuritis, and reduced level of consciousness. A significant percentage of affected persons are left with permanent neurologic sequelae. About 20% of hospitalized patients will have an exanthem. The exanthema of WNV is nonpruritic and composed of 50–100 erythematous, poorly defined macules 0.5–1 cm in diameter, primarily on the trunk and proximal extremities, with papular and psoriasiform variants rarely reported. It lasts 5–7 days and resolves without scaling, and one study suggested development of the rash was associated with better prognosis.

Sandfly Fever

Sandfly fever is also known as phlebotomus fever and pappataci fever. The vector, *Phlebotomus papatasii*, is found in the Mediterranean area (Sicilian fever, Naples fever, and Toscana virus), Russia, China, and India. Sicilian and Naples sandfly fever viral infections disappeared or dramatically decreased with mosquito eradication programs, Toscana virus infection is still common. Although most infected persons are asymptomatic, 80% of aseptic meningitis cases in the summer in endemic areas are caused by this agent. Small, pruritic papules appear on the skin after the sandfly bite and persist for 5 days. After an incubation period of another 5 days, fever, headache, malaise, nausea, conjunctival injection, stiff neck, and abdominal pains suddenly develop. The skin manifestations consist of a scarlatiniform eruption on the face and neck. Recovery is slow, with recurring bouts of fever. No specific treatment is available.

Dengue

More than 100 million cases of dengue occur annually worldwide, and the global prevalence is growing. In European hospitals that evaluate patients with fever after trips to the tropics, dengue is the most common febrile illness in travelers returning from Southeast Asia who develop a fever within 1 month of the trip. It is transmitted by *Aedes* mosquitoes, which have adapted well to living around humans in urban environments. It affects primarily tropical regions where temperatures rarely drop below 20°C, favoring the reproduction of the mosquito vector. Southeast Asia and the Western Pacific are the most severely affected regions, but India, Cuba, and the tropical Americas also have numerous cases. There have been several U.S. outbreaks, in Houston, Texas, Hawaii, and Key West, Florida, and many of these cases appear *not* to have been imported, suggesting dengue is potentially endemic in these climates. Climate change has led to an expanded habitat for the *Aedes* vector, including in the southern continental United States. Persons of African ancestry seem to be at much less risk of developing dengue.

Dengue fever begins 2–15 days after the infectious mosquito bite. The clinical features are characteristic and consist of the sudden onset of high fevers accompanied by myalgias, headache, and the skin rash; patients may also have retro-orbital pain, and severe backache (breakbone fever). Common associated laboratory findings include elevated LFTs (about three times normal on average), thrombocytopenia (platelet count <100,000 in 50% of patients), and a leukopenia. These are present during the acute illness and help to suggest dengue as the correct diagnosis. About 50% of patients will develop a characteristic skin eruption. In 90% of patients, the eruption begins between days 3 and 5 of the illness, often as the fever defervesces. The skin eruption occurs in less than 10% of patients before the onset of fever. The eruption is most often generalized (50%) or involves only the extremities (30%) or the trunk (20%). Lesions are macular or morbilliform and are usually confluent, characteristically sparing small islands of normal skin—"islands of white in a sea of red" (Fig. 19.42). Persistent blanching after pressing the skin can also be seen. A "tourniquet test" involves taking the blood pressure, leaving the cuff inflated for 5 minutes, waiting 2 minutes, and counting petechiae; 10 or more per square inch is considered positive and a clue to dengue. Facial flushing may be prominent. The rash is either asymptomatic or only mildly pruritic. Petechiae may be present, but the finding of cutaneous hemorrhage should raise the suspicion of dengue hemorrhagic fever/dengue shock syndrome (DHF/DSS, severe dengue). Complete recovery occurs in 7–10 days. Biopsy of the exanthem shows minimal findings and is of no value in predicting the severity of the patient's condition or in identifying DHF/DSS/severe dengue. Helpful clues to suggest dengue from other tropical febrile illnesses in one predictive study in Honduras included petechiae, skin rash, myalgia, retro-ocular pain, positive tourniquet test, and gingival bleeding.

Fig. 19.42 Dengue fever. Linear bleeding points appeared after application of a blood pressure cuff.

There are four serotypes of dengue. After infection with one serotype, the individual is resistant to reinfection with that serotype. However, if that person becomes infected with another serotype, the individual is at risk of developing severe complications from the second episode of dengue. The patient's antidengue antibodies are incapable of preventing infection by or replication of the new dengue virus type. However, antibodies do trigger increased viral phagocytosis by mononuclear cells and amplified cytokine production. The World Health Organization (WHO) 2009 classification system divides cases into dengue without warning signs, dengue with warning signs, and severe dengue. This more objective schema is more sensitive in identifying patients with early, severe dengue. Signs of severe dengue in one systematic review included hepatomegaly, lethargy, abdominal pain, bleeding, and complete blood count abnormalities. The potentially fatal syndromes that can occur in dengue infection are characterized by hemorrhage (dengue hemorrhagic fever/DHF), at times with extensive plasma leakage (dengue shock syndrome/DSS/severe dengue). The fatality rate for severe dengue may be as high as 40%. The diagnosis of dengue is made by detection of dengue-specific IgM in the sera by ELISA, with acute and convalescent serologies demonstrating seroconversion. Some laboratories can detect viral RNA in acute serum samples. An effective vaccine has not been developed; the only preventive strategy for travelers is to avoid mosquito bites. In children, dengue fever and Kawasaki disease have occurred simultaneously. These two syndromes may be almost identical in

their presentation, so this differential diagnosis can be extremely difficult. When both diagnoses have been made simultaneously, the patient had persistent fever (>1 week), a reactive thrombocytosis after the initial thrombocytopenia, and in some cases, characteristic cardiac lesions.

Alphavirus

Sindbis Virus

In Finland, Sindbis virus infection is transmitted by the *Culiseta* mosquito. An eruption of multiple, erythematous, 2–4 mm papules with a surrounding halo is associated with fever and prominent arthralgias. The eruption and symptoms resolve over a few weeks. Histologically, the skin lesions show a perivascular lymphocytic infiltrate with large, atypical cells, simulating lymphomatoid papulosis. CD30 does not stain the large cells, however, allowing their distinction.

Chikungunya Virus

Chikungunya virus is transmitted by the *Aedes* mosquito. Derived from the Makonde language of sub-Saharan Africa, *chikungunya* means "that which bends up," describing the characteristic stooped posture resulting from the joint symptoms of the disease. It is endemic in Africa, India, Sri Lanka, Southeast Asia, the Philippines, Hong Kong, the islands of the Indian Ocean, and the Caribbean region. The first U.S. cases of chikungunya infection were reported during summer 2014 in southern Florida. More continental U.S. cases have occurred in humid, Southern states, as the climate for the vector expands due to climate change. The incubation period is 2–7 days. The patient presents with abrupt onset of high fever. Significant joint symptoms are characteristic and occur in 40% of infected patients. Most often, there is swelling and pain in the small joints of the hands and feet. The joint symptoms may persist for weeks to months, with about 50% of patients still having some symptoms at 6 months. Patients may develop neuropathic acral findings, including Raynaud phenomenon, erythromelalgia, or severe acral coldness, as late sequelae. Headache occurs in 70% of patients and nausea and vomiting in 60%. Lymphopenia, thrombocytopenia, and elevated LFTs can be observed in the first week of the illness. Although generally a nonfatal and self-limited illness, severe complications can occur with chikungunya infection, causing death in about 1 in 1000 infected patients.

About half to three quarters or more of patients with chikungunya virus infection develop a rash. It is pruritic in 20%–50% of the patients. The most common and characteristic exanthem is described as morbilliform and most frequently affects the arms, upper trunk, and face. It can be confluent, and islands of sparing can be seen. It appears by the second day of the fever in more than half of patients, and in another 20% on the third or fourth day; only about one fifth of patients develop the eruption after the fifth day of the illness. Ecchymoses may appear during the acute illness. Aphthous-like ulcerations can occur in the oral, penoscrotal, and less often the axillary regions. These may be preceded by intense erythema and pain in the affected area. After acute chikungunya infection, striking hyperpigmentation of the skin may occur, including postinflammatory hyperpigmentation, freckling, streaks, and broad areas of hyperpigmentation.

A bullous eruption may occur in acute chikungunya virus infection. About 90% of those with a bullous eruption are under 1 year of age, and most of the severe cases occur before age 6 months. In children, 17% develop a vesiculobullous component to their eruption, compared with only 3% of adults. There is an initial exanthem, followed in hours or days by flaccid or tense nonhemorrhagic blisters that rupture easily. Nikolsky sign is positive. The genitalia, palms, and soles are spared. There is a close resemblance to toxic epidermal necrolysis, and up to 80% of the total body surface area may become denuded. High titers of virus are recovered from blister fluid (in excess of that present in blood). Biopsy demonstrates an intraepidermal blister with acantholytic cells floating free in the blister cavity. These patients are managed similar to burn patients, and most recover. Skin grafting usually is not required.

The diagnosis of chikungunya virus infection is made by detecting virus-specific IgM in the serum. Confirmation is by seroconversion over the next several months, with development of virus-specific IgG. PCR-based methods may detect viral genome in the blisters or serum during the acute illness.

It may be difficult to differentiate dengue from chikungunya fever, because both are endemic in the same geographic regions, and their clinical symptoms and laboratory findings are similar. Arthralgias occur in a significant percentage of patients with chikungunya virus infection, approaching 100% in those with a rash, but also occur in patients with dengue. Neutropenia is seen in 80% of dengue patients and only 10% of chikungunya patients. A positive tourniquet test does not distinguish these two infections, but thrombocytopenia is more common in dengue (85% or greater) than chikungunya (35%) patients.

Zika Virus

In late 2015 to early 2016 the emergency of Zika virus was recognized as a dangerous pathogen with the potential for devastating consequences during fetal infection. Zika's primary vector is the *A. aegypti* mosquito, though the *Aedes albopictus* may transmit the virus as well; these are found in 30–41 U.S. states. Most cases occur in tropical regions of Central and South America, such as Brazil. Travel associated cases account for the majority of cases in the continental United States, but isolated outbreaks of locally acquired Zika have been reported, and Puerto Rico experienced rapid, extensive spread of the virus. Twenty-five percent of Puerto Rican individuals, including 6000–10,000 pregnant women, were suspected of Zika infection in 2016. Rapid mosquito control efforts, including avoiding standing water, application of insecticides and larvicides, and widespread use of repellant, helped contain the Miami outbreak but are not always as successful in endemic areas. Sexual transmission may occur, and the virus may persist in semen for many months after infection.

Zika infection was rapidly recognized for its potential for serious birth defects, including microcephaly and brain damage. In adults, neurologic diseases such as Guillain-Barré can complicate infection, and severe thrombocytopenia has been reported. The long-term consequences of birth defects and brain damage to babies born with Zika-related birth defects is anticipated to be devastating, with over 1700 cases of microcephaly reported in Northeastern Brazil alone. Pregnant women should avoid travel to areas with Zika, and long-sleeved shirts and insect repellents with DEET are advised. As Zika can persist in semen for months, condom use is recommended for men who have been in Zika-affected areas.

Clinically, patients with Zika infection present with fever, rash, joint pain, and often a conjunctivitis. Hyperemic sclerae appears to be a helpful clue; petechiae on the palate, or elsewhere, occasionally with gingival bleeding, and a diffuse papular eruption, descending in a cranial-caudal fashion, have been described. One model suggests that rash with pruritus or conjunctival hyperemia, without any other signs such as fever, petechiae, or anorexia, may be the best clinical clue to differentiate Zika from other arboviruses.

PAPOVAVIRUS GROUP

Papovaviruses are naked dsDNA viruses characterized as slow growing. They replicate inside the nucleus. Because papovaviruses contain no envelope, they are resistant to drying, freezing, and solvents. In addition to the human papillomaviruses, which cause warts, papillomaviruses of rabbits and cattle, polyomaviruses of mice, and vacuolating viruses of monkeys are some of the other viruses in the papovavirus group.

Warts (Verruca)

There are more than 150 types of human papillomavirus (HPV). The genome of HPV consists of early genes (*E1*, *E2*, *E4*, *E5*, *E6*, and *E7*), two late genes (*L1* and *L2*), and in between an upstream regulatory region (URR). *L1* and *L2* code for the major and minor capsid proteins. *L1* encodes for the major capsid protein and self-assembles into virus-like particles (VLPs). These VLPs are the antigens in currently available HPV vaccines. The *L2* gene encodes the minor capsid protein and has at least two important functions. L2 protein helps expose the keratinocyte-binding determinant of the L1 protein, allowing for the HPV to bind onto the basal keratinocyte and to be taken into the cell. The processing of HPV surface proteins in the skin takes up to 24 hours, allowing for exposure to anti-HPV antibodies. The L2 protein also is immunomodulatory, downregulating the function of Langerhans cells through the phosphoinositide 3-kinase pathway. A new HPV type is defined when there is less than 90% DNA homology with any other known type in the *L1* and *E6* genes. Viruses with 90%–98% homology are classified as subtypes. The gene sequences from HPVs throughout the world are similar. Most HPV types cause specific types of warts and favor certain anatomic locations, such as plantar warts, common warts, and genital warts. HPVs 1, 2, 27, and 57 cause the vast majority of cutaneous (nongenital) warts. HPV-1 is associated with plantar warts in children younger than 12 years. HPV-2 is more common in hand warts. HPV-27 and HPV-57 are associated with common and plantar warts in adults (>21 years). External genital warts are caused by HPV-6/11 and anogenital dysplasia by HPV-16/18. A large proportion of the HPV types rarely cause warts and appear to be pathogenic only in immunosuppressed patients or those with epidermodysplasia verruciformis. However, many persons may carry, or may be latently infected with, these rare wart types, explaining the uniformity of gene sequence and clinical presentation worldwide. In the immunosuppressed patient, HPV types may cause warty lesions of a different clinical morphology than in an immunocompetent host.

Infection with HPV may be clinical, subclinical, or latent. Clinical lesions are visible by gross inspection. Subclinical lesions may be seen only by aided examination (e.g., acetic acid soaking). Latent infection describes the presence of HPV or viral genome in apparently normal skin. Latent infection is thought to be common, especially in genital warts, and explains in part the failure of destructive methods to eradicate warts.

Infection with HPV is extremely common; most people will experience infection during their lifetime. In Australia 22% and in The Netherlands 33% of schoolchildren were found to have nongenital cutaneous warts. Common warts are found in about 10%–15% of children, plantar warts in 6%–20% (higher in The Netherlands than Australia), and flat warts are only reported in schoolchildren from Australia (2%). White persons have visible cutaneous warts twice as frequently as other ethnicities. Genital warts begin to appear with sexual activity, with 10% of women acquiring HPV infection before they have intercourse, suggesting oral/digital/genital-to-genital contact is capable of transmitting HPV. HPV infection rates, including latent infection, exceed 50% in sexually active populations in many parts of the world.

Human papillomaviruses have coexisted with humans for many millennia, and humans are their primary host and reservoir. HPVs have been successful pathogens of human because they evade the human immune response. This is achieved primarily through avoiding the expression of antigens on the surface of keratinocytes until the keratinocytes are above the level of the antigen-presenting cells in the epidermis. HPVs also reduce Langerhans cells in the vicinity of infection and inactivate them through the L2 protein on their surface. Through *E6* and *E7*, HPV reduces local production of key immune reactants (e.g., TLR9, IL-8), muting the local immune response. HPVs thus live in equilibrium with their human hosts through a combination of immune evasion and programmed immune suppression (tolerance).

Management of warts is based on their clinical appearance and location and the patient's immune status. In general, warts of all types are more common and more difficult to treat in persons with suppressed immune systems (Fig. 19.43). Except in WHIM syndrome (warts, hypogammaglobulinemia, infection, and myelokathexis: gain-of-function mutation of *CXCR4*), syndromes of reduced immunoglobulin production or B-cell function are not associated with increased HPV infection. Medical conditions or treatments associated with suppression of cell-mediated immunity are associated with high rates of clinical HPV infection and HPV-induced neoplasias. The common clinical scenarios are iatrogenic medications (e.g., in organ transplant recipients), viral infections that result in T-cell deficiency (e.g., HIV), and congenital syndromes of T-cell immunodeficiency. Patients with GATA2 deficiency frequently present with extensive warts. WILD syndrome is the association of primary lymphedema, disseminated warts, and anogenital dysplasia with depressed cell-mediated immunity and probably represents

Fig. 19.43 Extensive warts as seen in immunodeficiencies such as WHIM and DOCK8.

Fig. 19.44 Warts.

GATA2 deficiency. Idiopathic CD4 lymphopenia and autosomal recessive hyper-IgE syndrome caused by DOCK8 deficiency are two other T-cell immunodeficiency states associated with HPV infection. Because warts in some anatomic regions are important cofactors in cancer, histologic evaluation of warty lesions in the immunodeficient patient can be critically important.

Verruca Vulgaris

Common warts are a significant cause of concern and frustration for patients and parents (Fig. 19.44). Social activities can be affected, lesions can be uncomfortable or bleed, and treatment is often painful and frustratingly ineffective. Human papillomavirus types 1, 2, 4, 27, 57, and 63 cause common warts. Common warts occur most commonly between ages 5 and 20, and only 15% occur after age 35. Frequent immersion of hands in water is a risk factor for common warts. Warts often spread from infected close contacts. Public exposures such as swimming pools, public showers, and going barefoot are associated to a lesser degree. Meat handlers (butchers), fish handlers, and other abattoir workers have a high incidence of common warts of the hands. Warts in butchers are caused by HPV-2 and HPV-4; up to 27% of hand warts from butchers are caused by HPV-7, which is found only on the hands where there is direct contact with meat but interestingly not on the slaughtered animals. HPV-7 is rarely found in warts in the general population (<0.3%), although there is a recent report showing HPV-7 in warts in toe web spaces. HPV-57 has been reported to cause dystrophy of all 10 fingernails, with marked subungual hyperkeratosis and destruction of the nail plate without periungual involvement. Clinicians usually do not determine the subtype of HPV when treating warts, but there are certain types of high-risk HPV types, such as 16 and 18, that have a higher risk of SCC.

The natural history of common warts is for spontaneous resolution. Reported clearance rates in children are 23% at 2 months, 30% at 3 months, 50% at 1 year, 65%–78% at 2 years, and 90% over 5 years. Common warts are usually located on the hands, favoring the fingers and palms. Periungual warts are more common in nail biters and may be confluent, involving the proximal and lateral nailfolds. Other sources of maceration can worsen warts including wearing sports gloves and overwashing. Fissuring may lead to bleeding and tenderness. Lesions range in size from pinpoint to more than 1 cm, most averaging about 5 mm. They grow in size for weeks to months and usually present as elevated, rounded papules with a rough, grayish surface, which is so characteristic that it has given us the word "verrucous," used to describe lesions with similar surface character (e.g., seborrheic keratosis). In some cases, a single wart (mother wart) appears and grows slowly for a long time, and then suddenly many new warts erupt. On the surface of the wart, tiny black dots may be visible, representing thrombosed, dilated capillaries. This clinical sign is very useful to differentiate from corns, callus, or other unusual cutaneous growths such as epitheliod sarcoma. Trimming the surface keratin makes the capillaries more prominent and may be used to aid diagnosis. The dermatoglyphics (fingerprint/toeprint folds) will stop at the base of a wart, in contrast to calluses, in which these lines are accentuated.

Common warts may occur anywhere on the skin including the lip margin and face, spreading from the hands by autoinoculation. In nail biters, warts may be seen on the lips and tongue, usually in the middle half or the oral commissures. Digitate or filiform warts tend to occur on the face and scalp and present as single or multiple projection with multiple small spikes at the tip on close inspection.

Pigmented Warts

Pigmented warts have frequently been reported in Japan although likely occurs in any patient with types III to VI skin. They appear on the hands or feet and resemble common warts or plantar warts, except for their hyperpigmentation. They are caused by HPV-4, HPV-60, and HPV-65. The pigmentation is caused by melanocytes in the basal cell layer of the HPV-infected tissue that contain large amounts of melanin. This is proposed to be caused by "melanocyte blockade," or the inability of the melanocytes to transfer melanin to the HPV-infected cells.

Flat Warts (Verruca Plana)

Human papillomavirus types 3, 10, 28, and 41 most often cause flat warts. Children and young adults are primarily affected. Sun

Fig. 19.45 Flat warts.

exposure appears to be a risk factor for acquiring flat warts. Flat warts present most often as 2–4 mm, flat-topped papules that are slightly erythematous or brown on pale skin and hyperpigmented on darker skin. They occur more commonly on the sun-exposed surfaces likely due to immunosuppression. The face and extremities are most common, especially the forehead, cheeks, nose, and particularly the area around the mouth and the backs of the hands, but the lesions can occur anywhere, including the neck, dorsa of the hands, wrists, elbows, or knees. They are generally multiple and are grouped or in lines induced by koebnerization forming linear, slightly raised, papular lesions (Fig. 19.45). They are more common in swimmers. People with autism spectrum disorders or obsessive compulsive disorders who wash excessively and have dorsal had dermatitis can get exuberant flat warts. In shaved skin, numerous flat warts may develop as a result of autoinoculation. Hyperpigmented lesions occur, and when scarcely elevated, may be confused with lentigines or ephelides. Plaquelike lesions may be confused with verrucous epidermal nevus, lichen planus, lichen striatus, angiofibromas in tuberous sclerosis, and molluscum contagiosum. When lesions occur only on the central face and are erythematous, they can be easily confused with papular acne vulgaris. Of all clinical HPV infections, flat warts have the highest rate of spontaneous remission and are the most challenging to treat because they are so flat to the skin. Topical retinoids are often the treatment of choice because they can be used on the face.

Plantar Warts (Verruca Plantaris)

Human papillomaviruses 1, 2, 27, and 57 cause plantar warts. These warts generally appear at pressure points on the ball of the foot, especially over the midmetatarsal area, but may be anywhere on the sole. Frequently, several lesions develop on one foot (Fig. 19.46). Sometimes they are grouped, or several contiguous warts fuse so that they appear as one "mosaic" wart. The soft, pulpy cores are surrounded by a firm, horny ring. Plantar warts may be confused with corns or calluses but warts have a soft, central core and black or bleeding points from the superficial capillaries when pared down, features that calluses lack.

The myrmecia type of verruca occurs as smooth-surfaced, deep, often inflamed and tender papules or plaques, mostly on the palms or soles, but also beside or beneath the nails, or less often on the pulp of the digits (Fig. 19.47). They are distinctively dome shaped and much bulkier beneath the surface than they appear. Myrmecia are caused by HPV-1. They can be mistaken for a paronychia or digital mucinous cyst.

HPV-60 causes a peculiar type of plantar wart called a ridged wart because of the persistence of the dermatoglyphics across the surface of the lesion. Typically, the warts are slightly elevated, skin-colored, 3–5 mm papules. They occur on non–weight-bearing areas and lack the typical features of plantar warts. HPV-60 also causes plantar verrucous cysts, 1.5–2 cm, epithelium-lined cysts on the plantar surface. These cysts tend to occur on weight-bearing areas, suggesting that HPV-infected epidermis is implanted into the dermis, forming the cyst. It is common to see ridged warts near plantar verrucous cysts.

Fig. 19.46 Plantar warts.

Fig. 19.47 Myrmecia.

Histologic Features

Typical nongenital warts rarely require histologic confirmation, although a biopsy may be useful in several settings. Histology can be used to distinguish a wart from a corn and, more important, epithelioid sarcoma that can present as a papule or nodule on the palm or sole. Cytologic atypia and extension into the dermis suggest the diagnosis of an HPV-induced SCC. There is a correlation between HPV type and the histologic features of the wart, allowing identification of the HPV types that cause specific lesions, a useful feature in the diagnosis of epidermodysplasia verruciformis, for example.

Treatment of Common and Plantar Warts

The quality of evidence regarding the efficacy of therapies for warts is low. Studies have not used standard treatment protocols, and until recently, HPV type has not been evaluated along with treatment response. This hinders the development of evidence-based guidelines. The form of therapy used depends on patient preference, the type of wart being treated, the patient's age and immune status, and previous therapies used and their success or failure. With any treatment modality, at least 3 months of sustained management is considered a reasonable therapeutic trial. With immunologic treatments, this may be insufficient to see a response. No treatment should be abandoned too quickly or prolonged too long if not effective. Because many nongenital warts will spontaneously regress, the treatment algorithm should allow for nonaggressive options, and the patient should be offered the option of no treatment. Indications for treatment are pain, interference with function, social embarrassment, and risk of malignancy. The ideal aims of therapy are as follows:

1. Wart resolution
2. Avoidance of scarring or permanent sequelae from the treatment
3. Ideally, to induce lifelong immunity to that HPV type

Because the therapeutic options are similar for common and plantar, the therapies are considered together. In general, plantar warts are more refractory to any form of treatment than are common warts. The exception is HPV-1–induced plantar warts in children under 12 years, which have a high response rate (>50%).

Therapeutic Options

Destructive/Occlusive Therapy. Destructive methods are most often used as initial therapy by most practitioners for all types of warts with the exception of flat warts. Cryotherapy is a reasonable first-line treatment. In plantar warts, no trial has demonstrated cryotherapy to be superior to placebo in treating plantar warts. The cure rate is 20%–50% with repeated applications over several months. The wart should be frozen adequately to produce a blister after 1 or 2 days. This correlates with a thaw time of 30–45 seconds for most common warts. A sustained 10-second freeze with a spray gun was found to be more effective than simply freezing to obtain a 2–3 mm halo around the wart. Liquid nitrogen freezes to a lower temperature than other agents used for cryotherapy and is thus preferred. Aggressive cryotherapy can produce significant blistering and may be complicated by significant postprocedural pain for several days. A single freeze-thaw cycle was found may be as effective as two cycles. The ideal frequency of treatment is every 2 or 3 weeks, just as the old blister peels off to avoid regrowth in between treatments. No device used to apply liquid nitrogen should be allowed to touch multiple patients due to risk of spread. Children may be frightened by a spray device, so a cotton-tipped swab is an option for them. Cryotherapy can be effective for periungual warts. Damage to the matrix is unusual or rare, because periungual warts usually affect the lateral nailfolds, not the proximal one. Complications of cryotherapy include hypopigmentation, depigmentation, scarring (infrequent), and, rarely, damage to the digital nerve from freezing too deeply on the side of the digit. Patients with Fanconi anemia, cryoglobulinemia, poor peripheral circulation, and Raynaud phenomenon may develop severe blisters when cryotherapy is used to treat their warts. Doughnut warts, with central clearing and an annular recurrence, may complicate cryotherapy or more typically cantharone (see later discussion).

Topical salicylic acid in concentrations ranging from 10%–26% over the counter is an effective patient-applied treatment. Results have been conflicting, with some studies showing equal efficacy with cryotherapy and others showing marked inferiority to cryotherapy. To optimize salicylic acid treatment, the following treatment approach is suggested. After the wart-affected area is soaked in water for 5–10 minutes, the topical medication is applied, allowed to dry, and covered with a strip bandage for 24 hours. This is repeated daily. The superficial keratinous debris may be removed by scraping with a table knife, pumice stone, or emery board (each of which should be washed or discarded between therapies).

Silver nitrate has been used in limited studies with cure rates higher than placebo but caution is advised due to risk of silver impregnation into the skin.

The initial enthusiasm for occlusive therapy with tape (e.g., duct tape) has not been substantiated by follow-up studies. Occlusive therapy is inferior to cryotherapy, and success rates in adults are about the same as with placebo. If occlusive therapy is contemplated, a relatively impermeable tape should be used and the wart kept occluded at least $6\frac{1}{2}$ and up to 7 days of the week. Fenestrated and semipermeable dressings have not been studied and may not be effective. Occlusive therapy is a good initial option for young children (<12 years) with plantar warts, in whom spontaneous resolution is high, and for others unwilling to have alternate forms of treatment. Unfortunately, in adults, the efficacy of duct tape for common warts is very low. Two months of treatment resolved common warts in only 20% of patients, and 75% of "resolved" warts recurred.

Cantharone (0.7% cantharidin) is applied to the wart, allowed to dry, and covered with occlusive tape for 24 hours or until the patient experiences burning. A blister, similar to that produced by cryotherapy, develops in 24–72 hours. These blisters may be as painful as or more painful than those following cryotherapy. Treatment is repeated every 2–3 weeks. Perhaps more than any other method, cantharidin tends to produce doughnut warts, a round wart with a central clear zone at the site of the original wart, and due to inconsistent efficacy, many do not use this modality first line. Cantharadin has the advantage that it can be applied painlessly to children.

Surgical ablation of warts can be effective treatment, but even complete destruction of a wart and the surrounding skin does not guarantee that the wart will not recur. Surgical methods should be reserved for warts that are refractory to more conservative approaches. Pulsed dye laser therapy initially appeared to have similar efficacy to cryotherapy, but low fluences were used. In recent reports, therapies with high efficacy for refractory warts (70%–90%) used fluences of 12.5–15 J/cm^2 (average 14 J/cm^2 in one study). Local anesthesia is required in the majority of patients. A short pulse duration (1.5 ms) is most effective. A 7-mm spot size is used, and treatment is extended 2 mm beyond the visible wart. The cryospray is inactivated because epidermal destruction is the goal. Immediately after treatment, the skin has a gray-black discoloration from thermal damage. The treated area becomes an eschar over 10–14 days. Treatment is repeated every 2–4 weeks, as soon as the eschar falls off, and multiple treatments may be required. In immunocompetent patients, response rates for refractory common and plantar warts are 70%–90% with this approach. The pulsed dye laser can also be used to treat warts around the nail that may have extended below the nail plate, because the laser will penetrate the nail plate. Carbon dioxide (CO_2) laser destruction requires local anesthesia, causes scarring, and may lead to nail dystrophy. Efficacy is 56%–81% in refractory warts. A potentially infectious plume is produced with the CO_2 laser. Frequency-doubled neodymium:yttrium-aluminum-garnet (Nd:YAG) laser, 532-nm potassium titanyl phosphate (KTP) laser, and PDT are options in refractory cases.

Heat treatment, either localized to the wart and delivered by radiofrequency or applied to the affected part by soaking it in a hot bath, has been reported to be effective. Treatment for 15 minutes at 43°C–50°C (107.6°F–122°F) to as short as 30 seconds at higher temperatures has been used. Extreme caution must be exercised to avoid scalding.

Immunologic Therapy. Immunotherapy with topical and intralesional agents has become a mainstay of wart therapy. The goal is not only that the wart will be eradicated, but that the immune reaction induced in the wart may also lead to widespread and permanent immunity against warts.

Oral cimetidine, 25–40 mg/kg/day, has been anecdotally reported to lead to resolution of common warts, perhaps because of its immunomodulatory effects. When used as a single agent, however, in both children and adults, the efficacy is low (30%), comparable with placebo. Cimetidine may be beneficial as an adjunct to other methods, especially for patients using immunotherapy without a brisk response to the antigen. Side effects appear to be limited.

Oral zinc seems to have benefit in patients who are zinc deficient, but efficacy was not shown in a randomized controlled trial, and therapy is limited by GI upset.

The topical agents typically used are topical DNCB, squaric acid dibutyl ester, and diphencyprone.

For the topical immunogens, patients may be initially sensitized at a distant site (usually the inner upper arm) with the topical agents, or the agents may be applied initially to the warts directly. Two treatment approaches are used, and their efficacies have not been compared. Some practitioners apply topical agents in the office in higher concentrations (2%–5%), but only about every 2 weeks. Others give their patients take-home prescriptions to use up to daily, although initially at lower concentrations (0.2%–0.5%). In most cases, the agents are dissolved in acetone. The treated wart should be kept covered for 24 hours after application. If the reaction is overly severe, the strength of the application may be reduced. Wart tenderness may indicate the need to reduce treatment concentration. Warts may begin to resolve within 1 or 2 weeks, but on average, 2–3 months or more of treatment is required. Overall cure rates for all three topical sensitizers and for intralesional antigen injection is 60%–80%. Side effects of treatment include local pruritus, local pain, and mild eczematous dermatitis. Most patients have no limitation of activities or function with topical immunotherapy.

The efficacy of imiquimod for common warts appears to be significantly less than with cryotherapy or topical immunotherapy and is considerably more expensive. The routine use of imiquimod in the treatment of common or plantar warts cannot be recommended. Unpublished placebo-controlled trials demonstrated no better response than placebo, with cure rates of about 10%.

Intralesional *Candida* antigen has become widely used with significant success rates. Injection of 0.1 mL to one to three lesions is repeated every 3–4 weeks with most benefit seen after multiple treatments. Some report up to 80% cure rate. Intralesional *Candida* injections may be associated with cytokine-mediated side effects, such as swelling, fever, shaking chills, and a flulike feeling. These begin 6–8 hours after treatment and resolve over 24–48 hours. Patients should be advised of these possible side effects. In a population previously immunized with bacille Calmette-Guérin (BCG), BCG antigen may be used.

Antiproliferative Therapy. Bleomycin has high efficacy but is reserved for recalcitrant common warts in adults. It is used at a concentration of 1 U/mL, which is injected into and immediately beneath the wart until it blanches. The multipuncture technique of Shelley—delivering the medication into the wart by multiple punctures with a needle through a drop of bleomycin—may also be used, as may an air jet injector. Even a concentration of 0.1 U/mL injected by this method can be effective. For small warts (<5 mm), 0.1 mL is used, and for larger warts, 0.2 mL. Combination use of bleomycin injections or *Candida* antigen injections with pulse dye laser may be useful in particularly refractory periungual and plantar warts. The injection of bleomycin is painful enough to require local anesthesia in some patients. Pain can occur for up to 1 week. The wart becomes black, and the black eschar separates in 2–4 weeks. Treatment may be repeated every 3 weeks, but it is unusual for common warts to require more than one or two treatments. Scarring is rare. Response rates vary by location, but average 90% with two treatments for most common, nonplantar warts, even periungual ones. Treatment of finger warts with bleomycin infrequently may be complicated by localized Raynaud phenomenon of treated fingers. Bleomycin treatment of digital warts may rarely result in digital necrosis and permanent nail dystrophy, so extreme caution should be used in treating warts around the nailfolds. Lymphangitis/cellulitis is a rare complication. In a patient receiving a total of 14 U for plantar warts, flagellate urticaria followed by characteristic bleomycin flagellate hyperpigmentation occurred.

Intralesional 5-FU and topical 5-FU have been used with variable results. Trials in which 5-FU cream was applied after cryotherapy demonstrated no additional benefit over the cryotherapy alone. Topical 5-FU is sometimes combined with salicylic acid, especially in plantar warts, with high cure rates.

Oral administration of acitretin or isotretinoin may also be used in refractory cases.

The value of quadrivalent HPV vaccination for the treatment of common warts is unknown. One study reported resolution of common and plantar warts in four young persons (three under 12 years) after HPV immunization.

Direct Antiviral Therapy. Topical cidofovir has been used in difficult situations and in immunosuppressed patients. It is compounded in a 1%–3% concentration (rarely up to 5%) and applied directly to the wart once or twice daily. The method of compounding is critical to the efficacy of topical cidofovir, so a reliable source known to compound an active gel is important. It is extremely expensive, however, and local irritation and erosion may occur. Cidofovir may also be delivered intralesionally in up to 5% concentration.

Flat Warts. Flat warts frequently undergo spontaneous remission, so therapy should be as mild as possible, and potentially scarring therapies should be avoided. If lesions are few, light cryotherapy is a reasonable consideration, although in patients with types III to VI skin, caution is advised, especially on the face due to risk of dyspigmentation. Topical salicylic acid products can also be used but not typically on the face. Treatment with topical retinoid once or twice daily, in the highest concentration tolerated (tazarotene may be most effective) to produce mild erythema of the warts without frank dermatitis, can be effective over several months. Imiquimod 5% cream used up to once daily can be effective. If the warts fail to react initially to the imiquimod, tretinoin may be used in conjunction. Should this fail, 5-FU cream 5%, applied twice daily, may be effective but in children, parents should be alerted that this is a topical chemotherapy. Anthralin, although staining, could be similarly used for its irritant effect. For refractory lesions, laser therapy in very low fluences or photodynamic therapy (PDT) might be considered before electrodesiccation because of the reduced risk of scarring. Ranitidine, 300 mg twice daily, cleared 56% of refractory flat warts in one study, with similar results using cimetidine (25–40 mg/kg). Three months of oral isotretinoin therapy at 30 mg/day was highly successful and might be considered when the previous topical approaches have failed. Immunotherapy with dinitrochlorobenzene (DNCB), squaric acid, or diphencyprone, or intralesional *Candida* or other antigens, can be used on limited areas of flat warts, with the hope that the immune response will clear distant warts. Peels have shown some benefit including those with glycolic acid and trichloracetic acid.

Genital Warts (External Genital Warts). Genital warts are the most common STD. Among sexually active young adults in the United States and Europe, infection rates as high as 50% in some cohorts have been found using sensitive PCR techniques. It is estimated that the lifetime risk for infection in sexually active young adults may be as high as 80%. The number of new U.S.

cases of genital wart infection diagnosed yearly may approach 1 million. In the about two thirds of couples in whom one has evidence of HPV infection, the partner will be found to be concordantly infected. A large portion of genital HPV infection is either subclinical or latent. Unfortunately, the infectivity of subclinical and latent infection is unknown. Subclinical and latent infection is probably responsible for most "recurrences" after treatment of genital warts. Because the methodology for determining HPV infection in men is less accurate, and women have the major complication of HPV infection, cervical cancer, virtually all data on HPV infection rates and epidemiology are derived from studies of women.

Genital HPV infection is closely linked to cancer of the cervix, glans penis, anus, vulvovaginal area, and periungual skin. Cancer occurs when there is integration of the HPV genome into the host DNA. In high-risk genital HPV types, *E6* and *E7* gene products bind to and inactivate p53 and retinoblastoma protein (pRb), respectively. This is thought to be important in their ability to cause cancer. In most persons, genital HPV infection appears to be transient, lasting about 1–2 years, and results in no sequelae. In a small proportion, about 2% of immunocompetent persons, infection persists, and in a small proportion of those with persistent HPV infection, cancer may develop (Fig. 19.48). Certain cofactors, such as the HPV type causing the infection, location of infection, cigarette smoking, uncircumcised status, and immunosuppressed status, are associated with progression to cancer. The transition zones of the cervix and anus are at highest risk for the development of cancer.

More than 30 HPV types are associated with genital warts. Patients are typically infected with multiple HPV types, although one HPV type probably causes most of the clinical lesions. Many HPV types are found in studies where the surface is sampled, but deeper in the epithelium, one type of HPV predominates, making studies that use surface sampling difficult to interpret. The HPV types producing genital infection are divided into two broad categories: those that produce benign lesions, or low-risk types, and those associated with cancer, the so-called high-risk or oncogenic types. The most common low-risk genital HPV types are HPV-6 and HPV-11, and most HPV-induced genital dysplasias are caused by HPV-16 and HPV-18. A strong correlation exists between the HPV type and the clinical appearance of HPV-induced genital lesions. Virtually all condylomata acuminata are caused by "benign" HPV-6 and HPV-11. High-risk HPV-16/18 produce flat or sessile, often hyperpigmented lesions. For this reason, biopsy and HPV typing of typical condyloma is rarely necessary. Since the advent of HPV vaccination targeting the high-risk HPV strains, the rates of HPV 6/11/16/18, as well as cervical and anogenital dysplasia, have fallen dramatically.

Genital HPV infection is strongly associated with sexual exposure. Female virgins rarely harbor HPV (about 1%). For women, insertive vaginal intercourse is strongly associated with acquiring genital HPV infection, with 50% of women testing positive for genital HPV within 5 years of the first sexual intercourse. However, sexual contact does not need to be penile-vaginal; the risk of acquiring genital HPV infection was 10% in women who had nonpenetrative sexual exposure versus 1% of women who had no such exposure. This suggests oral/digital/genital-genital exposure can transmit HPV infection to the introital skin. This infection may then be spread to other sites by self-inoculation. For this reason, women who have sex with women may have genital HPV infection and still require regular gynecologic evaluation. Condom is not fully protective for acquisition of genital HPV infection. In men, risk of genital HPV infection is associated with being uncircumcised, having had sex before age 17, having had more than six sexual partners in their lifetime, and having had sex with professional sex workers. Smokers are at increased risk of developing genital warts.

Condylomata Acuminata. Condylomata on the skin surface appear as lobulated papules that average 2–5 mm in size, but they may range from microscopic to many centimeters in diameter and height. Lesions are frequently multifocal. Numerous genital warts may appear during pregnancy. Condylomata acuminata occur in men anywhere on the penis (Fig. 19.49) or about the anus. Scrotal condylomata occur in only 1% of immunocompetent male patients with warts. Intraurethral condylomata may present with terminal hematuria, altered urinary stream, or urethral bleeding. In women, lesions appear on the mucosal surfaces of the vulva or cervix, on the perineum, or about the anus (Fig. 19.50). Cauliflower-like masses may develop in moist, occluded areas such as the perianal skin, vulva, and inguinal folds. As a result of accumulation of purulent material in the clefts, these may be malodorous. Their color is generally gray, pale yellow, or pink. When perianal lesions

Fig. 19.48 Squamous cell carcinoma in persistent HPV infection.

Fig. 19.51 Bowenoid papulosis. (Courtesy Steven Binnick, MD.)

occur, a prior history of receptive anal intercourse will usually predict whether intraanal warts are present and will help to determine the need for anoscopy. Immunosuppressed individuals and those with infection by known high-risk HPV types at other sites should have routine anal Papanicolaou (Pap) smears to detect malignant change.

Genital warts are sexually transmitted, and other STDs may be found in patients with genital warts. A complete history should be taken and the patient screened for other STDs as appropriate. The whole genital area should be carefully examined because external genital wart (EGW) infection is often multifocal. HIV testing is recommended. Women with EGWs should have a routine cervical cytologic screening to detect cervical dysplasia.

Bowenoid Papulosis and HPV-Induced Genital Dysplasias. Bowenoid papulosis is characterized by flat, often hyperpigmented papules a few millimeters to several centimeters in diameter. These occur singly or, more often, may be found in multiples on the penis, near the vulva, or perianally (Fig. 19.51). At times, similar lesions are seen outside the genital area in the absence of

Fig. 19.52 Buschke-Lowenstein tumor. (Courtesy Shyam Verma, MBBS, DVD.)

genital bowenoid papulosis. They occur most frequently on the neck or face and are more common in men. They contain HPV-16, HPV-18, or other high-risk HPV types. In the standard terminology for lower anogenital squamous lesions, this is called HSIL (high-grade squamous intraepithelial lesion). It is usually caused by HPV-16. On the glabrous external genitalia, bowenoid papulosis usually behaves similar to other EGWs but may progress to SCC. Patients may simultaneously have bowenoid papulosis of the genitalia and SCC in situ, especially in the periungual area, both caused by the same HPV type. On the glans penis of an uncircumcised male and on the cervical, vaginal, or rectal mucosa, progression to invasive SCC is more likely. Female partners of men with bowenoid papulosis and women with bowenoid papulosis have an increased risk of cervical dysplasia. Histologically, the biopsies of SCC in situ and HSIL caused by HPV (bowenoid papulosis) are very similar. Pigmentation of the epithelium and numerous mitoses, especially in metaphase, are characteristic but not diagnostic of HPV-induced HSIL on the external genitalia.

Giant Condyloma Acuminatum (Buschke-Lowenstein Tumor). Giant condyloma acuminatum is a rare, aggressive, verrucous growth that is a verrucous carcinoma. Unlike other HPV-induced genital carcinomas, this tumor is usually caused by HPV-6. It occurs most often on the glans or prepuce of an uncircumcised male; less often, it may occur on perianal skin or the vulva (Fig. 19.52). Despite its bland histologic picture, it may invade deeply, and infrequently it may metastasize to regional lymph nodes. Treatment is by complete surgical excision. Recurrence after radiation therapy may be associated with a more aggressive course.

Diagnosis of Genital Warts. Even in women with confirmed cervical HPV infection, serologic tests are positive in only 50%, making serologic diagnosis of HPV infection of little use to the practicing clinician. HPV typing by in situ hybridization (ISH) or PCR is useful in managing HPV infection of the cervix and in some cases of prepubertal HPV infection, but not in the management of EGW. Virtually all condylomata can be diagnosed by inspection. Bright lighting and magnification should be used when examining for genital HPV infection. Flat, sessile, and pigmented lesions suggest bowenoid papulosis and may require

a biopsy. Subclinical and latent infections are no longer sought or investigated because they are very common, and no management strategy is known to eradicate these forms of HPV infection. Soaking with acetic acid is not generally necessary but may be helpful to detect early lesions under the foreskin. In patients with multiple recurrences, acetic acid soaking may determine the extent of infection, helping to define the area for application of topical therapies. The procedure is performed by soaking the external genitalia in men and the vagina and cervix in women with 3%–5% acetic acid for up to 10 minutes. Genital warts turn white (acetowhitening), making them easily identifiable. Any process that alters the epidermal barrier will be acetowhite (e.g., dermatitis), however. In atypical cases, a 2-week trial is attempted with a 1% hydrocortisone preparation plus a topical anticandidal imidazole cream. If the acetowhitening persists, a biopsy is performed and histologic evidence of HPV infection sought. IP or ISH methods may aid in evaluation. PCR can aid in difficult clinical diagnosis especially in childhood cases. The high background rate of latent infection (up to 50%) makes interpretation of a positive PCR impossible. In contrast, chromogenic ISH clearing demonstrates the localization of positive nuclei within the lesion and can confirm a lesion to be HPV induced.

Treatment. Because no effective virus-specific agent exists for their treatment, genital warts frequently recur. Prevention with HPV vaccination if possible is imperative. Treatment is not proved to reduce transmission to sexual partners or to prevent progression to dysplasia or cancer. Specifically, the treatment of male sexual partners of women with genital warts does not reduce the recurrence rate of warts in these women. Therefore the goals of treatment must first be discussed with the patient and perhaps with the sexual partner. Observation represents an acceptable option for some patients with typical condylomata acuminata. Because genital warts may cause discomfort, genital pruritus, foul odor, bleeding, and substantial emotional distress, treatment is indicated if requested by the patient. Bleeding genital warts may increase the sexual transmission of HIV and hepatitis B and C. Bowenoid papulosis may be treated as discussed next when it occurs on the external genitalia. Lesions with atypical histology (high-grade squamous intraepithelial) on mucosal surfaces and periungually are special cases, and treatment must be associated with histologic confirmation of eradication in patients receiving topical treatments.

The treatment chosen is in part dictated by the size of the warts and their location. The number of EGWs at the initial evaluation is strongly predictive of wart clearance. Patients with four or fewer EGWs will be clear with three or fewer treatments, whereas only 50% of patients with 10 or more EGWs will be clear after three treatments. 20% of patients with 10 or more EGWs will still have lesions after eight treatments. A more effective or aggressive treatment approach might be considered in patients with high numbers of EGWs.

Podophyllin is more effective in treating warts on occluded or moist surfaces, such as on the mucosa or under the prepuce. It is available as a crude extract, usually in 25% concentration in tincture of benzoin. It is applied weekly by the physician and can be washed off 4–8 hours later by the patient, depending on the severity of the reaction. After six consecutive weekly treatments, approximately 40% of patients are free of warts, and 17% are free of warts at 3 months after treatment. Purified podophyllotoxin 0.5% solution or gel is applied by the patient twice daily for 3 consecutive days of each week with 4 days without therapy to allow recovery from irritation in 4- to 6-week treatment cycles. Efficacy approaches 60% for typical condylomata, and side effects are fewer than with standard, physician-applied podophyllin preparations. Therefore whenever possible, podophyllotoxin should be used instead of classic podophyllin solutions.

Imiquimod, an immune response modifier that induces IFN locally at the site of application, has efficacy similar to cryotherapy (about 50%) and yields a low recurrence rate (22%). Imiquimod may be used to treat penile condyloma in circumcised and uncircumcised men, anal and perianal condyloma, vulvar condyloma and bowenoid papulosis. It may be used as the initial treatment or when recurrence has been frequent after attempting other forms of treatment. The 5% cream is applied daily or every other day for up to 16 weeks. The 3.75% cream is applied daily for 2 weeks, followed by a 2-week rest period, to a maximum of 8 weeks of treatment. The 3.75% cream is less effective than the 5% cream, resulting in only a 33% clearance but with fewer side effects. Imiquimod 5% cream is more effective than podophyllotoxin in treating women with EGW infection, but only equally or slightly less effective in men, especially for warts on the penile shaft. Imiquimod is less effective than cryotherapy in the treatment of EGWs. Therapeutic response to imiquimod is slow, requiring several weeks in some patients to see any effect. Treatment results in mild to moderate irritation, less than with podophyllin or cryotherapy in men, but with a similar side effect profile in women. Rare complications reported with the 5% cream include flaring of psoriasis and psoriatic arthritis, vitiligo-like hypopigmentation, induction of genital ulcers in a patient with Behçet disease, and the production of a local neuropathy. Imiquimod should be used cautiously in persons with psoriasis. Neuropathy is associated with application of excessive amounts, occlusion of the medication, and application to an eroded mucosa.

Imiquimod (and sinecatechins) has also been used as a maintenance therapy after destructive methods, the cream applied to the area for 12–16 weeks to prevent recurrence and eradicate subclinical lesions. The use of imiquimod after surgical destruction of condyloma should be considered in all immunocompetent patients, especially those with recurrence after a previous surgical procedure. Suppositories containing about 5 mg of imiquimod appear to reduce the risk of recurrence of anal condyloma in immunocompetent men after surgical ablation of extensive anal disease.

The topical application of green tea extract containing sinecatechins (Polyphenon E or Veregen) can be effective in treating EGWs. A 15% ointment applied three times daily leads to EGW clearance in 60% of women and 45% of men. Placebo cleared 35% of patients in this blinded study. The average time to complete clearance is 16 weeks. Erythema and erosions at the application site occur in 50% of patients, and 67% had moderate to severe reactions.

Bichloracetic acid or TCA 35%–85% can be applied to condylomata weekly or biweekly. TCA is safe for use in pregnant patients. Compared with cryotherapy, TCA has the same or lower efficacy and causes more ulcerations and pain. It is not generally recommended for EGWs, because other available treatments are more effective and cause less morbidity.

Cryotherapy with liquid nitrogen is more effective than podophyllin and imiquimod, approaching 70%–80% resolution during treatment and 55% at 3 months after treatment. One or two freeze-thaw cycles are applied to each wart every 1–3 weeks. A zone of 2 mm beyond the lesion is frozen. Cryotherapy is effective in dry as well as moist areas. Perianal lesions are more difficult to eradicate than other genital sites, and two freeze-thaw cycles are recommended in this location. Cryotherapy is safe to use in pregnant patients. EMLA cream with or without subsequent lidocaine infiltration may be beneficial in reducing the pain of cryotherapy. The addition of podophyllin to cryotherapy does not result in a higher cure rate but the response rate may be faster.

Electrofulguration or electrocauterization with or without snip removal of the condyloma is more effective than TCA, cryotherapy, imiquimod, or podophyllin. Wart clearance during therapy is almost 95%, and wart cure at 3 months exceeds 70%. Local anesthesia is required, and scarring may occur. Surgical removal is ideal for large, exophytic warts that might require multiple treatments with other methods. It has high acceptance in patients who have had

recurrences from other methods because results are immediate and cure rates higher.

The use of CO_2 laser in the treatment of genital warts has not been shown to be more effective than simpler surgical methods. Although visible warts are eradicated by the laser, HPV DNA can still be detected at the previous site of the wart. The CO_2 laser has the advantage of being bloodless, but it is more costly and requires more technical skill. It should be reserved for treatment of extensive lesions in which more cost-effective methods have been attempted and failed. Adjunctive PDT does not prevent recurrence of EGW after CO_2 laser ablation. Compared with CO_2 laser ablation of EGWs, 5-aminolevulinic acid (ALA) with PDT demonstrated higher efficacy and fewer recurrences and was less painful. ALA-PDT response rate is about 75%. ALA-PDT should be considered before CO_2 laser ablation for the treatment of multiple small, but refractory condyloma.

Any surgical method that generates a smoke plume is potentially infectious to the surgeon. HPV DNA is detected in the plumes generated during CO_2 laser or electrocoagulation treatment of genital warts. The laser-generated plume results in longer-duration HPV aerosol contamination and wider spread of detectable HPV DNA. If these methods of wart treatment are used, an approved face mask and smoke evacuator should be used and the equipment decontaminated after the surgery.

5-Fluorouracil 5% cream applied twice daily may be effective, especially in the treatment of flat, hyperpigmented lesions, such as those in bowenoid papulosis. Care must be taken to avoid application to the scrotum, because scrotal skin is prone to painful erosions. Twice-daily instillation of 5-FU into the urethra can be used to treat intraurethral condylomata. The cone from a tube of lidocaine (Xylocaine) jelly will fit onto the thread of the 5-FU tube, or the cream may be instilled with a syringe. It is typically left in place for 1 hour before the patient voids. Care should be taken that drips of urine containing the medication do not contact the scrotum. 5-FU may also be used to treat intravaginal warts by instillation in the vagina, but this is often associated with severe irritation. Intermittent therapy (twice weekly for 10 weeks) is better tolerated than daily therapy. 5-FU is not usually recommended for the treatment of typical EGWs because other methods of treatment are available.

Immunotherapy can also be effective for refractory EGWs. This is usually delivered by injection of *Candida*, BCG, purified protein derivative (PPD), or another antigen, rather than through topical application, because of the difficulty in preventing exposure of normal skin with a topical solution. Immunotherapy may be combined with destructive methods in refractory cases. The injection of HPV-6 VLPs was found to speed the clearance of warts simultaneously treated with cryotherapy, podophyllin, or TCA.

Human Papillomavirus Vaccination. The HPV VLPs are composed of spontaneously assembling L1 molecules and have been used to develop a polyvalent vaccine against HPVs 6, 11, 16, and 18, but a newer nine-valent vaccine targets these four, as well as HPVs 31, 33, 45, 52, and 58. HPV vaccination is highly effective and is now approved in more than 100 countries for the immunization of prepubertal girls and boys. Vaccination is recommended for unvaccinated females through age 26 and males age 13–21. HIV-infected men and women should receive immunization through age 26. In older women (age 24–45) the vaccine is also effective and may be given as a "catch-up" vaccine in women with no evidence of prior genital HPV infection with HPVs 6, 11, 16, or 18. The incidence of the targeted HPVs in addition to cervical intraepithelial neoplasia have been reduced dramatically. Even condyloma in nonvaccinated women and men (who were not yet eligible for immunization) were reduced, demonstrating herd immunity. HPV-related genital HSIL was also reduced by 47% in fully vaccinated women. In countries where HPV-16/18 vaccination was widely applied, the burden of HPV disease caused by HPV-6 and HPV-11 has decreased, suggesting some benefit across HPV types.

Genital Warts in Children. Children can acquire genital warts through vertical transmission perinatally and through digital inoculation or autoinoculation, fomite or social nonsexual contact, and sexual abuse. HPV typing has demonstrated that most warts in the genital area of children are "genital" HPV types, and most children with genital warts have family members with a genital HPV infection.

Human papillomavirus typing can be performed. However, the presence of genital types of HPV does not prove abuse, and finding a nongenital HPV type does not exclude sexual abuse. In children younger than 1 year, vertical transmission is probably the most common means of acquisition. The risk for sexual abuse is highest in children older than 3 years. A careful history should be taken evaluating for any warts on the child or parent that could have been innocuously transferred to the child. When abuse is suspected, children should be referred to child protection services if the practitioner is not skilled in evaluating children for sexual abuse. Children 1–3 years old are primarily nonverbal and are difficult to evaluate but fortunately vertical transmission and not sexual abuse can be the source. Management of such patients is on a case-by-case basis. Other STDs should be screened for in children who have a genital HPV infection.

Usually, management of children with anogenital warts requires a multidisciplinary team that should include a pediatrician (Fig. 19.53). Genital warts in children often spontaneously resolve (75%), so no intervention may be a reasonable consideration. Genital warts in children usually respond quickly to topical therapy, such as podophyllotoxin, imiquimod, or light cryotherapy. In refractory cases, surgical removal or electrocautery may be used but care must be exercised not to cause undue emotional stress on the parent or child.

Recurrent Respiratory (Laryngeal) Papillomatosis

Papillomas associated with HPV may occur throughout the respiratory tract, from the nose to the lungs. Recurrent respiratory papillomatosis has a bimodal distribution: in children under age 5 years and after age 15. Affected young children are typically born to mothers with genital condylomata and present with hoarseness. The HPV types found in these lesions, HPV-6 and HPV-11, are the types seen in genital condylomata. Carcinoma

Fig. 19.53 Perianal warts in 18-month-old infant.

that is often fatal develops in 14% of patients, even in young children. The incidence of carcinoma is higher in those treated with radiation therapy. These patients often have recurrences and require numerous surgeries, usually with the CO_2 laser. Scarring can result from frequent ablations, leading to speech and breathing difficulties. Adjunctive cidofovir has been combined with surgical ablation to help reduce recurrences, with some positive preliminary results. Also, HPV vaccination has been combined with laser ablation, with preliminary results demonstrating reduced recurrences. It is hoped that HPV immunization of young women will reduce the prevalence of condyloma and thus of respiratory papillomatosis.

Heck Disease

Small, white to pinkish papules occur diffusely in the oral cavity in Heck disease, also known as focal epithelial hyperplasia. It occurs most frequently in Native Americans of North, Central, and South America; in Inuits; in Greenland Eskimos; and in descendants of Khoi-San in South Africa. In these populations, prevalence rates can be as high as 35%. It is five times more common in females. HPV-13 and HPV-32 have been classically associated with Heck disease. Clinically, the lesions may be papular or papillomatous and favor the buccal and labial mucosa and the commissures of the mouth. Lesions may spontaneously resolve. Treatment options include cryosurgery, CO_2 laser, electrosurgery, and topical, intralesional, or systemic IFN.

Epidermodysplasia Verruciformis

Epidermodysplasia verruciformis (EV) is a rare, inherited disorder characterized by widespread HPV infection and cutaneous SCCs. EV is most commonly inherited as an autosomal recessive trait, although autosomal dominant and X-linked inheritance have also been reported. About 10% of EV patients are from consanguineous marriages. HPV types associated with this syndrome include those infecting normal hosts, such as HPV-3 and HPV-10, as well as many "unique" HPV types, often β-HPVs. These HPV types are called "EV HPVs" and include HPVs 4, 5, 8, 9, 12, 14, 15, 17, 19–25, 36–38, and 47. HPV-5 and HPV-8 are found in 90% of the skin cancers in EV patients. The genetic mutations causing EV are found in two closely linked genes, *EVER1* and *EVER2*. The function of these genes and how they cause this syndrome are unknown.

The condition presents in childhood and continues throughout life. Skin lesions include flat wart–like lesions of the dorsal hands, extremities, face, and neck. They appear in childhood or young adulthood, apparently earlier in sunnier climates. The characteristic lesions are flatter than typical flat warts (Fig. 19.54) and may be quite abundant, growing to confluence. Typical flat warts may be admixed. In addition, lesions on the trunk are red, tan, or brown patches/plaques or hypopigmented, slightly scaly plaques resembling tinea versicolor. Plaques on the elbows may resemble psoriasis. Seborrheic keratosis–like lesions may also be seen on the forehead, neck, and trunk. Common warts are reported to occur infrequently in some EV cohorts.

The histologic features of an EV-specific HPV infection are very characteristic. The cells of the upper epidermis have a clear, smoky, or light-blue pale cytoplasm and a central pyknotic nucleus.

In about one third of EV patients, SCCs develop an average of 24 years after the appearance of the characteristic EV skin lesions. Most often, skin cancers appear on sun-exposed surfaces, but they can appear on any part of the body. Skin cancers are less common in African patients, suggesting a protective effect of skin pigmentation. The SCCs may appear de novo, but usually appear on the background of numerous actinic keratoses and lesions of Bowen disease (Fig. 19.55). Surgical treatment is recommended. Radiation therapy is contraindicated. If skin grafting is required, the grafts should be taken from sun-protected skin, such as the buttocks or inner upper arm.

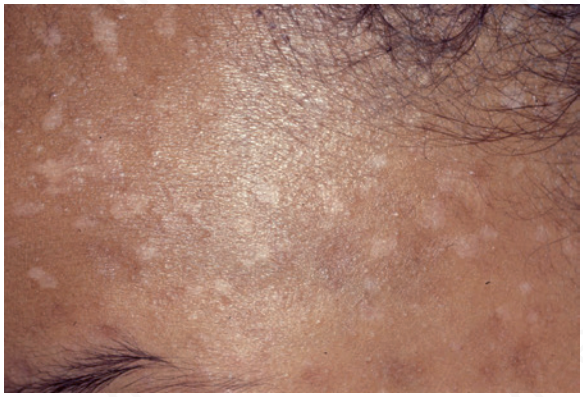

Fig. 19.54 Epidermodysplasia verruciformis in an HIV-infected patient.

Fig. 19.55 Multiple SCCs in epidermodysplasia verruciformis.

Aside from surgical intervention for skin cancer, treatment for EV consists largely of preventive measures. Strict sun avoidance and protection should be started as soon as the syndrome is diagnosed. An approach similar to that for children with xeroderma pigmentosa could be instituted. ALA-PDT, topical 5-FU, imiquimod, and oral retinoids may all be used to treat the lesions of patients with EV, but when treatment is discontinued, lesions usually recur.

The mechanism by which cancer occurs in patients with EV is unclear. HPV-5 proteins do not bind to p53 or pRb. The p53 mutations present in the SCCs of patients with EV are characteristic of those induced by UVB light, confirming the close association of UV exposure and the development of cancer in patients with EV. HPV DNA of EV has been reported in 35% of the general population in very low copy number, suggesting that the presence of these EV HPVs alone is not the cause of the skin cancers. Rather, the *EVER* genes apparently control important immune responses in the epidermis that control HPV replication, and in

their absence, viral replication goes unchecked and can eventually lead to skin cancer in sun-damaged skin. Supporting this concept is a report of a polyomavirus-positive Merkel cell carcinoma in an EV patient. Infection with EV HPV types has been reported in immunosuppressed patients, especially those with HIV. This has been called "acquired EV." SCC has not been reported in these patients.

Other Immunodeficiencies Associated With Warts

Some patients with extensive (>100) common and plantar warts that never resolve and simply grow to confluence have been called "generalized verrucosis." These patients do not develop skin cancers and live into adulthood. Some of these patients have been identified with mutations in *GATA2* (WILD syndrome), *DOCK8*, or *CXCR4* (WHIM syndrome) or with idiopathic CD4 lymphopenia (see Chapter 5). Patients with WHIM have been treated with Plerixifor that blocks CXCL12 activation of CXCR4 and can help restore immune function. Some of these patients, unlike EV patients, are at high risk for anogenital HPV disease and its complications.

Immunosuppressed Patients

Patients with defects in cell-mediated immunity may have an increased frequency of HPV infection. Predisposing conditions include organ transplantation, immunosuppressive medications, congenital immunodeficiency diseases, lymphoma, and HIV infection.

Organ transplant recipients begin to develop warts soon after transplantation, and by 5 years, up to 90% of transplant patients have warts. Initially, these are common and plantar warts, but later, numerous flat warts appear, particularly in sun-exposed areas. Genital warts are also increased, and especially in women, genital dysplasias are more frequent. Keratotic lesions should be evaluated closely for NMSC in transplant patients. It is especially important in immunosuppressed patients to monitor the genital and anal areas regularly for changing lesions and to have a low threshold for performing a biopsy.

In HIV disease, common, plantar, flat, oral, and genital warts are all common. Warty keratoses at the angle of the mouth, often bilateral, are a characteristic manifestation of HPV infection in patients with AIDS. The warts are caused predominantly by HPVs 2, 27, and 57. HPV-7 can be found in cutaneous, oral, and perioral warts in nonbutchers with HIV infection. Genital warts are increased 15-fold among HIV-infected women. Fifty percent or more of HIV-infected MSM have evidence of anal HPV infection. Genital neoplasia associated with HPV-16 and HPV-18 occurs much more frequently in HIV-infected women and MSM. Infrequently, HIV patients develop HPV-5/8–induced EV-like lesions. With antiretroviral therapy, warts may disappear. Paradoxically, increased rates of genital and oral warts may be seen in HIV patients in the first several years of adequate control of their HIV infection, likely as part of IRIS. The likelihood of clearance of common warts in persons with HIV is related to the nadir of their Th cell count. HIV-infected persons whose Th count never falls below 200 cells are more likely to have sustained remission of their warts.

The treatment of warts in immunosuppressed hosts can be challenging. Although standard methods are used, their efficacy may be reduced. For common and plantar warts, surgically ablative methods, cryotherapy, bleomycin injections, PDT, and aggressive pulsed dye laser therapy would be expected to be more effective, because the agents designed to induce an immune response would be less effective in the immunosuppressed patient. In one study using intralesional *Candida* antigen for common warts, the response rate was less than 50% in HIV patients, and no patient showed a distant benefit for untreated warts. Imiquimod has low efficacy in these patients; only 8% had complete clearance of common warts, and 50% had no response. For genital warts, treatment is determined by size. Any wart larger than 2 cm should be sent for consideration of surgical removal and histologic evaluation. Smaller warts can be treated with electrosurgery, cryotherapy, topical 5-FU, and ALA-PDT. Imiquimod can be attempted and is most effective for EGWs on occluded skin (intraanal, under the prepuce). Most transplant patients tolerate imiquimod well, without inducing enough systemic immune response to cause rejection of their transplanted organ. However, widespread use of imiquimod in one renal transplant patient led to acute renal failure.

Topical cidofovir (1%–5% concentration) and intralesional cidofovir (7.5 mg/mL) have been effective in refractory anogenital and common warts in immunodeficient patients. Although topical cidofovir is very expensive, is irritating, and can cause skin erosion and ulceration, it is active against the HPV and thus does not require participation of the patient's immune system to eradicate the wart. Addition of sirolimus to the immunosuppressive regimen may be associated with a decrease in the number of warts in organ transplant patients. In four pediatric transplant patients, substitution of leflunomide for mycophenolate in the immunosuppressive regimen, resulted in clearance or dramatic improvement of cutaneous warts and molluscum contagiosum. The mycophenolate was reinstituted and leflunomide stopped without recurrence of the warts. In organ transplant patients with widespread actinic damage and many precancerous lesions, PDT can be considered.

Trichodysplasia Spinulosa (Viral-Associated Trichodysplasia)

Immunosuppressed patients with lymphoreticular malignancies and organ transplant recipients on immunosuppressive regimens will rarely develop a characteristic eruption of erythematous, 1–3 mm fine, monomorphic facial papules. The midface, glabella, and chin are primarily affected. More widespread involvement, including the arms, has been rarely reported. Lesions are numerous, may reach confluence, and can rarely cause nasal distortion similar to that seen in rosacea and sarcoidosis (Fig. 19.56). Some papules have a central, keratotic white excrescence similar to the follicular spicules that may be seen in multiple myeloma. Alopecia of the eyebrows and eyelashes may occur, but the scalp is spared. Histology is characteristic, showing massively distended, bulbous follicles with expansion of the inner root sheath cells and containing numerous trichohyaline granules. Abrupt, inner root, sheath-type cornification is present. Abortive hair shaft–like material may be present in the affected follicles. Electron microscopy demonstrates numerous viral particles in the affected hair follicles. Immunohistochemistry may highlight select polyoma antigens. This virus has been identified as a unique polyomavirus called trichodysplasia spinulosa–associated polyomavirus. It differs from the Merkel cell polyomavirus. Treatments that may benefit patients with trichodysplasia spinulosa include reduction of the immunosuppressive regimen or topical cidofovir. Other therapies have been used in some cases, including oral valganciclovir.

Fig. 19.56 Trichodysplasia. (Courtesy Len Sperling, MD.)

Recently one group reported on three patients, two of whom were immunosuppressed, with chronic generalized, scaly, hyperpigmented papules and plaques, with histologic findings of "tiered parakeratosis" or "peacock plumage" that demonstrated human polyomavirus 6 and 7 by PCR and cytoplasmic viral inclusions on electron microscopy. They suggest the term "HPyV6- and HPyV7-associated pruritic and dyskeratotic dermatoses."

RETROVIRUSES

These oncoviruses are unique in that they contain RNA, which is converted by a virally coded reverse transcriptase to DNA in the host cell. The target cell population is primarily CD4+ lymphocytes (primarily helper T cells), but also, in some cases, macrophages. For this reason, the retroviruses are called human T-lymphotropic viruses (HTLVs). Transmission may be through sexual intercourse, blood products/IV drug use, and from mother to child during childbirth and breastfeeding. There is often a very long "latent" period from time of infection until presentation with clinical disease.

Human T-Lymphotropic Virus 1

Human T-lymphotropic virus 1 is endemic in Japan, the Caribbean region, South America (Brazil, Peru, Colombia), sub-Saharan Africa, and Romania; among Australian Aborigines; and in the southeastern United States. In endemic areas, infection rates may be quite high, with only a small percentage of infected patients ever developing clinical disease (estimated 3%). HTLV-1 is spread primarily by mother-to-infant transmission during breastfeeding but also can be transmitted sexually (primarily male to female) or through blood transfusion or IV drug use. HTLV-1 uses the GLUT glucose transporter to enter cells. HTLV-1 is responsible for several clinical syndromes.

About 1% of infected persons will develop adult T-cell leukemia-lymphoma (ATL), with more HTLV-1–infected persons in Japan developing ATL than in other populations. Infection in childhood through breastfeeding seems to be a risk factor for developing ATL. HTLV-1–associated myelopathy or tropical spastic paraparesis (HAM/TSP) is a less common degenerative neurologic syndrome. Patients with this have gone on to develop other autoimmune diseases, including rheumatoid arthritis, lupus, and Sjögren. There are four forms of ATL: smoldering, chronic, acute, and lymphomatous, usually progressing in that order. ATL is characterized by lymphadenopathy, hepatosplenomegaly, hypercalcemia, and skin lesions (60% of patients). Skin lesions in ATL include erythematous papules or nodules (Fig. 19.57). Prurigo may be a prodrome to the development of ATL. Histologically, the cutaneous infiltrates are pleomorphic, atypical lymphocytes with characteristic "flower cells" representing HTLV-1–infected

Fig. 19.57 HTLV-1–associated adult T-cell leukemia-lymphoma.

lymphocytes. Epidermotropism may be present, mimicking mycosis fungoides.

Three quarters or more of HTLV-1–infected patients will have an abnormal skin examination. The most common skin conditions are dermatophytosis (30%), seborrheic dermatitis (25%), and xerosis/acquired ichthyosis (up to 80%), and vitiligo has also been reported. In patients with HAM/TSP, chronic eczema/photosensitivity occurs in up to 20%. The disease closely resembles more common causes of eczematous dermatitis and the diagnosis can be delayed if not considered. Biopsies from the areas of chronic eczema/photosensitivity may show features of ATL in up to 25% of patients (smoldering ATL). Scabies is seen in 2% of asymptomatic HTLV-1–infected patients and in 5% of those with HAM/TSP. The scabies may be of the hyperkeratotic (crusted) type, and the presence of hyperkeratotic scabies in a person from an HTLV-1–endemic region should trigger serologic testing for the virus. The spectrum of skin disease seen in symptomatic HTLV-1–infected patients is remarkably similar to that seen in HIV-infected patients with CNS disease: xerosis/eczema, seborrheic dermatitis, and scabies.

Infective dermatitis, infective dermatitis associated with HTLV 1 infection (IDH), or HTLV-1–associated infective dermatitis (HAID) occurs in children and less frequently in adults with HTLV-1 infection. It is much rarer in Japan than other HTLV-1–endemic, more tropical countries, suggesting climate and malnutrition/socioeconomic factors may play a role. Infective dermatitis is diagnosed by major and minor criteria. Clinically, the children present at an early age (18 months onward) with a chronic eczema of the scalp, axilla, groin, external auditory canal, retroauricular area, eyelid margins, paranasal areas, and neck. Involvement of the scalp and retroauricular area is universal, followed by the body folds (neck, axillae, groin, paranasal skin, and ears). Exudation and crusting are the hallmarks of the skin lesions. Pruritus is mild. Clinically, infective dermatitis resembles a cross between infected AD and infected seborrheic dermatitis. There is a chronic nasal discharge. Cultures from the skin and nares are positive for *Staphylococcus aureus* or β-hemolytic streptococcus, and the condition responds rapidly to antibiotics and topical corticosteroids. Infective dermatitis is relapsing and recurrent. Skin biopsies show a nonspecific dermatitis; however, close examination may show atypical CD4+ cells infiltrating the epidermis, at times simulating ATL or cutaneous T-cell lymphoma. Careful neurologic examination of children with IDH will often reveal abnormal neurologic findings: weakness, lumbar pain, dysesthesias, and urinary disturbances.

Human Immunodeficiency Virus

Human immunodeficiency virus (HIV) infects human helper T (Th) cells, leading to a progressive immunodeficiency disease. In its end stages, HIV infection is called *acquired immunodeficiency syndrome (AIDS)*. Patients with HIV should be screened for other STDs and often require multidisciplinary care with experienced physicians to get the most up-to-date, disease-specific care. Patients with HIV should be counseled regarding disease transmission and safe sex, and there is evidence suggesting preexposure prophylaxis with antiretroviral drugs may reduce transmission within serodiscordant couples.

Cutaneous manifestations are prominent, affecting up to 90% of HIV-infected persons. Many patients have multiple skin lesions of different types. The skin lesions or combinations of skin conditions are so unique that the diagnosis of HIV infection or AIDS can often be suspected from the skin examination alone. The skin findings can be classified into three broad categories: infections, inflammatory dermatoses, and neoplasms. The skin conditions also tend to appear at a specific stage in HIV progression, making them useful markers of the stage of HIV disease.

The natural history of HIV infection in the vast majority of patients is a gradual loss of Th cells. The rate of this decline is variable, with some patients progressing rapidly and others very slowly or not at all (long-term nonprogressors). Soon after infection, there is a seroconversion syndrome called primary HIV infection, or acute infection (group I). Patients recover from this syndrome and enter a relatively long latent period (asymptomatic infection, or group II), which averages about 10 years. During this period, patients may have persistent generalized lymphadenopathy (group III). When symptoms begin to appear, they are often nonspecific and include fever, weight loss, chronic diarrhea, and mucocutaneous disease (group IVA). Th counts in group II, III, and IVA patients usually range from 200–500 cells. The skin findings at this stage (originally called AIDS-related complex, ARC) include seborrheic dermatitis, psoriasis, Reiter syndrome, AD, herpes zoster, acne rosacea, oral hairy leukoplakia, onychomycosis, warts, *S. aureus* skin and soft tissue infections (including recurrent MRSA), and mucocutaneous candidiasis.

Once the Th count is 200 cells or less, the patient is defined as having AIDS. In this stage of HIV disease, the skin lesions are more characteristic of immunodeficiency and include characteristic opportunistic infections: chronic herpes simplex, molluscum contagiosum, bartonellosis (bacillary angiomatosis), systemic fungal infections (cryptococcosis, histoplasmosis, coccidioidomycosis, penicilliosis), and mycobacterial infection. Paradoxically, patients at this stage also have hyperreactive skin and frequently, inflammatory, often pruritic skin diseases. These skin conditions include eosinophilic folliculitis, granuloma annulare, drug reactions, enhanced reactions to insect bites, refractory seborrheic dermatitis, AD, and photodermatitis.

When the Th count falls below 50 cells, the patient is often said to have "advanced AIDS." These patients may have very unusual presentations of their opportunistic infections, including multicentric, refractory molluscum contagiosum; chronic herpes simplex; chronic cutaneous varicella-zoster infection; cutaneous CMV ulcerations, cutaneous acanthamebiasis, cutaneous atypical mycobacterial infections (including *Mycobacterium avium* complex and *Mycobacterium haemophilum*), penicilliosis, and crusted scabies. Treatment of their infections is often difficult because of the significant chronic immunosuppression.

It is now clear that HIV itself is the cause of the loss of Th cells and that effective treatment of HIV infection may halt or reverse the natural history of HIV disease. The numerous antiretroviral agents are usually used in combinations called "cocktails." This combination treatment is called highly active antiretroviral therapy (HAART). A significant percentage of HIV-infected patients respond to HAART and may show dramatic improvement of their HIV disease. HIV disappears from the blood and Th-cell counts rise. As expected, in patients who respond to HAART, opportunistic infections no longer occur, and subsequently mortality rate decreases. This is also true of cutaneous infectious conditions. HIV-associated psoriasis usually improves substantially, especially if the patient did not have psoriasis before HIV infection. Because full reconstitution of the immune system with HAART may take several years, some skin conditions may be slow to resolve (seborrheic dermatitis). Others, such as MC and KS, generally begin to improve within months.

HAART is typically associated with resolution of all forms of HIV-related cutaneous complications. However, some conditions may initially appear or be exacerbated by the sudden improvement of the immune status that occurs with eradication of HIV viremia and with increase in Th-cell counts. This complex of manifestations is called the immune reconstitution inflammatory syndrome. IRIS occurs in 15%–25% of HIV-infected persons started on HAART. Persons with an opportunistic infection (OI), specifically cryptococcosis, tuberculosis, penicilliosis, leprosy, or *Pneumocystis* pneumonia, may be at higher risk if HAART is started as the OI is being treated. This marked inflammatory syndrome can be severe, and in resource-poor countries 5% of AIDS-related deaths in treated patients can be attributed to IRIS during the first year of HAART therapy. Half of IRIS-related conditions are dermatologic. The following three forms of IRIS occur:

1. A hidden OI is unmasked as the reconstituted immune system attacks the hidden pathogen. The presentation may be atypical. The appearance of cutaneous mycobacterial infections with HAART is an example.
2. In the setting of a documented OI, when HAART is started, the patient has worsening of the infection with new findings. This is not treatment failure, but enhanced immune response to the pathogen. This typically occurs with tuberculosis or cryptococcosis.
3. The development of new disorders is seen, infectious or inflammatory, or enhanced inflammatory responses around malignancies, especially KS. Eosinophilic folliculitis, acne flares, drug eruptions, Reiter syndrome, lupus erythematosus, alopecia universalis, at times HPV infections (especially oral and genital), increased outbreaks of genital and orolabial herpes simplex, molluscum contagiosum, herpes zoster, CMV ulcerations, type I reactions in Hansen disease, cutaneous mycobacterial and fungal infections, leishmaniasis, tattoo and foreign body granulomas, and sarcoidosis can be part of IRIS in the skin.

Infection with HIV is now being effectively controlled in many patients through HAART. However, the constant struggle of the immune system to control viral replication and side effects from multiple medications has led to senescence of the immune system similar to that seen with chronologic aging. Chronic HIV disease is characterized by the same combination of immunodeficiency and inflammation that occurs with aging. This has led to increased rates and earlier onset of cardiovascular disease, metabolic disorders, osteoporosis, and some cancers in HIV disease, including KS developing in patients with normal CD4 counts due to immune senescence. Frailty, or the variability with which persons acquire health problems and the consequent inability to tolerate stressors (vulnerability), is becoming the primary consequence of HIV infection in many countries.

Primary HIV Infection (Acute Seroconversion Syndrome)

Several weeks after infection with HIV, an acute illness develops in a large proportion of individuals. The clinical syndrome is similar to primary EBV infection, with fever, sore throat, cervical adenopathy, a rash, and oral, genital, and rectal ulceration. The skin eruption can be polymorphous. Most characteristic is a papular eruption of discrete, slightly scaly, oval lesions of the upper trunk. The lesions have a superficial resemblance to pityriasis rosea, but the peripheral scale is not prominent, and there is focal hemorrhage in the lesions. A Gianotti-Crosti–like papular eruption may also occur. Purpuric lesions along the margins of the palms and soles, as seen in immune complex disease, have been reported. The mucosal erosions resemble aphthae but are larger and can affect all parts of the mouth (Fig. 19.58), pharynx, esophagus, and anal mucosa. Dysphagia may be prominent. The Th-cell count falls abruptly during seroconversion. The level of immune impairment may allow oral candidiasis or even *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia to develop. The diagnosis should be suspected in any at-risk individual with the correct constellation of symptoms. A direct measurement of HIV viral load will confirm the diagnosis, as antibody testing may be inaccurate during acute infection and seroconversion. Combination antiviral therapy is instituted immediately.

HIV-Associated Pruritus

From early in the HIV epidemic, it was clear that pruritus was a marker of HIV infection throughout the world, occurring in up to 30% of patients. Pruritus is usually not caused by HIV disease

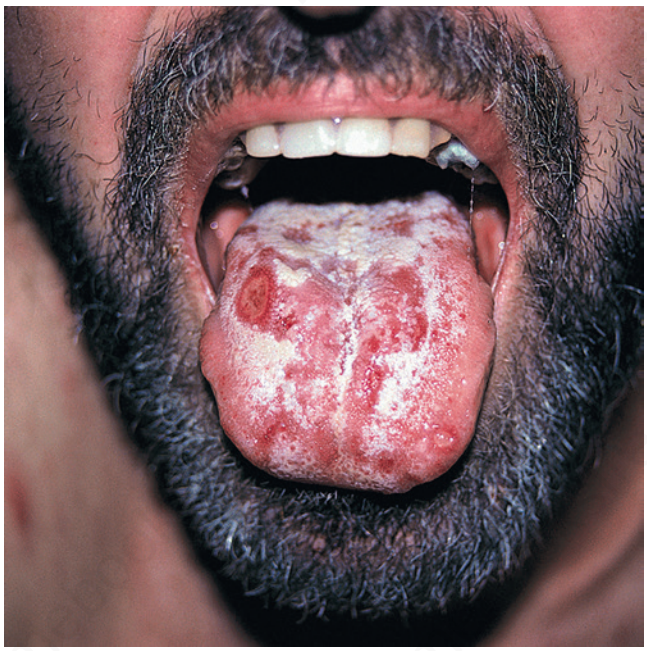

Fig. 19.58 Primary HIV infection. (Courtesy Ginat Mirowski, MD.)

Fig. 19.59 Eosinophilic folliculitis in an HIV-infected patient.

Fig. 19.60 Herpes simplex and seborrheic dermatitis in an HIV-infected patient.

itself but is related to inflammatory dermatoses associated with the disease. "Papular pruritic eruption" is not a specific disease, but rather a "wastebasket diagnosis" used to encompass patients with many forms of HIV-associated pruritus. Worldwide, it most often represents enhanced insect bite reactions. These pruritic eruptions are best subdivided into follicular and nonfollicular eruptions. The relative prevalence of these two patterns of pruritic eruptions is geographically distinct. In tropical and semitropical regions, where biting insects are prominent, nonfollicular eruptions are most common and probably represent insect bite hypersensitivity. In temperate regions, follicular pruritic eruptions are more common.

Eosinophilic folliculitis (EF) is the most common pruritic follicular eruption (Fig. 19.59). It is seen in patients with a Th count of about 200 cells. Clinically, EF presents with urticarial follicular papules on the upper trunk, face, scalp, and neck. Pustular lesions are uncommon; pustules are usually smaller than in bacterial folliculitis and represent end-stage lesions. These lesions are infrequently seen because the pruritus is so severe that the pustules are excoriated before the lesion evolves to this degree. About 90% of lesions occur above the nipple line on the anterior trunk, and lesions typically extend down the midline of the back to the lumbar spine. EF waxes and wanes in severity and may spontaneously clear, only to flare unpredictably. A peripheral eosinophilia may be present, and the serum IgE level may be elevated, suggesting this is a disorder mediated by Th2 cells. Histologically, an infiltrate of mononuclear cells and eosinophils is seen around the upper portion of the hair follicle at the level of the sebaceous gland. As lesions evolve, eosinophils and lymphocytes enter the follicular structure and the sebaceous glands. Pustules are formed late and represent aggregates of eosinophils in the uppermost part of the follicle. Rarely, there will be increased mucin within the follicular epithelium, making distinction from follicular mucinosis difficult.

Initial treatment of EF is topical corticosteroids and antihistamines. If the patient fails to respond, phototherapy (UVB or PUVA) or itraconazole, 200 mg twice daily, may be effective. In some patients, repeated applications of permethrin (every other night for up to 6 weeks) may be of benefit. Permethrin therapy is directed at *Demodex* mites, which may be the antigenic trigger of EF. Isotretinoin is also effective, often after a few months, in a dose of about 0.5–1 mg/kg/day. HAART may lead to a flare of EF (as part of IRIS) but usually leads eventually to its resolution. Staphylococcal folliculitis, which may be severely pruritic in patients with HIV disease, and *Pityrosporum* folliculitis should be included in the differential diagnosis. These are excluded by bacterial culture and skin biopsy, respectively. *Demodex* folliculitis should also be in the differential.

The other pruritic dermatoses that are not follicular can be divided into the primarily papular eruptions and the eczematous reactions. The papular eruptions include scabies, insect bites, transient acantholytic dermatosis, granuloma annulare, and prurigo nodularis. The eczematous dermatoses include atopic-like dermatitis, seborrheic dermatitis, nummular eczema, xerotic eczema, photodermatitis, and drug eruptions. Patients may have multiple eruptions simultaneously, making differential diagnosis difficult (Fig. 19.60). A skin biopsy from a representative lesion of every morphologic type on the patient may elucidate the true diagnosis (or diagnoses). Patients on HAART who had higher VL at onset of ART may have higher rates of pruritic papular eruptions. Treatment is determined by the diagnosis and is similar to treatment in persons without HIV infection with these same dermatoses. Special considerations in AIDS patients include the use of topical therapy plus ivermectin for crusted scabies and thalidomide for prurigo nodularis and photodermatitis. Both these systemic agents are very effective if used appropriately.

HIV-Associated Neoplasia

Neoplasia is prominent in HIV infection and in some cases is highly suggestive of HIV infection. KS is an example. Other common neoplasms seen in patients with HIV infection include superficial BCCs of the trunk, SCCs in sun-exposed areas, genital HPV-induced SCC, and extranodal B-cell and T-cell lymphomas. Lipomas, angiolipomas, and dermatofibromas may occur. In the case of lipomas, their appearance is usually related to the peripheral fat loss that occurs with some HIV treatment regimens and with HIV disease itself.

Nonmelanoma skin cancers (NMSCs) are very common in HIV patients. HAART does not protect against the development of NMSC in HIV infection. BCCs usually occur as superficial multicentric lesions on the trunk in fair-skinned patients, younger than typically seen, particularly in men in their twenties to fifties. The ratio of BCC to SCC is not reversed in HIV disease as it is in organ transplant recipients, but HIV-infected patients are at higher risk than noninfected patients of developing SCC and not

BCC, and the risk correlates with lower CD4 and higher VL. BCCs behave in the same manner as they do in the immunocompetent host, and standard management is usually adequate.

Actinically induced SCCs are also quite common and present in the standard manner as nodules, keratotic papules, or ulcerations. In most cases, their behavior is relatively benign and standard management is adequate. Removal of SCCs in sun-exposed areas by curettage and desiccation in patients with HIV infection is associated with an unacceptably high recurrence rate of about 15%. Complete excision is therefore recommended. In a small subset of patients with AIDS, actinic SCCs can be very aggressive; they may double in size over weeks and may metastasize to regional lymph nodes or viscerally, leading to the death of the patient.

Genital SCCs, including cervical, vaginal, anal, penile, and periungual SCC, all occur in patients with HIV infection. These neoplasms are increased in frequency, and the progression from HPV infection to neoplasia appears to be accelerated. This is analogous to the situation in organ transplant and other immunosuppressed patients. It appears that these cancers are associated with primarily "high-risk" HPV types.

High-risk genital HPV infection in patients with HIV can produce perianal dysplasia in MSM who have a history of receptive anal intercourse. Dysplasia in this area may present as velvety white or hyperpigmented plaques involving the whole anal area and extending into the anal canal. These lesions may erode or ulcerate. Histology will demonstrate SCC in situ. The risk of progression of the lesions to anal SCC is unknown but is estimated to be at least 10 times higher than the rate of cervical cancer in women in the general population. The management of such lesions is unclear, but regular follow-up is clearly indicated, and any masses in the anal canal should be immediately referred for biopsy. At some centers, Pap smear equivalents are performed. Imiquimod has been used as an adjunct in the management of genital warts and HPV-associated genital in situ dysplasias (not genital SCC). Although it may be of benefit in patients with reconstituted immune systems receiving HAART, especially in combination with surgical ablation, the response rate is much lower than in immunocompetent patients. In the only placebo-controlled trial, done before standard HAART was available, imiquimod was no more effective than placebo in clearing genital warts (11%) in HIV infection. Small case series of patients receiving HAART suggest clearance rates of about 30%–50%. Topical cidofovir can be used to treat genital HPV infection in patients with low-risk and high-risk HPV types.

The vulvar and penile skin may develop flat, white or hyperpigmented macules from a few millimeters to several centimeters in diameter. These show SCC in situ and are analogous to bowenoid papulosis in the immunocompetent host. Lesions of the penile shaft and glabrous vulvar skin, not at a transition zone or on mucosal surfaces, have a low risk of progressing to invasive SCC. Lesions of the glans penis that are red and fixed should be biopsied. If the changes of SCC in situ are found, these should be managed aggressively as SCC in situ. Topical 5-FU and superficial radiation therapy are effective. Close clinical follow-up is indicated. Periungual SCC has also been seen in patients with HIV infection. Any persistent keratotic or hyperpigmented lesion in the periungual area must be carefully evaluated. Management is surgical excision, though digital HPV-associated SCC lesions display a high rate of recurrence, and Mohs should be considered in many cases due to the anatomic site and risk of recurrence. Some advocate for postoperative adjuvant therapy with laser, curettage, cryotherapy, or imiquimod. Perianal and vulvovaginal lesions should be managed as intraepithelial neoplasia types AIN-3 and VIN-3, respectively.

Extranodal B-cell and less often T-cell lymphomas are associated with the advanced immunosuppression of AIDS. The B-cell lymphomas and some of the T-cell lymphomas present as violaceous or plum-colored papules, nodules, or tumors. Once the diagnosis is established by biopsy, systemic chemotherapy is required. EBV is found in some cases. HAART is both protective against the development of non-Hodgkin lymphoma (NHL) and Hodgkin disease in HIV and substantially improves prognosis of HIV-infected patients with NHL. Mycosis fungoides can also be seen in patients with HIV infection, often in those who have not yet developed AIDS. It presents with pruritic patches or plaques and may progress to tumor stage. EBV is not found in these cases. CD8+ pseudolymphoma is also seen in patients with untreated HIV infection and may resolve with HAART.

Malignant melanoma (MM) is seen at increased rates in persons with HIV infection. HIV-infected melanoma patients demonstrate the same risk factors as other melanoma patients: multiple nevi, fair skin type, and prior intermittent but intense sun exposure. HIV patients with melanoma in the pre-HAART era had significantly shorter disease-free survival and reduced overall survival. Many fair-skinned patients infected with HIV complain of the new onset of atypical moles (analogous to organ transplant patients). Whether these confer an increased risk of melanoma is unknown.

AIDS and Kaposi Sarcoma

Kaposi sarcoma (KS) was, along with *Pneumocystis* pneumonia, the harbinger of the AIDS epidemic. Many MSM and bisexual men presented with this tumor in the early 1980s, with a prevalence of up to 25% in some cohorts. HHV-8, a γ-herpesvirus, has been identified in these lesions. The clinical features of KS in patients with AIDS are different than those seen in elderly men who do not have AIDS. Patients with AIDS present with symmetric widespread lesions, often numerous. Lesions begin as macules that may progress to tumors or nodules (Fig. 19.61). Any mucocutaneous surface may be involved, but areas of predilection include the hard palate, face, trunk, penis, and lower legs and soles. Visceral disease may be present and progressive. Edema may accompany lower leg lesions, and if significant, it is often associated with lymph node involvement in the inguinal area.

A diagnosis of KS is established by skin biopsy, which should be taken from the center of the most infiltrated plaque. Excessive bleeding is not usually a problem. Early macular lesions show atypical, angulated, ectatic vessels in the upper dermis associated with an inflammatory infiltrate containing plasma cells. Plaque lesions show aggregates of small vessels and endothelial cells in the upper dermis and surrounding adnexal structures. Nodules and tumors show the classic pattern of a spindle cell neoplasm with prominent extravasation of red blood cells.

Fig. 19.61 Kaposi sarcoma in AIDS patient.

HAART has reduced the incidence of KS in HIV-infected patients by 10-fold. However, KS remains an important complication of HIV infection for the following two reasons:

1. HIV-associated KS is still common in sub-Saharan Africa. With HAART therapy, survival in Africa for HIV-infected persons for more than 1 year is almost 100%, if they do not have KS. In patients with HIV disease and KS, however, survival is only 77%. This results from the lack of effective cytotoxic therapy for KS in Africa. HIV-KS is more common in women than men in some clinics in Africa.
2. Although HAART has substantially reduced the prevalence of KS in HIV disease in the developed world, HAART has not eliminated the disease. In fact, there remains a fairly substantial proportion of primarily gay men with HIV disease who also have KS (up to 13% of some cohorts). Twenty percent or more of these AIDS-KS patients have well-controlled HIV disease with long-term undetectable viral load and CD4 counts above 300. These patients have an overall good prognosis but still may require cytotoxic or radiation therapy to control their KS. Patients with AIDS-KS and lower CD4 counts and detectable viral loads are more likely to have visceral disease. Up to one third of these AIDS-KS patients died despite HAART and chemotherapy, suggesting that AIDS-KS in the setting of poor HIV control is a poor prognostic finding.

The treatment of AIDS-associated KS depends on the extent and aggressiveness of the disease. Effective HAART after about 6 months is associated with involution of KS lesions in 50% of patients. This should be the initial management in most patients with mild to moderate disease (<50 lesions, and <10 new lesions/month) who are not receiving anti-HIV treatment. Intralesional vinblastine, can be infiltrated into lesions (as for hypertrophic scar), and lesions will involute over several weeks. Hyperpigmentation usually remains. Cryotherapy is also effective but will leave postinflammatory hypopigmentation in pigmented persons. Persistent individual lesions and lesions of the soles and penis respond well to local irradiation therapy (one single treatment of 80 Gy or fractionated treatments to 150 Gy). For patients with moderate disease (>10 lesions, or mucosal or visceral involvement), HAART alone may not be adequate in controlling KS, and liposomal doxorubicin may need to be added to the treatment. For patients with symptomatic visceral disease, aggressive skin disease, marked edema, and pulmonary disease, systemic chemotherapy is indicated. Triple therapy with vincristine, bleomycin, and etoposide has been utilized in one study of KS in Malawai.

20 Parasitic Infestations, Stings, and Bites

Bonus images for this chapter can be found online at expertconsult.inkling.com

The major groups of animals responsible for bites, stings, and parasitic infections in humans belong to the phyla Arthropoda, Chordata, Cnidaria (formerly Coelenterata), Nemathelminthes, Platyhelminthes, Annelida, and Protozoa. This chapter reviews parasitic diseases and the major causes of bites and stings, as well as strategies for prevention.

PHYLUM PROTOZOA

The protozoa are one-celled organisms, divided into classes according to the nature of their locomotion. Class Sarcodina organisms move by temporary projections of cytoplasm (pseudopods); class Mastigophora by means of one or more flagella; and class Ciliata by short, hairlike projections of cytoplasm (cilia). Class Sporozoa have no special organs of locomotion.

CLASS SARCODINA

Amebiasis Cutis

Entamoeba histolytica–induced cutaneous ulcers usually result from extension of an underlying amebic abscess; the most common sites are the trunk, abdomen, buttocks, genitalia, and perineum. Those on the abdomen may result from hepatic abscesses. Penile lesions are usually sexually acquired and associated with anal intercourse. Most lesions begin as deep abscesses that rupture and form ulcerations with distinct, raised, cordlike edges, and an erythematous halo approximately 2 cm wide. The base is covered with necrotic tissue and hemopurulent pus containing amebas. These lesions are from a few centimeters to 20 cm wide. Without treatment, slow progression of the ulcer occurs in an increasingly debilitated patient until death ensues. Patients may also present with fistulas, fissures, polypoid warty lesions, or nodules. Deep lesions are more likely to be associated with visceral lesions.

The sole manifestation of early amebiasis may be chronic urticaria. An estimated 10 million invasive cases occur annually, most of them in the tropics. Infection may be asymptomatic, or bloody diarrhea and hepatic abscesses may be present. In the United States the disease occurs chiefly in institutionalized patients, world travelers, recent immigrants, migrant workers, and men who have sex with men. Penile ulcers are associated with insertive anal intercourse.

The histologic findings are those of a necrotic ulceration with many lymphocytes, neutrophils, plasma cells, and eosinophils. *E. histolytica* is found in the tissue, within blood and lymph vessels. The organism measures 50–60 μm in diameter and has basophilic cytoplasm and a single, eccentric nucleus with a central karyosome. The organism is frequently demonstrable in fresh material from the base of the ulcer by direct smear. Culture of the protozoa confirms the diagnosis. Indirect hemagglutination test results remain elevated for years after the initial onset of invasive disease, whereas the results of gel diffusion precipitation tests and counterimmunoelectrophoresis become negative at 6 months. This property can be used to test for recurrent or active disease in persons coming from endemic areas.

When the perianal or perineal areas are involved, granuloma inguinale, lymphogranuloma venereum, deep mycosis, and syphilis must be considered. In chronic urticaria, fresh stool examinations by a trained technician are necessary.

The treatment of choice is metronidazole (Flagyl), 750 mg orally three times daily for 10 days. Abscesses may require surgical drainage.

Other Amebas

Amebas of the genera *Acanthamoeba* and *Balamuthia* may also cause skin lesions in infected hosts. These organisms are ubiquitous in the environment and are found in soil, water, and air. Granulomatous amebic encephalitis is the most common manifestation of infection with these amebas. In the case of *Acanthamoeba*, invasive infections are almost always in immunocompromised individuals, including those with acquired immunodeficiency syndrome (AIDS) and organ transplant patients, although *Acanthamoeba* can also involve the cornea in those who use homemade contact lens solution. Disseminated lesions present as pink or violaceous nodules that then enlarge, suppurate, and form ulcers with a necrotic eschar (Fig. 20.1). Other findings include fever, nasal congestion or discharge, epistaxis, cough, headaches, lethargy, altered mental status, and seizures. In patients infected with *Acanthamoeba* who have disease of the central nervous system (CNS), death usually occurs within days to weeks. The organisms are visible on skin biopsy, and culture is definitive. In patients without CNS involvement, mortality rate is 75%, with successfully treated cases often managed with a combination of 5-fluorocytosine and sulfadiazine. In patients infected with *Balamuthia mandrillaris*, involvement of the central face is typical. Treatment paradigms are changing, and in vitro evidence suggests that diminazene aceturate is more active than miltefosine or pentamidine, and artemether shows promise (Fig. 20.2). Chlorhexidine topically and surgical debridement are local adjunctive measures that may prove beneficial.

CLASS MASTIGOPHORA

Organisms belonging to this class, the mastigophorans, are also known as flagellates. Many have an undulating membrane with flagella along their crest.

Trichomoniasis

Trichomonas vulvovaginitis is a common cause of vaginal pruritus, with burning and a frothy leukorrhea. The vaginal mucosa appears bright red from inflammation and may be mottled with pseudomembranous patches. The male urethra may also harbor the organism; in the male it causes urethritis and prostatitis. Occasionally, men may develop balanoposthitis. Erosive lesions on the glans

Fig. 20.1 Disseminated acanthameba in HIV disease.

Fig. 20.2 Balamuthia infection. (Courtesy Paco Bravo, MD.)

and penis or abscesses of the median raphe may occur. Neonates may acquire the infection during passage through the birth canal, but they require treatment only if symptomatic or if colonization lasts more than 4 weeks. Because this is otherwise almost exclusively a sexually transmitted disease (STD), *Trichomonas* vulvovaginitis in a child should prompt suspicion of sexual abuse.

Trichomoniasis is caused by *Trichomonas vaginalis*, a colorless piriform flagellate 5–15 μm long. *T. vaginalis* is demonstrated in smears from affected areas. Testing by direct immunofluorescence is sensitive and specific, and polymerase chain reaction (PCR) analysis is now available.

Fig. 20.3 Old World leishmaniasis.

Metronidazole, 2 g in a single oral dose, is the treatment of choice. Alternatively, 500 mg twice daily for 7 days may be given, and intravaginal metronidazole/miconazole is also effective. Patients should be warned not to drink alcohol for 24 hours after or dosing because of the disulfiram-type effects of this medication. Male sex partners should also be treated. The use of metronidazole is contraindicated in pregnant women, and clotrimazole, applied intravaginally at 100 mg a night for 2 weeks, may be used instead. Disulfiram and nithiamide show in vitro evidence of activity and could prove useful for resistant organisms.

de Brum Vieira P, et al: Challenges and persistent questions in the treatment of trichomoniasis. Curr Top Med Chem 2017; 17: 1249.

Leishmaniasis

All forms of leishmaniasis are caused by morphologically indistinguishable protozoa of the family Trypanosomidae, called *Leishmania* (pronounced leesh-may-nea). The clinical features of the leishmaniases differ, and in general, these diseases have different geographic distribution. The variable clinical manifestations may result from the diversity of the organism and the person's immune status and genetic ability to initiate an effective cell-mediated immune response to the specific infecting organism. It is known that the antigen-specific T-cell responses, which lead to the production of interferon (IFN) and interleukin-12 (IL-12), are important for healing of the lesions and the induction of lifelong, species-specific immunity to reinfection that results after natural infection. Both CD4+ and CD8+ lymphocytes appear to be active in the immune response. IL-10–producing natural regulatory T cells may play a role in the downregulation of infection-induced immunity.

Cutaneous Leishmaniasis

There are several types of lesion. All tend to occur on exposed parts because all are transmitted by the sandfly. Old World leishmaniasis manifests mainly in the skin and has also been called Baghdad boil, Oriental sore, leishmaniasis tropica, Biskra button, Delhi boil, Aleppo boil, Kandahar sore, and Lahore sore. Mild visceral disease may occur. Skin lesions of New World infection have been termed uta, pian bois, and bay sore or chiclero ulcer.

Clinical Features. In Old World leishmaniasis, lesions may present in two distinct types. One is the moist or rural type, a slowly growing, indurated, livid, indolent papule (Fig. 20.3), which enlarges

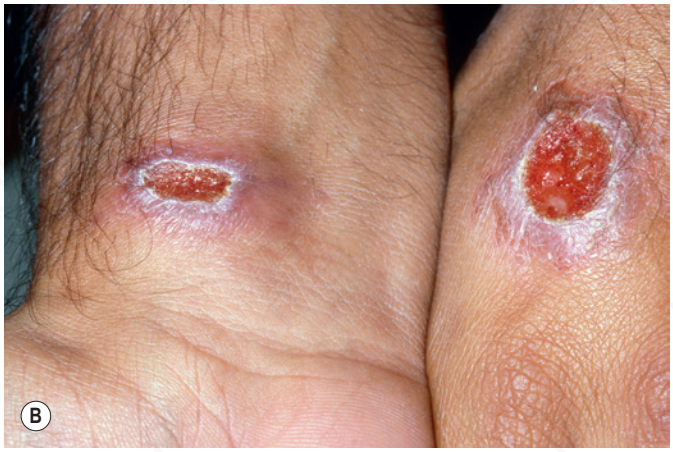

Fig. 20.4 (A and B) New World leishmaniasis.

in a few months to form a nodule that may ulcerate in a few weeks to form an ulcer as large as 5 cm in diameter. Spontaneous healing usually takes place within 6 months, leaving a characteristic scar. This type is contracted from rodent reservoirs such as gerbils via the sandfly vector. The incubation period is relatively short (1–4 weeks). The dry or urban type has a longer incubation period (2–8 months or longer), develops much more slowly, and heals more slowly than the rural type. In both types, the ulcer or crust forms on a bed of edematous tissue.

Rarely, after the initial or "mother" lesion is healed, at the borders of the healed area a few soft red papules may appear that are covered with whitish scales and have the "apple jelly" characteristics of granulomatous diseases such as lupus vulgaris. These spread peripherally on a common erythematous base and are the lupoid type. This is also known as leishmaniasis recidivans and occurs most often with the urban type of disease, caused by *Leishmania tropica*. New World disease may also induce purely cutaneous lesions, of varied morphology. The primary papule may become nodular, verrucous, furuncular, or ulcerated, with an infiltrated red border (Fig. 20.4). Subcutaneous peripheral nodules, which eventually ulcerate, may signal extension of the disease. A linear or radial lymphangitic (sporotrichoid) pattern may occur

Fig. 20.5 New World leishmaniasis.

with lymphadenopathy, and the nodes may rarely yield organisms. Facial lesions may coalesce and resemble erysipelas. Recidivans lesions are unusual in the New World form of disease. In Yucatan and Guatemala, a subtype of New World disease exists: the chiclero ulcer. The most frequent site of infection is the ear (Fig. 20.5). The lesions ulcerate and occur most frequently in workers who harvest chicle for chewing gum in forests, where there is high humidity. This form is a more chronic ulcer that may persist for years, destroying the ear cartilage and leading to deformity. The etiologic agent is *Leishmania mexicana* and the sandfly vector, *Lutzomyia flaviscutellata*.

Uta is a term used by Peruvians for leishmaniasis occurring in mountainous territory at 1200–1800 m above sea level. The ulcerating lesions are found on exposed sites and mucosal lesions do not occur.

Disseminated cutaneous leishmaniasis may be seen in both New and Old World disease. Multiple nonulcerated papules and plaques, chiefly on exposed surfaces, characterize this type. The disease begins with a single ulcer, nodule, or plaque from which satellite lesions may develop and disseminate to cover the entire body. The disease is progressive, and treatment is usually ineffective. It is characterized by anergy to the organism. This type of leishmaniasis must be differentiated from lepromatous leprosy, xanthoma tuberosum, paracoccidioidal granuloma, Lobo disease, and malignant lymphoma.

Etiologic Factors

Leishmania tropica, *L. major*, *L. aethiopica*, and *L. infantum*, the cause of Mediterranean visceral leishmaniasis, may cause cutaneous leishmaniasis. Purely cutaneous leishmaniasis is also caused by several species present in the New World. *L. mexicana* does not induce mucosal disease. *Leishmania braziliensis guyanensis* produces cutaneous disease, as does *L. b. braziliensis* and *L. b. panamensis;* however, the latter two may also result in mucocutaneous disease.

Epidemiology. Cutaneous leishmaniasis is endemic in Asia Minor and to a lesser extent in many countries around the Mediterranean. Iran and Saudi Arabia have a high occurrence rate. In endemic

areas, deliberate inoculation on the thigh is sometimes practiced so that scarring on the face—a frequent site for Oriental sore—may be avoided. Purely cutaneous lesions may also be found in the Americas. In the United States leishmaniasis is largely restricted to southern Texas, although rare reports of human cutaneous disease have occurred as far north as Pennsylvania, and visceral leishmaniasis in immunosuppressed humans is being recognized as an emerging infection in areas not previously thought to be endemic for the disease.

Pathogenesis. The leishmania protozoan has an alternate life in vertebrates and in insect hosts. Humans and other mammals, such as dogs and rodents, are the natural reservoir hosts. The vector hosts are *Phlebotomus* sandflies for the Old World type and *Phlebotomus perniciosus* and *Lutzomyia* sandflies for New World cutaneous leishmaniasis. After the insect has fed on blood, the flagellates (leptomonad, promastigote) develop in the gut in 8–20 days, after which migration occurs into the mouth parts; from here, transmission into humans occurs by a bite. In humans, the flagella are lost, and a leishmanial form (amastigote) is assumed.

Histopathology. An ulcer with a heavy infiltrate of histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes is seen. The parasitized histiocytes form tuberculoid granulomas in the dermis. Pseudoepitheliomatous hyperplasia may occur in the edges of the ulcer. Leishmanias are nonencapsulated and contain a nucleus and a paranucleus. Wright, Giemsa, and monoclonal antibody staining may be helpful in identifying the organisms within histiocytes, where they often line up at the periphery of a vacuole. PCR primers are available for a variety of species. PCR is more sensitive than microscopy but less sensitive than culture.

Diagnosis. In endemic areas, the diagnosis is not difficult. In other localities, cutaneous leishmaniasis may be confused with syphilis, yaws, lupus vulgaris, and pyogenic granulomas. The diagnosis is established by demonstration of the organism in smears. A punch biopsy specimen from the active edge of the ulcer is ideal for culture. It can be placed in Nicolle-Novy-MacNeal (NNN) medium and shipped at room temperature. Parasites can also be cultured from tissue fluid. A hypodermic needle is inserted into the normal skin and to the edge of the ulcer base. The needle is rotated to work loose some material and serum, which is then aspirated. A culture on NNN medium at 22°C–35°C (71.6°F–95°F) is recommended to demonstrate the leptomonads. PCR is now available and is the most sensitive diagnostic test for cutaneous leishmaniasis.

Treatment. Spontaneous healing of primary cutaneous lesions occurs, usually within 12–18 months, shorter for Old World disease. Reasons to treat a self-limited infection include avoiding disfiguring scars in exposed areas, avoiding secondary infection, controlling disease in the population, and failure of spontaneous healing. In the diffuse cutaneous and recidivans types, leishmaniasis may persist for 20–40 years if not treated.

In areas where localized cutaneous leishmaniasis is not complicated by recidivans or sporotrichoid forms or by mucocutaneous disease, treatment with such topical modalities as paromomycin sulfate 15% plus methylbenzethonium chloride 12%, ketoconazole cream under occlusion, cryotherapy, local heat, 5-aminolevulinic acid hydrochloride (10%) plus visible red light (633 nm), and laser ablation, or with intralesional sodium stibogluconate antimony or emetine hydrochloride may be effective and safe.

In the setting of Old World cutaneous leishmaniasis, some data suggest that intramuscular meglumine antimoniate in combination with intralesional meglumine antimoniate may be superior to intralesional therapy alone. A meta-analysis of studies of Old World cutaneous leishmaniasis concluded that pentamidine was similar in efficacy to pentavalent antimonials, and that both were superior to the other agents studied. Since then, a Pakistani study concluded that itraconazole was more effective and more economical and had fewer side effects than meglumine antimoniate in both wet and dry types of cutaneous leishmaniasis. The number of patients studied was relatively small, and other studies have been disappointing. Oral fluconazole and zinc sulfate have been used to treat *Leishmania major* infection. A similar meta-analysis of studies of New World cutaneous leishmaniasis concluded that meglumine might be the best agent in its class. Intralesional therapy may be acceptable for small, solitary lesions in areas with a low risk of mucosal disease. Azithromycin has been used in New World disease but is inferior to antimonials. Perilesional injections of IFN-γ have also been reported to be effective but are expensive.

In immunosuppressed patients or those who acquire infection in areas where mucocutaneous disease may occur, systemic therapy is recommended. As with topical treatment, many alternatives have been reported to be effective. Sodium antimony gluconate (sodium stibogluconate) solution is given intramuscularly or intravenously, 20 mg/kg/day in two divided doses for 28 days. It can be obtained from the U.S. Centers for Disease Control and Prevention (CDC) Drug Service (Atlanta, GA 30333). Repeated courses may be given. Antimony *n*-methyl glutamine (Glucantime) is used more often in Central and South America because of its local availability.

Other systemic medications reported to be effective include fluconazole (200 mg/day for 6 weeks), ketoconazole, dapsone, rifampicin, and allopurinol. Some of these have not been subjected to controlled clinical trials, as is true of most topical treatments. The recidivans and disseminated cutaneous types may require prolonged courses or adjuvant IFN therapy. Amphotericin B may be used in antimony-resistant disease. Lipid formulations of amphotericin B are highly effective in short courses but are expensive. Liposomal amphotericin B may be especially helpful for *Leishmania braziliensis* and *L. guyanensis* infections. Intramuscular pentamidine is also used for *L. guyanensis* cutaneous leishmaniasis, because this infection is resistant to systemic antimony. Miltefosine is being used for cutaneous disease in some areas of the world and may prove to be the treatment of choice for diffuse cutaneous leishmaniasis and post–kala-azar dermal leishmaniasis. However, some studies have shown miltefosine to be ineffective in *L. major* and *L. braziliensis* infections. Posaconazole has been used in Old World disease. Control depends chiefly on the success of antifly measures taken by health authorities and personal protection with protective clothing, screening, and repellents. Vaccines are being investigated but are not available.

Mucocutaneous Leishmaniasis (Leishmaniasis Americana, Espundia)

Clinical Features. The initial leishmanial infection, which occurs at the site of the fly bite, is a cutaneous ulcer. Secondary lesions on the mucosa usually occur at some time during the next 5 years. The earliest mucosal lesion is usually hyperemia of the nasal septum with subsequent ulceration (Fig. 20.6), which progresses to invade the septum and later the paranasal fossae. Perforation of the septum eventually takes place. For some time, the nose remains unchanged externally, despite the internal destruction. At first, only a dry crust is observed, or a bright-red infiltration or vegetation on the nasal septum, with symptoms of obstruction and small hemorrhages. Despite the mutilating and destructive character of leishmaniasis, it never involves the nasal bones. When the septum is destroyed, the nasal bridge and tip of the nose collapse, giving the appearance of a parrot beak, camel nose, or tapir nose.

It is important to recall that the four great chronic infections—syphilis, tuberculosis, Hansen disease, and leishmaniasis—have a predilection for the nose. The ulcer may extend to the lips (Fig. 20.7) and continue to advance to the pharynx, attacking the soft

Fig. 20.6 Mucocutaneous leishmaniasis.

Fig. 20.7 Severe destructive mucocutaneous leishmaniasis. (Courtesy Debra Kalter, MD.)

palate, uvula, tonsils, gingiva, and tongue. The eventual mutilation is called espundia. Two perpendicular grooves at the union of the osseous palate and soft tissues, in the midst of the vegetative infiltration of the entire pharynx, are called the palate cross of espundia.

Only in exceptional cases does American leishmaniasis invade the genital or ocular mucous membranes. The frequency of mucous membrane involvement is variable. In Yucatan and Guatemala, it is an exception; in other countries, such as Brazil, it may occur in 80% of cases.

Etiologic Factors. Mucocutaneous leishmaniasis is mainly caused by *Leishmania (Viannia) braziliensis braziliensis* and *L. b. panamensis*, although some Old World organisms, including *L. infantum*, *L. major*, and *L. tropica*, can cause mucosal ulceration. Leishmania has two forms: the nonflagellated form or leishmania, which is found in the tissues of humans and animals susceptible to the inoculation of the parasite; and the flagellated form or leptomonad, which is found in the digestive tract of the vector insect (*Lutzomyia* in mucocutaneous disease) and in cultures. The typical morphology of leishmania, as found in vertebrates, is round or oval, usually with one extremity more rounded than the other, measuring 2–4 μm × 1.5–2.5 μm, with cytoplasm, nucleus, and blepharoplast or kinetoplast.

Epidemiology. Mucocutaneous leishmaniasis is predominantly a rural disease. It most often occurs in damp and forested regions. The disease can be contracted at any time of the year, but the risk is highest just after the rainy season. All ages and races and both genders are equally affected. Epidemics parallel the El Niño cycle.

Histopathology. In ulcerous leishmaniasis, marked irregular acanthosis and sometimes pseudoepitheliomatous hyperplasia can be found. The dermis shows a dense infiltration of histiocytes, lymphocytes, and plasma cells. In new lesions, some neutrophils are observed. Large Langhans giant cells or typical tubercles are occasionally seen. Numerous organisms are present (mostly in histiocytes), which are nonencapsulated and contain a nucleus and a paranucleus. Wright, Giemsa, and monoclonal antibody staining may be helpful in identifying the organisms. In patients with granulomatous infiltrates containing intracellular parasites within histiocytes, leishmaniasis is one of several diseases to be considered, including rhinoscleroma, histoplasmosis, granuloma inguinale, Chagas disease, *Penicillium marneffei* infection, and toxoplasmosis. Touch smears stained with Giemsa are helpful in many cases of cutaneous and mucocutaneous leishmaniasis.

Laboratory Findings. Leishmania is demonstrated in the cutaneous and mucous membrane lesions by direct smears or cultures. In Wright-stained biopsy material, intracellular and extracellular organisms are seen with typical morphology of two chromatic structures: nucleus and parabasal body. In later mucosal lesions, the scarcity of parasites makes identification difficult. The culture is done on NNN medium for leptomonads. PCR is now widely used, and specimens obtained from lesion scarification and blood sample–enriched leukocytes compare favorably with indirect immunofluorescence reaction and culture techniques.

Prophylaxis. Although it is impractical to eliminate the insect vector, it is still the only valid measure for the control of this prevalent disease. Effective vaccines are not available for mucocutaneous leishmaniasis.

Treatment. Treatment is the same as described for cutaneous leishmaniasis, except that antimony resistance is common in mucocutaneous disease. Combination therapy using antimonials with drugs such as rifampin or azithromycin, or adding immunomodulators such as IFN-γ, IL-2, or imiquimod may result in cure. Amphotericin B treatment may be necessary.

Visceral Leishmaniasis (Kala-Azar, Dumdum Fever)

Clinical Features. The earliest lesion is the cutaneous nodule or leishmanioma, which occurs at the site of the initial sandfly inoculation. Kala-azar, meaning "black fever," acquired its name because of the patchy macular darkening of the skin caused by deposits of melanin that develop in the later course of the disease. These patches are most marked over the forehead and temples, periorally, and on the midabdomen.

The primary target for the parasites is the reticuloendothelial system; the spleen, liver, bone marrow, and lymph nodes are attacked. The incubation period is 1–4 months. An intermittent fever, with temperatures ranging from 39°C–40°C (102°F–104°F), ushers in the disease. Hepatosplenomegaly, agranulocytosis, anemia, and thrombocytopenia occur. Chills, fever, emaciation, weight loss, weakness, epistaxis, and purpura develop as the disease progresses. Susceptibility to secondary infection may produce pulmonary and gastrointestinal (GI) infection, ulcerations in the mouth (cancrum oris), and noma. Death occurs about 2 years from onset in untreated individuals.

Most infections are subclinical or asymptomatic. In patients with AIDS, papular and nodular skin lesions may occur.

Dermatofibroma-type or Kaposi sarcoma–like, brown to purple nodules are most frequently reported, although random biopsies of normal skin will reveal organisms. Therefore clinical correlation is necessary to attribute skin findings to *Leishmania* specifically.

Etiologic Factors. *Leishmania donovani* spp. *donovani*, *infantum*, and *chagasi* cause visceral leishmaniasis and are parasites of rodents, canines, and humans. They are nonflagellate oval organisms about 3 mm in diameter, known as Leishman-Donovan bodies. In the sandfly, it is a leptomonad form with flagella.

Epidemiology. *Leishmania donovani donovani* causes visceral leishmaniasis in India, with the major reservoir being humans and the vector being *Phlebotomus argentipes. L .donovani infantum* occurs in China, Africa, the Near East and Middle East, and the Mediterranean littoral, where the major reservoirs are dogs; *Phlebotomus perniciosus* and *P. ariasi* are the vectors of the Mediterranean type. American visceral leishmaniasis is caused by *L. donovani chagasi* and is transmitted by the sandfly *Lutzomyia longipalpis*. American visceral leishmaniasis principally affects domestic dogs, although explosive outbreaks of the human infection occur sporadically, when the number of *Lutzomyia longipalpis* builds up to a high level in the presence of infected dogs. Canine visceral infections with *Leishmania infantum* have been reported in foxhounds in various parts of the United States and Canada.

Diagnosis. Leishman-Donovan bodies may be present in the blood in individuals with kala-azar of India. Specimens for examination, in descending order of utility, include spleen pulp, sternal marrow, liver tissue, and exudate from lymph nodes. Culturing on NNN medium may also reveal the organisms.

Treatment. General supportive measures are essential. Pentavalent antimony has long been the drug of choice. In areas of drug resistance, amphotericin B is usually effective, but it is expensive and toxic, and requires intravenous administration. Miltefosine, an oral alkyl-phosphocholine analog, has proved as effective as amphotericin B in some trials. It is often used to treat visceral disease in India and Ethiopia. Mixed infections involving both *Leishmania* and *Trypanosoma cruzi* are becoming increasingly common in Central and South America because of overlapping endemic areas. Amiodarone has been used as an unconventional antiparasitic drug in this setting in addition to standard therapy.

Post–Kala-Azar Dermal Leishmaniasis

In kala-azar, the leishmanoid (amastigote) forms may be widely distributed throughout apparently normal skin. During and after recovery from the disease, a special form of dermal disease known as post–kala-azar dermal leishmaniasis appears. This condition appears during or shortly after treatment in the African form, but its appearance may be delayed up to 10 years after treatment in the Indian form. It follows the treatment of visceral leishmaniasis in 50% of Sudanese patients and 5%–10% of those seen in India. There are two constituents of the eruption: a macular, depigmented eruption found mainly on the face, arms, and upper part of the trunk and a warty, papular eruption in which amastigotes can be found. Because it may persist for up to 20 years, these patients may act as a chronic reservoir of infection. This condition closely resembles Hansen disease. High concentrations of IL-10 in the blood of visceral leishmaniasis patients predict those who will be affected by post–kala-azar dermal leishmaniasis. Miltefosine may become the drug of choice.

Viscerotropic Leishmaniasis

Twelve U.S. soldiers developed systemic infection with *Leishmania tropica* while fighting in Operation Desert Storm in Iraq and Kuwait. None had symptoms of kala-azar, but most had fever, fatigue, malaise, cough, diarrhea, or abdominal pain, and none had cutaneous disease. Diagnostic tests yielded positive results on bone marrow aspiration; lymph node involvement was also documented. Treatment with sodium stibogluconate led to improvement.

Human Trypanosomiasis

Three species of trypanosome are pathogenic to humans: *Trypanosoma gambiense* and *T. rhodesiense* in Africa and *T. cruzi* in America. The skin manifestations are usually observed in the earlier stages of trypanosomiasis as evanescent erythema, erythema multiforme, and edema, especially angioedema.

In the early stage of African trypanosomiasis, a trypanosome chancre may occur at the site of a tsetse fly bite. Erythema with circumscribed swellings of angioedema then occurs, with enlargement of the lymph nodes, fever, malaise, headache, and joint pains. In the West African (Gambian) form, the illness is chronic, lasting several years, with progressive deterioration, whereas the East African (Rhodesian) form is an acute illness, with a stormy, fatal course of weeks to months. The Rhodesian form is more often associated with cutaneous signs. Annular or deep erythema nodosum–like lesions are frequent manifestations (Fig. 20.8). Lymphadenopathy is generalized, but frequently there is a pronounced enlargement of the posterior cervical group (Winterbottom sign).

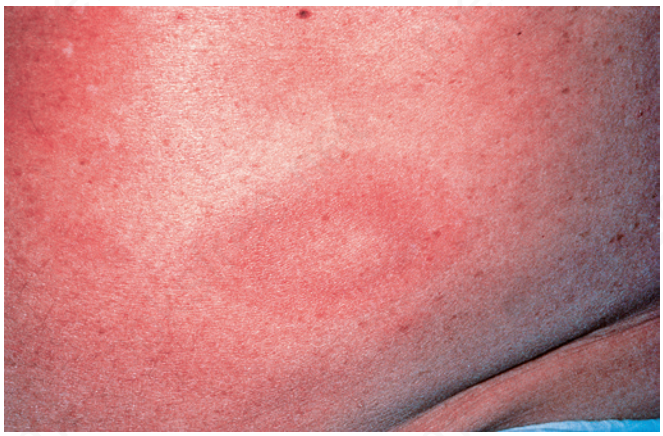

Fig. 20.8 African trypanosomiasis.

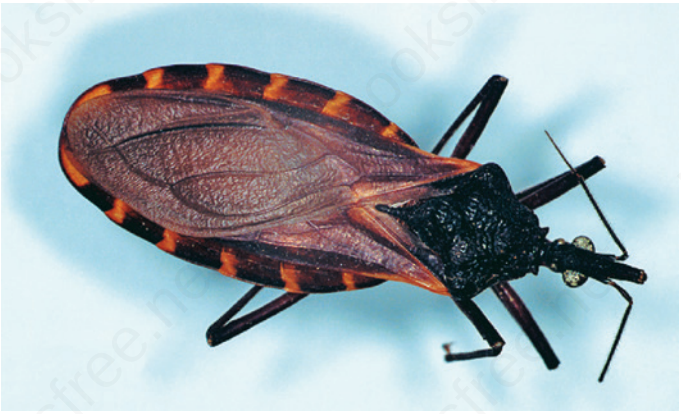

Fig. 20.9 Triatome reduviid bug.

In American trypanosomiasis (Chagas disease), similar changes take place in the skin. The reduviid bug (kissing bug, assassin bug) usually bites at night, frequently at mucocutaneous junctions, where the bug's infected feces are deposited when it feeds (Fig. 20.9). The unsuspecting sleeping person rubs the feces into the bite and becomes infected. If the bite of the infected bug occurs near the eye, Romana sign develops, consisting of unilateral conjunctivitis and edema of the eyelids, with an ulceration or chagoma in the area. The bite of a "kissing bug" becomes extremely swollen and red, whether or not trypanosomes are involved. Acute Chagas disease is usually a mild illness of fever, malaise, edema of the face and lower extremities, and generalized lymphadenopathy. Skin lesions occurring in this phase include nodules at the site of inoculation, disseminated nodules, or morbilliform and urticarial lesions. In chronic Chagas disease, which occurs in 10%–30% of infected persons years to decades later, the heart (myocarditis, arrhythmias, thromboembolism, cardiac failure) and GI system (megaesophagus, megacolon) are most often involved. During the remaining infected but asymptomatic indeterminate phase, patients may transmit the disease through transfusion. When such patients become immunosuppressed (with AIDS or organ transplantation), reactivation skin lesions may occur with a wide range of morphologies, including panniculitis.

Rhodesian trypanosomiasis is endemic among the cattle-raising tribes of East Africa, with the savannah habitat of the vectors determining its geographic distribution. Wild game and livestock are reservoir hosts, in addition to humans. The tsetse fly, *Glossina morsitans*, is the principal vector.

For Gambian trypanosomiasis, humans are the only vertebrate host, and the palpalis group of tsetse flies is the invertebrate host. These flies are found close to the water, and their fastidious biologic requirements restrict their distribution and thus that of the disease. Incidence is seasonal, with humidity and temperature being determining factors. The highest incidence is in men age 20–40 in tropical areas of West and Central Africa.

Chagas disease is prevalent in Central and South America from the United States to Argentina and Chile; the highest incidence is in Venezuela, Brazil, Uruguay, Paraguay, and Argentina. Approximately 29% of all male deaths in the 29–44 age-group in Brazil are attributed to Chagas disease.

Before CNS involvement has occurred in the Rhodesian form, suramin, a complex, non–metal-containing, organic compound, is the treatment of choice. When the CNS is involved, melarsoprol is the drug of choice. Pentamidine isethionate is the drug of choice for the Gambian disease. Eflornithine appears to be a good alternative to melarsoprol for second-stage West African trypanosomiasis. For American trypanosomiasis, treatment is of limited efficacy. The nitroaromatic compounds nifurtimox and benznidazole clear the parasitemia and reduce the severity of the acute illness, but there is a high incidence of adverse effects. Although benznidazole reduces parasite load during the acute phase, it does not prevent chronic cardiac lesions. Ruthenium complexation improves bioavailability of benznidazole and has the potential to improve outcomes. Conservative treatment is the typical approach to the patient with congestive heart failure from Chagas myocarditis, but recent data suggest that clomipramine, a tricyclic antidepressant that inhibits *Trypanosoma cruzi*'s trypanothione reductase, improves the course of cardiac disease in animal models. GI complications may be treated surgically.

CLASS SPOROZOA

Toxoplasmosis

Toxoplasmosis is a zoonosis caused by a parasitic protozoan, *Toxoplasma gondii*. Infection may be either congenital or acquired. Cerebral disease has been reported in the setting of rituximab therapy and widespread lesions can mimic melanoma metastases on positron emission tomography (PET) scans. Congenital infection occurs from placental transmission. Abortion or stillbirth may result. However, a full-term child delivered to an infected mother may have a triad of hydrocephalus, chorioretinitis, and cerebral calcification. In addition, there may be hepatosplenomegaly and jaundice. Skin changes in toxoplasmosis are rare and clinically nonspecific.

In congenital toxoplasmosis, macular and hemorrhagic eruptions predominate. Blueberry muffin lesions, reflecting dermatoerythropoiesis, may be seen. Occasionally, abnormal hair growth and exfoliative dermatitis have also been observed. The differential diagnosis of congenital toxoplasmosis is the TORCH syndrome (toxoplasmosis, other agents, rubella, cytomegalovirus, and herpes simplex). In acquired toxoplasmosis, early skin manifestations consist of cutaneous and subcutaneous nodules and macular, papular, and hemorrhagic eruptions. These may be followed by scarlatiniform desquamation, eruptions mimicking roseola, erythema multiforme, and dermatomyositis or lichen planus, as well as exfoliative dermatitis. As a rule, the exanthem is accompanied by high fever and general malaise.

Diagnosis of acquired toxoplasmosis is of special importance to three groups of adults: healthy pregnant women concerned about recent exposure; adults with lymphadenopathy, fever, and myalgia, who might have some other serious disease (e.g., lymphoma); and immunocompromised persons, such as patients with AIDS, in whom toxoplasmosis might be fatal. It is the most common cause of focal encephalitis in AIDS patients, and this may be accompanied by a widespread papular eruption.

Toxoplasma gondii is a crescent-shaped, oval, or round protozoan that can infect any mammalian or avian cell. Toxoplasmosis is often acquired through contact with animals, particularly cats. Reservoirs of infection have been reported in dogs, cats, cattle, sheep, pigs, rabbits, rats, pigeons, and chickens. The two major routes of transmission of *T. gondii* in humans are oral and congenital. Meats consumed by humans may contain tissue cysts, thus serving as a source of infection when eaten raw or undercooked. There is no evidence of direct human-to-human transmission, other than from mother to fetus.

The diagnosis cannot be made on clinical grounds alone. It may be established by isolation of *T. gondii;* demonstration of the protozoa in tissue sections, smears, or body fluids by Wright or Giemsa stain; characteristic lymph node histology; and serologic methods. In the patient with bone marrow transplantation, the organism has caused interface dermatitis, creating the potential for misdiagnosis as graft-versus-host disease.

A combination of pyrimethamine (Daraprim) and sulfadiazine acts synergistically and forms an effective treatment, but toxicity is substantial. Dosages and total treatment time vary according to the age and immunologic competence of the infected patient.

PHYLUM CNIDARIA

The cnidarians include the jellyfish, hydroids, Portuguese men-of-war, corals, and sea anemones. These are all radial marine animals, living mostly in ocean water.

Portuguese Man-of-War Dermatitis

Stings by the Portuguese man-of-war (*Physalia physalis* in Atlantic or much smaller *Physalia utriculus* or "bluebottle" in Pacific Ocean) are characterized by linear lesions that are erythematous, urticarial, and even hemorrhagic. The forearms, sides of the trunk, thighs, and feet are common sites of involvement. The usual local manifestation is sharp, stinging, and intense pain. Internally, there may be severe dyspnea, prostration, nausea, abdominal cramps, lacrimation, and muscular pains. Death may occur if the areas stung are large in relation to the patient's size.

The fluid of the nematocysts contains toxin that is carried into the victim through barbs along the tentacle. The venom is a neurotoxic poison that can produce marked cardiac changes. Each Portuguese man-of-war is a colony of symbiotic organisms consisting of a blue to red float or pneumatophore with a gas gland, several gastrozooids measuring 1–20 mm, reproductive polyps, and the fishing tentacles bearing the nematocysts from which the barbs are ejected. The hydroid is found most frequently along the southeastern Florida coastline and in the Gulf of Mexico as well as on windward coasts throughout the mid-Pacific and South Pacific. Safe Sea, a barrier cream, has been reported as being effective at preventing jellyfish stings off the coast of Florida, but studies of barrier creams in general have been mixed.

Jellyfish Dermatitis

Jellyfish dermatitis produces lesions similar to those of the Portuguese man-of-war, except that the lesions are not so linear. Immediate allergic reactions occur infrequently as urticaria, angioedema, or anaphylaxis. Delayed and persistent lesions also rarely occur.

The Australian sea wasp, *Chironex fleckeri*, which is colorless and transparent, is the most dangerous of all jellyfish, with a sting that is often fatal (Fig. 20.10). Another sea wasp, *Carybdea marsupialis*, is much less dangerous and occurs in the Caribbean Sea. *Rhopilema nomadica*, common in the Mediterranean Sea, has been reported to cause severe delayed dermatitis.

Seabather's eruption is an acute dermatitis that begins a few hours after bathing in the waters along the Atlantic coast. It affects covered areas of the body as cnidarian larvae become entrapped under the bathing suit and the nematocyst releases its toxin because of external pressure. Thus the buttocks and waist are affected primarily, with the breast also involved in women (Fig. 20.11).

Fig. 20.10 Sea wasp dermatitis. (Courtesy Curt Samlaska, MD.)

Fig. 20.11 Seabather eruption. (Courtesy Scott Norton, MD.)

Erythematous macules and papules appear and may develop into pustules or vesicles. Urticarial plaques are also present in a smaller number of patients. Crops of new lesions may occur for up to 72 hours, and the eruption persists for 10–14 days on average. It is quite pruritic.

Outbreaks in Florida are usually caused by larvae of the thimble jellyfish, *Linuche unguiculata*, which patients report as "black dots" in the water or their bathing suits. The larvae of the sea anemone *Edwardstella lineata* caused one epidemic of seabather's eruption in Long Island, New York. This organism also has nematocysts; thus the mechanism of the eruption is the same as with the jellyfish-induced eruption. It is likely that different cnidarian envenomations in different waters produce a similar clinical picture. Other reports focus on spring plants, dinoflagellates, protozoans, or crustaceans as potential causes. Because the eruption results from trapping of cnidarian larvae with their nematocysts or other toxic or irritant substances under the bathing suit, it may be limited by seabathers who remove their suit and shower soon after leaving the water.

Hydroid, Sea Anemone, and Coral Dermatitis

Patients contacting the small marine hydroid *Halecium* may develop a dermatitis. The organism grows as a 1-cm–thick coat of moss on the submerged portions of vessels or pilings. Sea anemones (Fig. 20.12) produce reactions similar to those from jellyfish and hydroids. Coral cuts are injuries caused by the exoskeleton of the corals *Milleporina*. They have a reputation for becoming inflamed and infected and for delayed healing. The combination of implantation of fragments of coral skeleton and infection (because cuts

Fig. 20.12 Sea anemone.

occur most often on feet) probably accounts almost entirely for these symptoms. Detoxification as soon as possible after the injury is recommended for all these types of sting or cut.

Treatment of Stings and Cuts

Hot water immersion may be an effective remedy for many stings, but scald injuries must be avoided. In the case of box jellies, ice has been shown to be equally effective, but ice can worsen stings of some other jellies. Undischarged nematocytes should be removed. Fresh water, and even sea water, may cause them to discharge. Pacific *Chironex* (box jellyfish) nematocytes should always be inactivated with 5% acetic acid (vinegar) when it is available, but Pacific *Physalia* (bluebottle) nematocytes may discharge on contact with vinegar. Large, visible tentacles may be removed with forceps in a double-gloved hand. Remaining nematocysts may be removed by applying a layer of shaving cream and shaving the area gently. Meat tenderizer may cause tissue damage and has been shown to be no better than placebo in some studies.

Pressure dressings and abrasion will worsen the envenomation. Topical anesthetics or steroids may be applied after decontamination. Systemic reactions may occur through either large amounts of venom or a previously sensitizing exposure from which anaphylaxis may result, and systemic treatment with epinephrine, antihistamines, or corticosteroids may be needed. Specific antivenin is available for the box jellyfish, *Chironex fleckeri.* This should be administered intravenously to limit myonecrosis. Magnesium sulfate ($MgSO_4$) may also be of value in the setting of box jellyfish envenomation. Recurrent jellyfish reactions have shown partial responses to tacrolimus ointment 0.1%.

Sponges and Bristleworms

Sponges have horny spicules of silicon dioxide and calcium carbonate. Some sponges produce dermal irritants, such as halitoxin and okadaic acid, and others may be colonized by Cnidaria. Allergic or irritant reactions may result. Bristleworms may also produce stinging. All these may be treated by first using adhesive tape to remove the spicules, then applying vinegar soaks, as previously described, and lastly, topical corticosteroids.

Sea Urchin Injuries

Puncture wounds inflicted by the brittle, fragile spines of sea urchins, mainly of genus *Diadema* or *Echinothrix*, are stained blue-black by the black spines and may contain fragments of the spines. The spines consist of calcium carbonate crystals, which most frequently induce an irritant reaction with pain and inflammation of several days' duration. Foreign body or sarcoid-like granulomas may develop (Fig. 20.13), as may a vesicular hypersensitivity reaction, 10 days after exposure. Injuries by spines of the genus *Tripneustes* have been reported to cause fatal envenomation, but this genus is not found on U.S. coasts.

Fig. 20.13 Sea urchin granuloma. (Courtesy Steven Binnick, MD.)

Starfish also have thorny spines that can sting and burn if they are stepped on or handled. Several different types of stinging fish also produce puncture wounds. Stingrays, scorpionfish, stonefish, catfish, and weaverfish may cause such envenomations.

These wounds should be immersed in nonscalding water (45°C [113°F]) for 30–90 minutes or until the pain subsides. Calcified fragments may be visible on x-ray evaluation, with fluoroscopy guiding extraction of spines, especially on the hands and feet. Sea urchin spines have been effectively removed using the erbium:yttrium-aluminum-garnet (YAG) laser. Debridement and possibly antibiotic therapy for deep puncture wounds of the hands and feet are recommended. There is a specific antivenin for stonefish stings.

Seaweed Dermatitis

Although caused by a marine alga and not by an animal, seaweed dermatitis deserves mention with other problems associated with swimming or wading. The dermatitis occurs 3–8 hours after the individual emerges from the ocean. The distribution is in parts covered by a bathing suit: scrotum, penis, perineum, and perianal area. The dermatitis is caused by a marine plant, *Lyngbya majuscula* Gomont. It has been observed only in bathers swimming off the windward shore of Oahu, Hawaii. Seabather's eruption, clam digger's itch, and swimmer's itch must be differentiated from seaweed dermatitis caused by marine algae. Prophylaxis is achieved by refraining from swimming in waters that are turbid with such algae. Swimmers should shower within 5 minutes of swimming. Active treatment in severe cases is the same as for acute burns.

Dogger Bank Itch

Dogger Bank itch is an eczematous dermatitis caused by the sea chervil *Alcyonidrium hirsutum*, a seaweed-like animal colony. These sea mosses or sea mats are found on the Dogger Bank, an immense shelflike elevation under the North Sea between Scotland and Denmark.

PHYLUM PLATYHELMINTHES

Phylum Platyhelminthes includes the flatworms, of which two classes, trematodes and cestodes, are parasitic to humans. The trematodes, or blood flukes, parasitize human skin or internal organs. The cestodes are segmented, ribbon-shaped flatworms that inhabit the intestinal tract as adults and involve the subcutaneous tissue, heart, muscle, and eye in the larval form. This is encased in a sac that eventually becomes calcified.

CLASS TREMATODA

Schistosome Cercarial Dermatitis

Cercarial dermatitis is a severely pruritic, widespread, papular dermatitis caused by cercariae of schistosomes for which humans are not hosts; the usual animal hosts are waterfowl and rodents, such as muskrats. The eggs in the excreta of these animals, when deposited in water, hatch into swimming miracidia. These enter a snail, where further development occurs. From the snail, the free-swimming cercariae emerge to invade human skin on accidental contact. The swimming, colorless, multicellular organisms are slightly less than 1 mm long. Exposure to cercariae occurs when a person swims or, more often, wades in water containing them. They attack by burrowing into the skin, where they die. The species that causes this eruption cannot enter the bloodstream or deeper tissues.

After coming out of the water, the bather begins to itch, and a transient erythematous eruption appears, but after a few hours, the eruption subsides, together with the itching. After a quiescent period of 10–15 hours, the symptoms then recur, and erythematous macules and papules develop throughout the exposed parts that were in the water (Fig. 20.14). After several days, the dermatitis heals spontaneously. There are two types: the freshwater swimmer's itch and the saltwater marine dermatitis, or clam digger's itch. Cercarial dermatitis is not communicable.

Various genera and species of organism have been reported from various locations worldwide. An outbreak of cercarial dermatitis was reported from Delaware in 1991 in which the avian schistosome *Microbilharzia variglandis* was implicated as the causative organism. *Schistosoma spindale* cercaria caused a recent epidemic in southern Thailand.

Fig. 20.14 Swimmer itch. (Courtesy Camille Introcaso, MD.)

Thoroughly washing, then drying with a towel after exposure, can prevent the disease. Some advocate rubbing with alcohol as an additional preventive measure. Snail populations can be controlled, or waterfowl may be treated with medicated feed-corn to destroy the adult schistosomes and prevent outbreaks of swimmer's itch.

Visceral Schistosomiasis (Bilharziasis)

The cutaneous manifestation of schistosomiasis may begin with mild itching and a papular dermatitis of the feet and other parts after swimming in polluted streams containing cercariae. The types of schistosome causing this disease can penetrate into the bloodstream and eventually inhabit the venous system, draining the urinary bladder *(Schistosoma haematobium)* or the intestines (*Schistosoma mansoni* or *Schistosoma japonicum*). After an asymptomatic incubation period, the person may develop a sudden illness with fever and chills, pneumonitis, and eosinophilia. Petechial hemorrhages may occur.

Cutaneous schistosomal granulomas most frequently involve the genitalia, perineum, and buttocks. The eggs of *S. haematobium* or *S. mansoni* usually cause these bilharziomas (Fig. 20.15). Vegetating, soft, cauliflower-shaped masses, fistulous tracts, and extensive hard masses occur; these are riddled by sinuses that exude a seropurulent discharge with a characteristic odor. Phagedenic ulcerations and pseudoelephantiasis of the scrotum, penis, or labia are sometimes encountered. Histologically, the nodules contain bilharzial ova undergoing degeneration, with calcification and a surrounding cellular reaction of histiocytes, eosinophils, and occasional giant cells. In some cases, eventual malignant changes have been noted in chronic lesions. Animal studies have shown a moderate helper T-cell type 1 (Th1) response to parasite antigens in most tissues, but a strong Th2 response that propagates fibrogenesis within the liver. Infrequently, ectopic or extragenital lesions may occur, mainly on the trunk. This is a papular eruption tending to group in plaques and become darkly pigmented and scaly. A severe urticarial eruption known as urticarial fever or Katayama fever is frequently present along with *S. japonicum* infection; it occurs with the beginning of oviposition, 4–8 weeks after infection. This condition is seen mainly in China, Japan, and the Philippines. In addition to the urticaria, fever, malaise, abdominal cramps, arthritis, and liver/spleen involvement are seen. This is thought to be a serum sickness–like reaction.

Preventive measures include reducing infection sources, preventing contamination by human excreta of snail-bearing waters, control of snail hosts, and avoiding exposure to cercaria-infested waters. Prophylactic measures are constantly sought to control one of the world's worst parasitic diseases, but as yet, none has been found to be practical. For both *S. haematobium* and *S. mansoni*,

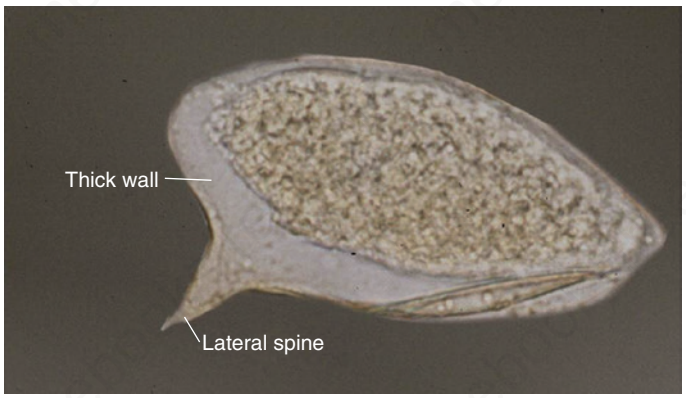

Fig. 20.15 Ova of *Schistosoma mansoni* are characterized by a thick chitinous wall and lateral spine.

praziquantel (Biltricide), 40 mg/kg orally for each of two treatments in 1 day, is the therapy of choice. *S. japonicum* treatment requires 60 mg/kg in three doses in 1 day. Schistosomicides exhibit toxicity for the host as well as for the parasite, and the risk of undesirable side effects may be enhanced by concomitant cardiac, renal, or hepatosplenic disease.

Patel TA, et al: Treatment of schistosomiasis in a patient allergic to praziquantel. Am J Trop Med Hyg 2016; 95: 1041.

Cysticercosis Cutis

The natural intermediate host of the pork tapeworm, *Taenia solium*, is the pig, but under some circumstances, humans act in this role. The larval stage of *T. solium* is *Cysticercus cellulosae*. Infection takes place by the ingestion of food contaminated with the eggs or by reverse peristalsis of eggs or proglottides from the intestine to the stomach. Here the eggs hatch, freeing the oncospheres. These enter the general circulation and form cysts in various parts of the body, such as striated muscles, brain, eye, heart, and lung.

In the subcutaneous tissues, the lesions are usually painless nodules that contain cysticerci. They are more or less stationary, usually numerous, and often calcified and are therefore demonstrable radiographically. Pain and ulceration may accompany the lesions. The disease is most prevalent in countries where pigs feed on human feces. It may be confused with gumma, lipoma, and epithelioma. A positive diagnosis is established solely by incision and examination of the interior of the calcified tumor, where the parasite will be found. Fine-needle aspiration has also been used to establish the diagnosis.

Albendazole or praziquantel is effective; however, the status of the CNS, spinal, and ocular involvement needs to be thoroughly assessed before treatment. The length of therapy and use of concomitant corticosteroids depend on the location of the cysts. However, none of the regimens clears the calcified parasites, which need to be surgically removed.

Sparganosis

Sparganosis is caused by the larva of the tapeworm *Spirometra*. The adult tapeworm lives in the intestines of dogs and cats. This is a rare tissue infection occurring in two forms. Application sparganosis occurs when an ulcer or infected eye is poulticed with the flesh of an infected intermediate host (such poultices are frequently used in the Orient). The larvae become encased in small nodules in the infected tissue. Ingestion sparganosis occurs when humans ingest inadequately cooked meat, such as snake or frog, or when a person drinks water that is contaminated with *Cyclops*, which is infected with plerocercoid larvae. One or two slightly pruritic or painful nodules may form in the subcutaneous tissue or on the trunk, breast, genitalia, or extremities. Cerebral disease may also occur. Diagnosis is usually made by excision of the nodule, although noninvasive imaging has also been used.

Humans are the accidental intermediate host of the sparganum, which is the alternative name for the plerocercoid larva. Treatment is surgical removal or ethanol injection of the infected nodules (Fig. 20.16). This may be difficult because of the swelling and extensive vascularity.

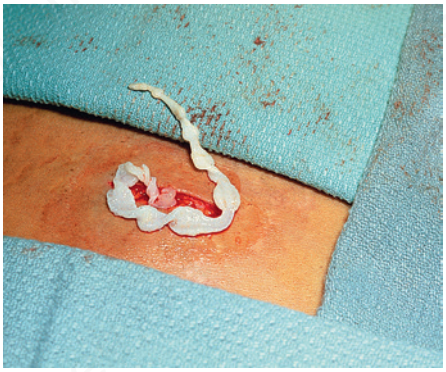

Fig. 20.16 Sparganosis.

Echinococcosis

Echinococcosis is also known as hydatid disease. In humans, infection is produced by the ova reaching the mouth from the hands, in food, or from containers soiled by ova-contaminated feces from an infected dog. This leads to *Echinococcus granulosus* infestation of the liver and the lungs. Soft, fluctuating, semitranslucent, cystic tumors may occur in the skin, sometimes in the supraumbilical area as fistulas from underlying liver involvement. These tumors become fibrotic or calcified after the death of the larva. Eosinophilia, intractable urticaria and pruritus, and even acute generalized exanthematous pustulosis may be present. Such reactive findings may be present as skin manifestations of many of the helminthic infections, including other types of tapeworm. The treatment is excision, with care being taken to avoid rupturing the cyst. Albendazole combined with percutaneous drainage may also be used. *Hymenolepis nana* is a cosmopolitan dwarf tapeworm endemic in the tropics that may cause a treatment-resistant pruritic papular eruption associated with eosinophilia. Stool specimens for ova and parasites are definitive, and praziquantel is curative.

Moosazadeh M, et al: Epidemiological and clinical aspects of patients with hydatid cyst in Iran. J Parasit Dis 2017; 41: 356.

PHYLUM ANNELIDA

LEECHES

Leeches, of the class Hirudinea, are of marine, freshwater, or terrestrial types. After attaching to the skin or mucosa, they secrete an anticoagulant, hirudin, and then engorge themselves with blood. Local symptoms at the site of the bite may include bullae, hemorrhage, pruritus, whealing, necrosis, or ulceration. Allergic reactions, including anaphylaxis, may result. Leeches may be removed by applying salt, alcohol, or vinegar or by use of a match flame. Bleeding may then be stopped by direct pressure or by applying a styptic pencil to the site.

Leeches may be used medicinally to salvage tissue flaps that are threatened by venous congestion. However, bleeding, *Aeromonas* infection, anetoderma, and pseudolymphoma may be complications of their attachment.

Tilahun T: Vaginal leech infestation. Ethiop J Health Sci 2015; 25: 377.

PHYLUM NEMATHELMINTHES

Phylum Nemathelminthes includes the roundworms, both free-living and parasitic forms. Multiplication is usually outside the host. Both the larval and the adult stage may infect humans.

CLASS NEMATODA

Enterobiasis (Pinworm Infection, Seatworm Infection, Oxyuriasis)

The chief symptom of pinworm infestation, which occurs most frequently in children, is nocturnal pruritus ani. There is intense

itching accompanied by excoriations of the anus, perineum, and pubic area. The vagina may become infested with the gravid pinworms. A pruritic papular dermatosis of the trunk and extremities may be observed infrequently. Restlessness, insomnia, enuresis, and irritability are a few of the many symptoms ascribed to this exceedingly common infestation. Exacerbation of mastocytosis has been described.

Oxyuriasis is caused by the roundworm *Enterobius vermicularis*, which may infest the small intestines, cecum, and large intestine of humans. The worms, especially gravid ones, migrate toward the rectum and at night emerge to the perianal and perineal regions to deposit thousands of ova; then the worm dries and dies outside the intestine. These ova are then carried back to the mouth of the host on the hands. The larvae hatch in the duodenum and migrate into the jejunum and ileum, where they reach maturity. Fertilization occurs in the cecum, thus completing the life cycle.

Humans are the only known host of the pinworm, which probably has the widest distribution of all the helminths. Infection occurs from hand-to-mouth transmission, often from handling soiled clothes, bedsheets, and other household articles. Ova under the fingernails are a common source of autoinfection. Ova may also be airborne and collect in dust that may be on furniture and the floor. Investigation may show that all members of the family of an affected person also harbor the infection. It is common in orphanages and mental institutions and among people living in communal groups.

Rarely is it feasible to identify a dead pinworm in the stool. Diagnosis is best made by demonstration of ova in smears taken from the anal region early in the morning before the patient bathes or defecates. Such smears may be obtained with a small, eye curette and placed on a glass slide with a drop of saline solution. It is also possible to use cellophane tape, looping the tape sticky-side out over a tongue depressor and then pressing it several times against the perianal region. The tape is then smoothed out on a glass slide. A drop of a solution containing iodine in xylol may be placed on the slide before the tape is applied to facilitate detection of any ova. These tests should be repeated on 3 consecutive days to rule out infection. Ova may be detected under the fingernails of the infected person.

Albendazole, 400 mg, or mebendazole, 100 mg, or pyrantel pamoate, 11 mg/kg (maximum 1 g), given once and repeated in 2 weeks, is effective. Personal hygiene and cleanliness at home are important. Fingernails should be cut short and scrubbed frequently; nails should be thoroughly cleaned on arising, before each meal, and after using the toilet. Sheets, underwear, towels, pajamas, and other clothing of the affected person should be laundered thoroughly and separately.

Hookworm Disease (Ground Itch, Uncinariasis, Ancylostomiasis, Necatoriasis)

The earliest skin lesions (ground itch) are erythematous macules and papules, which in a few hours become vesicles. These itchy lesions usually occur on the soles, toe webs, and ankles; they may be scattered or in groups. The content of the vesicles rapidly becomes purulent. These lesions are produced by invasion of the skin by the *Ancylostoma* or *Necator* larvae, and they precede the generalized symptoms of hookworm disease by 2 or 3 months. The cutaneous lesions last less than 2 weeks before the larvae continue their human life cycle. There may be as high as 40% eosinophilia about the fifth day of infection.

The onset of the constitutional disease is insidious and is accompanied by progressive iron deficiency anemia and debility. During the course of hookworm disease, urticaria often occurs. The skin ultimately becomes dry and pale or yellowish.

Hookworm is a specific communicable disease caused by *Ancylostoma duodenale* or *Necator americanus*. In the soil, under propitious circumstances, hookworms attain the stage of infective larvae in 5–7 days. When they come into accidental contact with bare feet, these tiny larvae (which can scarcely be seen with a small pocket lens) penetrate the skin and reach the capillaries. They are carried in the circulation to the lungs, where they pass through the capillary walls into the bronchi. They move up the trachea to the pharynx and, after being swallowed, eventually reach their habitat in the small intestine. Here they bury their heads in the mucosa and begin their sexual life.

Hookworm is prevalent in most tropical and subtropical countries and is often endemic in swampy and sandy localities in temperate zones. In these latter regions, the larvae are killed off each winter, but the soil is again contaminated from human sources the following summer. *N. americanus* prevails in the Western Hemisphere, Central and South Africa, South Asia, Australia, and the Pacific islands.

The defecation habits of infected individuals in endemic areas are largely responsible for its widespread distribution, as is the use of human feces for fertilization in many parts of the world. In addition, the climate is usually such that people go barefoot because of the heat or because they cannot afford shoes. Infection is thereby facilitated, especially through the toes.

Finding the eggs in the feces of a suspected individual establishes the diagnosis. The ova appear in the feces about 5 weeks after the onset of infection. The eggs may be found in direct fecal films if the infection is heavy, but in light infections, it may be necessary to resort to zinc sulfate centrifugal flotation or other concentration methods. Mixed infections frequently occur.

Albendazole, 400 mg once, or mebendazole, 100 mg twice daily for 3 days or 500 mg once, or pyrantel pamoate, 11 mg/kg (maximum 1 g) each day for 3 days, is effective. Prophylaxis is largely a community problem and depends on preventing fecal contamination of the soil. This is best attained by proper sanitary disposal of feces, protecting individuals from exposure by educating them about sanitary procedures, and mass treatment through public health methods.

Nematode Dermatitis

A patient in one report developed a persistent widespread folliculitis caused by *Ancylostoma caninum*. It was apparently acquired by lying in grass contaminated by the droppings of the patient's pet dogs and cats. A biopsy revealed hookworm larvae within the hair follicle. Oral thiabendazole was curative.

Creeping Eruption (Larva Migrans)

Creeping eruption is a term applied to twisting, winding linear skin lesions produced by the burrowing of larvae. People who go barefoot on the beach, children playing in sandboxes, carpenters and plumbers working under homes, and gardeners are often victims. The most common areas involved are the feet, buttocks, genitals, and hands.

Slight local itching and the appearance of papules at the sites of infection characterize the onset. Intermittent stinging pain occurs, and thin, red, tortuous lines are formed in the skin. The larval migrations begin 4 days after inoculation and progress at the rate of about 2 cm/day. However, they may remain quiescent for several days or even months before beginning to migrate. The linear lesions are often interrupted by papules that mark the sites of resting larvae (Fig. 20.17). As the eruption advances, the old parts tend to fade, although purulent manifestations may be caused by secondary infection in some cases; erosions and excoriations caused by scratching frequently occur. If the progress of the disease is not interrupted by treatment, the larvae usually die in 2–8 weeks, with resolution of the eruption, although rarely it has been reported to persist for up to 1 year. At times, the larvae are removed from the skin by the fingernails in scratching. Eosinophilia may be present.

Fig. 20.17 Cutaneous larva migrans.

Loeffler syndrome, consisting of a patchy infiltrate of the lungs and eosinophilia as high as 50% in the blood and 90% in the sputum, may complicate creeping eruption.

The majority of U.S. cases of larva migrans occur along the southeast coast and are caused by penetration by the larvae of a cat and dog hookworm, *Ancylostoma braziliense*. It is acquired from body contact with damp sand or earth that has been contaminated by the excreta of dogs and cats. The larvae of *A. caninum*, which also infests the dog and the cat, rarely produce a similar dermatitis. The diagnosis is typically made clinically, although biopsy may sometimes demonstrate the organism, and even dermoscopy has been used.

Ivermectin, 200 µg/kg, generally given as a single 12-mg dose and repeated the next day, or albendazole, 400 mg/day for 3 days, is an effective treatment. Criteria for successful therapy are relief of symptoms and cessation of tract extension, which usually occurs within 1 week. Both ivermectin and metronidazole have been used topically, as has thiabendazole, compounded as a 10% suspension or a 15% cream. Another condition, not to be confused with this helminthic disease, which also is called creeping eruption (or sandworm, as it is known in South Africa, particularly in Natal and Zululand), is caused by a small mite about 300 µm long that tunnels into the superficial layers of the epidermis.

Gnathostomiasis

Migratory, intermittent, erythematous, urticarial plaques characterize human gnathostomiasis. Each episode of painless swelling lasts from 7–10 days and recurs every 2–6 weeks. Movement of the underlying parasite may be as much as 1 cm/hr. The total duration of the illness may be 10 years. Histopathologic examination of the skin swelling will demonstrate eosinophilic panniculitis. The clinical manifestation has been called larva migrans profundus.

The nematode *Gnathostoma dolorosi* or *G. spinigerum* is the cause, and most cases occur in Asia or South America. Eating raw flesh from the second intermediate host, most often freshwater fish, especially eel, in such preparations as sashimi and ceviche, allows humans to become the definitive host. Eating raw squid or snake is a less common exposure. As the larval cyst in the flesh is digested, it becomes motile and penetrates the gastric mucosa, usually within 24–48 hours of ingestion. Symptoms then occur as migration of the parasite continues. Surgical removal is the treatment of choice, if the parasite can be located. This may be combined with albendazole, 400 mg/day or twice daily for 21 days, or ivermectin, 200 µg/kg/day for 2 days.

Creeping eruption caused by a recently recognized causative parasite of the nematode superfamily Spiruroidea has been reported in Japan. Eating raw squid was associated with the onset of long, narrow lesions that were pruritic, linear, and migratory. Surgical removal is the treatment of choice currently, as data on ivermectin are mixed.

Larva Currens

Intestinal infections with *Strongyloides stercoralis* may be associated with a perianal larva migrans syndrome called larva currens because of the rapidity of larval migration (currens means "running" or "racing"). Larva currens is an autoinfection caused by penetration of the perianal skin by infectious larvae as they are excreted in the feces. An urticarial band is the prominent primary lesion of cutaneous strongyloidiasis. Strongyloidiasis, as with the creeping eruption secondary to it, is often a chronic disease; infections may persist for more than 40 years. Approximately one third of patients infected are asymptomatic.

Signs and symptoms of systemic strongyloidiasis include abdominal pain, diarrhea, constipation, nausea, vomiting, pneumonitis, urticaria, eosinophilic folliculitis, and a peripheral eosinophilia. The skin lesions originate within 30 cm of the anus and characteristically extend as much as 10 cm/day.

Fatal cases of hyperinfection occur in immunocompromised patients; the parasite load increases dramatically and can produce a fulminant illness. Widespread petechiae and purpura are helpful diagnostic signs of disseminated infection, and chronic urticaria is a possible presenting sign. Periumbilical ecchymoses may appear as if they were caused by a thumbprint.

Administration of ivermectin, 200 µg/kg/day for 2 days, or thiabendazole, 50 mg/kg/day in two doses (maximum 3 g/day) for 2 days, is the treatment of choice. Immunosuppressed hosts may be treated with thiabendazole, 25 mg/kg twice daily for 7–10 days.

Free-living strongyloides known as *Pelodera* can also produce a creeping eruption. In one reported case, widespread follicular, erythematous, dome-shaped papules and pustules appeared on the patient within 24 hours of working under a house. This eruption persisted for 1 month before presentation. Scraping the lesions revealed live and dead larvae of the free-living soil nematode *Pelodera strongyloides*. Treatment with oral thiabendazole led to resolution.

Dracunculiasis (Guinea Worm Disease, Dracontiasis, Medina Worm)

Guinea worm disease is now limited to remote villages in several sub-Saharan African countries. It is caused by *Dracunculus medinensis* and is contracted through drinking water that has been contaminated with infected water fleas in which *Dracunculus* is parasitic. In the stomach, the larvae penetrate into the mesentery, where they mature sexually in 10 weeks. The female worm then burrows to the cutaneous surface to deposit her larvae and thus causes the specific skin manifestations. As the worm approaches the surface, it may be felt as a cordlike thickening and forms an indurated cutaneous papule. The papule may vesiculate, and a painful ulcer develops, usually on the leg. The worm is often visible. When the parasite comes in contact with water, the worm rapidly discharges its larvae, which are ingested by water fleas *(Cyclops)*, contaminating the water.

Fig. 20.18 Dracunculiasis.

Fig. 20.19 Filarial elephantiasis.

The cutaneous lesion is usually on the lower leg, but it may occur on the genitalia, buttocks, or arms (Fig. 20.18). In addition to the ulcers on the skin, there may be urticaria, GI upset, eosinophilia, and fever.

Dracunculiasis may be prevented by boiling drinking water, providing safe drinking water through boreholes, or filtering the water through mesh fibers. Native treatment consists of gradually extracting the worm a little each day, taking care not to rupture it; otherwise, the larvae escape into the tissues and produce fulminating inflammation. Surgical removal is the treatment of choice. Metronidazole, 500 mg/day, resolves the local inflammation and permits easier removal of the worm. Immersion in warm water promotes emergence of the worm. Global eradication is within reach, and Guinea worm disease may become a historical footnote.

Filariasis

Elephantiasis Tropica (Elephantiasis Arabum)

Filariasis is a widespread tropical disorder caused by infestation with filarial worms of *Wuchereria bancrofti*, *Brugia malayi*, or *Brugia timori* species. It is characterized by lymphedema, with resulting hypertrophy of the skin and subcutaneous tissues, and by enlargement and deformity of the affected parts, usually the legs, scrotum, or labia majora. The disease occurs more frequently in young men than women.

The onset of elephantiasis is characterized by recurrent attacks of acute lymphangitis in the affected part, associated with chills and fever (elephantoid fever) that last for several days to several weeks. These episodes recur over several months to years. After each attack, the swelling subsides only partially, and as recrudescences supervene, thickening and hypertrophy become increasingly pronounced. The overlying epidermis becomes stretched, thin, and shiny, and over years, leathery, insensitive, and verrucous or papillomatous from secondary pyogenic infection. The patient may have a dozen or more attacks in a year.

In addition to involvement of the legs and scrotum, the scalp, vulva, penis, female breasts, and arms can be affected, either alone or in association with the other regions. The manifestations vary according to the part involved. When the legs are attacked, both are usually affected somewhat symmetrically, with the principal changes occurring on the posterior aspects above the ankles and on the dorsa of the feet. At first, the thickening may be slight and associated with edema that pits on pressure. Later, the parts become massive and pachydermatous, the thickened integument hanging in apposing folds, between which there is a fetid exudate (Fig. 20.19).

When the scrotum is affected, it gradually reaches an enormous size, and the penis becomes hidden in it. The skin, which at first is glazed, is later coarse and verrucous, or in far-advanced cases, ulcerated or gangrenous. Resistant urticaria may occur. Filarial orchitis and hydrocele are common. A testicle may enlarge rapidly to the size of an apple and may be extremely painful. The swelling may subside within a few days, or the enlargement may be permanent. As a result of obstruction and dilation of the thoracic duct or some of its lower abdominal tributaries into the urinary tract, chyle appears in the urine, which assumes a milky appearance. Lobulated swellings of the inguinal and axillary glands, called varicose glands, are caused by obstructive varix and dilation of the lymphatic vessels.

Filaria are transmitted person to person by the bites of a variety of mosquitoes of the *Culex*, *Aedes*, and *Anopheles* species. The adult worms are threadlike, cylindrical, and creamy white. The females are 4–10 cm long. Microfilarial embryos may be seen as coiled, each in its own membrane near the posterior tip. Fully grown, sheathed microfilariae are 130–320 μm long. The adult worms live in the lymphatic system, where they produce microfilariae. These either remain in the lymphatic vessels or enter the peripheral bloodstream. An intermediate host is necessary for the further development of the parasite.

It is important to realize that infestation by the filaria is often asymptomatic, and elephantiasis usually occurs only if hundreds of thousands of mosquito bites occur over a period of years, with episodes of intercurrent streptococcal lymphangitis. Filariasis was endemic in the considerable Samoan population of Hawaii for half a century, and only one case of elephantiasis has occurred among this group.

The microfilariae should be sought on fresh coverslip films of blood (collected at night), urine, or other body fluid and examined with a low-power objective lens. Calcified adult worms may be demonstrated on x-ray examination, and ultrasound can detect adult worms. At times, adult filariae are found in abscesses or in material taken for pathologic examination. Specific serologic tests and a simple card test for filarial antigen are available. The prognosis in regard to survival is good, but living becomes burdensome unless the condition is alleviated.

Diethylcarbamazine, in increasing doses over a 14-day period, is the treatment of choice. This regimen clears microfilariae but not adult worms. A single dose of ivermectin may also be effective. Doxycycline and rifampicin kill the intracellular symbiotic bacteria, *Wolbachia*. This leads to long-term sterility of adult female worms and both are being studied to determine their place in the treatment of both bancroftian filariasis and onchocerciasis. A worldwide effort to eliminate these diseases is underway. Surgical procedures have

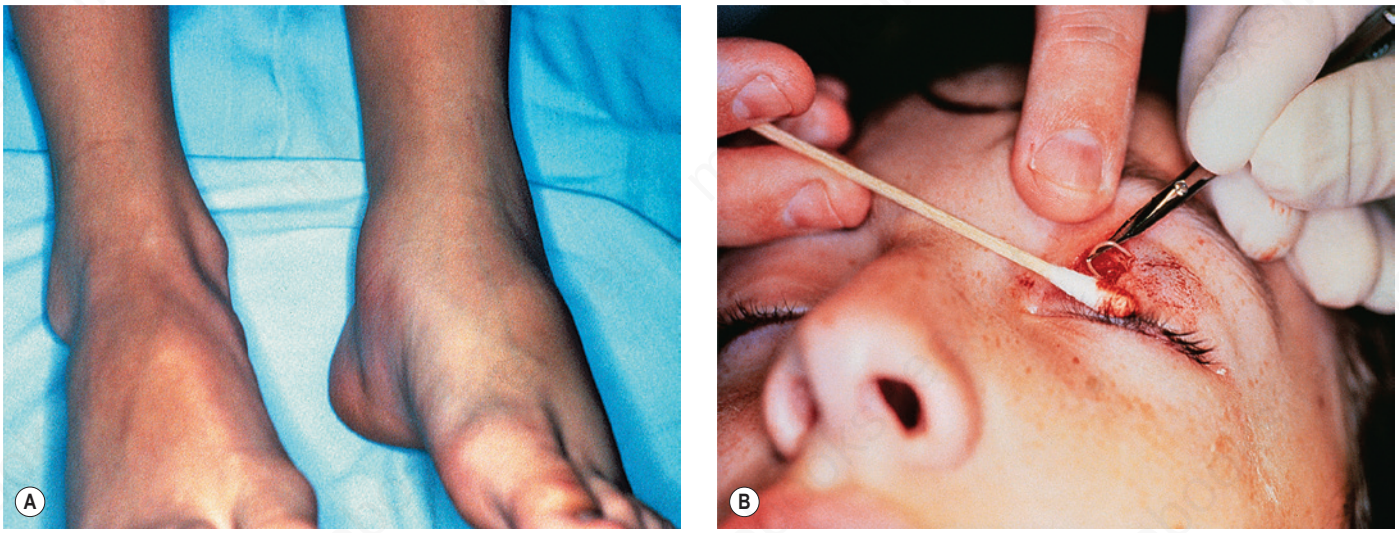

Fig. 20.20 (A and B) Loiasis. (Courtesy Curt Samlaska, MD.)

been devised to remove the edematous subcutaneous tissue from the scrotum and breast. Prophylactic measures consist of appropriate mosquito control. Diethylcarbamazine has been effective in mass prophylaxis. If a trip of over 1 month to areas with endemic *Wuchereria bancrofti* is planned and extensive exposure to mosquitoes is likely, taking diethylcarbamazine, 500 mg/day for 2 days each month, is recommended.

Loiasis (Loa Loa, Calabar Swelling, Tropical Swelling, Fugitive Swelling)

Infection with *Loa loa* is often asymptomatic. In infected persons, the parasite develops slowly, and even 3 years can elapse between infection and appearance of symptoms, although the usual interval is 1 year. The first sign is often painful, localized, subcutaneous, nonpitting edema called Calabar or fugitive swelling (Fig. 20.20A). One or more, slightly inflamed, edematous, transient swellings occur, usually about the size of a hen's egg. They typically last a few days and then subside, although recurrent swellings at the same site may eventually lead to a permanent, cystlike protuberance. These swellings may result from hypersensitivity to the adult worm or to materials elaborated by it. Eosinophilia may be as high as 90% and often is 60%–80%.

The filariae may be noticed subcutaneously in the fingers, breasts, eyelids, or submucosally under the conjunctivae. The worm may be in the anterior chamber of the eye, the myocardium, or other sites. It has a predilection for loose tissues such as the eye region, the frenum of the tongue, and the genitalia. The wanderings of the adult parasite may be noticed because of a tingling and creeping sensation. The death of the filaria in the skin may lead to the formation of fluctuant cystic lesions.

Loiasis is widely distributed in West and Central Africa, where it is transmitted by the mango fly, *Chrysops dimidia* or *Chrysops silacea*. This fly bites only in the daytime. Humans are the only important reservoir for the parasite. The observation of the worm under the conjunctiva, Calabar swellings, eosinophilia, and microfilariae in peripheral blood establish the diagnosis. Demonstration of the characteristic microfilariae in the blood during the day is possible in only about 20% of patients. Specific serologic tests are available, and luciferase immunoprecipitation systems can provide rapid diagnostic results, with improved sensitivity and specificity compared with enzyme-linked immunosorbent assay (ELISA).

Removal of the adult parasite whenever it comes to the surface of the skin is mandatory (Fig. 20.20B). This must be done quickly by seizing the worm with forceps and placing a suture under it before cutting down to it. Worms that are not securely and rapidly grasped may escape into the deeper tissues.

Fig. 20.21 Onchocerciasis with papules and dyspigmentation. (Courtesy Scott Norton, MD.)

Diethylcarbamazine kills both adults and microfilariae and is given in increasing doses for 21 days. In regions where onchocerciasis and loiasis both are endemic, and where ivermectin is used in a community-based elimination strategy for onchocerciasis, simultaneously infected patients with a high *L. loa* load have a greater risk of serious side effects. If ivermectin treatment of these patients is undertaken, proper monitoring and appropriate supportive treatment should be available in anticipation of this risk. Diethylcarbamazine is an effective chemopreventive therapy, using 300 mg/week in temporary residents of regions of Africa where *L. loa* is endemic.

Onchocerciasis

The skin lesions of onchocerciasis are characterized by pruritus, dermatitis, and onchocercomas. The dermatitis is variable in appearance, probably related to chronicity of infection, age of the patient, geographic area where acquired, and relative immune responsiveness. Early in the course of the infection, an itchy papular dermatitis may occur (Fig. 20.21), and in visitors who become infected, this may be localized to one extremity. In Central America, papules may appear only on the head and neck area. This unusual

localization of insect bite–appearing papules with excoriations may lead to the diagnosis in travelers returning to their home countries. In Central America, another manifestation of the acute phase of onchocerciasis is acute swelling of the face with erythema and itching, known as erisipela de la costa. In Zaire and Central America, an acute urticarial eruption is seen. The inflammation, which is accompanied by hyperpigmentation, is known as mal morado.

As time passes, the dermatitis becomes chronic and remains papular; however, thickening, lichenification, and depigmentation occur. Later, atrophy may supervene. When the depigmentation is spotted, it is known as leopard skin; when the skin is thickened, it is called elephant skin. When local edema and thickened, wrinkled, dry dermatitic changes predominate, it is sometimes called lizard skin.

In Saudi Arabia, Yemen, and East Africa, a localized type of onchocerciasis exists called sowda, Arabic for "black." It is characterized by localized, pruritic, asymmetric, usually darkly pigmented, chronic lichenified dermatitis of one leg or one body region. It is also known as the chronic hyperreactive type, and an association with antidefensin antibodies suggests a reason for this enhanced reactivity against the parasite.

After a time, firm subcutaneous nodules, pea-sized or larger, develop on various sites of the body. These nodules are onchocercomas (Fig. 20.22) containing myriad microfilariae. These occur in crops, are frequently painful, and their site varies. In parts of Africa, where natives are wholly or nearly unclothed, the lesions occur on the trunk, axillae, groin, and perineum. In Central and South America, the head, especially the scalp, is the usual site of involvement. Firm, nontender lymphadenopathy is a common finding in patients with chronically infected onchocerciasis. "Hanging groin" describes the loose, atrophic skin sack that contains these large inguinal nodes (Fig. 20.23). In about 5% of affected persons, serious eye lesions arise late in the disease, gradually leading to blindness.

Onchocerciasis is caused by *Onchocerca volvulus*, which is transmitted to humans by the bite of the black fly of the genus *Simulium*. It breeds in fast-flowing streams. When the black fly bites, it introduces larvae into the wound. The larvae reach adulthood in the subdermal connective tissue in about 1 year. Millions of the progeny then migrate back into the dermis and the aqueous humor of the eye.

Onchocerciasis occurs in Africa on the west coast, in the Sahara, Sudan, and the Victoria Nile division, where it is known as river blindness. In Central and South America, this disease can be found in Guatemala, Brazil, Venezuela, and southern Mexico.

The presence of eosinophilia, skin lesions, and onchocercomas with ocular lesions is highly suggestive in endemic areas. Frequently, the microfilariae may be found in skin shavings or dermal lymph, even when no nodules are detectable. The scapular area is the favorite site for procuring specimens for examination by means of a skin snip. This is performed in the field or office by lifting the skin with an inserted needle and then clipping off a small, superficial portion of the skin with a sharp knife or scissors. The specimen is laid in a drop of normal saline solution on a slide with a coverslip and examined under the microscope. The filariae wriggle out at the edges of the skin slice.

Specific serologic and PCR-based diagnostic tests from blood and skin biopsies are available. Other filarial parasites can be detected in similar systems. When patients with suspected onchocerciasis were given a single oral dose of 50 mg of diethylcarbamazine, a reaction consisting of edema, itching, fever, arthralgias, and exacerbation of pruritus was described as a positive Mazzotti test reaction, which supported the diagnosis of onchocerciasis.

Community-based treatment protocols have the objective of eliminating onchocerciasis from endemic areas. Severe reactions, including neurologic disease, may occur in patients simultaneously infected with *Loa loa*. Onchocercomas may be surgically excised whenever feasible. Ivermectin as a single oral dose of 150 µg/kg is the drug of choice. Skin microfilaria counts remain low at the end of 6 months' observation. Ivermectin should be repeated every 6 months to suppress the dermal and ocular microfilarial counts. More frequent dosing does not appear to reduce microfilarial counts further.

Doxycycline kills the intracellular symbiotic bacteria, *Wolbachia*, that appear to cause Mazzotti reactions and is being tested for long-term effects and determination of its place in the treatment of onchocerciasis and bancroftian filariasis. If there is eye involvement, prednisone, 1 mg/kg, should be started several days before treatment with ivermectin. Moxidectin and emodepside also appear promising as alternative drugs.

Trichinosis

Ingestion of *Trichinella spiralis* larva–containing cysts in inadequately cooked pork, bear, or walrus meat may cause trichinosis. It usually causes a puffy edema of the eyelids, redness of the conjunctivae, and sometimes urticaria or angioedema associated with hyperpyrexia, headache, erythema, GI symptoms, muscle pains, and

Fig. 20.22 Onchocercoma.

Fig. 20.23 Onchocerciasis.

neurologic signs and symptoms. Ten percent of patients develop a bilateral, asymptomatic hand swelling that is especially prominent over the digits, as well as erythema along the perimeters of the palms and volar surfaces of the digits, which progresses to desquamation. In 20% of cases, a nonspecific macular or petechial eruption occurs, and splinter hemorrhages are occasionally present. Eosinophilia is not constant but may be as high as 80%. In the average patient, eosinophilia begins about 1 week after infection and attains its height by the fourth week.

The immunofluorescence antibody test has the greatest value in establishing early diagnosis. The bentonite flocculation test, ELISA, and other serologic tests are limited by their inability to detect infection until the third or fourth week. Diagnosis is confirmed by a muscle biopsy that demonstrates larvae of *T. spiralis* in striated muscle. Unfortunately, trichinae cannot usually be demonstrated unless eosinophilic vasculitis and granulomas have been described on biopsy. A 2-mm-thick slice of the muscle biopsy may be compressed between two glass slides to demonstrate the cysts.

Trichinosis is treated with albendazole, 400 mg twice daily for 14 days. Corticosteroid agents are effective in controlling the often severe symptoms and should be given at doses of 40–60 mg/day.

PHYLUM ARTHROPODA

Phylum Arthropoda contains more species than all the other phyla combined. The classes of dermatologic significance are Myriapoda, Insecta, and Arachnida. Mosquitoes, flies, ticks, and fleas transmit diseases throughout the world. Although always prevalent, bites (Fig. 20.24) and stings increase dramatically after natural disasters such as hurricanes and flooding.

Prevention of Arthropod-Related Disease

Mosquitoes remain the most important vectors of arthropod-borne disease, and mosquito control programs are an essential component of the public health efforts of many U.S. states. Insect repellents are effective in preventing disease transmission and are especially important during travel to areas where vector-borne disease is endemic. Most are based on DEET (*N,N*-diethyl-3-methylbenzamide, previously called *N,N*-diethyl-*m*-toluamide). DEET has been tested against a wide range of arthropods, including mosquitoes, sandflies, ticks, and chiggers. The American Academy of Pediatrics recommends concentrations of 30% or less in products intended for use in children. Some evidence suggests that children do not have a higher incidence of adverse reactions than adults, but even in adults, neurotoxicity has been occasionally reported. High concentrations of DEET can produce erythema and irritation or bullous eruptions. Extended-release products reduce the need for repeated application and appear to minimize the risk of complications. Overall, DEET has a good safety record in widespread use. Picaridin is a piperidine-derived repellent ingredient that is also effective against a range of arthropods. Some studies have shown that picaridin is less irritating than DEET while providing comparable efficacy. The best studies for the evaluation of repellents are field trials that involve a range of arthropods. "Arm box" studies are still performed but must be interpreted with caution.

Fig. 20.24 Insect bites.

Citronella candles have little documented efficacy, but neem oil is an effective mosquito repellent used in many areas of the world that are endemic for malaria. Geraniol candles show some efficacy, but only in the area immediately surrounding the candles. Repellency decreases significantly at a distance of even 2 m. Candles with geraniol are twice as effective as those with linalool and five times as effective as those with citronella. IR3535 (ethyl-butyl-acetyl aminopropionate) in a variety of formulations has also demonstrated good efficacy against mosquitoes, with complete protection in field trials of 7.1–10.3 hours.

Travelers to malaria-endemic areas should follow CDC guidelines for malaria prophylaxis. They should also avoid nighttime outdoor exposure and use protective measures such as repellents and bed netting. The anopheline mosquitoes that carry malaria tend to bite at night, so bed nets and screens are important measures. Mosquitoes that carry dengue mostly bite during the day. Repellents play a greater role in protection against dengue, because it is more difficult to limit daytime outdoor activity. Mosquito control programs depend largely on drainage of stagnant water and spraying of breeding areas. In developing countries, water barrels may be stocked with fish or turtles to consume mosquito larvae. Both can soil the water, however, and the relative risks must be evaluated; some studies clearly show the risk favors stocking the barrel. Mosquito traps (e.g., Mosquito Magnet) have been effective for the control of mosquitoes in limited areas. Generally, mosquitoes fly upwind to bite and downwind to return to their resting area. Mosquito traps must be positioned between the breeding and resting areas and the area to be protected.

Mosquito traps commonly use carbon dioxide (CO_2), heat, and chemical attractants. Some *Culex* mosquitoes are repelled by octenol, and the manufacturer may provide guidelines for areas where the attractant should not be used.

Prevention of Disease From Ticks and Chiggers

Tick-borne diseases include rickettsial fevers, ehrlichiosis, Lyme disease, babesiosis, relapsing fever, and tularemia. Most require a sustained tick attachment of more than 24 hours for effective transmission, and frequent tick checks with prompt removal of ticks is an important strategy for the prevention of tick-borne illness. Unfortunately, tick inspections frequently fail to identify the tick in time for prompt removal. Some data suggest that adult ticks are found and removed only 60% of the time within 36 hours of attachment. Nymphal ticks are even more difficult to detect and may be removed in as few as 10% of patients within the first 24 hours. Because of this, repellents and acaricides remain critical for preventing tick-borne illness.

Permethrin has killing activity against a wide range of arthropods. Some North African *Hyalomma* ticks are resistant to permethrin and may exhibit a paradoxic pheromone-like attachment response when exposed to the agent, but permethrin performs very well with other species of tick, as well as mosquitoes and chiggers. It can be used to treat clothing, sleeping bags, mosquito netting, and tents. Permethrin-treated clothing, used in conjunction with a repellent, provides exceptional protection against bites in most areas of the world. Permethrin has a good record of safety, although there is a report of congenital leukemia with 11q23/*MLL* rearrangement in a preterm female infant whose mother had abused permethrin because of a pathologic fear of spiders. Permethrin can induce cleavage of the *MLL* gene in cell culture, providing a plausible link between the agent and the leukemia. It should be emphasized that permethrin in this case was not used according to the manufacturer's instructions, and the theoretic risk of carcinogenicity should be weighed against the very real risk of death from arthropod-borne disease. Cardiac glycosides have also been used topically as acaricides and have performed well in limited studies.

Ixodes scapularis is the major North American vector for Lyme disease, human granulocytic ehrlichiosis, and human babesiosis. A Lyme vaccine marketed in the United States was a commercial failure and withdrawn. Prevention of Lyme disease now centers on prevention of tick attachments and prompt tick removal. Backyards and recreational areas adjacent to wooded areas have higher rates of tick infestation. Tick numbers can be reduced by deer fencing, removal of leaf debris, application of an acaricide, and creation of border beds with wood chip mulch or gravel. Bait boxes and deer feeding stations can deliver a topical acaricide while the animal feeds. Parasitic wasps control tick numbers in nature, but wasp populations may fluctuate, and investment in wasp control may be a risky venture compared with other forms of tick control. Other natural forms of tick control have been investigated because of their potential to become self-sustaining in the environment, at least for a time; fungi and nematodes show some promise. In southern U.S. states, fire ants control tick populations by eating tick eggs.

Prevention of Flea-Borne Illness

Fleas are important vectors of plague and endemic typhus. They may also be vectors of cat-scratch disease. Lufenuron is a maturation inhibitor that prevents fleas from breeding. It is often used in oral and injectable forms for the prevention of flea infestation in cats and dogs. Fipronil is used topically for the prevention of flea and tick infestation. Other agents in use include imidacloprid, selamectin, and nitenpyram. House sprays often include pyrethroids or pyriproxyfen. Powdered boric acid may be helpful for the treatment of infested carpets or floor boards. A knowledgeable veterinarian and an exterminator should be consulted.

Fig. 20.25 Centipede bite.

CLASS MYRIAPODA

Morphologically and genetically, the class Myriapoda is distinct from other groups of arthropod. This group contains the centipedes and millipedes, both capable of producing significant skin manifestations.

Centipede Bites (Chilopoda)

Centipede bites are manifested by paired hemorrhagic marks that form a chevron shape caused by the large, paired mouthparts. The bite is surrounded by an erythematous swelling (Fig. 20.25) that may progress into a brawny edema or lymphangitis. Locally, there may be intense itching and pain, often associated with toxic constitutional symptoms. Most centipede bites run a benign, self-limited course, and treatment is only supportive. Children are often bitten when they try to handle centipedes. Some species of *Scolopendra* in the western United States will attain a length of 15–20 cm, and the child may describe it as a snake. Recognition of the characteristic chevron shape is important to avoid inappropriate treatment with snake antivenin. In the eastern United States, the common house centipede, *Scutigera coleoptrata*, does not bite humans. *Scolopendra subspinipes*, in Hawaii, inflicts a painful bite. As exotic species appear more often at pet stores and swap meets, envenomation by them will become more common.

In some tropical and subtropical areas, centipede bites account for about 17% of all envenomations, compared with 45% caused by snakes and 20% by scorpions. Most bites occur at home and involve an upper extremity. Local pain and edema occur in up to 96% of patients, depending on the species involved. Treatment is largely symptomatic. Rest, ice, and elevation may be sufficient, but topical or intralesional anesthetics may be required in some cases. Tetanus immunization should be considered if the patient has not been immunized within the past 10 years. Centipede bites can result in Wells syndrome, requiring topical or intralesional corticosteroids. Rarely, bites may produce more serious toxic responses, including rhabdomyolysis, myocardial ischemia, proteinuria, and acute renal failure. These have been reported after the bite of *Scolopendra heros*, the giant desert centipede. Although centipedes have sometimes been found in association with corpses, injuries from the centipede tend to be postmortem and are rarely the cause of death. Ingestion of centipedes by children is usually associated with transient, self-limited toxic manifestations.

Fig. 20.26 Millipede.

Millipede Burns (Diplopoda)

Some millipedes secrete a toxic liquid that causes a brownish pigmentation or burn when it comes into contact with skin. Burns may progress to intense erythema and vesiculation. Millipedes may be found in laundry hung out to dry, and millipede burns in children have been misinterpreted as signs of child abuse. Recognition of the characteristic curved shape of the burn can be helpful in preventing misdiagnosis. Some millipedes can squirt their venom, and ocular burns are reported. Washing off the toxin as soon as possible will limit the toxic effects. Other treatment is largely symptomatic.

Diplopods have evolved a complex array of chemicals for self-defense (Fig. 20.26). Some primates take advantage of these chemicals. Two millipede compounds, 2-methyl-1,4-benzoquinone and 2-methoxy-3-methyl-1,4-benzoquinone, demonstrate a repellent effect against *Aedes aegypti* mosquitoes. Tufted and white-faced capuchin monkeys anoint themselves with the secretions to ward off mosquitoes. Effective commercial repellents are available for human use; millipede juice is not recommended.

CLASS INSECTA

Order Lepidoptera

Order Lepidoptera includes butterflies, moths, and their larval forms, caterpillars. Severe systemic reactions have resulted from ingestion of some caterpillars, and with some species, the sting alone can produce severe toxicity. *Lonomia achelous*, found in Latin America, can cause a fatal bleeding diathesis. The Spanish pine caterpillar, *Thaumetopoea pityocampa*, causes both dermatitis and anaphylactoid symptoms. Pine caterpillars are also an important cause of systemic reactions in China and Israel. The tussock moth, *Orgyia pseudotsugata*, causes respiratory symptoms in forestry workers in Oregon.

Caterpillar Dermatitis

Irritation is produced by contact of caterpillar hairs with the skin. Toxins in the hairs can produce severe pain, local pruritic erythematous macules, and wheals, depending on the species. If the hairs embed in the clothing, widespread persistent dermatitis may result. Not only the caterpillars, but also their egg covers and cocoons usually contain stinging hairs. In the United States the most common caterpillars of medical importance are the brown-tail moth caterpillar *(Nygmia phoeorrhoea)*, puss caterpillar

Fig. 20.27 Puss caterpillar.

Fig. 20.28 Characteristic "railroad track" purpura of a puss caterpillar sting.

(Megalopyge opercularis) (Figs. 20.27 and 20.28), saddleback caterpillar (*Sibine stimulate;* Fig. 20.29), io moth caterpillar *(Automeris io)*, crinkled flannel moth caterpillar *(Megalopyge crispata)*, Oklahoma puss caterpillar *(Lagoa crispata)*, Douglas fir tussock moth caterpillar *(Orgyia pseudotsugata)*, buck moth caterpillar *(Hemileuca maia)*, and flannel moth caterpillar *(Norape cretata)*. The hairs of the European processionary caterpillar *(Thaumetopoea processionea)* are especially dangerous to the eyes, but ophthalmia nodosa (papular reaction to embedded hairs) can be seen with a wide variety of caterpillars and moths. Airborne processionary caterpillar hairs have caused large epidemics of caterpillar dermatitis.

Moth Dermatitis

Moth dermatitis may be initiated by the hairs of the brown-tail moth *(Euproctis chrysorrhoea)*, goat moth *(Cossus cossus)*, puss moth *(Dicranura vinula)*, gypsy moth *(Lymantria dispar)*, and Douglas fir tussock moth *(Hemenocampa pseudotsugata)*. In Latin America, the moths of the genus *Hylesia* are most frequently the cause of moth dermatitis. Severe conjunctivitis and pruritus are the first signs and may persist for weeks aboard ships that have docked in ports where the moth is common. Caripito itch is named after Caripito, Venezuela, a port city where the moth is found. Korean yellow moth dermatitis is caused by *Euproctis flava* Bremer. Saturnid caterpillars (*Lonomia* sp.) are associated with a severe and often

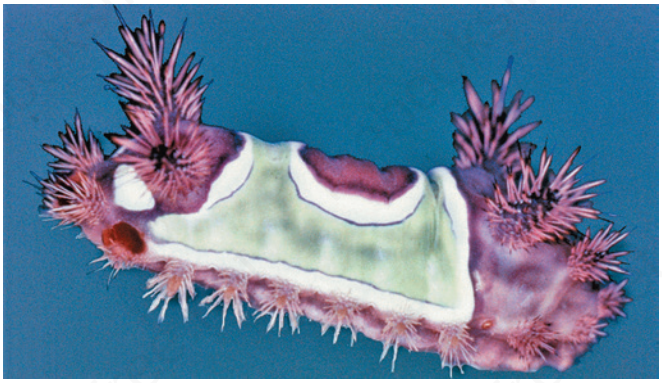

Fig. 20.29 Saddleback caterpillar.

Fig. 20.30 Bedbug.

fatal hemorrhagic diathesis. In India, inhalation of tiger moth fluids, scales and hairs has been implicated as a causes of severe fever and death during the monsoon season.

Topical applications of various analgesics, antibiotics, and oral antihistamines are of little help. Topical or oral corticosteroids are sometimes helpful, as is scrubbing and tape stripping of skin. Contaminated clothing may need to be discarded if dermatitis persists after the clothing is washed.

Wills PJ, et al: Population explosions of tiger moth Lead to lepidopterism mimicking infectious fever outbreaks. PLoS One 2016; 11: e0152787.

Order Hemiptera

The true bugs belong to the order Hemiptera. The order includes bedbugs, water bugs, chinch bugs, stink bugs, squash bugs, and reduviid bugs (kissing bugs, assassin bugs). The latter are vectors of South American trypanosomiasis. In most true bugs, the wings are half sclerotic and half membranous and typically overlap. In bedbugs, the wings are vestigial.

Cimicosis (Bedbug Bites)

Bedbugs have flat, oval bodies and retroverted mouthparts used for taking blood meals (Fig. 20.30). *Cimex lectularius* is the most common species in temperate climates, and *Cimex hemipterus* is most common in tropical climates. Both are reddish brown and about the size of a tick. *C. hemipterus* is somewhat longer than *C. lectularius*. They breed through traumatic insemination, in which the male punctures the female and deposits sperm into her body cavity. Bedbugs hide in cracks and crevices, then descend to feed while the victim sleeps. It is common for bedbugs to inflict a series of bites in a grouping or row ("breakfast, lunch, and dinner") (Fig. 20.31). Bites may mimic urticaria, and patients with papular urticaria commonly have antibodies to bedbug antigens. Unilateral eyelid swelling has been described as a common sign of bedbug bites in children. Bullous and urticarial reactions also occur. Bedbugs have been suggested as vectors for Chagas disease, *Bartonella quintana*, and hepatitis B, although data are sparse.

Fig. 20.31 Bedbug bites.

Bedbugs often infest bats and birds, and these hosts may be responsible for infestation in houses. Management of the infestation may require elimination of bird nests and bat roosts. Cracks and crevices should be eliminated and the area treated with an insecticide such as dichlorvos or permethrin. Because most insecticides have poor residual effect on mud bricks, wood, and fabric, frequent retreatment may be necessary. Microencapsulation of insecticides enhances persistence. Permethrin-impregnated bednets have been shown to be effective against bedbugs in tropical climates. Ivermectin treatment is emerging as a potential ancillary measure. Bedbugs that fed once on humans 3 hours after they received 200 μg/kg of oral ivermectin had a 63% mortality rate, and survivors were unable to complete their life cycle.

Raab RW, et al: New introductions, spread of existing matrilines, and high rates of pyrethroid resistance result in chronic infestations of bed bugs (*Cimex lectularius* L.) in lower-income housing. PLoS One 2016; 11: e0117805.

Zorrilla-Vaca A: Bedbugs and vector-borne diseases. Clin Infect Dis 2014; 59: 1351.

Reduviid Bites

Triatome reduviid bugs (kissing bugs, assassin bugs, conenose bugs) descend on their victims while they sleep and feed on an exposed area of skin. The bite is typically painless, although the bugs are capable of producing a more painful defensive bite. Swelling and itching occur within hours of the bite (Fig. 20.32). Many Latin American species have a pronounced gastrocolic reflex and defecate when they feed. Romana sign is unilateral eye swelling after a nighttime encounter with a triatome bug. It resembles the "eyelid sign" associated with bedbugs. *Trypanosoma cruzi* is transmitted

Fig. 20.32 Triatome bite.

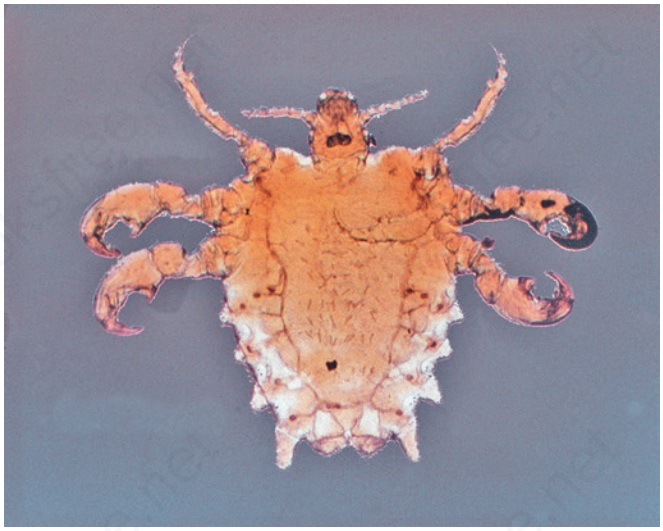

Fig. 20.33 Crab louse.

by the feces and rubbed into the bite. American trypanosomiasis can produce heart failure and megacolon. Triatome bugs infest thatch, cracks, and crevices, and infestation is associated with poor housing conditions. In nonendemic areas, bites are sporadic and often followed by a red swelling suggestive of cellulitis. Anaphylaxis has also occurred. A related arthropod, the wheel bug *Arilus cristatus*, is widely distributed and has an extremely painful defensive bite, but it is not known to carry disease.

Kapoor R, et al: What's eating you? Triatome reduviids. Cutis 2011; 87: 114.

Order Anoplura

Pediculosis

Three varieties of the flattened, wingless Anoplura insects infest humans: *Pediculus humanus* var. *capitis* (head louse), *P. humanus* var. *corporis* (body louse), and *Phthirus pubis* (pubic or crab louse) (Fig. 20.33). Rarely, zoonotic lice or louselike psocids will cause infestation.

Pediculosis Capitis. Pediculosis capitis is more common in children but also occurs in adults. Patients present with intense pruritus of the scalp and often have posterior cervical lymphadenopathy. Excoriations and small specks of louse dung are noted on the scalp, and secondary impetigo is common. Lice may be identified, especially when combing the hair. Nits may be present throughout the scalp but are most common in the retroauricular region. Generally, only those ova close to the scalp are viable, and nits noted along the distal hair shaft are empty egg cases. In extremely humid climates, however, viable ova may be present along the entire length of the hair shaft. Peripilar keratin (hair) casts are remnants of the inner root sheath that encircle hair shafts and may be mistaken for nits. Whereas nits are firmly cemented to the hair, casts move freely along the hair shaft. Head lice readily survive immersion in water but remain fixed to scalp hairs. There is no evidence that swimming pools contribute to the spread of head lice.

Effective therapeutic agents must kill or remove both lice and ova. Ulesfia (containing benzyl alcohol) is the first nonneurotoxic U.S. Food and Drug Administration (FDA)–approved treatment for lice and represents a significant advancement. Topical spinosad, 4% dimeticone liquid gel, malathion gel, and topical ivermectin are other innovations in the treatment of head lice, but permethrin remains the most widely used pediculicide in the United States, despite widespread resistance. It is available as an over-the-counter (OTC) 1% cream rinse (Nix) and a 5% prescription cream (Elimite) that is marketed for the treatment of scabies. The 1% cream rinse must be applied after shampooing and drying the hair completely. Applying to dry hair lessens dilution of the medication. Product labeling states the medication should be applied for 10 minutes, then rinsed off, but longer applications may be required. Shampooing should not take place for 24 hours afterward. Permethrin has a favorable safety profile, although congenital leukemia has been reported, as noted earlier, and the use of insecticidal shampoos is statistically associated with leukemia. Other reported side effects include acute onset of stuttering in a toddler. Pyrethrins, combined with piperonyl butoxide (RID, A-200, R+C shampoo), are other OTC products. Lindane is rarely used because of low efficacy and potential neurotoxicity. Carbaryl is used in many parts of the world, but not in the United States. Because of the potential toxicity associated with chemical pediculicides, future therapies will be asphyxiating agents, such as those containing benzyl alcohol or dimeticone. Cure rates with dimethicone are significantly higher than with permethrin in some studies, but some dimethicone products are flammable. Other agents that asphyxiate or desiccate contain isopropyl myristate 50% or Neem oil.

Nit combing is an important adjunct to treatment but is impractical as a primary method of therapy. Metal combs are more effective than plastic combs. Acidic cream rinses make the hair easier to comb but do not dissolve nit cement, which is similar in composition to amyloid. Various "natural" remedies are marketed that contain coconut oil, anise oil, and ylang ylang oil, but these agents are potential contact allergens, and data are sparse regarding their safety and efficacy. Some data support the efficacy of tea tree oil, which is more potent than lavender or lemon oil. Other studies also support combination lotions containing 5% lavender, peppermint, and eucalyptus oils, or 10% eucalyptus and peppermint oils in various combinations of water and alcohol. The addition of 10% 1-dodecanol improves efficacy.

Aliphatic alcohols show promise as pediculicides, and crotamiton (Eurax), an antiscabietic agent, has some efficacy in the treatment of pediculosis. Because no treatment is reliably ovicidal, retreatment in 1 week is reasonable for all patients.

Resistance to pediculicides is an emerging problem in many parts of the world. The emergence of resistance to an agent is related to the frequency of its use. Knockdown resistance (KDR) is a common mechanism of resistance that manifests as lack of immobilization of the lice. Responsible gene mutations (*T929I*

Fig. 20.34 Pediculosis corporis.

and *L932F*) have been identified and can be used to screen for KDR. Cross-resistance among pyrethroids is typical. In the United Kingdom, resistance to malathion has been reported, and multidrug-resistant lice have been identified. KDR results in slower killing of lice, but this may be overcome to some degree by longer applications. Monooxygenase-based resistance to pyrethrins may be overcome by synergism with piperonyl butoxide.

Simple public health measures are also of value when epidemics of louse infestation occur in schools. Hats, scarves, and jackets should be stored separately under each child's desk. Louse education and inspections by the school nurse facilitate targeted treatment of infested individuals.

Pediculosis Corporis. Pediculosis corporis (pediculosis vestimenti, "vagabond's disease") is caused by body lice that lay their eggs in the seams of clothing. The parasite obtains its nourishment by descending to the skin and taking a blood meal. Generalized itching is accompanied by erythematous (Fig. 20.34), blue and copper-colored macules, wheals, and lichenification. Secondary impetigo and furunculosis are common.

Body louse infestation is differentiated from scabies by the lack of involvement of the hands and feet, although infestation by both lice and scabies is common, and a given patient may have lice, scabies, and flea infestation.

Lice may live in clothing for 1 month without a blood meal. If discarding the clothing is feasible, this is best. Destruction of body lice can also be accomplished by laundering the clothing and bedding. Clothing placed in a dryer for 30 minutes at 65°C (149°F) is reliably disinfected. Pressing clothing with an iron, especially the seams, is also effective. Permethrin spray or 1% malathion powder can be used to treat clothing and reduce the risk of reinfestation.

Body lice are vectors for relapsing fever, trench fever, and epidemic typhus. These diseases are most prevalent among refugee populations. The trench fever organism is also an important cause of endocarditis among homeless persons.

Pediculosis Pubis (Crabs). Phthirus pubis, the crab louse, is found in the pubic region, as well as hairy areas of the legs, abdomen, chest, axillae, and arms. Pubic lice may also infest the eyelashes and scalp. The lice spread through close physical contact and are usually transmitted sexually. A diagnosis of pediculosis pubis should initiate a search for other STDs, including Human immunodeficiency virus (HIV) infection. Contaminated bedding is also a source of infestation. Pubic louse nits are attached to the hairs at an acute angle. Other than the presence of lice and nits in the hair, the signs and symptoms are similar to those of body louse infestation.

Occasionally, blue or slate-colored macules occur in association with pediculosis pubis. Called maculae ceruleae, these are located chiefly on the sides of the trunk and the inner aspects of the thighs and are probably caused by altered blood pigments.

Treatment of pediculosis pubis is similar to that for head lice. The affected person's sexual contacts should be treated simultaneously. For eyelash involvement, a thick coating of petrolatum can be applied twice daily for 8 days, followed by mechanical removal of any remaining nits. Fluorescein and 4% pilocarpine gel are also effective. Clothing and fomites should be washed and dried by machine, or laundered and ironed.

Order Diptera

Order Diptera includes the two-winged biting flies and mosquitoes. Adult dipterids bite and spread disease, whereas larvae parasitize humans in the form of myiasis. Medically important families of flies include the Tabanidae (horsefly, deerfly, gadfly), which inflict extremely painful bites, and the Muscidae (housefly, stablefly, tsetse fly). Tsetse fly bites transmit African trypanosomiasis. Simulidae include the black fly (buffalo gnat, turkey gnat), the vector of onchocerciasis. These flies are dark colored and "hunchbacked." They may produce extremely painful bites that may be associated with fever, chills, and lymphadenitis. Black flies are seasonal annoyances in the northern United States and Canada.

Psychodidae sandflies (Diptera: Phlebotominae) are small, hairy-winged flies that transmit leishmaniasis, sandfly fever, and verruga peruana. Sandfly fever viruses are a problem in Africa, the Mediterranean basin, and Central Asia and are carried by *Phlebotomus* flies. *Lutzomyia* flies are common in Latin America and south Texas.

Culicidae, or mosquitoes, are vectors of many important diseases, such as filariasis, malaria, dengue, and yellow fever. Their bites may cause severe urticarial reactions. Ceratopogonidae, the biting midges or gnats, fly in swarms and produce erythematous, edematous lesions at the site of their bite.

Mosquito Bites

Moisture, warmth, CO_2, estrogens, and lactic acid in sweat attract mosquitoes. Drinking alcohol also stimulates mosquito attraction. Mosquito bites are a common cause of papular urticaria. More severe local reactions are seen in young children, individuals with immunodeficiency, and those with new exposure to indigenous mosquitoes. Immediate-type hypersensitivity can be controlled with antihistamines, and prophylactic rupatadine, 10 mg daily, has been effective in the treatment of immediate mosquito-bite allergy. Both necrotizing fasciitis and the hemophagocytic syndrome have been reported after mosquito bites, and exaggerated hypersensitivity reactions to mosquito bites are noted in a wide variety of Epstein-Barr virus (EBV)–associated lymphoproliferative disorders, especially natural killer (NK) cell proliferations.

Mosquito bites may play a key role in reactivation of latent EBV infection.

Ked Itch

The sheep ked *(Melophagus ovinus)* feeds by thrusting its sharp mouthparts into the skin and sucking blood. Occasionally, it attacks woolsorters and sheepherders, causing pruritic, often hemorrhagic papules, typically with a central punctum. Deer keds attack humans in a similar way. The papules are persistent and may last for up to 12 months. Favorite locations are the hips and abdomen.

Myiasis

Myiasis is the infestation of human tissue by fly larvae. Forms of infestation include wound myiasis, furuncular myiasis, plaque myiasis, creeping dermal myiasis, and body cavity myiasis. Wound myiasis occurs when flies lay their eggs in an open wound. Furuncular myiasis often involves a mosquito vector that carries the fly egg. Plaque myiasis typically involves many maggots and occurs after flies lay their eggs on clothing. Creeping myiasis develops when the larvae of the *Gasterophilus* fly wander intradermally. The most common species are *Gasterophilus nasalis* and *Gasterophilus intestinalis*. An itching pink papule develops, followed by a tortuous line that extends by 1–30 cm a day. Body cavity myiasis may involve the orbit, nasal cavity, GI tract, or urogenital system.

The human botfly, *Dermatobia hominis*, is a common cause of furuncular myiasis in the neotropical regions of the New World (Fig. 20.35). The female glues its eggs to the body of a mosquito, stablefly, or tick. When the unwitting vector punctures the skin by biting, the larva emerges from the egg and enters the skin through the puncture wound. Over several days, a painful furuncle develops in which the larva is present. Other larvae that frequently cause furuncular lesions in North America are the common cattle grub *(Hypoderma lineatum)*, rabbit botfly *(Cuterebra cuniculi)*, and *Wohlfahrtia vigil*. The *W. vigil* fly can penetrate infant skin, but not adult skin, so almost all reported cases have occurred in infants. The New World screw worm, *Cochliomyia hominivorax*, often involves the head and neck region. Larvae of Calliphoridae flies, especially *Phaenicia sericata*, the green blowfly, cause wound myiasis. Other blowflies, flesh flies (Sarcophagidae), and humpbacked flies (Phoridae) are less common causes of wound myiasis. In tropical Africa, the Tumbu fly *(Cordylobia anthropophaga)* deposits her eggs on the ground or on clothing. The young maggots penetrate the skin and often form a plaque with many furuncular-appearing lesions. *Cordylobia ruandae* and *Cordylobia rodhaini* are less frequent causes of plaque myiasis. *Oestrus ovis* causes ophthalmomyiasis that may be misdiagnosed as bacterial conjunctivitis.

Removal of the maggots of furuncular myiasis can be accomplished by injection of a local anesthetic into the skin, which causes the larva to bulge outward. The opening of the furuncle can also be occluded with hair gel, surgical lubricant, lard, petrolatum, or bacon, causing the larva to migrate outward. Successful treatment with ivermectin has also been reported.

Order Coleoptera

Blister Beetle Dermatitis

Blister beetle dermatitis occurs after contact with several groups of beetle (Fig. 20.36). The Meloidae and Oedemeridae families produce injury to the skin by releasing a vesicating agent, cantharidin. Members of the family Staphylinidae (genus *Paederus*) contain a different vesicant, pederin. None of the beetles bites or stings; rather, they exude their blistering fluid if they are brushed against, pressed, or crushed on the skin. Many blister beetles are attracted at night by fluorescent lighting.

Slight burning and tingling of the skin occur within minutes, followed by the formation of bullae, often arranged linearly. "Kissing lesions" are observed when the blister beetle's excretion is deposited in the flexures of the elbows or other folds. Ingestion of beetles or cantharidin results in poisoning, presenting with hematuria and abdominal pain. In many tropical and subtropical habitats, rove beetles (genus *Paederus*) produce a patchy or linear, erythematous vesicular eruption (dermatitis linearis) (Fig. 20.37). In parts of South America, it is known as podo. It occurs frequently during the rainy season and appears predominantly on the neck and exposed parts. Lymphadenopathy and fever are common. In the

Fig. 20.35 Myiasis.

Fig. 20.36 Blister beetle.

Fig. 20.37 Paederus (beetle) dermatitis. (Courtesy Shyam Verma, MBBS, DVD.)

southwestern United States, outbreaks of rove beetle dermatitis have followed unusually rainy periods. In southeastern Australia, corneal erosions are caused by small Corylophidae beetles (*Orthoperus* spp). Blister beetle derivatives, including cantharidin, norcantharidin, cantharidimide, and norcantharimide, have significant potential as phosphoprotein phosphatase inhibitors in cancer treatment.

Treatment of blister beetle dermatitis consists of draining the bullae and applying cold wet compresses and topical antibiotic preparations. Early cleansing with acetone, ether, soap, or alcohol may be helpful to remove cantharidin.

Other Beetles

Papulovesicular and urticarial dermatitis is caused by the common carpet beetle (Dermestidae: *Anthrenus scrophulariae*). The eruption involves the chest, neck, and extremities. The larvae inhabit warm houses throughout the winter months. They are reddish brown, fusiform, about 6 mm long, and covered by hairs. A generalized pruritic eruption has been attributed to the larvae of the carpet beetle, *Anthrenus verbasci*. Bombardier beetles of the family Carabidae (subfamily Brachininae) can cause skin burns with a deep yellow-brown color. Chemicals released when these beetles are crushed include acids, phenols, hydrocarbons, and quinines. When the beetle is threatened, chemical reactions produce an explosive spray of boiling-hot benzoquinones from the tip of the abdomen. Dermestidae (skin beetles) and Cleridae (bone beetles) infest exposed human remains and are useful in estimating the postmortem interval. Rare cases of allergic angioedema have been reported after exposure to ladybugs.

Singh A, et al: Blister beetle dermatitis. Int J Prev Med 2013; 4: 241.

Order Hymenoptera

Hymenopterids include bees, wasps, hornets, and ants. Stings by any of these may manifest the characteristic clinical and histologic features of eosinophilic cellulitis (Wells syndrome), complete with flame figures.

Fig. 20.38 Fire ant stings.

Bees and Wasps

Yellowjackets are the principal cause of allergic reaction to insect stings, because they nest in the ground or in walls and are disturbed by outdoor activity, such as gardening or lawn mowing. Bees are generally docile and sting only when provoked, although Africanized bees display aggressive behavior. The allergens in vespid venom are phospholipase, hyaluronidase, and a protein known as antigen 5. Bee venom contains histamine, mellitin, hyaluronidase, a high-molecular-weight substance with acid phosphatase activity, and phospholipase A. The barbed ovipositor of the honeybee is torn out of the bee and remains in the skin after stinging. The bumblebee, wasp, and hornet are able to withdraw their stinger.

The reaction to these stings ranges from pain and mild local edema to exaggerated reactions that may last for days. Serum sickness, characterized by fever, urticaria, and joint pain, may occur 7–10 days after the sting. Severe anaphylactic shock and death may occur within minutes of the sting. Most hypersensitivity reactions have been shown to be mediated by specific IgE antibodies. Anaphylaxis to vespids may also be the presenting symptom of mastocytosis, with no demonstrable, specific IgE against wasp venom. Granuloma annulare and subcutaneous granulomatous reactions have been reported. Contact allergy to propolis is common among beekeepers.

Treatment of local reactions consists of immediate application of ice packs or topical anesthetics. Chronic reaction sites may be injected with triamcinolone suspension diluted to 5 mg/mL with 2% lidocaine. Oral prednisone may be required for severe local reactions.

For severe systemic reactions, 0.3 mL of epinephrine (1 : 1000 aqueous solution) is injected intramuscularly. This may need to be repeated after 10 minutes. Susceptible persons should carry a source of injectable epinephrine. Corticosteroids and epinephrine may be required for several days after severe reactions. Hyposensitization by means of venom immunotherapy can reduce the risk of anaphylaxis in people at risk. Those at risk should be evaluated by an allergist. Rush desensitization regimens exist, and ultrarush sublingual immunotherapy looks promising.

Ants

The sting of most ants is painful, but that of fire ants (*Solenopsis invicta*, *S. geminata*, or *S. richteri*) is especially painful. Fire ants are vicious and will produce many burning, painful stings within seconds if their mound is disturbed. The sting causes intense pain and wheeling. Later, an intensely pruritic, sterile pustule develops at the site (Fig. 20.38). Anaphylaxis, seizures, and mononeuropathy have been reported. The sting of harvester ants and soldier ants

Fig. 20.39 Cat flea.

may produce similar reactions. Treatment options are similar to those for vespid stings.

Order Siphonaptera

Fleas are wingless, with highly developed legs for jumping. They are blood-sucking parasites, infesting most warm-blooded animals. Fleas are important vectors of plague, endemic typhus, brucellosis, melioidosis, and erysipeloid.

Pulicosis (Flea Bites)

The species of flea that most frequently attack humans are the cat flea (*Ctenocephalides felis;* Fig. 20.39), human flea *(Pulex irritans)*, dog flea *(Ctenocephalides canis)*, and oriental rat flea (*Xenopsylla cheopis)*. The stick-tight flea *(Echidnophaga gallinacea)*, mouse flea *(Leptopsylla segnis)*, and chicken flea *(Ceratophyllus gallinae)* are sometimes implicated.

Fleas are small, brown insects about 2.5 mm long, flat from side to side, with long hind legs. They slip into clothing or jump actively when disturbed. They bite about the legs and waist and may be troublesome in houses where there are dogs or cats. The lesions are often grouped and may be arranged in zigzag lines. Hypersensitivity reactions may appear as papular urticaria (Fig. 20.40), nodules, or bullae. Camphor and menthol preparations, topical corticosteroids, and topical anesthetics can be of benefit.

Vectors of Disease

Xenopsylla cheopis and *Xenopsylla braziliensis* are vectors of plague and endemic typhus. The cat flea *(Ctenocephalides felis)* is the vector for *Rickettsia felis*, a cause of endemic typhus. Plague and tularemia are transmitted by the squirrel flea, *Diamanus montanus.* Several species of flea are intermediate hosts of the dog tapeworm and rat tapeworm, which may be an incidental parasite of humans.

Tungiasis

Tunga penetrans is also known as nigua, the chigoe, sand flea, or jigger. It is a reddish brown flea about 1 mm long. It resides in the Caribbean, equatorial Africa, Central and South America, India, and Pakistan. It was first reported in crewmen who sailed with Christopher Columbus.

The female chigoe burrows into the skin, often adjacent to a toenail, where she may be seen with the aid of dermoscopy. Once embedded, the flea becomes impregnated and ova develop. Skin lesions are pruritic swellings the size of a small pea (Fig. 20.41). These may occur on the ankles, feet, and soles, as well as the anogenital areas. The lesions become extremely painful and secondarily infected. Wearing open shoes and the presence of pigs in the area are risk factors for disease.

Fig. 20.40 Flea bites. (Courtesy Curt Samlaska, MD.)

Fig. 20.41 Tungiasis. (Courtesy Catherine Quirk, MD.)

Curettage or excision may be required, but many lesions will respond to topical ivermectin, metrifonate, dimethicone, thiabendazole or oral thiabendazole, 25 mg/kg/day. Antibiotics should be used for the secondary infection and tetanus prophylaxis given. These lesions can be prevented by the wearing of shoes. Infested ground and buildings may be disinfected with insecticides and growth inhibitors.

Fig. 20.42 Dermacentor variabilis.

Fig. 20.43 Lone star tick.

CLASS ARACHNIDA

Arachnida includes the ticks, mites, spiders, and scorpions. Adult and nymph stages of arachnids have four pairs of legs, and larval forms have six legs. Their bodies consist of cephalothorax and abdomen, in contrast to insects, which have three body segments.

Order Acarina

Tick Bite

Several varieties of the family Ixodidae (hard ticks) and Argasidae (soft ticks) will attack human skin, but only hard ticks remain attached. In the United States *Ornithodoros hermsi*, *O. turicata*, and *O. parkeri* transmit tick-borne relapsing fever. The wood tick *(Dermacentor andersoni)* is an important disease vector in western states. It carries Rocky Mountain spotted fever, tularemia, ehrlichiosis, and Colorado tick fever. The dog tick (*Dermacentor variabilis;* Fig. 20.42) is prevalent in the eastern U.S. states and is the most common vector of Rocky Mountain spotted fever. It also carries tularemia. *Dermacentor marginatus* transmits tick-borne lymphadenopathy in Spain. *Haemaphysalis longicornis* ticks are vectors for severe fever with thrombocytopenia syndrome, associated a high mortality rate in China, South Korea and Japan. The brown dog tick *(Rhipicephalus sanguineus)* is a vector of Rocky Mountain spotted fever, tularemia, and boutonneuse fever. The lone star tick (*Amblyomma americanum;* Fig. 20.43) carries Rocky Mountain spotted fever, tularemia, and human monocytic ehrlichiosis. *Ixodes ricinus* in Europe and *I. scapularis* and *I. pacificus* in the United States transmit *Borrelia burgdorferi*, the cause of Lyme disease.

Fig. 20.44 Tick bite.

Ixodes ticks also transmit human granulocytic ehrlichiosis and babesiosis. The risk of disease transmission increases with the duration of tick attachment. Unfortunately, ticks often attach in areas where they are not noticed, allowing them to engorge and transmit disease.

The female hard tick attaches itself to the skin by sticking its proboscis into the flesh to suck blood from the superficial vessels. The insertion of the hypostome is generally unnoticed by the subject. The attached tick may be mistaken by the patient for a new mole (Fig. 20.44). The parasite slowly becomes engorged and then falls off. During this time, which may last for 7–12 days, the patient may have fever, chills, headache, abdominal pain, and vomiting (tick bite pyrexia). Removal of the engorged tick causes a subsidence of the general symptoms in 12–36 hours.

The bites may be followed by small, severely pruritic, fibrous nodules (tick bite granulomas) that persist for months or by pruritic, circinate and arciform, localized erythemas that may also persist over months. Tick bite–induced alopecia has been reported, and both *Amblyomma americanum* and *Ixodes* tick bites are associated with the development of IgE antibodies to the carbohydrate galactose-α-1,3-galactose, causing delayed urticaria and anaphylaxis after consumption of red meat.

Histologically, bite reactions demonstrate wedge-shaped necrosis with a neutrophilic infiltrate and vascular thrombosis or hemorrhage. Chronic bite reactions often have atypical CD30+ lymphocytes and eosinophils. Pseudolymphomas and immunocytomas may occur.

Tick Paralysis

Tick paralysis most often affects children and carries a mortality rate of about 10%. Flaccid paralysis begins in the legs, then the arms, and finally the neck, resembling Landry-Guillain-Barré syndrome. Bulbar paralysis, dysarthria, dysphagia, and death from respiratory failure may occur. Prompt recovery occurs if the tick is found and removed before the terminal stage. *Dermacentor* ticks in North America and *Ixodes* ticks in Australia are the most important causes of tick paralysis. Because *Dermacentor* ticks typically attach to the scalp, they may go unnoticed.

Mites

Scabies. *Sarcoptes scabiei*, the itch mite, is an oval, ventrally flattened mite with dorsal spines. The fertilized female burrows into the stratum corneum and deposits her eggs. Scabies is characterized by pruritic papular lesions, excoriations, and burrows. Sites of predilection include the finger webs (Fig. 20.45), wrists, axillae, areolae, umbilicus, lower abdomen, genitals (Fig. 20.46), and buttocks (Fig. 20.47). An imaginary circle intersecting the main sites of involvement—axillae, elbow flexures, wrists and hands, and crotch—has long been called the circle of Hebra. In adults, the scalp and face are usually spared, but in infants, lesions are usually present over the entire cutaneous surface (Fig. 20.48). The burrows appear as slightly elevated, grayish, tortuous lines in the skin. A vesicle or pustule containing the mite may be noted at the end of the burrow, especially in infants and children. To identify burrows quickly, a drop of India ink or gentian violet can be applied to the infested area, then removed with alcohol. Thin, threadlike burrows retain the ink.

The eruption varies considerably, depending on the length of infestation, previous sensitization, and prior treatment. It also varies with climate and the host's immunologic status. Lichenification, impetigo, and furunculosis may be present. Bullous lesions may contain many eosinophils, resembling bullous pemphigoid. Positive immunofluorescent findings may also be noted. Scabies has also been reported to trigger epidermolysis bullosa (EB) pruriginosa, a variant of dystrophic EB. Scabies may also resemble

Fig. 20.45 Scabies.

Fig. 20.47 Scabies.

Fig. 20.46 Scabies. (Courtesy Dr. Shyam Verma.)

Fig. 20.48 Scabies.

Fig. 20.49 Nodular scabies.

Fig. 20.50 Crusted scabies in an HIV-infected patient. (Courtesy Curt Samlaska, MD.)

Langerhans cell histiocytosis clinically and histologically. Misdiagnosis has led to systemic treatment with toxic agents.

Dull-red nodules may appear during active scabies; these are 3–5 mm in diameter, may or may not itch, and persist on the scrotum, penis (Fig. 20.49), and vulva. Intralesional steroids, tar, or excision are methods of treatment for this troublesome condition, termed nodular scabies. Histologically, the lesions may suggest lymphoma.

Crusted scabies (Norwegian or hyperkeratotic scabies) is found in immunocompromised or debilitated patients, including those with neurologic disorders, Down syndrome, organ transplants, graft-versus-host disease, adult T-cell leukemia, Hansen disease, or AIDS. In these patients, the infestation assumes a heavily scaling and crusted appearance. Crusts and scales teem with mites, and the face is involved, especially the scalp. Itching may be slight. Psoriasis-like scaling is noted around and under the nails. The tips of the fingers are swollen and crusted and the nails distorted. Severe fissuring and scaling of the genitalia and buttocks may be present (Fig. 20.50). Pressure-bearing areas are the sites of predilection for the heavy keratotic lesions, in which the mites may abound.

Scabies is usually contracted by close personal contact, although it may also be transmitted by contaminated linens and clothing. Screening for other STDs is appropriate in adults. Sensitization begins about 2–4 weeks after onset of infection. During this time, the parasites may be on the skin and may burrow into it without causing pruritus or discomfort. Severe itching begins with sensitization of the host. In reinfections, itching begins within days, and the reaction may be clinically more intense. The itching is most intense at night, whereas during the daytime, the pruritus is tolerable but persistent. The eruption does not involve the face or scalp in adults. In women, itching of the nipples associated with a generalized pruritic papular eruption is characteristic; in men, itchy papules on the scrotum and penis are equally typical. When more than one member of the family has pruritus, scabies should be suspected. Whenever possible, however, it is advisable to identify the mite, because a diagnosis of scabies usually requires treatment of close physical contacts in addition to the patient. Because scabies cannot always be excluded by examination, treatment on presumption of scabies is sometimes necessary.

Positive diagnosis is made only by the demonstration of the mite under the microscope. A burrow is sought and position of the mite determined. A surgical blade or sterile needle is used to remove the parasite. A drop of mineral or immersion oil can be placed on a lesion and gently scraped away with the epidermis beneath it. The majority of mites are found on the hands and wrists, less frequently (in decreasing order) at the elbows, genitalia, buttocks, and axillae. Children have often gathered mites and ova under the nails when scratching. A blunt curette can be used to gather material from under the nails for examination. Noninvasive techniques include dermoscopy and digital photography.

Permethrin 5% cream, 6%–10% precipitated sulfur in petrolatum, and benzyl benzoate are the most widely used topical agents. Permethrin is a synthetic pyrethroid that has low toxicity for humans, although some concern has been raised about a possible association between topical insecticides and hematopoietic malignancy. Lindane (γ-benzene hexachloride) is rarely used as a first-line agent and is banned in some locations because of concerns about neurotoxicity. Oral ivermectin at a dose of 200 μg/kg is typically repeated in 7–10 days, but is often used in a single dose for mass infestations in resource-constrained settings. European guidelines cite permethrin, oral ivermectin and benzyl benzoate as first line agents. They list topical formulations of malathion, ivermectin and sulfur as alternatives. Japanese guidelines list topical phenothrin or oral ivermectin as first line agents and topical sulfur, crotamiton or benzyl benzoate as alternatives. German guidelines also list crotamiton as a second-line agent. Moxidectin and *Tinospora cordifolia* lotion appear promising and have the potential to replace other treatments.

Topical scabicides should be thoroughly rubbed into the skin from the neck to the feet, with particular attention given to the creases, perianal areas, umbilicus, and free nail edge and folds. They are washed off 8–10 hours later. Clothing and bed linen are changed and laundered thoroughly. Crotamiton (Eurax) has a lower cure rate than other available agents. When used, it should be applied on five successive nights and washed off 24 hours after the last use.

In the crusted type of scabies, ivermectin should be used in conjunction with a topical agent. It may need to be repeated two or three times at intervals of 1–2 weeks. Individuals in close contact with the patient should be treated. Scabies in long-term health care facilities is an increasing problem. Delays in treating close contacts may result in large numbers of persons requiring treatment. Ivermectin has no selective fetal toxicity in animal studies. Permethrin is often used in pregnancy, but because of the reported association between pyrethroids and leukemia, some prefer sulfur in this setting.

Animal Scabies. Zoonotic scabies and scab mites may affect humans who come in close contact with the animal. The reaction resembles scabies but typically runs a self-limited course. Burrows are usually absent.

Fig. 20.52 Chigger bites.

Other Mite Diseases

Demodex Mites. *Demodex folliculorum* is a vermiform mite that inhabits the pilosebaceous units of the nose, forehead, chin, and scalp. The mite has a flattened head, four pairs of short, peglike legs, and an elongated abdomen. *Demodex brevis* is shorter and more often found on the trunk.

In dogs, the lesions of demodectic mange contain numerous mites. In humans, there are convincing reports of demodectic blepharitis, demodectic folliculitis, demodectic abscess, and demodectic alopecia that respond to eradication of the mites. Some rosacea-like lesions may also be caused by *Demodex*. Treatment of the eruptions in which *Demodex* has been implicated consists of applying permethrin, sulfur, lindane, benzyl benzoate, or benzoyl peroxide. Oral ivermectin and metronidazole have also been used.

Cheyletiella Dermatitis. *Cheyletiella yasguri*, *Cheyletiella blakei*, and *Cheyletiella parasitovorax* are three species of nonburrowing mite that are parasitic on dogs, cats, and rabbits, respectively, where they present as "walking dandruff." They may bite humans when there is close contact with the animals, producing an itchy dermatitis (Fig. 20.51) resembling scabies or immunobullous disease. The mites are similar in diameter to *Sarcoptes scabiei* but are elongated and have prominent anterior hooked palps. They may be found by brushing the animal's hair over a dark piece of paper. The brushings can be placed in alcohol, where the scales and hair sink while the mites float. The pet should be treated by a qualified veterinarian.

Chigger Bite. The trombiculid mites are known as chiggers, mower's mites, or red bugs. In North America, *Trombicula (Eutrombicula) alfreddugesi* attacks humans and animals. In Europe, the harvest mite, *Neotrombicula autumnalis*, is a common nuisance. Attacks occur chiefly during the summer and fall, when individuals have more frequent contact with mite-infested grass and bushes. The lesions occur chiefly on the legs (Fig. 20.52) and at the belt line and other sites where clothing causes constriction. Penile lesions are common in males. Lesions generally consist of severely pruritic, hemorrhagic puncta surrounded by red swellings. On the ankles, intensely pruritic, grouped, excoriated papules are noted. Several varieties of trombiculid mite in East Asia and the South Pacific are vectors of scrub typhus (tsutsugamushi fever).

Gamasoidosis. Gamasoidosis is caused by two genera of mites, *Ornithonyssus* and *Dermanyssus*, and occurs after contact with canaries, pigeons, and poultry. Because of the association with pigeons, the dermatitis is common among urban dwellers, and because of the small size of the mites and their tendency to leave the host after biting, the diagnosis may not be considered. In pet stores, bird mites may be transmitted to rodents with human disease related to contact with a gerbil or hamster. The mites are active at night and hide during the day. The resulting dermatosis occurs chiefly on the hands and arms as itchy macules, papules, or vesicles. Any body area may be attacked, and common additional sites are the groin, areolae, umbilicus, face, and scalp. The mites may wander from bird nests as soon as the young birds begin to fly, and they may infest terrace cushions and patio furniture. The tropical fowl mite *(Ornithonyssus bursa)* and the red chicken mite *(Dermanyssus gallina)* are the major culprits. *Dermanyssus* mites may carry *Erysipelothrix rhusiopathiae*.

Grocer's Itch. Grocer's itch is a pruritic dermatitis of the forearms, with occasional inflammatory and urticarial papules on the trunk. It results from the handling of figs, dates, and prunes, when it is caused by *Carpoglyphus passularum*, or from exposure to the cheese mite *(Glyciphagus domesticus)*. This must be distinguished from grocer's eczema, which is caused by sensitization to flour, sugar, cinnamon, chocolate, and similar items.

Grain Itch. Grain itch is also known as straw itch, barley itch, mattress itch, and prairie itch. Causative mites include *Pyemotes tritici*, *Pyemotes ventricosus*, *Cheyletus malaccensis*, and *Tyrophagus putrescentiae* (copra itch mite). Those mainly affected are harvesters of wheat, hay, barley, oats, and other cereals or farm hands and packers who have contact with straw. Grain itch has a typical lesion consisting of an urticarial papule on which there is a small vesicle. There is intense pruritus, with lesions occurring predominantly on the trunk. Frequently, an initial central hemorrhagic punctum rapidly turns into an ecchymosis with hemosiderin pigmentation.

Other Mite-Related Dermatitides. *Dermatophagoides pteronyssinus* and *D. farinae* are dust mites implicated in atopic diseases. *Lepidoglyphus destructor* is the hay mite. There have been outbreaks of *Pyemotes boylei* bites in homes fumigated for termites. Although mites do not appear capable of survival when forced to share an environment with termites, they thrive in locations where there are termite carcasses. Vanillism is a dermatitis caused by *Acarus siro* and occurs in workers handling vanilla pods. Copra itch occurs on persons handling copra who are subject to *Tyrophagus longior* mite bites. Coolie itch is found on tea plantations in India and is caused by *Rhizoglyphus parasiticus*; it causes sore feet. Rat mite itch, caused by *Ornithonyssus bacoti*, the tropical rat mite, may result in an intensely pruritic dermatitis. This papulovesicular urticarial eruption is seen in workers in stores, factories, warehouses, and stockyards. The rat mite may transmit endemic typhus, rickettsialpox, equine encephalitis, tularemia, plague, and relapsing fever. Feather pillow dermatitis is a pruritic papular dermatitis traced to the Psoroptid carpet mite, *Dermatophagoides scheremetewskyi*, which may infest feather pillows. The house mouse mite, *Allodermanyssus (Liponyssoides) sanguineus*, is the vector of *Rickettsia akari*, the causative organism of rickettsialpox.

Order Scorpionidae

Scorpion Sting

Scorpions are different from other arachnids in that they have an elongated abdomen ending in a stinger (Fig. 20.53). They also have a cephalothorax, four pairs of legs, pincers, and mouth pincers. Two poison glands in the back of the abdomen empty into the stinger. Scorpions are found worldwide, especially in the tropics. They are nocturnal and hide during the daytime under tabletops and in closets, shoes, and folded blankets. Ground scorpions may burrow into gravel and children's sandboxes. Buthid scorpions include the most venomous species of medical importance. Important scorpions include *Tityus serrulatus*, found in Brazil; *Buthotus tamulus*, in India; *Leiurus quinquestriatus* and *Androctonus crassicauda*, in North Africa and southwest Asia; and *Centruroides suffusus*, in Mexico. *Centruroides exilicauda* and *C. sculpturatus* are the most toxic scorpions in the United States. *Vaejovis* scorpions in the southeastern United States have been reported to cause "brown recluse–like" dermonecrotic reactions.

Scorpions sting only by accident or in self-defense. The venom causes pain, paresthesia, and variable swelling at the site. The sting of the Egyptian scorpion *(L. quinquestriatus)* has a mortality rate of 50% in children. The neurotoxic venom may produce numbness at the sting site, laryngeal edema, profuse sweating and salivation, cyanosis, nausea, and paresthesia of the tongue. There is minimal or no visible change at the sting site, and some studies have confirmed the typical absence of histologic inflammation. Death may occur from cardiac or respiratory failure, especially in children. Renal and hepatic toxicity may also occur.

Treatment depends on the species and toxic symptoms. Antiarrhythmics, antiadrenergic agents, vasodilators, and calcium channel blockers may be required. Antivenin is available for many species of scorpion and generally represents the most effective intervention.

Order Arachnidae

Arachnidism

Spiders are prevalent throughout the world. Most are beneficial to humans, trapping many insects, but a few species are dangerous. Many spider venoms are not well characterized, and in most cases of envenomation, the responsible spider is never identified. The Brazilian armed spider *(Phoneutria nigriventer)* is well characterized. Its venom contains neurotoxins that may be fatal in children. Various reactions to spider bites have been reported, including dermonecrotic reactions, systemic toxicity, and acute generalized exanthematous pustulosis.

Latrodectism

The various species of *Latrodectus* have similar toxins and cause similar reactions in humans. The black widow spider, *Latrodectus mactans*, is of chief concern in the continental United States. It may also be found in the Caribbean region. Black widows are web-building spiders and are typically found in woodpiles and under outhouse seats. Their venom may be less potent than that of related brown widow spiders, but black widows inject more venom. *Latrodectus curacaviensis* is native to South America, and Australia and New Zealand have related red-back spiders *(Latrodectus mactans hasselti)*. *Latrodectus indistinctus* is found in Africa, and the brown widow, *Latrodectus geometricus*, is native to southern Africa and Madagascar.

The female *L. mactans* spider is 13 mm long and shiny black, with a red hourglass-shaped marking on its abdomen (Fig. 20.54). The legs are long, with a spread of up to 4 cm. The black widow

Fig. 20.53 Common Centruroides scorpion.

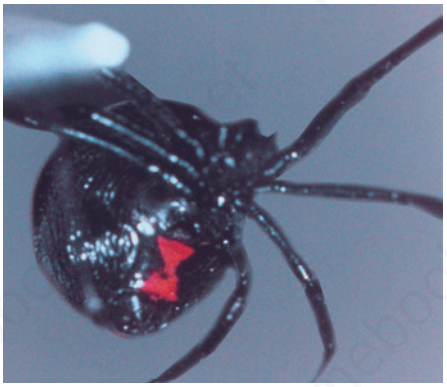

Fig. 20.54 Black widow.

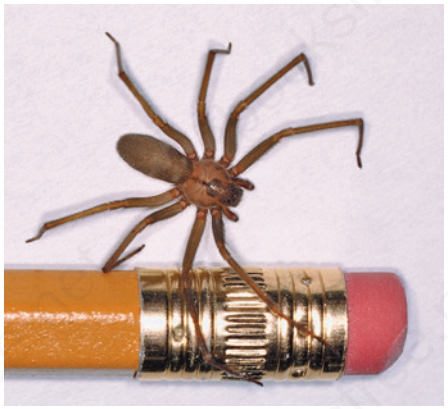

Fig. 20.55 Brown recluse spider.

Fig. 20.56 Brown recluse spider bite. (Courtesy Steven Binnick, MD.)

spider is not aggressive and bites only when disturbed. Severe pain usually develops within a few minutes and spreads throughout the extremities and trunk. Within a few hours, the victim may have chills, vomiting, violent cramps, delirium or partial paralysis, spasms, and abdominal rigidity. The abdominal pains are frequently most severe and may be mistaken for appendicitis, colic, or food poisoning. Toxic morbilliform erythema may occur. Myocarditis has also been reported.

Antivenin is indicated for severe symptoms of envenomation. Benzodiazepines reduce the associated tetany.

Loxoscelism

The brown recluse spider *(Loxosceles reclusa)* is the major cause of necrotic arachnidism in the United States (Fig. 20.55). It is most common in the lower Midwest and Southwest. This reclusive spider may be identified by a dark, violin-shaped marking over the cephalothorax and three sets of eyes, rather than the usual four. It is light brown and about 1 cm long, with a small body and long delicate legs. It is found in storage closets, basements, and cupboards and among clothing. Outdoors it has been found in woodpiles, in grass, on rocky bluffs, and in barns. It stings in self-defense and is not an aggressive spider. The incidence of brown recluse bites is grossly overestimated. *Loxosceles rufescens*, *L. deserta*, and *L. arizonica* cause lesser degrees of skin necrosis. *Loxosceles laeta*, *L. intermedia*, *L. gaucho*, and *L. similis* are found in Latin America and produce changes similar to those of *L. reclusa*. The venom contains a phospholipase enzyme, sphingomyelinase D, which is the major toxin. Hyaluronidase contributes to a gravity-dependent spread of the necrotic lesions.

In the localized type of reaction, known as necrotic cutaneous loxoscelism, extensive local necrosis develops. A painful, severe edematous reaction occurs within the first 8 hours, with development of a bulla with surrounding zones of erythema and ischemia. In about 1 week, the central portion becomes dark, demarcated, and gangrenous (Fig. 20.56). Systemic loxoscelism is rare but may be associated with minor-appearing bite reactions. Systemic toxic symptoms are associated with disseminated intravascular coagulation.

Treatment. Treatment of loxoscelism consists of rest, ice, and elevation. Tetanus toxoid should be given if the patient has not received the immunization within 10 years. Some data suggest a trend toward better outcomes with injection of intralesional triamcinolone, with anecdotal reports of the injection site being spared necrosis but the areas above and below the site showing necrosis. Antibiotics and conservative debridement may be needed for necrotic wounds. Dapsone has been used, but some studies show that it is no better than placebo; dapsone also may be toxic, especially in the setting of venom-induced hemolysis. Colchicine has also been disappointing in animal models, but tetracyclines show some promise and deserve further study. Hyperbaric oxygen has been used for slowly healing wounds.

Funnel Web Spiders

Funnel web spiders include *Tegenaria agrestis* (hobo spider or aggressive house spider of Pacific Northwest) and *Atrax robustus* (Sydney funnel web spider of Australia). Australian funnel web spiders are dangerous, but antivenin is available.

Tarantulas (Lycosidae: Theraphosidae)

Tarantulas are large, hairy hunting spiders. American species have urticating hairs that produce cutaneous wheal and flare reactions and embed in the cornea, causing ophthalmia nodosa.

PHYLUM CHORDATA

Stingray Injury

The two stingray families, Dasyatidae and Myliobatidae, are among the most venomous fish known to humans. Attacks generally occur as a result of an unwary victim stepping on a partially buried stingray. A puncture-type wound occurs about the ankles or feet and later ulcerates. Sharp, shooting pain develops immediately, with edema and cyanosis. Symptoms of shock may occur. Histologically, granulomatous dermatitis and panniculitis with necrosis have been reported.

Persons wading in shallow, muddy waters where stingrays may be found should shuffle their feet through the mud to frighten

the fish away. Successful treatment is usually attained by immersing the injured part in hot water for 30–60 minutes. The water should be as hot as can be tolerated, because the venom is detoxified by heat. Meperidine hydrochloride administered intravenously or intramuscularly may be necessary. If the ulcer remains unhealed after 8 weeks, excision is indicated.

Snakebite

Bites by venomous snakes are a serious problem in some parts of the world. In the United States the rattlesnake, water (cottonmouth) moccasin, copperhead, and coral snake are the venomous snakes most frequently encountered. Patients are usually young men, with 98% of bites on the extremities, most often the hands or arms. In Europe, 39% of envenomations from exotic pets are snakebites from rattlesnakes, cobras, mambas, or other venomous snakes. Almost 30 enzymes are found in snake venom, most of which are hydrolases. Snake venom has effects on the cardiovascular, hematologic, respiratory, and nervous systems. Severe envenomation may mimic brain death, with loss of other brainstem reflexes. Local effects at the bite site include the rapid onset of swelling, erythema, and ecchymosis. In more severe reactions, bullae and lymphangitis may appear. Fang marks are often visible and pain is common, except with Mojave rattlesnake bites. Antivenin is used in severe envenomation, and antitetanus measures are indicated. In the eastern United States, copperheads inflict most snakebites, followed by rattlesnakes and cottonmouths. Most of these children can be managed conservatively, although Crotalidae antivenin, antibiotics, and fasciotomy may be needed.

Lizard Bite

Heloderma suspectum, the Gila monster, is found chiefly in Arizona and New Mexico. Another venomous lizard is the beaded lizard of southwestern Mexico, *Heloderma horridum*. Bites from these poisonous lizards may cause paralysis, dyspnea, and convulsions. Systemic toxicity usually resolves spontaneously with supportive care within 1 or 2 days. Death is rare. There is no antivenin.

21 Chronic Blistering Dermatoses

Bonus images for this chapter can be found online at expertconsult.inkling.com

In noninherited chronic blistering (vesicular or bullous) dermatoses, the cause of blistering is usually an autoimmune reaction, and the location where antibodies bind determines the clinical, histologic, and immunofluorescent pattern. A thorough understanding of the basement membrane zone (BMZ) structure and location of specific autoantigens and the target proteins of autoantibodies is critical. The desmoglein compensation hypothesis, based on the differential expression of desmoglein 1 and 3 at different amounts at different levels of the epidermis and mucosa, for instance, perfectly explains the observed differences in the phenotypes of pemphigus foliaceus and vulgaris. Autoantibodies that bind at the BMZ will often lead to tense bullae—but those that bind to proteins higher in that structure will often not scar, whereas antibodies against deeper parts of the BMZ will often lead to scarring and milia formation. High-frequency ultrasound has been anecdotally reported as a potential tool to determine blister location. Although the clinical and histologic findings are important, often it is the pattern of immunofluorescence that is critical in establishing the diagnosis. Usually, antibodies are circulating and can be found bound in perilesional and nonbullous lesional skin, whereas blistered skin often fails to demonstrate deposits. Biopsies of lower extremity skin should be avoided if possible, because it may be prone to false-negative results.

Salt-split-skin preparations are useful in determining the site of deposition of the autoantibodies. A 1-M solution of sodium chloride (NaCl) predictably splits skin at the level of the lamina lucida. Localization of immune deposits to the roof or floor of this split is diagnostically useful. On direct immunofluorescence (DIF) evaluation of nonsplit skin, the identification of n-serrated and u-serrated patterns of immunoglobulin deposition may provide the same information and may make salt-split-skin immunofluorescence unnecessary in some cases. An n-serrated pattern corresponds to a split above the basal lamina, whereas a u-serrated pattern corresponds to a sub–lamina densa split (see images on ExpertConsult). The subtle patterns are best seen in areas where the BMZ curves. Newer immunohistochemical stains such as C3d stain may also aid in the diagnosis in some cases. Immunoprecipitation, enzyme-linked immunosorbent assay (ELISA), and immunoblotting have helped to define the molecular targets of the autoantibodies and have revolutionized testing for immunobullous diseases. Data vary concerning the sensitivity and specificity of these tests, and not every test is universally available. In the setting of bullous pemphigoid, ELISA can produce apparent false-positive results at rates of 7% or higher, based on non-NC16a antibodies, as well as on anti–BP 180 antibodies that bind to the pathogenic NC16a domain but do not produce clinical disease and are not associated with positive indirect immunofluorescent findings. False-negative results also occur and are discussed later.

Transient acantholytic dermatosis (Grover disease) is an idiopathic nonimmune vesiculobullous disease that may mimic some histologic patterns of immunobullous disease, but shows no specific findings on DIF. Specific dermatoses of pregnancy are discussed under the differential diagnosis of herpes gestationis.

The outlook for immunobullous diseases has improved since the introduction of rituximab, intravenous immunoglobulins, and more targeted, autoantibody-directed therapies helping shift away from broadly toxic immunosuppressive regimens. Oral and ocular involvement often requires early aggressive therapy and a multidisciplinary approach.

PEMPHIGUS VULGARIS

Clinical Features

Pemphigus vulgaris (PV) is characterized by mucosal erosions and by thin-walled, relatively flaccid, easily ruptured bullae that appear on apparently normal skin and mucous membranes or on erythematous bases (Fig. 21.1). The fluid in the bulla is clear at first but may become hemorrhagic or even seropurulent. The bullae rupture to form erosions. The denuded areas soon become partially or totally covered with crusts that have little or no tendency to heal. When they finally heal, lesions often leave hyperpigmented patches but no scarring.

Usually, PV appears first in the mouth (60% of cases; Fig. 21.2) or at the site of a burn, radiation therapy, or other skin injury. Other common sites include the groin, scalp, face, neck, axillae, and genitals. Nikolsky sign is present (intact epidermis shearing away from underlying dermis, leaving a moist surface). The sign is elicited by slight pressure, twisting, or rubbing. The "bulla-spread phenomenon" (Asboe-Hansen sign) is elicited by pressure on an intact bulla, gently forcing the fluid to spread under the adjacent skin. The autoimmune bullous skin disorder intensity score (ABSIS), pemphigus vulgaris activity score (PVAS), and pemphigus disease activity index (PDAI) are scoring tools used in trials to track disease severity.

Short-lived bullae quickly rupture to involve most of the mucosa with painful erosions. The lesions extend onto the lips and form heavy, fissured crusts on the vermilion. Involvement of the throat produces hoarseness and difficulty in swallowing. The mouth odor is offensive. The esophagus may be involved, and sloughing of its entire lining in the form of a cast (esophagitis dissecans superficialis) may occur, even when the cutaneous disease appears to be well controlled because mucosa lacks desmoglein 1 and depends entirely on desmoglein 3. The conjunctiva, nasal mucosa, vagina, penis, and anus may also be involved. Chronic lesions may involve the face (Fig. 21.3), scalp, or flexures. Widespread cutaneous disease (Fig. 21.4) may cause death through sepsis or fluid and electrolyte imbalance.

The diagnosis is made by histology, immunofluorescence pattern of perilesional skin or plucked hairs, indirect immunofluorescence (IIF) testing of serum, or ELISA testing for anti–desmoglein 1 (Dsg1) and anti-Dsg3 autoantibodies. As in other autoimmune diseases, specific antibodies may be present in relatives of patients with pemphigus without the disease.

Epidemiology

PV occurs with equal frequency in men and women, usually in the fifth and sixth decades of life. It is rare in young persons. PV occurs more often in Jewish people and those of Mediterranean descent. Before the advent of corticosteroids, PV was frequently fatal; now, patients tend to suffer more from treatment-related complications.

Etiologic Factors

Antibodies in PV are most often directed against Dsg3. The presence of antibodies to both Dsg1 and Dsg3 correlates with

Fig. 21.1 Pemphigus vulgaris. (Courtesy Curt Samlaska, MD.)

Fig. 21.2 Oral pemphigus vulgaris.

Fig. 21.3 Pemphigus vulgaris.

Fig. 21.4 Widespread pemphigus vulgaris.

mucocutaneous disease. If autoantibodies are only directed against Dsg3, mucosal lesions predominate as the mucosa lacks sufficient Dsg1 expression to compensate for the anti-Dsg3 antibody-mediated loss of keratinocyte cohesion on mucosal surfaces. Both humoral and cellular autoimmunity are important in the pathogenesis of skin lesions. Antibody alone cannot produce acantholysis, without complement or inflammatory cells. Both IgG1 and IgG4 autoantibodies to Dsg3 occur in patients with pemphigus, but some data suggest that the IgG4 antibodies are pathogenic, and patients may have circulating nonpathogenic antibodies. Plasminogen activator is associated with antibody-mediated acantholysis. Involved T cells are usually CD4 cells that secrete a T-helper type 2 (Th2)–like cytokine profile, although Th1 cells may also be involved in antibody production in chronic disease. IgG is found in both involved and clinically normal skin. C3 deposits are heavier in acantholytic areas. DIF may remain positive for years after clinical remission, and conversion to negative predicts sustained remission after withdrawal of therapy. Pemphigus may be associated with myasthenia gravis and thymoma. Recent studies suggest patients with pemphigus may have an elevated rate of ulcerative colitis. PV can affect the esophagus and cause dysphagia, and patients may be misdiagnosed with steroid-side effects initially. PV-associated interstitial lung disease is reported but very rare, and some cases may have actually had paraneoplastic pemphigus.

The PV antigen (130-kD transmembrane desmosomal glycoprotein) shows homology with the cadherin family of calcium-dependent cell adhesion molecules. With IIF, circulating antibodies can be demonstrated in 80%–90% of patients. Circulating intercellular antibodies may also be present in patients with thermal or actinic burns and in patients with drug eruptions. These antibodies are not directed against Dsg3. They do not bind to the epidermis in vivo and are often directed against ABO blood-group antigens.

Drug-induced cases are uncommon, traditionally from penicillamine or angiotensin-converting enzyme (ACE) inhibitors, though recently reports of biologic-therapy associated PV have emerged. Penicillamine treatment of rheumatoid arthritis has induced pemphigus, though more often of the foliaceous type. Almost all the reported cases have had a positive DIF, and more than half have had a positive IIF. Penicillamine and captopril may induce acantholysis in organ explant cultures in the absence of autoantibody. The doses responsible for induction of disease have ranged from 250–1500 mg/day, and the drugs were taken for an average of 13 months before the onset of pemphigus. A long list of drugs, including captopril, enalapril, penicillin, thioproline, interleukin-2

(IL-2), nifedipine, piroxicam, and rifampicin, has also been reported to induce pemphigus. Many of these contain either a sulfhydryl or an amide group. Secukinumab has been reported to induce PV in one case. Only 10%–15% of patients with drug-induced pemphigus have had oral lesions. Most disease resolves when the medication is discontinued, but some cases have persisted for many months.

Many studies have indicated a genetic predisposition to pemphigus and an association with other autoimmune diseases. A strong association exists with human leukocyte antigen (HLA)–DRB1 (with variability between specific alleles in certain ethnic/racial populations), HLA-DR4, or HLA-DR6. In addition, an HLA-DQ restriction fragment has been identified in many patients with pemphigus. A non-HLA marker "suppression of tumorigenicity 18 protein" that regulates inflammation was associated with PV in Jewish and Egyptian patients but not Europeans. The incidence in Israel is among the highest in the world, with Jewish patients, particularly Ashkenazis, at three times increased risk to Arab patients, and higher rates in women than men. HLA-G is associated with pemphigus in Jewish patients. Thus there may be a genetically inherited susceptibility to the disease. Additionally, a predisposition to develop other autoimmune diseases may occur in relatives of pemphigus patients.

Histopathology

The characteristic findings of PV consist of suprabasilar acantholysis with intraepidermal blister formation. Acantholytic cells are round and show no intercellular bridges. Regeneration of the epidermis occurs and may cause the split to appear to be higher as cells regenerate beneath the cleft. At least some areas typically still demonstrate the characteristic "tombstone row" of basal keratinocytes underneath the bulla. An early intact bulla shows the most characteristic histology. Asboe-Hansen modification of the Nikolsky test may be used to extend the bulla beyond its original margin to where secondary regenerative changes have not taken place. Immunohistochemistry for IgG4 may be useful in diagnosis of PV (and PF).

In early disease, spongiosis with eosinophils may be noted in the epidermis, in the absence of acantholysis. In the setting of immunobullous disease, spongiosis with eosinophils is more likely to represent pemphigoid than pemphigus, and immunofluorescent findings readily distinguish the two. DIF demonstrates a "chicken wire" pattern of intercellular IgG in perilesional skin or plucked hairs. C3 may also be present. The staining is uniform, not granular. IIF shows a similar pattern of staining. Prozone reactions occur, so the serum should be tested at a wide range of dilutions. Positive tests may be confirmed with ELISA for the antibody.

Treatment

Pemphigus is a severe and potentially deadly disease, with patients having an increased mortality rate, and warrants aggressive immunosuppressive treatment. Large-scale, prospective, double-blinded studies are few, and the management of PV is based largely on smaller, open trials and clinical experience. A survey of 24 experienced clinicians showed that half used prednisone in doses of 1 mg/kg/day and half used higher doses. Adjuvant steroid-sparing agents were frequently employed, with almost half the respondents reporting the use of azathioprine. Because of its tolerability and simpler dosing schedule, mycophenolate mofetil (MMF) is often used in place of azathioprine. Other agents used less frequently include cyclophosphamide and methotrexate. Almost 40% of the clinicians aimed to replace prednisone with a steroid-sparing agent, whereas others were content to continue a low dose of prednisone. The survey suggests that, even among the world's experts, there is significant variation in how this difficult disease is managed. Rituximab therapy has produced dramatic responses in some patients, and some authorities now consider rituximab appropriate first-line therapy for patients with severe disease. Intravenous immune globulin (IVIG) may also be effective, and some have combined rituximab with IVIG.

Most agents used to treat the disease are immunosuppressive, although the mechanism of action may not merely be suppression of T cells and antibody production. Methylprednisolone can directly block pemphigus antibody–induced acantholysis. It also upregulates expression of the genes encoding Dsg3 and periplakin; increases measurable levels of E-cadherin, Dsg1, and Dsg3; and interferes with phosphorylation of these adhesion molecules. Many of these effects antagonize those of pemphigus antibodies. Reversion of DIF to negative predicts sustained remission after withdrawal of medication. Plucked hairs are an alternative to skin biopsy to provide a specimen for immunofluorescence; the pilar sheath epithelium of the anagen hair typically demonstrates immunofluorescence comparable to skin.

Topical Treatment

The skin lesions are extremely painful in advanced cases. When there are extensive raw surfaces, prolonged daily baths are helpful in removing the thickened crusts and reducing the foul odor. Silver sulfadiazine (Silvadene) 1%, widely used for local therapy of burns, is an effective topical antimicrobial agent, suitable for treatment of limited disease, though broad use can lead to absorption and side effects. Silver nitrate–impregnated cotton batting, manufactured for burn units, can be used in more extensive disease. Very localized areas can be treated with silver nitrate–impregnated dressings. Painful ulcerations of the lips and mouth may benefit from topical application of a mixture of equal parts of simethicone (Maalox) and elixir of diphenhydramine hydrochloride (Benadryl) or viscous lidocaine (Xylocaine), especially before meals. The various commercial antiseptic mouthwashes are helpful in alleviating discomfort and malodor. Potent topical corticosteroids and topical tacrolimus have been successful in some patients with limited disease. The likelihood of complete remission is correlated with age of onset and initial mucosal involvement. Infection is a common complication and relates to severity of the pemphigus and the presence of diabetes mellitus.

Systemic Therapy

A common method of treatment for severe PV is to begin with doses of prednisone adequate to control the disease. High doses of prednisone (100–150 mg) are sometimes needed, but prolonged high doses are associated with significant morbidity and mortality, so adjuvant therapy should be started early. During the early phase of therapy, if prednisone at 1 mg/kg/day proves inadequate, the drug may be increased to a split dose of 1 mg/kg twice daily. As the course of corticosteroid therapy is typically longer than initially anticipated, it is good practice to begin vitamin D, calcium, weight-bearing exercise, and bisphosphonate therapy early in the course of treatment. Routine pneumocystis prophylaxis does not appear to be warranted in monotherapy, but in patients on high doses of steroids as part of combination therapy should be considered. Notably dapsone may be somewhat effective for both prophylaxis and against pemphigus. The sooner the diagnosis of PV is established and the sooner treatment is given, the more favorable the prognosis. The therapeutic effects are estimated by the number of new lesions per day and the rate of healing of new lesions. In patients with and Dsg3 antibodies, mucosal disease may still be active when cutaneous disease appears to be in remission. Pemphigus antibody titers can be performed on esophageal substrate, watching for a fall in titer. If, after 4–8 weeks of treatment, new blister formation is not suppressed, prednisone dosage may be increased to 150 mg/day. Dosage adjustments are made more frequently and aggressively in severe, progressive disease. Dividing

the daily dose will usually result in greater efficacy but will also result in greater adrenal suppression. Additionally, intravenous pulse therapy with megadose corticosteroids, such as methylprednisolone (Solu-Medrol), at a dose of 1 g/day over 2–3 hours, repeated daily for 5 days, may be employed for patients unresponsive to oral doses. Untreated disease is often fatal, but the clinician should remember that, in treated patients, side effects of therapy are the most common cause of death. Adjuvant therapy to decrease steroid dependence has reduced the mortality rate.

Medication is continued until clinical disease is suppressed and pemphigus antibody disappears from the serum. Once the antibody is no longer present, a DIF test is repeated. A negative DIF is predictive of sustained remission after withdrawal of therapy.

MMF is usually chosen as a steroid-sparing agent, at a dose of 1–1.5 g twice daily. Gastrointestinal (GI) intolerance is the most common side effect, and blood counts must be monitored. If the disease does not respond, either plasmapheresis or IVIG may be added to the regimen. Azathioprine is less expensive than MMF and is often used as an alternative when cost is an overriding issue. Azathioprine is best dosed based on measurement of the patient's thiopurine methyltransferase (TPMT) level. Most patients metabolize the drug quickly and may be underdosed if TPMT is not measured. Patients with high levels of the enzyme may require 2.5–3 mg/kg/day of azathioprine; patients with midrange levels are treated with 1–2.5 mg/kg/day. Patients deficient in TPMT may be treated with very low doses of azathioprine or with a different agent. Allopurinol interferes with metabolism of azathioprine, and increased serum levels may lead to toxicity.

Rituximab is rapidly becoming a first-line option for PV, with a recent study demonstrating efficacy as initial first-line treatment. An anti-CD20 monoclonal antibody, it leads to reduction in both CD20+ B cells, and possibly T-regulatory cells, with high response rates. There is a trend toward using rituximab early in the course of treatment if patients have significant disease, though it is still used for recalcitrant cases as well. Earlier treatment with rituximab may be associated with better clinical response. Dosing regimens include either rheumatoid arthritis dosing or lymphoma dosing, though lymphoma dosing appears to have slightly better outcomes. Patients on therapy who experience relapse tend to develop relapse as CD19+ B cells return, and when either Dsg1 or Dsg3 testing returns positive; low CD4+ T-cell count was also predictive of relapse. Human anti–chimeric antibody development can limit efficacy when they develop. Rituximab is generally well tolerated, but as with other suppressive agents, infections, including progressive multifocal leukencephalopathy, have been reported.

Patients with refractory disease may be treated with rituximab, IVIG, or cyclophosphamide, either alone or with plasmapheresis. Plasmapheresis alone is followed by rebound of antibody production, but the rebounding clone of plasma cells is sensitized to the effects of cytotoxic agents. Both daily cyclophosphamide dosing and pulse dosing schedules can be used alone or in combination with dexamethasone. Pulse dosing is usually given with mesna rescue and is associated with less bladder toxicity. Both dosing schedules should be planned early in the day, with vigorous hydration to minimize the risk of bladder toxicity. Blood counts must be monitored closely. Other risks of therapy with high doses of corticosteroids and immunosuppressants include diabetes, infection, hypertension, and cardiorespiratory disease. All these risks must be monitored, and all patients must receive gentle wound care and fluid and electrolyte management. In patients who cannot tolerate cyclophosphamide, chlorambucil has been used, but it is associated with a greater risk of hematologic malignancy. Cyclosporine and infliximab have also been used. Immunoadsorption represents a novel approach to therapy that could replace plasmapheresis. In addition to the use of IVIG as an adjuvant to conventional therapy, it has also been given as monotherapy. Onset of action is fairly rapid and may be seen within 1–2 weeks, and as an immunomodulatory and not suppressive agent with a good safety profile, it may represent a good alternative in select patients.

Immunosuppressant therapy alone has been reported as a successful treatment of patients with early, stable PV. If a contraindication to the use of corticosteroids exists, or if only limited disease is present, these may be used as single agents. In general, however, combined treatment with corticosteroids is superior in gaining early control of the disease. Dexamethasone-cyclophosphamide therapy and isolated oral cyclophosphamide are very effective options, but with high rates of adverse events. Oral cyclophosphamide was successful in 17 of 20 patients who had failed therapy with prednisone and an antimetabolite. The median time to achieve complete remission was 8.5 months, and the median duration of treatment was 17 months. Plasmapheresis was used in nine patients. Hematuria developed in five patients, and infections were noted in six. One patient developed bladder cancer 15 years after therapy.

Dapsone, nicotinamide, and tetracycline can be tried in patients with milder disease. Cyclosporine, etanercept, and infliximab have been used successfully in some patients. Intramuscular or oral gold is no longer commonly used. Gold is less effective than immunosuppressive therapy, but its advantages include lack of carcinogenicity and infertility. A minimum of 6 months is required to judge the effectiveness of gold therapy. Extracorporeal photochemotherapy has been used in a few patients. Platelet-rich plasma was reported as beneficial in a small study of seven patients with refractory oral erosions. Cutting-edge translational research into the use of specific chimeric antigen T cells to attack the pathogenic antibody-producing cells is being explored. Other monoclonal antibodies hold promise, including ofatumumab, belimumab, and veltuzumab, but there are insufficient data to recommend their use currently.

PEMPHIGUS VEGETANS

Pemphigus vegetans may present as localized plaques in the scalp or in two classic forms, the Neumann type, which generally begins and ends as typical pemphigus, and the Hallopeau type, which usually remains localized. Both types show pseudoepitheliomatous hyperplasia, and the Hallopeau type is characterized by eosinophil microabscesses within the epidermis.

Pemphigus vegetans may begin with flaccid bullae that become erosions and form fungating vegetations or papillomatous proliferations, especially in body folds or on the scalp. The tongue often shows cerebriform morphologic features early in the course of the disease. Lesions presenting as verrucous plaques on the scalp, finger, and genitalia have been reported. At times, the lesions tend to coalesce to form large patches or to arrange themselves into groups or figurate patterns.

The laboratory findings, etiologic factors, epidemiology, pathogenesis, and treatment of pemphigus vegetans are the same as those for pemphigus vulgaris. Pathogenic antibodies to desmocollins, specifically desmocollin-3 antibodies, have been reported in some cases and hypothesized to explain the different clinical features in vegetans versus vulgaris. Captopril-induced pemphigus vegetans has been reported.

Pemphigus vegetans must be differentiated from other conditions characterized by pseudoepitheliomatous hyperplasia and microabscesses, including halogenoderma, chromoblastomycosis, blastomycosis, granuloma inguinale, blastomycosis-like pyoderma, condyloma lata, and amebic granulomas. The Hallopeau type is distinguished by the presence of eosinophils, and both types by immunofluorescent findings.

PEMPHIGUS FOLIACEUS

Pemphigus foliaceus (PF) is characterized by flaccid bullae and localized or generalized exfoliation. Antibodies target Dsg1. Lesions start as small, flaccid bullae that rupture almost as they appear, leading to crusting (Figs. 21.5 and 21.6). Below each crust is a moist surface with a tendency to bleed. Nikolsky sign may be easily elicited by rubbing the skin. After a time, the exfoliative characteristics predominate, with few bullae. Adherent scale crusts may resemble cornflakes. A variant of pemphigus that has clinical features suggestive of dermatitis herpetiformis but has immunologic features of pemphigus has been called herpetiform pemphigus. This pustular variant can be mistaken for subcorneal pustular dermatosis, IgA pemphigus, or Sneddon-Wilkinson disease. Most of these patients represent a clinical variant of PF, with the remainder being PV patients. A few have also demonstrated desmocollin antibodies. Oral lesions are rarely seen, and then only as superficial erosive stomatitis. Several patients have been described whose clinical picture shifted from PF to PV, or vice versa, with an accompanying change in antibody profile. A rare variant of a

Fig. 21.5 Pemphigus foliaceus. (Courtesy Steven Binnick, MD.)

Fig. 21.6 Pemphigus foliaceus.

single fixed lesion of localized pemphigus on the face or scalp has been reported.

Most patients with PF are not severely ill. They complain of burning, pain, and pruritus. The lesions may persist for many years without affecting general health. PF occurs mostly in adults age 40–50 but has also been reported in children. The genders are affected equally. Prevalence of PF in people of Jewish heritage is much less than with PV. Endemic PF (fogo selvage) occurs in Brazil (see later discussion). The drugs listed under PV—penicillamine and ACE inhibitors, specifically captoprile—more frequently induce PF. Topical imiquimod and topical 5-fluorouracil have both been reported to induce PF in single case reports.

The principal histologic finding in PF consists of acantholysis in the upper epidermis, usually in the granular layer. The stratum corneum may be missing entirely or separated from the underlying epidermis. Individual elongated acantholytic cells are noted above the epidermis or clinging to the underside of the stratum corneum. DIF demonstrates intercellular IgG throughout the epidermis, although the deposits may be somewhat more prominent in the upper epidermis. IIF is positive in most patients, although prozone reactions occur and a wide range of dilutions should be tested. A sensitive and specific ELISA for detecting antibodies to Dsg1 is now available to confirm positive IIF results.

Patients with a distinct clinical picture of PF or PV may have a mix of antibodies. Western blot has shown Dsg1 in about 86% of PF patients and 25% of PV patients. ELISA has shown anti-Dsg1 antibodies in up to 71% of PF patients and 62% of PV patients. In one study, antibodies to Dsg3 were detected in 19 of 276 patients with PF and fogo selvagem who had only cutaneous disease. The antibody was capable of producing disease in laboratory animals, suggesting it was pathogenic in the PF patients. Therefore ELISA studies must always be interpreted in the context of clinical, histologic, and immunofluorescent findings. In PV, Dsg3 mediates mucosal disease, and cutaneous disease is associated with antibodies to Dsg1. A shift to predominantly Dsg1 antibodies has accompanied a clinical shift from PV to PF. Patients have also shifted from a pemphigus to a pemphigoid phenotype.

Dsg1, the antigen in PF, was first identified by immunoprecipitation consisting of polypeptides of molecular weight 260, 160, and 85 kilodaltons (kD). The 260-kD molecule is a complex of the 160-kD and 85-kD polypeptides. The PF antibody binds to a 160-kD glycoprotein extracted from normal epidermis. This glycoprotein is identical to Dsg1. The 85-kD glycoprotein is plakoglobulin, a desmosomal and adherens junction–associated molecule. Desmogleins are cadherin-type adhesion molecules found in desmosomes. The N-terminal extracellular domain of Dsg1 contains the dominant autoimmune epitopes in both PF and PV. Antibodies include both IgG1 and IgG4 subclasses. IgG4 antibodies appear to be pathogenic in most patients. In a subset of patients, IgG1 autoantibodies are pathogenic. E-cadherin autoantibodies often cross-react with Dsg1.

Treatment

Treatment of PF is similar to that for PVPF patients are generally less ill and may not need oral corticosteroid therapy. Dapsone and hydroxychloroquine may be useful, either alone in mild cases or to reduce the steroid dose level. Very mild disease may be treated with topical corticosteroids or topical calcineurin inhibitors. Nicotinamide and tetracycline may be more effective than in PV. Azathioprine, MMF, or cyclophosphamide may be needed, as in PV. As with PV, more reports are emerging of successful treatment with rituximab, with over 100 patients in the literature. Generally rituximab is effective though less dramatically than for PV, and patients with PF often require combination therapy or repeated treatments, and therefore have displayed slightly higher rates of infectious complications. The anti–IL6 receptor antibody tocilizumab, IVIG, and high-dose cyclophosphamide have been used for refractory disease. Etanercept has been used, and immunoadsorption with tryptophan-linked polyvinyl alcohol adsorbers or adsorption with plant lectins, such as wheat germ agglutinin, has been effective and holds promise as adjuvant therapy.

Herpes simplex superinfection, or *S. aureus* impetigo, can mimic PF and should be considered in recalcitrant or flaring cases.

Fig. 21.7 Fogo selvagem. (Courtesy Dermatology Division, University of Campinas, Brazil.)

ENDEMIC PEMPHIGUS (FOGO SELVAGEM)

Endemic pemphigus is found in tropical regions, mostly in certain interior areas of Brazil and Colombia, but also in North Africa, including Tunisia. Fifteen percent of cases are familial. HLA-DRB1 alleles *0404, *1402, *1406, and *0102 have been identified as risk factors. The disease is common in children, adolescents, and young adults, with about one third of cases occurring before age 20 and two thirds by 40 years. The initial lesions may be flaccid bullae, but later lesions are eczematoid, psoriasiform, impetiginous, or seborrheic in appearance. The midfacial areas may be involved (Fig. 21.7). Melanoderma and verrucous vegetative lesions are not unusual, and exfoliative dermatitis may occur. The mucous membranes usually are not involved. Nikolsky sign is present. The disease is often seen in those with arthropod exposure and may be initiated by an infectious agent, possibly carried by mosquitoes, sandflies, black flies, or other vectors, with those agents carrying a molecule triggering anti-Dsg1 antibodies through molecular mimicry.

Histologically and immunohistologically, fogo selvagem is identical to PF. As with PF, antibodies to desmosomal cadherins and E-cadherin may be present. The anti-Dsg1 autoantibodies cross-react with sandfly salivary LJM11 antigen. Endemic pemphigus has also been linked to the kissing bug *Triatoma matogrossensis* and to mercury poisoning. Peripheral blood mononuclear cells from patients produce more IL-1β than those from healthy controls. A strong Th2 bias is also observed. IgM anti-Dsg1 antibodies are common in fogo selvagem, but not in other forms of pemphigus.

A distinct subset has been described in a rural area in northeastern Colombia. This subset differs from previously described forms of endemic pemphigus and shares some immunoreactivity with paraneoplastic pemphigus. It is not, however, associated with malignant tumors. Clinically, the disease resembles Senear-Usher syndrome. A systemic form may affect internal organs and has a poorer prognosis. All patients appear to have antibodies to Dsg1. In addition, many sera react with desmoplakin I, envoplakin, and periplakin. DIF is noted in the pilosebaceous unit, adjacent neurovascular bundles and meibomian glands.

A few Brazilian sera also react with plakins. None of the Colombian patients' sera reacted with Dsg3, but about half of Brazilian

patients' sera reacted with Dsg3. This area of Colombia is a mining region, and the population is exposed to high environmental levels of mercuric sulfides and selenides; these compounds have been found in the skin of patients with endemic pemphigus.

PEMPHIGUS ERYTHEMATOSUS (SENEAR-USHER SYNDROME)

In Senear-Usher syndrome, the early lesions are circumscribed patches of erythema and crusting that clinically resemble lupus erythematosus and are immunopathologically positive for the lupus band in 80% of patients. The lesions are erythematous and thickly crusted, bullous, or even hyperkeratotic. These are usually localized on the nose, cheeks, and ears, sites frequently affected by lupus erythematosus. In addition, crusting and impetiginous lesions appear amid bullae on the scalp, chest, and extremities. In most patients, the disease runs an indolent course. Drug-induced cases with penicillamine, captopril, propranolol, heroin, and cefuroxime have been described.

The histopathology of pemphigus erythematosus is that of PF. DIF shows IgG and complement localized in both intercellular and BMZ sites. At the dermoepidermal junction (DEJ), the deposits are continuous and granular, as in lupus. In the epidermis, they resemble those of pemphigus. Antinuclear antibody is present in low titer in 30% of patients. Patients have demonstrated anti-Dsg1 but not anti-Dsg3 autoantibodies. Additional autoantibodies may be directed against bullous pemphigoid antigen 1 (BP230) and periplakin. Patients often respond to low doses of prednisone and may respond well to topical corticosteroids. Photoprotection is essential Immunosuppressants may be needed in severe cases. Cases have been reported in association with myasthenia and thymoma. All patients should be evaluated for features of systemic lupus.

PARANEOPLASTIC PEMPHIGUS

The initial description of this entity was a group of five patients with underlying neoplasms who presented with painful mucosal ulcerations and polymorphous skin lesions, which progressed to blistering eruptions. Most patients described since then have had associated neoplasms or Castleman disease. The mucosal lesions of paraneoplastic pemphigus (PNP) may appear lichenoid or may resemble Stevens-Johnson syndrome, with severe hemorrhagic crusting of the lips (Fig. 21.8). The skin lesions may appear as erythematous macules, lichenoid lesions, erythema multiforme

Fig. 21.8 Paraneoplastic pemphigus.

(EM)–like lesions, flaccid bullae, and erosions typical of pemphigus, or with tense, more deep-set bullae. Ocular involvement may be severe. It should be noted that all forms of pemphigus may be paraneoplastic. However, the specific disease dubbed "paraneoplastic pemphigus" has a characteristic clinical appearance as well as diagnostic immunologic findings, but it is not universally associated with a neoplasm. Many patients have devastating bronchiolitis obliterans as a manifestation of their disease.

Histologically, the lesions demonstrate epidermal acantholysis, suprabasal cleft formation, dyskeratotic keratinocytes, and vacuolar change of the basal epidermis. Biopsies that demonstrate both acantholysis and lichenoid change or individual cell necrosis should raise the suspicion of PNP. DIF reveals IgG and C3 deposition in the intercellular spaces of the epithelium. IIF shows a similar pattern in a wide range of stratified squamous epithelium and transitional epithelium (e.g., rat bladder). About 25% of cases will be negative. Immunoprecipitation is the definitive test. It reveals a complex immune response with autoantibodies directed against multiple high-molecular-weight keratinocyte proteins. Antibody targets are generally plakin family proteins at the desmosome and hemidesmosome, including desmoplakin 1 (250 kD), envoplakin (210 kD), and periplakin (190 kD), and both the major plaque protein of hemidesmosomes BPAg1 (230 kD) and plectin. Many cases also recognize an additional antigen at 170 kD. Antibodies to Dsg3, and less frequently Dsg1 and anti-α2-macroglobulin–like-1, are often present. Expanded testing has shown autoantibodies against desmocollins as well. One study suggested that antibodies to desmocollins and α2-macroglobulin–like-1 protein may be useful in making the diagnosis. Many patients have multiple antibodies. On DIF, some cases also demonstrate a linear or granular IgG and/or C3 at the BMZ. Detection of the characteristic immunologic pattern may be delayed, and tests should be repeated if the index of suspicion is high.

Whereas the dominant epitopes in PV reside in N-terminal regions of Dsg3, epitopes on Dsg3 in PNP are distributed more broadly through the extracellular domain. The N-terminal domains are still recognized more frequently than the C-terminal domains, with one study suggesting the N-terminus of envoplakin as the major epitope, particularly for patients with lichenoid inflammation and bronchiolitis obliterans. IgG subclasses in PNP are IgG1 and IgG2 dominant, contrasting with the IgG4 dominance in PV. There is a significant association in PNP with HLA-DRB1*03 allele (61.5% of those studied). In one study, eight of nine fatal PNP cases had distinctive cell surface antibodies detected in a beaded pattern by complement indirect immunofluorescence (CIIF) tests on monkey esophagus. Three long-term survivors with PNP

lacked this pattern, suggesting the test may have prognostic value. One study suggested that strong cytoplasmic staining on IIF should prompt investigation for possible PNP.

A wide variety of both benign and malignant tumors are seen in these patients, and some have no identifiable neoplasm. The most common associations are hematologic malignancies, including non-Hodgkin lymphoma, chronic lymphocytic leukemia (CLL), Castleman tumor, acute myeloid leukemia (AML), and thymoma; sarcoma has also been reported. Most reported patients die of their tumor. Others have died from disease-associated bronchiolitis obliterans.

Therapy for the bullous dermatoses with prednisone and/or immunosuppressive agents should be balanced with treatment of the tumor. Severe mucosal disease, particularly ocular disease, warrants rapid, intense therapy. High dose steroids, immunoablative high-dose cyclophosphamide without stem cell rescue, cyclosporin A, plasmapheresis, immunoapheresis, and rituximab and alemtuzumab (in CLL patients), and IVIG, either alone or in combination have been successful in some cases. Occasionally the blistering disease and/or underlying disorder may be controlled, but patients may still succumb to the bronchiolitis obliterans. Even with treatment, mortality remains higher than for other immunobullous diseases.

IGA PEMPHIGUS (INTRAEPIDERMAL NEUTROPHILIC IGA DERMATOSIS)

The initial description of this entity was an elderly man with chronic bullous dermatosis with unique histological and immunopathologic findings. The patient had generalized flaccid bullae, which rapidly ruptured and crusted and healed without scarring. No mucosal lesions were present. Histologically there were neutrophils linearly at the DEJ with exocytosis and some intraepidermal abscesses. DIF revealed intercellular IgA within the epidermis. No circulating antibodies were found.

Since that report, many additional patients with intraepidermal IgA deposition have been described. They have been classified as belonging to two subsets, one closely mimicking pemphigus and the second simulating subcorneal pustular dermatosis (SPD). The former starts with vesicles that become pustular within a few days, enlarge peripherally, and rupture in the center, then form a crust (Fig. 21.9). Continued peripheral vesiculation may lead to a flower-like appearance. The head, neck, and trunk are frequent sites of involvement. In some patients, the condition is induced by ultraviolet (UV) A light. The second subset, SPD, presents similar to Sneddon-Wilkinson disease, with serpiginous and annular pustules. A pemphigus vegetans–like pattern has also been described. Some cases have been induced by granulocyte-macrophage colony stimulating factor (GM-CSF). Some patients have had associated malignancies, and IgA pemphigus with PNP-like clinical features has been described, showing IgA antibodies to Dsg1/3 and desmocollin 3, as well as IgG and IgA antibodies to the BMZ. Monoclonal IgA gammopathy has also been reported.

Fig. 21.9 Intraepidermal neutrophilic IgA dermatosis. (Courtesy John Stanley, MD.)

Histologically, intraepidermal bullae with neutrophils, some eosinophils, and acantholysis are seen. DIF shows intraepidermal IgA deposition, usually throughout the epidermis, and IIF may reveal circulating autoantibody that binds to the same location. There is evidence that the IgA specificity in individual cases may be directed at either Dsg1, Dsg3, or desmocollin1-3. One study suggested polymeric immunoglobulin receptor as a candidate target protein. Some patients have concurrent IgG intercellular antibodies directed at Dsg1, with a growing number of recent reports identifying IgG/IgA overlap cases. IgG/IgA pemphigus patients clinically behave more similarly to classic IgG PV patients. It should be noted that IgA antibodies to Dsg1 and Dsg3 may occur in PV, PF, and PNP. Individual patients may express both anti–desmocollin 1 and anti-Dsg1 antibodies.

Therapy with topical corticosteroids may be effective in patients with mild intraepidermal neutrophilic IgA dermatosis. Dapsone is often effective, even at doses as low as 25 mg/day in some patients. Oral corticosteroids may be necessary, and some resistant cases have required immunosuppressive agents and plasmapheresis. Colchicine, acitretin, adalimumab, MMF, Rituximab, IVIG, and isotretinoin have been effective in some patients.

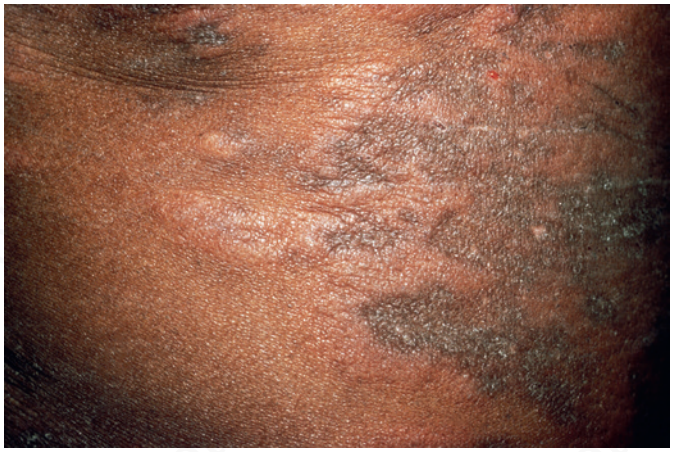

Fig. 21.11 Urticarial bullous pemphigoid.

BULLOUS PEMPHIGOID

Clinical Features

Bullous pemphigoid (BP) was described by Lever in 1953. Clinically, BP is characterized by large, tense, subepidermal bullae with a predilection for the groin, axillae, trunk, thighs, and flexor surfaces of the forearms (Fig. 21.10). Patients are frequently pruritic. Key features distinguishing BP from other immunobullous diseases include subepidermal separation at the DEJ, an inflammatory cell infiltrate that tends to be rich in eosinophils, and antibodies directed against two hemidesmosomal antigens, BP230 and BP180. Antibody detection rates vary by method, and many normal patients will have positive serologic tests but negative IIF. ELISA testing alone is not adequate for the diagnosis, and clinical examination, pathology, and immunofluorescence should be used together.

After the bullae rupture, large denuded areas are seen, but the bullae and denuded areas do not tend to increase in size as they do in PV. Instead, the denuded areas tend to heal spontaneously. In addition to the bullae, there often are erythematous patches and urticarial plaques (Fig. 21.11), with a tendency to central clearing. These patches and plaques may be present without bullae early in the course of the disease. Later, bullae often occur on an urticarial base. Sometimes, targetoid lesions are present.

Fig. 21.12 Vulvar pemphigoid.

BP may begin at a localized site, frequently on the thighs or shins. The disease may also be limited to areas of radiation therapy, burns, or plaques of psoriasis. BP may remain localized throughout its course or eventuate in generalized pemphigoid. Cases of the localized disease in which a vesicular eruption is limited to the palms or soles (dyshidrosiform pemphigoid) are occasionally observed. Young girls may present with localized vulvar erosions and ulcers that resemble the signs of child abuse (Fig. 21.12). These localized varieties have been shown to have circulating IgG antibody, which immunoprecipitates the 230-kD BP antigen.

Many other variants of BP have been described. A vesicular variant manifested by tense, small, occasionally grouped blisters is termed vesicular pemphigoid. Other patients, mostly women, have papules and nodules of the scalp and extremities, with sparing of the mucous membranes, in a pattern resembling prurigo nodularis (pemphigoid nodularis). Cases resembling pemphigus vegetans, but with IgG and C3 at the BMZ, are occasionally observed (pemphigoid vegetans). Erythroderma may be present (erythrodermic pemphigoid), or there may be no bullae at all (nonbullous variant). The latter type may present as generalized pruritus, pruritic eczema, or urticarial eruptions with peripheral eosinophilia. Overall, incidence of oral involvement is about 20%, but involvement of the pharynx, larynx, nasal mucosa, vulva, urethra, and eye is rare.

BP occurs most frequently in the elderly population. The age of onset averages 65–75 years. BP less commonly occurs in young children, but with clinical and pathologic findings similar to those in adults. Many of these cases begin with hand and foot bullae (Fig. 21.13). Facial involvement may be somewhat more common in children. In children, the course of disease is usually under 1 year, with most cases lasting 5 months or less.

In patients with lichen planus, a bullous eruption similar to BP may develop. This condition, called lichen planus pemphigoides, is sometimes related to the 230-kD antigen, the 180-kD antigen, or a unique 200-kD subepidermal antigen. A nonscarring eruption, with acute onset, widespread erosions, and severe mucous membrane involvement resembling toxic epidermal necrolysis or PV, has been referred to as anti-p105 pemphigoid. Linear IgG and C3 are noted at the BMZ. The 105-kD antigen is found in the lower portion of the lamina lucida.

Fig. 21.13 Childhood bullous pemphigoid.

Etiologic Factors

Circulating BMZ antibodies of the IgG class are present in approximately 70% of patients with BP. In most cases, the antibodies fix complement in vitro, in contrast to pemphigus antibodies, which fail to do so. Complement is activated by both the classical and the alternate pathway. No close correlation exists between the titer of antibodies and clinical disease activity. Passive-transfer mouse models suggest that subepidermal blistering is initiated by anti-BP180 antibodies. Blister formation involves complement activation, mast cells, and neutrophils. BMZ damage is caused by proteinases and reactive oxygen species released by the infiltrating neutrophils.

The site of IgG binding has been localized to the lamina lucida, with accentuation near hemidesmosomes. BP antigen 1 (BPAg1) is synthesized by the keratinocyte and is an intracytoplasmic hemidesmosomal plaque protein of 230 kD with disulfide-linked chains. The second BP antigen (180-kD BPAg2) is a transmembrane protein with a long C-terminal collagenous domain that projects into the extracellular region below the hemidesmosome. The antibody to BPAg2 is the primary pathogenic factor. The noncollagenous (NC) 16A domain harbors the major epitopes of autoantibodies in BP. A predominance of the IgG4 subclass has been observed in several studies. In addition to this humoral response, infiltrating T-helper lymphocytes with a mixed Th1/Th2 cytokine profile may play a role in blister formation. Peripheral blood eosinophilia is present in 50% of pemphigoid patients.

Recently IgE autoantibodies to BP180 and BP230 have been reported, though widespread clinical testing is not available, and at least the anti-BP180 autoantibodies appear to be pathogenic. IgE anti-BP230 autoantibodies correlating with nodular pemphigoid have been reported. Patients with IgE levels may also have more prominent urticarial lesions in some cases.

BP has occasionally been associated with other diseases, such as psoriasis, diabetes mellitus, rheumatoid arthritis, PF, dermatomyositis, ulcerative colitis, cardiovascular disease, and thymoma. Neurologic disorders have been reported in association with BP, particularly multiple sclerosis and possibly Parkinson disease, but also stroke, dementia, amyotrophic lateral sclerosis, and epilepsy. A systematic review and meta-analysis found no association of BP with overall malignancy, though noted a possible association with hematologic malignancy; as BP is generally a disease of the elderly, age appropriate screening is warranted. Patients with BP, particularly in the acute phase, have elevated risk of venous thromboembolism.

Drug-induced cases are uncommon. Agents reported to induce BP include penicillamine, furosemide, captopril, antibiotics (penicillin, amoxicillin, quinolones), sulfasalazine, nalidixic acid, escitalopram, TNF inhibitors, ustekinumab, and enalapril. Neuroleptic and diuretic agents have been reported most commonly. Gliptins, a class of oral hypoglycemic for diabetes, appear to have high rates of drug-induced BP, particularly vildagliptin. Radiation therapy, phototherapy, and photodynamic therapy can induce BP. The new class of anticancer agents, checkpoint inhibitors, have been reported to induce BP in multiple instances, and as their use is rapidly expanding, this is expected to be a more common observation in clinical practice.

Histopathology

The histologic changes of BP are characterized by subepidermal bullae, the absence of acantholysis, and a superficial dermal infiltrate containing many eosinophils. The amount of inflammatory infiltrate varies, and individual bullae may be "infiltrate poor" or "infiltrate rich." Often, the infiltrate contains many eosinophils, although neutrophil-predominant cases exist. Spongiosis with eosinophils occurs more frequently than in pemphigus. Urticarial lesions often demonstrate eosinophils lined up along the DEJ. Immunohistochemistry is being increasingly used in the diagnosis, with C3d deposits at the DEJ a clue to the diagnosis.

Atypical presentations are fairly common. In one study of 23 new cases of BP, only 7 of 22 biopsy specimens showed subepidermal blister formation, and only 12 of these had a predominance of eosinophils in the blister cavity. In 23% of patients, the biopsy was not particularly suggestive of BP. DIF, IIF, immunoblot analysis, and ELISA are critical in establishing the diagnosis in such patients.

The DIF test is more sensitive than IIF, as in pemphigus. In a positive test, continuous linear (tubular or toothpaste pattern) immunofluorescence is seen along the BMZ. IgG and/or C3 are best found in nonbullous lesional or perilesional skin. False-negative tests are somewhat more common on the lower extremities. When using perilesional or nonbullous lesional skin of the trunk, a positive DIF test is found in a high percentage of patients, with C3 most often present and IgG present in about 80% of cases. IgA and IgM are occasionally present. About 20% of patients have negative staining for IgG on DIF, even though C3 is present. In some of these patients, IgG may be present at subthreshold levels that cannot be detected. Also, the major subclass, IgG4, shows limited reactivity with most commercial antihuman IgG conjugates. Double-sandwich antibody immunofluorescence methods have been developed that offer greater sensitivity for IgG4 antibodies.

All histologic features present in BP may also be seen in epidermolysis bullosa acquisita (EBA). Therefore immunofluorescence testing on salt-split skin is sometimes performed to differentiate EBA from BP. Salt-split skin may be replaced by assessment of u-serrated (suggests EBA) and n-serrated (suggests BP) immunoglobulin patterns in DIF specimens and by serologic testing. C3 deposition is almost always present in BP, whereas it may be absent in EBA. Type IV collagen mapping in BP localizes to the base of the blister; in EBA, it stains the roof.

Bullous scabies can also mimic both the histology and the DIF findings of BP.

Treatment

Relatively few controlled trials have been performed, and many recommendations for BP therapy are based on experience and consensus of opinion. Using Cochrane criteria, seven randomized controlled trials (RCTs) were identified through 2003, enrolling a total of 634 patients. One comparing prednisolone, 0.75 mg/kg/day, with prednisolone, 1.25 mg/kg/day, found no statistical difference between the two treatments. The same was true of a trial comparing methylprednisolone with prednisolone. Higher doses of prednisolone were associated with more severe side effects in these studies. Two trials confirmed that adjuvant therapy with azathioprine or plasma exchange could reduce the required

corticosteroid dose. Another trial failed to confirm the superiority of combination treatment (with either azathioprine or plasma exchange) over corticosteroid alone, and one trial found no statistically significant difference between prednisolone and a combination of tetracycline and niacinamide. The steroid-treated group had more side effects. Another study compared ultrapotent topical corticosteroid treatment (clobetasol propionate cream, 40 g/day) with oral prednisone (0.5–1 mg/kg/day). In those with severe disease, 1-year survival was better in the topical corticosteroid group (76% vs. 58%). Disease control at 3 weeks was also better in the clobetasol than in the prednisone group (99% vs. 91%). Side effects were common in both groups, but more common in the prednisone group (29% vs. 54%). Among those with moderate disease, there were no significant differences between the two groups. One recent study randomized 132 patients to doxycycline and 121 to prednisolone, with doxycycline reducing blisters less effectively, but with half as many severe side effects. The authors concluded doxycycline is noninferior for blister control and safer long term.

Even in those with fairly extensive disease, topical corticosteroid treatment should be attempted. Prednisone has long been the standard approach to oral therapy, but the complication rate must be weighed carefully, especially in those with severe disease. Oral therapy with tetracycline, 500 mg four times daily, combined with niacinamide, 500 mg three times daily, is effective in some patients. Occasionally, patients with BP may respond to tetracycline or nicotinamide alone. Rituximab has proved effective in adults and has been used in infancy. Dapsone is also effective in some patients. Immunosuppressive therapy may still be necessary in resistant cases, either in combination with systemic or topical corticosteroids or as sole therapy. Azathioprine and MMF demonstrate similar efficacy when used as steroid-sparing agents, and cumulative corticosteroid doses are similar. MMF is more expensive but is easier to dose and associated with less toxicity. Methotrexate, cyclophosphamide, chlorambucil, IVIG, and cyclosporine have also proved effective in some patients, and some data suggest that outcomes are better with methotrexate than with prednisone. Low-dose oral methotrexate has been shown to induce apoptosis of tissue eosinophils in patients with BP. IVIG alone was effective in one study of 56 patients recalcitrant to steroids. The effectiveness of IVIG is often improved by the addition of an immunosuppressive agent. In exceptionally severe cases, pulse therapy with methylprednisolone can be rapidly effective. Again, some patients may also respond to dapsone, as well as sulfapyridine; these agents tend to be more effective in neutrophil-rich BP. Oral erythromycin and topical macrolactams have proved effective in some patients.

Double-filtration plasmapheresis (DFPP) may be more effective than conventional plasma exchange, possibly because it removes pathogenic cytokines. DFPP reduces a variety of cytokines, including IL-8, tumor necrosis factor (TNF)–α, and IL-2. IVIG produces faster clearance of antibody titers and may be helpful in inducing and maintaining remission. Some data suggest that single-chain variable fragments of anti–collagen XVII antibodies can interfere with pathogenic binding of autoantibodies, suggesting that interference with antibody binding may represent an alternative treatment approach to BP.

Rituximab is used less frequently for BP than for PV, but remains a highly effective option. One series of 12 patients treated with rituximab and IVIG achieved sustained remission in all cases, though 2 patients required redosing of rituximab. One single-center study of 19 patients treated with rituximab with steroids together as first-line treatment demonstrated good response rates, with a 20% rate of infection or serious adverse event. Omalizumab, a humanized monoclonal anti-IgE antibody, has been used in increasing numbers of reports recently, particularly in light of emerging studies highlighting the importance of IgE autoantibodies in the pathogenesis of BP in some patients.

A consensus statement from the European Academy of Dermatology and Venereology in 2015 provides expert opinion guidance for initial therapy. For limited disease, the Academy suggests that first-line treatment is high-potency topical steroids, with second-line options being oral steroids, tetracycline, or dapsone; for generalized disease, either ultrapotent topical or oral steroids, with second-line options azathioprine, mycophenolate, tetracycline, methotrexate, or chlorambucil. Rituximab, IVIG, cyclophosphamide, immunoadsorption, and plasma exchange are available as third-line options or for severe/recalcitrant cases.

Course and Prognosis

BP is usually self-limited over 5–6 years. This period is generally a year or less in children. Relapse occurs in 10%–15% of patients once therapy is discontinued. The presence of circulating anti-BP180 antibodies, but not anti-BP230, is associated with a statistically increased mortality risk in the first year after diagnosis. Other risk factors for death during the first year include older age, higher daily steroid dosage at discharge, low serum albumin, and erythrocyte sedimentation rate greater than 30 mm/hr. Much of the morbidity and mortality now relate to infection and side effects of drug therapy, but with improvements in treatment, pemphigoid patients have similar mortality to age-matched controls. Although IIF titers do not always correlate with disease activity, ELISA measurements of BP180NC16a show better correlation. The presence of IgE autoantibodies to BP180 correlate with a more severe course.

PEMPHIGOID GESTATIONIS (HERPES GESTATIONIS)

Clinical Features

Pemphigoid gestationis (PG) is an autoimmune, inflammatory, bullous disease with onset during pregnancy or during the postpartum period. It occurs in approximately 1 in 20,000 to 1 in 50,000 pregnancies. The onset is usually during the second trimester, though multigravida patients develop the disease earlier (21 weeks) than primigravid patients (31 weeks). Clinically urticarial plaques and papules developing around the umbilicus and extremities. Targetoid lesions may be present (Fig. 21.14). As the disease progresses, lesions may spread over the abdomen, back, chest, and extremities, including the palms and soles. The face, scalp, and oral mucosa are usually spared. Within the infiltrated erythematous plaques, tense vesicles and bullae erupt, often in an annular or polycyclic configuration. Pruritus is severe and universally present, and may be paroxysmal. The disease will often flare shortly after delivery and then remit spontaneously, usually within 3–6 months of delivery. There is no scarring, except that caused by excoriations or secondary infections. Recurrences with subsequent pregnancies are common, and the disease may be provoked by subsequent menstrual periods or oral contraceptives (OCs). A number of cases of persistent disease have been reported.

Most study data suggest that fetal loss is not statistically increased, although infants are often born prematurely and are small for gestational age. In fewer than 5% of cases, infants manifest the disease in the form of urticarial lesions or bullae. The lesions are usually limited, and clear spontaneously without the need for therapy. Neonatal convulsions have been reported.

Fig. 21.14 Pemphigoid gestationis.

Etiologic Factors

PG is an autoimmune, antibody-mediated disease, primarily caused by antibodies against the NC16-a domain of BP180. A complement-fixing IgG antibody is present in the serum and is deposited in the lamina lucida. The antigen, transmembrane collagen XVII, is a component of fetal membranes and promotes migration of placental cytotrophoblastic cells. The antigenic epitopes are usually restricted to the N-terminal portion of the extracellular domain of BP180 (BPAg2). The antigenic N-terminal portion of MCW-1 is located in the noncollagenous domain (NC16A) of BP180. Other antigens are located nearby, and four major PG epitopes are clustered within a 22–amino acid region of the BP180 ectodomain. ELISA-based assays correlate antibody levels to disease activity. Both IgG1 and IgG3 subtypes have been noted, but a more recent study found IgG4 to be the predominant subtype, as in BP.

Studies have documented an increased frequency of HLA-DR3, HLA-DR4, and HLA-C4 null alleles in patients with PG. A woman may have antibodies directed against her husband's HLA antigens. Black women rarely manifest PG, possibly related to the low incidence of HLA-DR4 in American black persons. From 10%–11% of patients develop Graves disease.

Pathogenesis

Pathogenesis is similar to that of BP. However, hormonal factors influence the disease manifestation. In addition to being seen in pregnant patients, menstruating women, and those taking OCs, the disease may occur in association with hydatidiform mole and choriocarcinoma. The IgG antibodies bind to the lamina lucida and fix complement. Activated eosinophils, neutrophils, and T cells with a predominant Th2 phenotype are involved in blister formation. Evidence of fetal microchimerism is lacking. Estrogen and progesterone may play a role given the diseases may flare immediately postpartum, during menstruation, and with OC use.

Patients with chronic PG tend to be older and multigravid, with a history of PG during previous pregnancies. They often have widespread cutaneous and mucosal involvement. The IgG1 subclass is often present. Antibodies to a C-terminal portion of BP180 have been noted in a patient with chronic PG. This same region is targeted in patients with cicatricial pemphigoid and some with BP.

Histopathology

A subepidermal bulla with eosinophils and some neutrophils is usually present in PG. In the urticarial stage, eosinophils may line up along the DEJ, as in urticarial BP. Civatte bodies may be present. On DIF, all patients have C3 deposited in a linear pattern at the DEJ; 25%–40% also have detectable IgG. On conventional IIF testing, approximately 25% of patients have a circulating IgG anti-BMZ antibody, but in almost 75%, the PG factor, a complement-fixing IgG antibody, can be demonstrated by complement-enhanced immunofluorescence. Immunoelectron microscopy has demonstrated that the blister occurs at the level of the lamina lucida, with deposition of C3 and IgG at this site, exactly as in BP.

Differential Diagnosis

The main diagnosis to be considered is pruritic urticarial papules and plaques of pregnancy (PUPPP). The differential diagnosis of PG also includes EM, drug reactions, and bullous scabies. Acrodermatitis enteropathica has also been reported to flare as a bullous eruption with each pregnancy. Biopsy, immunofluorescence findings, and clinical course establish the diagnosis.

Treatment

The use of potent topical steroids may be adequate in some patients with milder PG. Prednisone, about 40 mg/day orally, is usually effective in the remaining women. The dose is tapered to the lowest effective amount given on alternate days. Pyridoxine has been reported to be effective in some patients. Persistent PG after delivery has been treated with various tetracyclines, together with nicotinamide. A few women with severe PG have required treatment with rituximab, cyclophosphamide, dapsone, methotrexate, IVIG, or plasmapheresis.

OTHER PREGNANCY-RELATED DERMATOSES

Intrahepatic Cholestasis of Pregnancy (Prurigo Gravidarum)

This rare condition has wide geographic variability in reported frequency, with 4% of pregnancies in Chile versus 0.7% in the United Kingdom, though these numbers may overestimate the true rate. There may be a genetic predisposition, though seasonality, dietary factors, and hormones may confer additional risk. Women with prurigo gravidarum have no primary skin lesions and usually manifest only severe, generalized pruritus. Secondary excoriations may be present. The disease is caused by cholestasis with elevated serum bile salts and often other signs of liver dysfunction; serum bilirubin is elevated in 10%, and those patients develop jaundice. It occurs late in pregnancy, resolves after delivery, and recurs with subsequent pregnancies. There is an increased incidence of fetal complications. There may be an increased risk of preeclampsia. Both ursodeoxycholic acid and *S*-adenosylmethionine improve pruritus, but the former is more effective in improving liver function. Rifampicin has been used in severe cases in combination with ursodeoxycholic acid. Mentholated topical emollients may relieve the pruritus. Delivery closer to 37 weeks of gestation may be associated with better outcomes.

Polymorphic Eruption of Pregnancy

Some investigators have proposed grouping all the pruritic inflammatory dermatoses of pregnancy into the designation "polymorphic eruption of pregnancy." This argument has some merit, because many of the pruritic eruptions of pregnancy are nonspecific or variable manifestations of PUPPP, and there are no consistent hormonal or immunopathogenetic factors that reliably separate them. These eruptions occur in approximately 1 in 120 to 1 in 240 pregnancies. They are more common with male fetuses and multiple-gestation pregnancies.

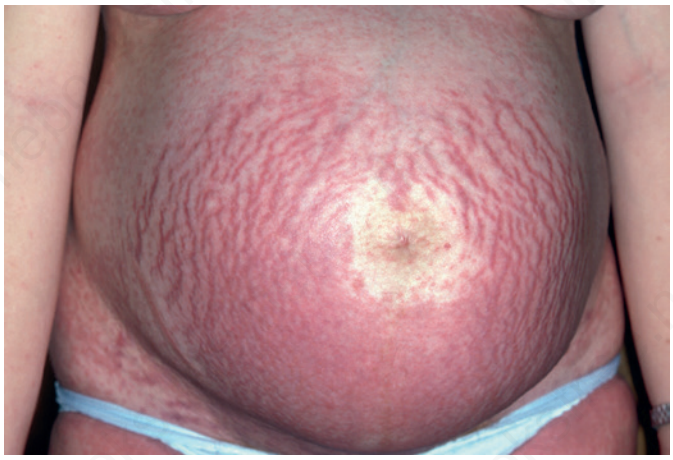

Fig. 21.15 Pruritic urticarial papules and plaques of pregnancy.

Pruritic Urticarial Papules and Plaques of Pregnancy

This eruption was first reported in 7 patients under the name pruritic urticarial papules and plaques of pregnancy in 1979. PUPPP is characterized by erythematous papules and plaques that begin as 1- or 2-mm lesions within the abdominal striae (Fig. 21.15). These then spread over a few days to involve the abdomen, buttocks, thighs, and in some cases the arms and legs. The upper chest, face, and mucous membranes are generally spared. The lesions coalesce to form urticarial plaques, sometimes in figurate patterns, and occasionally spongiotic vesicles are present. Intense pruritus is characteristic. In contrast to PG, postpartum onset or exacerbation is uncommon. Fetal and maternal outcomes are not affected by this eruption, and only rarely do newborns manifest transient lesions of PUPPP.

This eruption occurs in primigravidas 75% of the time and rarely recurs with subsequent pregnancies. It begins late in the third trimester and resolves with delivery. Many studies have investigated the relationship of maternal weight gain to the development of this dermatosis. Patients with PUPPP average more weight gain and greater abdominal distention than those without the disease. It is more common in primigravid women and those carrying twins or triplets.

Histologic findings consist of a perivascular lymphohistiocytic infiltrate in the upper and middle dermis, with a variable number of eosinophils and dermal edema. The epidermis is usually normal, although focal spongiosis, parakeratosis, or scales or crust may be present. The results of a DIF test are negative or nonspecific.

Usually, potent topical corticosteroids are required to control the eruption. Even short-duration use of strong steroids can lead to maternal absorption and fetal effects, and patients should be counseled and the use discussed with the obstetrician. A few patients require prednisone. PUPPP remits after delivery.

Papular Dermatitis of Pregnancy

Papular dermatitis of pregnancy is a controversial entity. It is defined as a pruritic, generalized eruption of 3–5 mm, erythematous papules, each surmounted by a small, firm, central crust. The lesions may erupt at any time during pregnancy and usually resolve with delivery. Marked elevation of the 24-hour urinary chorionic gonadotropin has been cited as a marker for the condition.

Administration of systemic corticosteroids is reportedly effective in controlling the eruption. Papular dermatitis may recur in subsequent pregnancies. The high incidence of fetal deaths reported by Spangler is now thought to have been overstated.

Prurigo Gestationis (Besnier)

Prurigo gestationis consists of pruritic, excoriated papules of the proximal limbs and upper trunk, occurring most often between the 20th and 34th weeks of gestation. It clears in the postpartum period and usually does not recur. Therapy with potent topical corticosteroids is recommended. No adverse effects on maternal or fetal health are seen. This eruption may simply be an expression of atopic dermatitis in pregnancy.

Pruritic Folliculitis of Pregnancy. Several authors have reported on pruritic folliculitis in gravid women, with small follicular pustules scattered widely over the trunk appearing during the second or third trimester and resolving by 2 or 3 weeks after delivery. Acute folliculitis and focal spongiosis with exocytosis of polymorphonuclear leukocytes are present on biopsy, and DIF results are negative. This condition may be a type of hormonally induced acne.

Linear IgM Dermatosis of Pregnancy

This entity was reported in a woman who developed small, red, follicular papules and pustules that, on immunofluorescence testing, showed linear deposits of IgM. This finding is common in a wide variety of dermatoses and is nonspecific.

Impetigo Herpetiformis

Impetigo herpetiformis is a form of severe pustular psoriasis occurring in pregnancy. It consists of an acute, usually febrile onset of grouped pustules on an erythematous base, which begins in the groin, axillae, and neck. There is a high peripheral white blood cell count, and hypocalcemia may be present. The histopathology is that of pustular psoriasis. The condition resolves with delivery, but recurrences with subsequent pregnancies may be expected. Fetal death can occur and results from placental insufficiency. Initial treatment is with systemic corticosteroids, in the range of 40–60 mg/day of oral prednisone. Impetigo herpetiformis is discussed in more detail in Chapter 10.

CICATRICIAL PEMPHIGOID (MUCOUS MEMBRANE PEMPHIGOID)

In 1953 Lever suggested the designation "benign mucosal pemphigoid" for what had previously been called ocular pemphigus, cicatricial pemphigoid, or essential shrinkage of the conjunctiva.

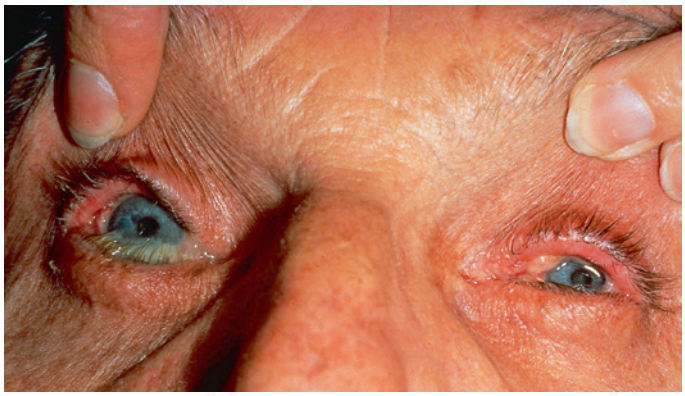

Fig. 21.16 Cicatricial pemphigoid.

Fig. 21.17 Desquamative gingivitis secondary to cicatricial pemphigoid.

Because of its scarring nature, the designation cicatricial pemphigoid (CP) has gained predominance, as "benign" is a misnomer. The term encompasses a group of immunologically distinct immunobullous diseases with scarring.

Clinical Features

CP usually occurs in older women, with a female/male ratio of approximately 2:1. CP is characterized by evanescent vesicles that rupture quickly, leaving behind erosions and ulcers. In most patients, the vesicles primarily occur on the mucous membranes, especially the conjunctiva (Fig. 21.16) and oral mucosa. Oral lesions occur in approximately 90% of patients and conjunctival lesions in 66%. The oral mucosa may be the only affected site for years. Desquamative gingivitis, diffuse erythema of the marginal and attached mucosa associated with mucosal desquamation and pain, is often the presenting sign (Fig. 21.17). The mucosa readily peels away in response to pressure from a cotton-tipped applicator or stream of air from a dental air hose. The gingivae are almost always involved, and the lingual surfaces less regularly. The palate, tongue, and tonsillar pillars may be involved. Patients may be misdiagnosed initially with mucosal lichen planus.

In contrast to BP, CP shows little tendency for remission. Although the disease is chronic and produces significant morbidity, the patient's general health is usually not jeopardized. In ocular cases, CP leads to scarring and progressive shrinkage of the ocular mucous membranes. Blindness may quickly result. It is usually bilateral and associated with redness and flaccid vesicles on the conjunctiva, xerosis, and fibrous adhesions (symblepharon).

Fig. 21.18 Antilaminin cicatricial pemphigoid with inguinal involvement. Blisters began at the same time colonic cancer was diagnosed.

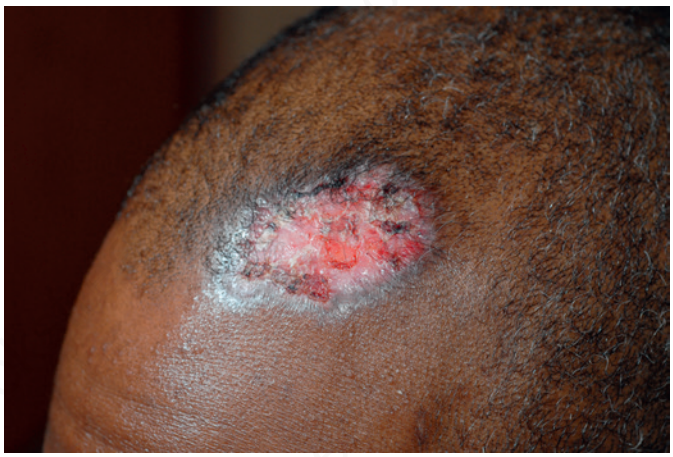

Fig. 21.19 Brunsting-Perry pemphigoid.

Entropion, trichiasis, and corneal opacities develop, and ultimately, the adhesions attach both lids to the eyeball and narrow the palpebral fissure. Scarring may also develop in the pharynx, esophagus, larynx, and anogenital mucosa. Esophageal stricture may occur, and deafness has been reported.

Cutaneous lesions are seen in approximately 25% of CP patients. These begin as tense bullae, similar to those in BP. The bullae may occur on the face, scalp, neck, inguinal region (Fig. 21.18), or extremities. Generalized lesions may also occur. Some of these patients will have circulating antibodies targeted against the classic BP antigens and should be classified as mucosal-predominant BP. Some have secondary antibodies against other antigens. Some patients have EBA, as their IgG autoantibody targets type VII collagen. Vegetating intertriginous lesions have been dubbed CP vegetans. Some patients have developed esophageal involvement, which can lead to strictures and other complications.

In Brunsting-Perry pemphigoid, there are no mucosal lesions, but one or several circumscribed erythematous patches develop, on which recurrent crops of blisters appear. Ultimately, atrophic scarring results (Fig. 21.19). Generally, the areas of involvement are confined to the head and neck. The average age at onset is 58, with a 2:1 male/female ratio.

Etiologic Factors

Although patients share a similar phenotype, CP is a heterogeneous group of autoimmune subepidermal blistering diseases. Circulating autoantibodies target the hemidesmosomal protein BP180, but the target epitopes differ from those usually targeted in BP. Whereas most BP patients react with the noncollagenous domain (NC16a) on the extracellular N-terminal portion of BP180, most CP antibodies target C-terminal domains. Fluorescence typically is found on the epidermal side of 1-M NaCl-split skin. The deeper location within the BMZ of the target autoantigen in this entity helps explain the observed scarring phenotype.

Whereas most patients' autoantibodies target BP180, others target laminin 5 (also called laminin 3-3-2), termed *antiepiligrin* or *antilaminin cicatricial pemphigoid*, or the β4 subunit of α6 β4 integrin. Integrin β4 appears to be the major autoantigen for pure ocular mucous membrane pemphigoid (MMP). Some patients with a CP phenotype have antibodies to multiple epitopes, including the β4 subunit, BP180, and BP230. Other subsets of patients targeting unique BMZ antigens will likely be identified.

A sensitive ELISA test for laminin 5 antibodies has made it easier to identify this subset of patients. Among those whose antibodies target laminin 5 (antiepiligrin CP), most exhibit antibodies to the α subunit, especially the G domains of the α3 subunit. Antibodies may also target the β3 and γ2 subunits. Other patients have been found to have autoantibodies that react with both laminin 6 and laminin 5, prompting the proposed designation of antilaminin cicatricial pemphigoid. In antilaminin cicatricial pemphigoid, IgG anti-BMZ autoantibodies bind to the dermal side of 1-M NaCl-split skin. As with other forms of CP, the disease rarely remits spontaneously. Some data suggest an increased relative risk for solid cancers (mostly adenocarcinomas) in these patients. Tumors are usually found during the first year of the disease. Other data suggest that antilaminin 332 autoantibodies are associated with severe MMP but not malignancy. These patients also have higher rates of oropharyngeal involvement. In contrast to the possible increased tumor risk in antilaminin 5 CP, some data suggest that patients with antibodies to the β4 integrin subunit have a decreased risk of cancer.

Histopathology

The histologic findings of CP are identical to those of BP, except that fibrosis and scarring may be present in the upper dermis. Basement membrane separation occurs in the lamina lucida or below the lamina densa, depending on the targeted antibody. The inflammatory infiltrate is variable. DIF testing of perilesional skin or mucosa reveals C3 and IgG at the lamina lucida in 80%–95% of patients. The BMZ of mucosal glands stains as well. IgA may be found occasionally. False-negative studies are not uncommon, and repeated biopsies increase the sensitivity for DIF to detect the disease. A circulating antibody to the BMZ is found by IIF in about 20% of CP patients. Immunoelectron microscopy shows that lamina lucida antibodies bind at a deeper level than with BP. Most IIF-positive cases show IgG binding to the epidermal side of salt-split skin, although combined staining and dermal staining may be present in different subtypes, as previously noted. Laser scanning confocal microscopy using fluorescein isothiocyanate–conjugated antihuman IgG antibody has been employed to determine the localization of IgG at the BMZ, and may be of value in patients with negative IIF. "Knockout" skin substrates and fluorescent overlay antigen mapping have also been used to differentiate between antiepiligrin CP and EBA.

Treatment

Because patients can rapidly develop blindness, early, aggressive treatment is indicated. Cyclophosphamide or rituximab-containing regimens are generally advised. A review of studies using the Cochrane criteria found two small RCTs, both in patients with severe eye involvement. In one, 6 months of cyclophosphamide was superior to prednisone. In the second RCT, 20 of 20 patients responded well to 3 months of cyclophosphamide, but only 14 of 20 responded to dapsone. Based on these limited data and other, uncontrolled trials, the reviewers concluded that patients with

severe ocular CP respond best to cyclophosphamide combined with corticosteroids, and that those with mild to moderate disease may respond to dapsone. MMF, methotrexate, and azathioprine have also been used effectively in some cases and are more effective than dapsone. Rituximab has emerged as an excellent additional option, with multiple studies indicating patients with rituximab added to their regimen demonstrating improved outcomes. One retrospective study showed 24 patients treated with rituxan with 100% achieving disease control, versus 25 patients treated with conventional immunosuppression. IVIG has been used in recalcitrant cases. TNF inhibitors have been reported to help some patients with severe, refractory disease (etanercept, infliximab, and also pentoxifylline).

In patients with mild CP, oral hygiene, topical corticosteroids, intralesional or perilesional triamcinolone, topical calcineurin inhibitors, or topical steroids occluded under vinyl inserts may be effective for desquamative gingivitis and other oral, genital, or cutaneous disease. Cream and gel formulations may be used, or the steroid may be compounded in Orabase. Topical sucralfate suspension may decrease the pain and healing time of the oral and genital ulcers. There have been reports of efficacy of thalidomide, tetracycline combined with niacinamide, dapsone, IVIG, etanercept, systemic corticosteroids, and immunosuppressive drugs.

EPIDERMOLYSIS BULLOSA ACQUISITA

Initial proposed criteria for EBA included the following:

1. Clinical lesions of dystrophic epidermolysis bullosa, including increased skin fragility, trauma-induced blistering with erosions (Fig. 21.20), atrophic scarring, milia over extensor surfaces, and nail dystrophy
2. Adult onset
3. Lack of a family history of epidermolysis bullosa
4. Exclusion of all other bullous diseases, such as porphyria cutanea tarda, pemphigoid, pemphigus, dermatitis herpetiformis, and bullous drug eruption

Fig. 21.20 Epidermolysis bullosa acquisita.

In 1981 Roenigk et al. extended these criteria to include the following:

5. IgG at the basement membrane zone by DIF
6. Demonstration of blister formation beneath the basal lamina
7. Deposition of IgG beneath the basal lamina

Patients may also have mucosal involvement. The antibodies have been found to target type VII collagen, a major component of anchoring fibrils. The target is the same as that in bullous lupus erythematosus. In some patients, it has been shown that autoantibodies bind to the NC-1 domain of collagen VII within the lamina densa. IIF studies reveal circulating anti-BMZ antibodies in approximately half of cases. B cells, dendritic cells, and macrophages are required to induce the CD4 helper T-cell response that results in the formation of pathogenic antibodies. Neutrophil activation and recruitment appear to play an important role. Type VII collagen ELISA using the NC1 and NC2 domains is useful for diagnosis, and antibody levels have been shown to correlate with disease severity.

The noninflammatory clinical presentation of EBA is the most frequently recognized type. A rare erythrodermic presentation has been reported. The association of EBA with many systemic diseases, such as myeloma, inflammatory bowel disease (especially Crohn disease), diabetes, lymphoma, leukemia, amyloidosis, hepatitis C infection, and carcinoma, is well established. EBA is associated with HLA-DR2, and in patients of African descent, HLA-DRB1*15:03.

Cases were reported describing patients with generalized inflammatory bullous disease that resembled BP clinically but with immunologic and ultrastructural features of EBA. Many of these patients have associated diabetes mellitus, are HLA-DR2 positive, and progress to the trauma-induced scarring type of EBA in the long term. Approximately 5%–10% of patients referred to medical centers as having BP may actually have EBA. Rare patients have been reported who meet criteria for both BP and EBA and appear to have both diseases.

Patients with EBA usually have a predominance of neutrophils over eosinophils, although this is variable. On IIF, EBA patients are more likely to have linear IgG without concomitant C3

Fig. 21.21 Inflammatory epidermolysis bullosa acquisita.

deposition than are patients with BP. Immunofluorescence on salt-split skin allows differentiation of the majority of cases without the need to resort to immunoblot techniques or immunoelectron microscopy. By DIF testing of the patient's salt-split-skin biopsy, EBA will manifest IgG deposition only on the dermal side of the split, whereas the majority of BP patients will have IgG bound only to the epidermal side or to both sides. The finding of a u-serrated pattern on DIF may make the salt-split-skin assay unnecessary. As noted earlier, some patients with BP have antibodies that target sub–lamina densa antigen. Absolute differentiation of these diseases is obtained by immunoelectron microscopy or immunoblot findings. In EBA, immunoblotting identifies 290-kD and 145-kD proteins, corresponding to type VII collagen. Blistering appears to be T-cell dependent.

Bullous systemic lupus erythematosus (SLE) and EBA demonstrate clinical and histologic overlap, but the following features favor EBA: skin fragility, predilection for traumatized areas, and healing with scars and milia. In bullous SLE, sun-exposed skin is involved by preference, and the patient has a diagnosis of SLE established by American College of Rheumatology criteria; bullous SLE patients usually have a dramatic response to dapsone. In addition to the cases of bullous SLE that show linear IgG staining below the lamina densa with circulating IgG autoantibodies to the 290-kD and 145-kD antigens, some patients will show granular staining of IgG at the BMZ without circulating IgG. EBA-like eruptions are rarely seen as a result of penicillamine therapy.

Purely IgA-mediated EBA has been described. The patients resemble linear IgA dermatosis or inflammatory IgG-mediated EBA. Only a minority demonstrate milia or scarring. Immunoblotting or fluorescence overlay antigen mapping using laser scanning confocal microscopy can distinguish the two diseases. IgM-type EBA has also been reported, with a milder phenotypes and predominantly mechanically induced bullae at sites of pressure.

Treatment

A review of the literature using Cochrane criteria failed to identify any RCTs. EBA is often resistant to therapy, but good responses have been reported in some patients treated with systemic corticosteroids alone or in combination with azathioprine or dapsone. Rituximab and IVIG together have helped patients resistant to standard therapy. Other agents reported to be effective include rituximab, MMF, IVIG, cyclosporine, colchicine, plasmapheresis, photophoresis, infliximab, minocycline, and daclizumab. Given the role of neutrophils, some have suggested further examination of treatments blocking neutrophil chemokines and cytokines. PDE-4 inhibitors were effective in an in vitro model. Supportive therapy, including control of infection, careful wound management, and maintenance of good nutrition, should be emphasized.

DERMATITIS HERPETIFORMIS (DUHRING DISEASE)

Clinical Features

Dermatitis herpetiformis (DH) is a chronic, relapsing, severely pruritic disease characterized by grouped, symmetric lesions on extensor surfaces, the scalp, nuchal area, and buttocks. The lesions are severely pruritic and thus generally present as excoriations rather than vesicles or bullae. The eruption usually occurs on an erythematous base and may be papular, papulovesicular, vesiculobullous (Fig. 21.22), bullous, or urticarial. Linear petechial lesions may be noted on the volar surfaces of the fingers, as well as the palms. Pigmented spots alone over the lumbosacral region should arouse suspicion of DH. The mucous membranes are involved in rare cases, mostly when bullae are numerous. Laryngeal lesions may manifest as hoarseness. Itching is usually intense, but spontaneous remissions lasting as long as 1 week and terminating abruptly with a new crop of lesions are a characteristic feature of the disease. Perimenstrual flares may rarely occur.

Between 77% and 90% of patients with DH and IgA deposits in the skin are HLA-B8 positive, a similar frequency to that observed in gluten-sensitive enteropathy (GSE). HLA antigens DR3 and DQw2 are also increased in frequency. Black and Asian patients are uncommon, possibly because of HLA differences. These HLA markers are associated with other autoimmune diseases

Fig. 21.22 Dermatitis herpetiformis.

and indicate patients who appear to have an overactive immune response to common antigens and who may clear immune complexes slowly. DH is more common in those with affected family members.

In childhood DH is usually similar to the adult type, has identical histologic and immunofluorescent findings, and has a high incidence of HLA-B8 and HLA-DR3 and abnormal jejunal biopsies. Palmar blisters and brown, hemorrhagic, purpuric macules may be more common than in adults. Treatment with sulfones results in prompt response in children, as in adults.

Gluten, a protein found in cereals, except for rice and corn, provokes flares of the disease. Villous atrophy of the jejunum and inflammation of the small bowel occur. IgA is bound to the skin, and this apparently activates complement, primarily through the alternate pathway. Oral iodides will cause a flare of the disease. Patch tests with 50% potassium iodide in petrolatum produce a bulla in uncontrolled DH, but only exceptionally in patients controlled by a gluten-free diet or by sulfone therapy.

Associated Disease

Thyroid disorders are increased in incidence in patients with DH. Neurologic disease, including ataxia, may occur. An increased incidence of malignancy, especially small bowel lymphoma, has also been noted in some studies, although others have reported this increase with celiac disease but not DH. In fact, the incidence of breast cancer may be lower in those with DH than in the general population. A high prevalence of cryofibrinogenemia was reported in one study.

Enteropathy

Between 70% and 100% of patients with DH have abnormalities in the jejunal mucosa, but most are asymptomatic. If given a high-gluten diet, virtually all patients with DH develop findings indistinguishable from celiac disease, and DH affects approximately 25% of patients presenting with celiac disease.

The dapsone requirement in DH is usually decreased after 3–6 months of a gluten-free diet. The majority of patients who adhere to a strict gluten-free diet can eventually stop their medication or significantly reduce the dosage. A gluten-free diet is not easy to follow but may decrease the incidence of intestinal lymphoma.

Diagnosis

The distinction of DH from linear IgA bullous dermatosis is often clinically impossible. Other conditions considered in the differential diagnosis at times are BP, bullous EM, scabies, contact dermatitis, atopic dermatitis, nummular eczema, neurotic excoriations, insect bites, and chronic bullous disease of childhood. The finding of IgA in a granular pattern at the DEJ with accentuation in the dermal papillae is specific for DH.

Autoantibodies

Circulating IgA antibodies against the smooth muscle cell endomysium (antiendomysial antibodies) are present in 70% of DH patients, in almost all patients with active celiac disease, and almost never in other conditions. Tissue transglutaminase (TTG) is the major autoantigen in GSE. IgA antibodies directed at TTG2 are common in patients with DH or celiac disease, but epidermal transglutaminase (TTG3) appears to be the most important antigen. Dietary exposure to gliadin proteins in wheat and related proteins from barley and rye induce flares of the disease. These proteins are high-affinity substrates for TTG. The two are often tightly bound, which may explain why an antibody response is generated against both gliadin and TTG. Gliadins can also be found in rice, corn, and oats, but these proteins are poor substrates for TTG.

Epidemiology

This disease has an equal male-to-female incidence. The average age of onset is 20–40 years. DH does occur with some frequency in children. Black and Asian persons are rarely affected.

Histopathology

The initial changes of DH are noted at the tips of the dermal papillae, where edema, focal fibrin, and neutrophilic microabscesses are seen. The cellular infiltrate contains many neutrophils but may also include a few eosinophils. A subepidermal separation is noted histologically. Ultrastructurally, the split may begin in the lamina lucida. In a study of 24 patients with confirmed DH, 37.5% had nonspecific findings on hematoxylin and eosin (H&E) staining, including a lymphocytic infiltrate, ectatic capillaries, and fibrosis in the dermal papillae. Because of the potential for nonspecific biopsy findings, DIF studies are essential. Histologic differentiation of linear IgA bullous dermatosis from DH is extremely difficult unless DIF is performed. DIF of noninvolved perilesional skin reveals deposits of IgA alone or together with C3 arranged in a granular pattern at the DEJ. The deposits are typically accentuated in the dermal papillae. IgM and IgG deposits are occasionally observed in association with IgA. Deposits may be focal, so multiple biopsies may be needed, and the deposits of antibody are more often seen in previously involved skin or normal-appearing skin adjacent to involved skin. IgA is observed by immunoelectron microscopy, either alone or in conjunction with C3, IgG, or IgM, as clumps in the upper dermis. A vertically oriented fibrillar staining pattern exists in a subset of patients, with immune deposits along dermal microfibrils, creating a "picket fence" pattern of immunofluorescence. The fibrillar pattern is present in a third of Japanese patients, and this group lacks the typical distribution of skin lesions and has a low association with celiac disease. A few patients will

have negative DIF despite typical clinical findings and evidence of antiendomysial antibodies. IIF is rarely positive.

Treatment

Adherence to a gluten-free diet is important, because it reduces the risk of intestinal disease. Compliance can often reduce the need for or dose of treatment. The drugs chiefly used for DH are dapsone and sulfapyridine. The most effective sulfone is diaminodiphenylsulfone (dapsone). The dose usually ranges from 50 mg/d to 150mg/d, with rare cases requiring up to 300mg/day. Doses are increased gradually to an effective level or until side effects occur. Once a favorable response is attained, the dosage is decreased to the minimum that does not permit recurrence of signs and symptoms. When dapsone is discontinued abruptly, large bullae similar to those seen in BP frequently occur. Hemolytic anemia, leukopenia, methemoglobinemia, agranulocytosis, or peripheral neuropathy may occur with dapsone. Acute hemolytic anemia (which may be severe) occurs in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency; therefore G6PD level should be measured before therapy. In those whose ethnic background makes G6PD deficiency unlikely, some authorities begin dapsone at a low starting dose (25 mg/day) and watch the patient closely for dark urine. The patient should be warned to report by telephone any incident of red or brown urine or blue nail beds or lips. A blood count should be done weekly for 4 weeks, bimonthly for the next 3 months, and every 2–6 months thereafter. Liver function tests should be monitored bimonthly for the first 4 months, then checked with the hematologic studies every 4–6 months.

Agranulocytosis is rare. It typically occurs 1–3 months after initiation of drug therapy and presents with sore throat, aphthae, or evidence of infection. The risk of agranulocytosis is higher in older patients (>60 years) and nonwhite persons. The incidence varies with the disease. It is rarely seen in patients with Hansen disease, but patients with DH have a 25-fold to 33-fold increased risk.

Sulfapyridine can also be used to treat the disease. After a test dose of 0.5 g of sulfapyridine, 1 tablet (0.5 g) is given four times daily. The dose is then increased if necessary, or reduced if possible. Usually 1–4 g/day is required for good control. The drug is less water soluble than dapsone, and patients should remain hydrated. Sulfasalazine, 500 mg three times daily, increased to 1.5 g three times daily as tolerated, may also be used, because sulfapyridine is a metabolic product. GI intolerance may limit the dosage.

In rare patients, it is necessary to find alternatives to the sulfone drugs. Tetracycline/nicotinamide and colchicine have controlled individual patients. Topical dapsone 5% gel may be effective. Rituximab has been used in one case of recalcitrant DH. Heparin has been used in the past but is generally unnecessary with newer options.

Gluten-Free Diet

Patients must strictly avoid wheat, barley, and rye. Moderate amounts of oats may be tolerated. In Canada, standards for growing, processing, testing, and labeling of pure, uncontaminated oats have allowed adults to consume up to 70 g (about one half to three quarters cup) of oats and children to consume up to 25 g (one quarter cup) daily without flares of disease. Corn and rice are generally well tolerated, corresponding to the poor binding of their gliadin proteins to TTG, but exacerbation of disease related to cornstarch has been reported. If a gluten-free diet is followed strictly, the patient will almost certainly be able to take less medication or stop it altogether. Some evidence suggests that this may decrease the incidence of associated malignancy; however, it is a very difficult diet to follow.

Once a prolonged remission has been obtained, some gluten may be tolerated in a subset of patients. In one study, 38 patients who had followed a gluten-free diet for a mean of 8 years reintroduced gluten to their diets. Thirty-one experienced recurrence within an average of 2 months, but seven remained in remission for a mean follow-up of 12 years. IgA deposits did not recur in their skin. This report suggests that clinical and histologic remission can be maintained in some patients with DH despite the reintroduction of dietary gluten.

For most patients, however, a gluten-free diet remains an important aspect of disease management. Fortunately, many grocery stores now have a section devoted to gluten-free products. Support may be obtained from the American Celiac Society/Dietary Support Coalition (www.americanceliacsociety.org/diet.html) or from celiac societies (www.nowheat.com/grfx/nowheat/primer/celisoc.htm or www.enabling.org/ia/celiac/groups/groupsus.html). A commercial website with a search engine can be found at www.celiac.com. Another commercial source for products can be found at www.glutenfreemall.com. An Internet search using the terms "celiac society" or "gluten-free diet" is a good starting point for patients with the disease who want more information about the diet and commercially available products.

LINEAR IGA BULLOUS DERMATOSIS

Linear IgA bullous dermatosis (LAD) is characterized by subepidermal blisters, a neutrophilic infiltrate, and a circulating IgA anti-BMZ antibody with linear BMZ deposits on DIF. As with CP, LAD is really a group of diseases with a similar immunofluorescent pattern.

Adult Linear IgA Disease

Adult patients with LAD may present with a clinical pattern of vesicles indistinguishable from DH or with vesicles and bullae having a BP-like appearance, with severe cases mimicking Stevens-Johnson syndrome. They may have urticarial lesions, and bullae may occur on an urticarial base, as in BP (Fig. 21.23). Unusual variants include morbilliform, prurigo-like, and eczematous presentation. Mucous membrane involvement may occur in up to 50% of patients. In some, oral and conjunctival lesions dominate the presentation, and scarring may occur, as in CP. Younger patients

Fig. 21.23 Adult linear IgA disease.

and those with mucosal disease appear to be at risk for chronic disease and less likely to achieve remission. In the majority of patients, there is no association with enteropathy or with HLA-B8. The disease remits after several years in approximately 60% of patients. IgA is typically directed against a 97-kD antigen in the lamina lucida. Some patients demonstrate both IgA and IgG antibodies to BP180, and IgA to LAD285. IgA and IgG reactivity has been found to all three portions of the BP180 ectodomain. In some patients, the strongest reactivity is to the C-terminal portion of BP180 (major antigenic area in CP). This may explain cases of clinical overlap with CP. Type VII collagen has been reported as the major autoantigen for LAD targeting the sublamina densa, possibly explaining the overlap with bullous SLE and EBA. Antigenic targets for LAD are expressed by both keratinocytes and fibroblasts. Recent cases have demonstrated LAD to laminin-332.

Linear IgA dermatosis frequently occurs as a drug-induced disease. In drug-induced LAD the eruption is self-limited, there is less mucosal involvement, and usually there is no detectable circulating autoantibody. The IgA may be deposited in the sub–basal lamina area. Vancomycin is the most frequently implicated culprit. Other causes of drug-induced disease include lithium, amiodarone, carbamazepine, captopril, penicillin, amoxicillin, trimethoprim/sulfamethoxazole, piperacillin-tazobactam, moxifloxacin, UV light, furosemide, oxaprozin, IL-2, interferon-α, phenytoin, ketoprofen, diclofenac, statins, tea tree oil, angiotensin receptor antagonists, sulfasalazine, buprenorphine, ustekinumab, infliximab, and glibenclamide. The lymphocyte stimulation test has been reported as a possible method to assess drug causality with improved specificity.

Some cases have been associated with internal malignancy, paraproteinemia, or infection. Sporadic reports have linked single cases with dermatomyositis, rheumatoid arthritis, acquired hemophilia, and multiple sclerosis, although these may be fortuitous associations.

Fig. 21.24 Childhood linear IgA disease.

Biopsies typically demonstrate papillary dermal microabscess with neutrophils. As in DH, eosinophils may be present. On DIF, a homogeneous linear (tubular or toothpaste) pattern of IgA is present at the BMZ. Some patients will have both linear IgA and IgG in combination at the BMZ. A lack of C3 may be a clue that both immunoglobulins recognize the 97-kD antigen.

By IIF, only a minority of LAD patients will have circulating IgA autoantibody with anti-BMZ specificity, and this is usually present in low titer. On salt-split skin, deposition may occur on the roof or base, or a combination of the two.

In drug-induced disease, the drug must be stopped. Many cases resolve quickly, but some patients require drug therapy with corticosteroids or dapsone. Idiopathic disease generally responds to dapsone in doses similar to that described for DH; sulfapyridine may also be used. Other patients require topical or systemic corticosteroids in addition, or as sole treatment. A combination of tetracycline, 2 g/day, and nicotinamide, 1.5 g/day, may be effective. Other patients have responded to MMF, IVIG, colchicine, trimethoprim-sulfamethoxazole, or erythromycin. The rare patients with associated GSE may respond to a gluten-free diet.

Childhood Linear IgA Disease (Chronic Bullous Disease of Childhood)

Chronic bullous disease of childhood (CBDC) is an acquired, self-limited bullous disease that may begin by the time the patient is 2 or 3 years old and usually remits by age 13. The average age of onset is 5 years. Bullae develop on either erythematous or normal-appearing skin, preferentially involving the lower trunk, buttocks, genitalia, and thighs (Fig. 21.24). Perioral and scalp lesions are common, and oral mucous membrane lesions may occur in up to 75% of patients. Bullae are often arranged in rosettes or an annular array, the so-called string of pearls configuration (Fig. 21.25). Tense individual bullae similar to those in BP are also seen. Pruritus is often severe.

The prime histologic finding is the presence of a subepidermal bulla filled with neutrophils. Eosinophils may be present, and in some cases they predominate. DIF reveals a linear deposition of IgA at the BMZ identical to that seen in the adult forms of the disease. IIF is positive for circulating IgA anti-BMZ antibodies

Fig. 21.25 Childhood linear IgA disease. (Courtesy Debabrata Bandyopadhyay, MD.)

in approximately 50% of patients, usually in low titer. In contrast to adults with LAD, children demonstrate an increased frequency of B8, DR3, and DQ2 and may be homozygous for these antigens. As in the adult disease, immunoelectron microscopy and immunomapping studies may demonstrate immune deposits within the lamina lucida, below the lamina densa, or both. Also as in adult disease, some children have both IgG and IgA deposits. GSE is rare, but IgA nephropathy may occur. Childhood linear IgA disease has occurred in conjunction with Crohn disease.

Many patients' antibodies target the 97-kD peptide. Some children with sub–basal lamina deposits target type VII collagen and have EBA. Patients with only IgA or with both IgG and IgA circulating autoantibodies may target BP230 or BP180. Individual patients may have a combination of IgA against the 97-kD peptide, and IgG against BP230 and BP180. Collagen XVII/BP180 is a transmembrane protein with a soluble 120-kD ectodomain. In linear IgA dermatosis and CBDC, IgA targets the soluble ectodomain more efficiently than the full-length protein. Some sera target the Col15 domain.

The untreated disease runs a variable course, typically with eventual spontaneous resolution by adolescence. Treatment with either dapsone or sulfapyridine is usually successful. Occasional cases respond to topical corticosteroids alone, and systemic corticosteroids are sometimes necessary. Other patients have responded to MMF, colchicine, topical calcineurin inhibitors, or dicloxacillin.

TRANSIENT ACANTHOLYTIC DERMATOSIS (GROVER DISEASE)

In 1970 Grover described a new dermatosis that occurred predominantly in persons over 50 years of age and consisted of a sparse eruption of limited duration. The lesions were fragile vesicles that rapidly turned into crusted and keratotic erosions. He termed the condition *transient acantholytic dermatosis* (TAD). Since then, the majority of cases have been found to persist or recur, and the term *persistent and recurrent acantholytic dermatosis* may be a more accurate description of the disorder. The distribution is predominantly limited to the chest or shoulder girdle area and upper abdomen, and there is a strong male predominance (Fig. 21.26). The condition often appears or flares during periods of heat, sweating, or hospitalization. Many patients are asymptomatic, and the condition may be an incidental finding on examination. Other

patients complain of pruritus. Asteatotic eczema occurs five times as often among patients with TAD as in controls. The disorder has been described in the setting of a variety of malignancies, but it may be associated with the hospitalization or type B symptoms rather than the malignancy itself. TAD has been reported with cetuximab. This pattern may also occur rarely as a side effect from chemotherapy. Patients on strict bed rest appear to have a higher incidence of the disease. The clinical differential diagnosis includes Galli-Galli disease, an acantholytic variant of Dowling-Degos disease that may resemble TAD clinically.

There are five histologic types, resembling Darier disease, PV, PF, benign familial pemphigus, or spongiotic dermatitis. The Darier type predominates. Often, two or more types can be found in a single biopsy specimen. DIF studies yield negative or nonspecific results. Although heat and sweating are significant risk factors, only a minority of cases are associated with acrosyringia histologically. Impairment of keratinocytic cholinergic receptors has been suggested as a pathogenic mechanism.

About 50% of patients respond to topical corticosteroids. Control of fever, hospital discharge, and avoidance of sun and sweating often result in improvement. Sustained remission has been described after a course of systemic corticosteroids. Topical antibiotics, topical calcipotriol, isotretinoin, and dapsone have been successful in some patients. Psoralen plus UVA (PUVA) has been reported to result in an initial flare followed by slow clearance, and UVB therapy may produce clearing in some patients. Photodynamic therapy with red light and 5-aminolevulinic acid has been reported as successful, and rituximab has produced clearing of TAD in patients being treated for lymphoma.

22 Nutritional Diseases

Bonus images for this chapter can be found online at expertconsult.inkling.com

A nutritional disease is caused either by insufficiency or, less often, by excess of one or more dietary essentials. Nutritional deficiencies are particularly common in developing countries but can also occur due to fad diets or restrictive eating practices in patients with behavioral or autism spectrum disorders. Infants and children are particularly at risk for deficiency states, especially malnutrition. Infants diagnosed with multiple food allergies who substitute other nutrition such as rice milk for breast milk or standard baby formulas are at particular risk. Frequently, patients have features of several nutrient deficiencies if their diet has generally been restricted. An intertriginous or acral eruption, a seborrheic dermatitis–like facial eruption, atrophic glossitis, and alopecia are common features of many nutritional deficiencies. This occurs because these nutrients are essential to overlapping metabolic pathways of fatty acid metabolism, resulting in abnormal differentiation of the epidermis and defective barrier function. The histologic findings in many types of nutritional dermatosis are also similar.

In developed countries, alcoholism is the main cause of nutritional diseases in adults. Nutritional diseases should also be suspected in postoperative patients; psychiatric patients, including those with anorexia nervosa and bulimia; patients on the autism spectrum who have textural issues with certain foods; patients on restrictive diets; patients with surgical or inflammatory bowel dysfunction, especially Crohn disease; patients who have had bowel bypass surgery; cystic fibrosis patients; and patients with severe oral erosive disease (e.g., pemphigus) that prevents eating. In the pediatric setting, nutritional deficiency may also occur because of parental ignorance of the nutritional requirements or restriction due to concern for perceived or actual food allergies.

The diagnosis of nutritional deficiency is often missed because physicians fail to take an adequate dietary history. When children have protein malnutrition, their albumin is low and thus cannot serve its role as an osmotic agent to hold serum in the vessels. Therefore children will gain weight, which clinically masks their severe deficiency in protein. The dermatitis produced by elevated glucagon levels from islet cell tumors of the pancreas (necrolytic migratory erythema) and a similar dermatosis seen in hepatitis C infection and other forms of hepatic insufficiency (necrolytic acral erythema, pseudoglucagonoma) probably also represent nutritional deficiency dermatoses. Deficiency states caused by inborn errors of metabolism are discussed in Chapter 26. In many cases, the clinical findings and socioeconomic scenario are adequate to lead to suspicion of a specific deficiency state, and replacement therapy can confirm the diagnosis. Laboratory testing may be costly and inaccurate in some deficiency states, and patients with poor nutrition are often deficient in many nutrients simultaneously. Testing is indicated to confirm the diagnosis of zinc deficiency, as well as the inborn errors of metabolism that can mimic zinc deficiency, such as propionyl-CoA carboxylase deficiency, methylmelnonic acidemia, isoleucine deficiency, holocarboxylase synthetase deficiency, and biotinidase deficiency; to assess essential fatty acid (EFA) deficiency; and to evaluate for possible glucagonoma syndrome in a child.

VITAMIN A

Hypovitaminosis A (Phrynoderma)

Vitamin A is a fat-soluble vitamin found as retinyl esters in milk, fish oil, liver, and eggs and as carotenoids in plants. Vitamin A deficiency is common in children in the developing world. It is rare in developed countries, where it is most often associated with diseases of fat malabsorption, such as bowel bypass surgery for obesity, pancreatic insufficiency, Crohn disease, inflammatory bowel disease (IBD), celiac disease, cystic fibrosis, and liver disease. Vitamin A is required for the normal keratinization of many mucosal surfaces. When it is deficient, the resultant abnormal keratinization leads to increased mortality risk from inflammatory disease of the gut and lung—diarrhea and pneumonia (especially in measles). Vitamin A supplementation of 200,000 IU/day for 2 days is recommended for children with measles; this may also prevent the risk of blindness.

Although phrynoderma had classically been ascribed to, and thought to be specific for, vitamin A deficiency, this clinical sign is in fact most frequently found as a disorder of multiple deficiencies, including vitamins A, B, C, and E and EFAs. Replacing all these deficiencies leads to rapid improvement. This explains patients in whom the cutaneous findings of phrynoderma were found without the classic eye findings of vitamin A deficiency. The skin eruption, termed *follicular hyperkeratosis* or *phrynoderma* ("toadskin"), resembles keratosis pilaris and the genodermatosis keratosis follicularis spinuloas decalvans. It consists of keratotic papules of various sizes distributed symmetrically over the extremities and shoulders, surrounding and arising from the pilosebaceous follicles (Fig. 22.1). Individual lesions are usually asymptomatic firm, pigmented papules containing a central, intrafollicular keratotic plug that projects from the follicle as a horny spine and leaves a pit when expressed. Lesions are of two sizes: 1–2 mm papules closely resembling keratosis pilaris and the more diagnostic, large, 2–6 mm, crateriform papules filled with a central keratotic plug. These latter lesions may simulate a perforating disorder. The eruption of small lesions usually begins on the anterolateral aspect of the thighs or the posterolateral aspect of the upper arms, although one study showed that the elbows were the most common initial site in 84%. It then spreads to the extensor surfaces of both the upper and the lower extremities, the shoulders, abdomen, back, and buttocks and finally reaches the face and posterior aspect of the neck. The hands and feet are not involved, and lesions occur only occasionally on the midline of the trunk or in the axillary and anogenital areas. On the face, the eruption resembles acne because of the presence of many large comedones, but it differs from acne in regard to dryness of the skin. The large, dome-shaped nodules are on the elbows and knees and have a surrounding red or brown rim. There is generalized dryness, fine scaling, and hyperpigmentation. Hair casts may also be seen.

Vitamin A deficiency may mimic vitamin C deficiency (scurvy) because both conditions cause follicular hyperkeratosis, although the characteristic follicular hemorrhage is more prominent in vitamin C deficiency. Bleeding and gingival disease can be a feature of vitamin A deficiency as well as scurvy. The histologic findings of "deficiency dermatitis," which are common to many deficiency states (zinc, EFAs, amino acids, glucagonoma, cystic

Fig. 22.1 Phrynoderma in a patient with inflammatory bowel disease.

fibrosis), are not features of either vitamin A or vitamin C deficiency.

In vitamin A deficiency, eye findings are prominent and often pathognomonic. These include night blindness, an inability to see bright light, xerophthalmia, xerosis corneae, and keratomalacia. The earliest finding is delayed adaptation to the dark (nyctalopia). Some patients have circumscribed areas of xerosis of the conjunctiva lateral to the cornea, occasionally forming well-defined white spots (Bitot spots); these are triangular, with the apex toward the canthus. Vitamin A deficiency is a major cause of blindness in children in developing countries.

The histologic findings of vitamin A deficiency are hyperkeratosis, horny plugs in the upper portion of the hair follicle, coiled hairs in the upper part of the follicle, severe atrophy of the sebaceous glands, and squamous metaplasia of the secretory cells of the eccrine sweat glands. If the follicles rupture, perifollicular granulomatous inflammation is found.

The diagnosis of vitamin A deficiency is confirmed by determination of the serum retinol level. The treatment is oral vitamin A, 100,000 IU/day for 2–3 days, followed by the recommended dietary requirement. Serum retinol levels are monitored to determine adequacy of supplementation and to avoid vitamin A toxicity.

HYPERVITAMINOSIS A

The skin findings of hypervitaminosis A are similar to the side effects of synthetic retinoid therapy (such as isotretinoin). Children are at greater risk for toxicity than adults. Excess megavitamin ingestion may be the cause. In adults, doses as small as 25,000 IU/day may lead to toxicity, especially in persons with hepatic compromise from alcoholic, viral, or medication-induced hepatitis. Patients on dialysis also are at increased risk, because vitamin A is not removed by dialysis. Standard hyperalimentation solutions contain significant amounts of vitamin A, and in burn victims with renal compromise, vitamin A toxicity can occur. If the patient is taking a synthetic retinoid, all vitamin A supplementation should be stopped.

Most cases of chronic hypervitaminosis A have been reported in children. There is loss of hair and coarseness of the remaining hair, loss of the eyebrows, exfoliative cheilitis, generalized exfoliation and pigmentation of the skin, and clubbing of the fingers. Moderate widespread itching may occur. Hepatomegaly, splenomegaly, hypochromic anemia, depressed serum proteins, and elevated liver function tests may be found. Bone growth may be impaired by premature closure of the epiphyses in children. Pseudotumor cerebri with papilledema may occur early, before any other signs appear. In infants, this may present as a bulging fontanelle.

In adults, the early signs are dryness of the lips and anorexia. These symptoms may be followed by joint and bone pains, follicular hyperkeratosis, branny desquamation of the skin, fissuring of the corners of the mouth and nostrils, dryness and loss of scalp hair and eyebrows, and dystrophy of the nails. Fatigue, myalgia, depression, anorexia, headache (from pseudotumor cerebri), strabismus, and weight loss frequently occur. Liver disease may be progressive and may lead to cirrhosis with chronic toxicity. Hypercalcemia often occurs in dialysis patients and be worsened by the hypervitaminosis A. Retinoids are teratogens, and birth defects may occur with excess vitamin A supplementation during pregnancy.

VITAMIN D

Although active vitamin D is produced in the skin, deficiency of vitamin D has no primary skin manifestations, except for alopecia. Low vitamin D levels correspond in some children with atopic dermatitis (AD) severity, but studies are conflicting. Some studies have found genetic polymorphisms associated with vitamin D not to be more prevalent in atopic patients, but more recently patients with polymorphisms in the CYp24a1 vitamin D–inactivating enzyme were found to have more severe AD. Some patients with AD may improve and manifest fewer infections with vitamin D supplementation. Elderly persons have decreased vitamin D cutaneous photosynthesis because of decreased sun exposure and poor intake of vitamin D, both of which predispose them to osteomalacia. Aggressive photoprotection may also reduce vitamin D levels. Patients with cutaneous lupus and other photosensitive diseases who are counseled to avoid the sun and use high sun protection factor (SPF) sunscreens are at particular risk. Other patients at

risk include those who are debilitated with limited sun exposure; those taking anticonvulsants; those with fat malabsorption; and patients with human immunodeficiency virus (HIV) infection, especially dark-skinned patients living in northern climes. Vitamin D_3 supplementation of 600 IU/day should be recommended in all these groups of patients for those up to age 70, and 800 IU for older patients; pediatric dosing is lower and based on age. Dermatologists who have patients at risk should also consider measuring vitamin 25 OH vitamin D levels.

VITAMIN K DEFICIENCY

Dietary deficiency of vitamin K, a fat-soluble vitamin, usually does not occur in adults because it is synthesized by bacteria in the large intestine. However, deficiency may occur in adults because of malabsorption caused by biliary disease, malabsorption syndromes, cystic fibrosis, or anorexia nervosa. Drugs such as coumarin, salicylates, cholestyramine, and antibiotics such as trimethoprim-sulfamethoxazole and the cephalosporins may induce a deficiency state. Newborns of mothers taking coumarin or phenytoin and premature infants with an uncolonized intestine can be vitamin K deficient. Standard practice is to administer intramuscular (IM) vitamin K at birth; however, some parents decline this, and those children are at 81 times greater risk of developing vitamin K bleeding than those who do receive it. Additionally, a rare condition exists that predisposes to bleeding, called hereditary combined deficiency of the vitamin K–dependent clotting factors. The liver synthesizes vitamin K–dependent clotting factors II, VII, IX, and X, and requires vitamin K as a cofactor. The result of vitamin K deficiency or severe liver disease is a decrease in the vitamin K–dependent clotting factors. The resulting cutaneous manifestations are purpura, hemorrhage, and ecchymosis and are similar to those seen with coumarin skin necrosis given the shared pathophysiology. Treatment is IM vitamin K for several days. In acute crises, fresh frozen plasma is used because it contains the clotting factors.

VITAMIN B_1 DEFICIENCY

Vitamin B_1 (thiamine) deficiency results in beriberi. The skin manifestations are limited to edema and red, burning tongue. Peripheral neuropathy is common, and congestive heart failure may develop. In addition to alcoholism and lack of dietary intake, deficiency in vitamin B_1 can occur from bariatric surgery and in intensive care settings without proper nutrition.

Tack J, Deloose E: Complications of bariatric surgery. Best Pract Res Clin Gastroenterol 2014; 28: 741.

VITAMIN B_2 DEFICIENCY

Vitamin B_2 (riboflavin) deficiency is seen most often in alcoholic patients; however, phototherapy for neonatal icterus, acute boric acid ingestion, hypothyroidism, and chlorpromazine therapy have also been reported as causes. The classic findings are the oral-ocular-genital syndrome. The lips are prominently affected with angular cheilitis (perlèche) and cheilosis. The tongue is atrophic and magenta in color (Fig. 22.2). A seborrheic-like dermatitis with follicular keratosis around the nares primarily affects the face. Genital dermatitis is worse in men than in women who have riboflavin deficiency. There is a confluent dermatitis of the scrotum, sparing the midline, with extension onto the thighs. In its mildest form, the dermatitis is slightly "irritating" and pruritic, especially when sweating. As the deficiency progresses, the scrotum goes through a mild, acute dry phase with erythema and slight scale to a severe, chronic dry phase with confluent red papules that spread to involve the perianal area and inner thighs, accompanied by fissuring and pain. Balanitis and phimosis may occur, requiring circumcision. In severe deficiency, the entire scrotum becomes wet, with increasing pain and fissuring. The final stage is accompanied by massive swelling, and the scrotum may reach the size

Fig. 22.2 Magenta tongue in riboflavin deficiency.

of a football. Photophobia and blepharitis angularis occur. The response to repletion is dramatic.

VITAMIN B_6

Pyridoxine Deficiency

Pyridoxine (vitamin B_6) deficiency may occur in patients with uremia and cirrhosis, as well as with the use of certain pharmacologic agents. Skin changes include a seborrheic dermatitis–like eruption, atrophic glossitis with ulceration, angular cheilitis, conjunctivitis, and intertrigo. Occasionally, a pellagra-like eruption may occur. Neurologic symptoms include somnolence, confusion, and neuropathy. Pyrodoxine has been used to prevent or treat chemotherapy-induced hand-foot syndrome but has not been consistently successful.

Pyridoxine Excess

A patient who ingested large doses of pyridoxine developed a subepidermal vesicular dermatosis and sensory peripheral neuropathy. The bullous dermatosis resembled epidermolysis bullosa acquisita. Exacerbation of rosacea was also reported in a patient taking isoniazide and pyridoxine.

VITAMIN B_{12} DEFICIENCY

Vitamin B_{12} (cyanocobalamin) is absorbed through the distal ileum after binding to gastric intrinsic factor in an acid pH. Deficiency is caused mainly by gastrointestinal (GI) abnormalities, such as a deficiency of intrinsic factor, achlorhydria (including that induced by medications), ileal diseases, and malabsorption syndromes resulting from pancreatic disease or sprue. Aggressive treatment for the eradication of *Helicobacter pylori* may cause B_{12} deficiency, as can metformin administration and long-term antacid ingestion. In food-cobalamin malabsorption syndrome, the body is unable to release vitamin B_{12} from food or intestinal transport proteins, especially with accompanying achlorhydria. These patients have adequate dietary vitamin B_{12} but often have atrophic gastritis. A Schilling test will be normal. Congenital lack of transcobalamin II can also produce B_{12} deficiency. Because of the large body stores of B_{12} in adults, deficiency occurs 3–6 years after GI abnormalities.

Glossitis, hyperpigmentation, and canities are the main dermatologic manifestations of vitamin B_{12} deficiency. The tongue is bright red, sore, and atrophic. Linear atrophic lesions may be an early sign. The hyperpigmentation is generalized, but more often it is accentuated in exposed areas, such as the face and hands, and in the palmar creases and flexures, resembling Addison disease. The nails may be pigmented. Premature gray hair may occur paradoxically. Megaloblastic anemia is often present. Weakness, paresthesias, numbness, ataxia, and other neurologic findings occur. Repletion of vitamin B_{12} can aid in chronic aphthous stomatitis in some patients.

Parenteral replacement with IM injections of B_{12}, 1, leads to a reversal of the pigmentary changes in the skin, nails, mucous membranes, and hair. Megadose oral replacement of 1–2 mg/day may replace body stores by simple diffusion, independent of intrinsic factor. Neurologic defects may or may not improve with vitamin B_{12} replacement.

FOLIC ACID DEFICIENCY

Diffuse hyperpigmentation, glossitis, cheilitis, and megaloblastic anemia, identical to vitamin B_{12} deficiency, occur in folic acid deficiency. Low folic acid is associated with neural tube defects, which are more common in light-skinned people, suggesting an association between ultraviolet (UV) light exposure and reduction in folic acid. Folic acid supplementation leads to fewer GI and liver side effects in patients on methotrexate.

VITAMIN C DEFICIENCY (SCURVY)

Scurvy, or vitamin C deficiency, is often diagnosed by dermatologists, because cutaneous manifestations are early and prominent. Elderly male alcoholics and patients with behavioral health and autism spectrum disorders on restrictive diets are most frequently affected. Iron overload due to multiple transfusions, neurologic disorders, smoking, and history of chemotherapy and dialysis patients are also risk factors. One patient with scurvy related to nilotinib has been reported.

The "four Hs" are characteristic of scurvy: hemorrhagic signs, hyperkeratosis of the hair follicles, hypochondriasis, and hematologic abnormalities. Perifollicular petechiae are the characteristic cutaneous finding (Fig. 22.3). In addition, ecchymoses of various sizes, especially on the lower extremities, are common. These may

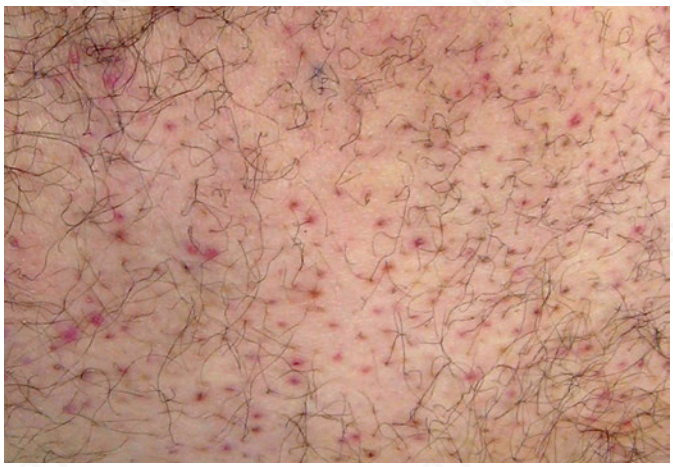

Fig. 22.3 Scurvy.

Fig. 22.4 Scurvy, gingivitis.

be associated with tender nodules (subcutaneous and intramuscular hemorrhage) and subperiosteal hemorrhage, leading to bone pain and possible pseudoparalysis in children. Woody edema may be present, simulating cellulitis. Subungual, subconjunctival, intramuscular, periosteal, and intraarticular hemorrhage may also occur. The referring diagnosis is often vasculitis due to the perifollicular hemorrhage with bone pain a prominent feature in advanced disease; Henoch-Schönlein purpura can easily be confused with scurvy. Another characteristic finding is keratotic plugging of the hair follicles, chiefly on the anterior forearms, abdomen, and posterior thighs. The hair shafts are curled in follicles capped by keratotic plugs, a distinctive finding called "corkscrew hairs." Hemorrhagic gingivitis occurs adjacent to teeth and presents as swelling and bleeding of the gums (Fig. 22.4). The teeth can be loose and the breath may be foul. Gingival hyperplasia and bleeding may be absent or may be the sole sign of scurvy. Edentulous areas do not develop gingivitis, and those with good oral hygiene have less prominent gingival involvement. Epistaxis, delayed wound healing, and depression may also occur. Frequently, anemia is present and may be the result of blood loss or associated deficiencies of other nutrients, such as folate.

The diagnosis of scurvy is usually made on clinical grounds and confirmed by a positive response to vitamin C supplementation or a low vitamin C level. Because vitamin C levels normalize very quickly, if needed, the blood test must be checked before any diet change. A biopsy will exclude vasculitis and demonstrate follicular hyperkeratosis, coiled hairs, and perifollicular hemorrhage in the absence of inflammation. Treatment is with ascorbic acid, 1000 mg/day for a few days to 1 week, and a maintenance dose of 100 mg/day should be considered.

NIACIN DEFICIENCY (PELLAGRA)

Pellagra usually results from a deficiency of nicotinic acid (niacin, vitamin B_3) or its precursor amino acid, tryptophan. It is associated classically with a diet almost entirely composed of corn, millet, or sorghum. Pellagra can occur within 60 days of dietary niacin deficiency. Malnutrition or other vitamin deficiencies, especially pyridoxine, which interfere with the conversion of tryptophan to niacin, often coexist. In developed countries, most cases of pellagra occur in alcoholics. Other possible causes of pellagra are as follows:

- Carcinoid tumors, which divert tryptophan to serotonin
- Hartnup disease (impaired absorption of tryptophan)
- Gastrointestinal disorders (e.g., Crohn disease, GI surgery)
- Prolonged intravenous (IV) supplementation
- Psychiatric disease, including anorexia nervosa
- Restrictive diets in adult patients with atopic dermatitis concerned about "food allergy"

Pellagra can also be induced by medications, most often isoniazid, azathioprine (and its metabolite 6-mercaptopurine), 5-fluorouracil, ethionamide, protionamide, and pyrazinamide. These medications may induce pellagra by interfering with niacin biosynthesis. The anticonvulsants, including hydantoins, phenobarbital, and carbamazepine, may rarely produce pellagra in a dose-dependent manner.

Clinical Features

Pellagra is a chronic disease affecting the GI tract, nervous system, and skin; thus the mnemonic of the "three Ds"—diarrhea, dementia, and dermatitis.

The most characteristic cutaneous finding is the photosensitive eruption, which worsens in the spring and summer. It occurs symmetrically on the face, neck, and upper chest (Casal necklace; Fig. 22.5); extensor arms; and backs of the hands. Initially, there is erythema and swelling after sun exposure, accompanied by itching and burning or pain. In severe cases, the eruption may be vesicular or bullous (wet pellagra). Compared with normal sunburn, the pellagrous skin takes about four times longer to recover from the acute phototoxic injury. After several phototoxic events, thickening, scaling, and hyperpigmentation of the affected skin occur. The skin has a copper or mahogany hue. In protracted cases, the skin ultimately becomes dry, smooth, paper-thin, and glassy with a parchment-like consistency. Scarring rarely occurs.

Fig. 22.5 Pellagra. (Courtesy Michelle Weir, MD.)

The nose is fairly characteristic. There is dull erythema of the bridge of the nose, with fine, yellow, powdery scales over the follicular orifices (sulfur flakes). The eruption resembles seborrheic dermatitis, except for its location. Plugs of inspissated sebum may project from dilated orifices on the nose, giving it a rough appearance.

At the onset, the patient has weakness, loss of appetite, abdominal pain, diarrhea, mental depression, and photosensitivity. Skin lesions may be the earliest sign, with phototoxicity the presenting symptom in some cases. Neurologic and GI symptoms can occur without skin changes. Delusions of parasitosis have been reported in pellagra. In the later stages, the neurologic symptoms may predominate. Apathy, depression, muscle weakness, paresthesias, headaches, and attacks of dizziness or falling are typical findings. Hallucinations, psychosis, seizures, dementia, neurologic degeneration, and coma may develop. Pellagra is progressive and can be fatal if untreated.

Histopathology

Histologically, the findings in the skin vary according to the stage of the disease. The most characteristic finding is pallor and vacuolar changes of the keratinocytes in a band in the upper layers of the stratum malpighii, just below the granular cell layer, which may be attenuated. If marked, a cleft may form in the upper epidermis, correlating with the blistering seen in wet pellagra. Langerhans cells were shown to be depleted in the skin of patients with pellagra.

Diagnosis and Treatment

If the characteristic skin findings are present, the diagnosis of pellagra is not difficult clinically. Dietary treatment to correct the malnutrition is essential. Animal proteins, eggs, milk, and vegetables are beneficial. Supplementation with nicotinamide, 100 mg three times daily for several weeks, should be given. Fluid and electrolyte loss from diarrhea should be replaced, and in patients with GI symptoms possibly interfering with absorption, initial IV supplementation should be considered. Within 24 hours of niacin therapy initiation, the skin lesions begin to resolve, confirming the diagnosis. Alcoholism must be treated if present, and the factors that may have led to pellagra must be corrected.

DISORDERS THAT PRESENT WITH ACRODERMATITIS-LIKE SKIN CHANGES

Biotin Deficiency

Biotin is universally available and is produced by intestinal bacteria. Therefore deficiency is rare but can occur in patients with a short gut or malabsorption. Sometimes biotin deficiency occurs in patients taking antibiotics or receiving parenteral nutrition. Avidin, found in raw egg white, may bind biotin, leading to deficiency. The three autosomal recessive syndromes of holocarboxylase synthetase deficiency (multiple carboxylase deficiency), biotinidase deficiency, and the rare syndrome of inability to transport biotin into cells all have similar clinical features, referred to as "multiple carboxylase deficiency." The holocarboxylase deficiency presents earlier and is termed the *neonatal* form, whereas the biotinidase deficiency may present later and is termed the *juvenile* form. Clinical presentation is variable, with some patients manifesting only certain features. Biotin deficiency may increase the inflammatory response from dendritic cells leading to excess inflammation.

The skin and nervous system are primarily affected. Dermatitis similar to that found in patients with zinc deficiency and EFA deficiency is seen. This periorificial dermatitis is characterized by patchy, red, eroded lesions on the face and groin (Fig. 22.6). *Candida* is regularly present on the lesions. Alopecia, in some cases total, including loss of the eyebrows and eyelashes, can occur. Congenital trichorrhexis nodosa may be present, and conjunctivitis may occur. Neurologic findings are prominent; in adults these include depression, lethargy, hallucinations, and limb paresthesias, and in infants, hypotonia, lethargy, a withdrawn behavior, ataxia, seizures, deafness, and developmental delay.

The diagnosis of the inherited forms is made by detecting organic aminoaciduria of 3-hydroxyisovaleric acid. Measurement of serum biotinidase can distinguish biotinidase deficiency from holocarboxylase deficiency.

Treatment consists of 10 mg/day of biotin, but depending on the severity of the enzyme mutation, higher doses may be required.

Fig. 22.6 Multiple carboxylase deficiency.

Fig. 22.7 Acrodermatitis enteropathica.

Skin lesions resolve rapidly, but the neurologic damage may be permanent; thus early diagnosis is important. Valproic acid treatment in children, may lead to partial biotinidase deficiency, and that the skin lesions (seborrheic dermatitis–like rash and alopecia) improved with biotin supplementation.

ZINC DEFICIENCY

Zinc deficiency may be an inherited abnormality, acrodermatitis enteropathica, or it may be acquired. Acrodermatitis enteropathica is an autosomal recessive disorder caused by mutations in the *SLC39A4* gene, which encodes the zinc transporter ZIP4. ZNT Acquired cases are termed *acquired acrodermatitis enteropathica* or *acrodermatitis enteropathica–like syndrome.* Premature infants are at particular risk because of inadequate body zinc stores, suboptimal absorption, and high zinc requirements. Normally, human breast milk has adequate zinc, and weaning classically precipitates clinical zinc deficiency in premature infants and in infants with acrodermatitis enteropathica. Zinc-binding proteins in cow's milk may also inhibit the bioavailability of zinc. However, clinical zinc deficiency may occur in full-term and premature infants still breastfeeding. This results from either low maternal breast milk zinc levels or a higher zinc requirement by the infant than the breast milk can provide (even though zinc level in breast milk is normal). A rare syndrome of congenital myopathy, recurrent diarrhea, microcephaly, and deafness has been associated with a neonatal bullous eruption characteristic of nutritional deficiency. These children have required very high doses of zinc supplementation.

Parenteral nutrition without adequate zinc content may lead to zinc deficiency. Acquired zinc deficiency also occurs in alcoholics as a result of poor nutritional intake and increased urinary excretion; as a complication of malabsorption, IBD, chronic granulomatous disorder, or GI surgery; and occasionally in patients with anorexia nervosa or acquired immunodeficiency syndrome (AIDS). Patients with severe erosive oral disease, such as pemphigus or graft-versus-host disease, may develop zinc deficiency from malnutrition. Zinc requirements increase during metabolic stress, so symptomatic deficiency may present during infections, after trauma or surgery, with malignancy, during pregnancy, and with renal disease. Diets containing mainly cereal grains are high in phytate, which binds zinc, and have caused endemic zinc deficiency in certain areas of the Middle East and North Africa.

The dermatitis found in all forms of zinc deficiency is pustular and bullous, but the lesions are often flaccid leading to the clinical appearance of crusting. There is an acral and a periorificial distribution. On the face, in the groin, and in other flexors there is a patchy, red, dry scaling with exudation and crusting (Fig. 22.7). Angular cheilitis and stomatitis may be present. The periungual areas are erythematous and scaling and may have superficial, flaccid pustules. Nail dystrophy may result, with thinning of the nails and accentuated longitudinal ridges. Low zinc levels have been found in patients with burning mouth syndrome, and zinc supplementation may alleviate the symptoms. Chronic lesions may be more psoriasiform. Generalized alopecia may occur. Inborn errors of metabolism, such as methylmelonic academia, biotinidase deficiency, propionic acidemia, and multiple carboxylase deficiency, as well as isoleucine deficiency during treatment of maple syrup urine disease, can all manifest with the scaling, intertriginous clinical appearance of acrodermatitis enteropathica.

Diarrhea is present in most cases. Growth retardation, ophthalmic findings, impaired wound healing, and central nervous system manifestations occur. Patients are particularly irritable and emotionally labile.

The histopathology of acquired and hereditary zinc deficiency is identical. There is vacuolation of the keratinocytes of the upper stratum malpighii. These areas of vacuolation may become confluent, forming a subcorneal bulla. In larger lesions, there may be total epidermal necrosis with subepidermal blister formation. Neutrophils are typically present. In the late stages of acrodermatitis enteropathica, this characteristic upper epidermal pallor is frequently absent, and the biopsy demonstrates only a psoriasiform dermatitis.

The diagnosis of zinc deficiency should be suspected in at-risk individuals with acral or periorificial dermatitis. In particular,

Fig. 22.8 Acrodermatitis enteropathica. (Courtesy Carrie Kovarik, MD.)

chronic diaper rash with diarrhea in an infant should lead to evaluation for zinc deficiency (Fig. 22.8). The diagnosis can be confirmed by low serum zinc levels. A low level of serum alkaline phosphatase, a zinc-dependent enzyme, may be a valuable (and more quickly reported) adjunctive test in which the serum zinc level is normal or near-normal. In some patients, even if the zinc level is in the normal range, a trial of zinc supplementation should be considered if the skin lesions are characteristic. Replacement is with zinc sulfate, 1–2 mg/kg/day (50 mg of elemental zinc per 220 mg zinc sulfate tablet).

In acquired cases, transient treatment and addressing the underlying condition are adequate. In patients with genetic causes of acrodermatitis enteropathica, zinc supplementation is 3 mg/kg/day and should be lifelong, whereas patients with inappropriate intake can be supplemented and, with appropriate changes in diet, stop the supplementation once replete. Overzealous zinc supplementation should be avoided, because it may lead to low serum copper levels.

ESSENTIAL FATTY ACID DEFICIENCY

Essential fatty acids (EFAs) are those that cannot be synthesized by the body. EFA deficiency may develop in multiple settings, including low-birth-weight infants, cystic fibrosis, GI abnormalities with diarrhea (e.g., IBD, intestinal surgery), and prolonged parenteral nutrition without EFA supplementation. The resulting dermatitis is similar to that seen in zinc and biotin deficiency, although characteristically more widespread, and with less prominent periorificial, mucous membrane, and nail involvement. There is a generalized xerosis because EFAs constitute up to one quarter of the fatty acids of the stratum corneum and are required for normal epidermal barrier function. Widespread erythema and an intertriginous weeping eruption are seen. The hair becomes lighter in color, and diffuse alopecia is present. Poor wound healing, growth failure, and increased risk of infection may occur. There is a decrease in linoleic acid and an increase in palmitoleic and oleic acids. A ratio of eicosatrienoic acid to arachidonic acid of more than 0.4 is diagnostic of EFA deficiency. IV lipid therapy reverses the process. In patients who develop pancreatitis from the fat emulsion infusion, topical safflower oil emulsion or soybean oil applications may be considered as a stopgap measure, waiting for the pancreatitis to improve. Topical treatment does not maintain liver and tissue stores.

The nutrient deficiency eruption seen in children with cystic fibrosis has been called "cystic fibrosis nutrient deficiency dermatitis" (CFNDD). It shares features of acrodermatitis enteropathica, kwashiorkor, and EFA deficiency. It presents at 2 weeks to 6 months of age with erythematous papules that may be annular. The diaper area and perioral/periorbital regions are initially affected. It spreads to the extremities and progresses to widespread plaques. The hair may turn gray, then repigment on supplementation. Laboratory abnormalities include anemia, hypoalbuminemia, elevated liver function tests (e.g., alkaline phosphatase), low or normal zinc, low vitamin E, and at times EFA deficiency. Biopsy shows psoriasiform dermatitis, but the upper dermal pallor may be absent. Treatment of CFNDD is general enhancement of the child's nutrition, addressing zinc, protein, and EFA deficiencies, as well as other nutritional deficits. Zinc therapy alone does not improve CFNDD.

IRON DEFICIENCY

Iron deficiency is common, especially among actively menstruating women, and particularly if they have minimal red meat in their diets and have not compensated with other foods. Iron deficiency has recently been reported in patients treated with extracorporeal photopheresis. Mucocutaneous findings include koilonychia, glossitis, angular cheilitis, pruritus, and telogen effluvium. Plummer-Vinson syndrome is the combination of microcytic anemia, dysphagia, and glossitis, seen almost entirely in middle-aged women. The lips are thin and the opening of the mouth is small and inelastic, creating a rather characteristic appearance. Smooth atrophy of the tongue is pronounced. Koilonychia is present in 40%–50% of patients, and alopecia may be present. An esophageal web in the postcricoid area may occur, presenting as difficulty swallowing, or the feeling that food is stuck in the throat. The diagnosis is confirmed by measuring the serum iron level. Treatment consists of iron sulfate supplementation.

SELENIUM DEFICIENCY

Selenium deficiency occurs in patients receiving parenteral nutrition, in areas where soil selenium content is poor, in cirrhosis patients with ineffective metabolism of selenomethionine, and in low-birthweight infants. Manifestations in children include hypopigmentation of the skin and hair (pseudoalbinism). Leukonychia and Terry-like nails have been reported. Cardiomyopathy, muscle pain, and weakness with elevated levels of muscle enzymes are the major features. Autoimmune thyroid disease has also been reported in patients with selenium deficiency. Treatment of deficiency consists of 3 μg/kg/day of selenium.

PROTEIN-ENERGY MALNUTRITION

Protein-energy malnutrition is a spectrum of related diseases, including marasmus, kwashiorkor, and marasmic kwashiorkor. These conditions are more common in parts of the developing world. Marasmus represents prolonged deficiency of protein and calories and is diagnosed in children who are below 60% of their ideal body weight without edema or hypoproteinemia. Kwashiorkor occurs with protein deficiency but a relatively adequate caloric intake and is diagnosed in children at 60%–80% of their ideal body weight with edema or hypoproteinemia. Marasmic kwashiorkor shows features of both conditions and is diagnosed in children who are less than 60% of their ideal body weight with features of edema or hypoproteinemia.

These conditions are rare in developed countries, but occasionally kwashiorkor may occur as a result of severe dietary restrictions. In the United States this may occur in infants because they garner most of their protein from breast milk or formula. When rice beverages or other low-protein beverage are substituted for breast milk, baby formula, or cow's milk (in older children) due to food allergies, they can become deficient in multiple nutrients, including protein. Therefore patients with food protein–induced enterocolitis or extensive food allergies should be counseled on proper nutrition while avoiding their allergens.

Marasmus

In cases of marasmus, the skin is dry, wrinkled, and loose because of marked loss of subcutaneous fat. The loss of the buccal fat pad is characteristic. In contrast to kwashiorkor, there is no edema or dermatosis.

Kwashiorkor

Kwashiorkor produces hair and skin changes, edema, impaired growth, and the characteristic potbelly. U.S. cases are caused by dietary restriction often seen in patients with eating disorders, autism spectrum disorders, or restrictive diets due to avoidance of food allergies. Altered gut microbiome may put certain infants at risk for kwashiorkor. Infants with atopy and multiple food allergies are at especially high risk if breastfeeding is stopped and properly fortified infant formula is not substituted. The resultant scaling can be confused for worsening atopic dermatitis. Patients with kwashiorkor have edema that can mask true growth failure due to the weight of the edema, delaying the diagnosis of malnutrition. The hair and skin changes are usually striking. The hair is hypopigmented, varying in color from a reddish yellow to gray or even white. The hair is dry and lusterless; curly hair becomes soft and straight; and marked scaling (crackled hair) is seen. Especially striking is the "flag sign," affecting long, normally dark hair. The hair grown during periods of poor nutrition is pale, so that alternating bands of pale and dark hair can be seen along a single strand, indicating alternating periods of good and poor nutrition. The nails are soft and thin.

The skin lesions are hypopigmented on dark skin and erythematous or purple on lighter skin (Fig. 22.9). Lesions first appear in areas of friction or pressure: the flexures, groin, buttocks, and elbows (Fig. 22.10). Hyperpigmented patches occur with slightly raised edges. As they progress, lesions resemble old, dark, deteriorating enamel paint with peeling or desquamation (Fig. 22.11). This has been described variously as "crazy pavement," crackled skin, mosaic skin, enamel paint, and flaky paint. In severe cases, the peeling leaves pale, ulcerated, hypopigmented areas with hyperpigmented borders. There may be concomitant zinc deficiency

CAROTENEMIA AND LYCOPENEMIA

Excessive ingestion of fruits and vegetables containing large amounts of β-carotene and lycopene can result in a yellow-orangish discoloration of the skin, which is especially prominent on the palms (Fig. 22.12), soles, and central face (areas of high sweat gland density). The sclerae are spared. Infants are most frequently affected, perhaps because pureeing fruits and vegetables makes these pigments more available for absorption. Carotenemia may also result from excess ingestion of β-carotene nutritional supplements and can be seen in hypothyroidism, patients with food allergies, and anorexia nervosa. Hypothyroidism can lead to carotenemia because thyroid hormone helps the conversion of beta carotene into retinol. In addition a familial form can be due to a deficiency in carotenoid 15,15′-monooxygenase, which is responsible for breaking β-carotene into vitamin A.

23 Diseases of Subcutaneous Fat

Bonus images for this chapter can be found online at expertconsult.inkling.com

An inflammatory disorder that is primarily localized in the subcutaneous fat is termed a *panniculitis*. This group of disorders may be challenging for both the clinician and the dermatopathologist. Clinically, in all forms of panniculitis, lesions present as subcutaneous nodules. Histopathologically, the subcutaneous fat is a rather homogeneous tissue, and inflammatory processes may show considerable overlap. One way of classifying panniculitis is to separate them into those that involve the septae between fat lobules (septal panniculitides) from those processes that primarily involve the fat lobules (lobular panniculitides). The prototypical septal panniculitis is erythema nodosum. Some lobular panniculitides are caused by vasculitis (e.g., polyarteritis nodosa) and are discussed in other chapters. The remaining lobular panniculitides are categorized by their pathogenesis. Weber-Christian disease, Rothmann-Makai disease, lipomembranous or membranocystic panniculitis, and eosinophilic panniculitis are reaction patterns and are not specific entities. Neutrophilic panniculitis may be infectious or may represent a variant of Sweet syndrome with primary involvement of the panniculus.

Given the depth of lesions in the panniculus, the choice of biopsy is critical in establishing the diagnosis. An incisional or excisional biopsy, narrow at the skin surface and wider in the panniculus, is the optimal procedure. An alternative double-punch method, using a 6–8 mm punch first, followed by a 4–6 mm punch at the depth of the first punch, may be considered, but it is less ideal. Depending on the amount of fat in the particular body location that is being biopsied and the age of the patient, the fat can be adequately sampled with the initial punch. Panniculitis is an area of dermatopathology where the skill of the dermatopathologist is critical in establishing good clinicopathologic correlation. If the biopsy report from an adequate specimen does not match the clinical findings, the clinician should repeat the biopsy or ask for a second opinion on the original specimen.

SEPTAL PANNICULITIS (ACUTE AND CHRONIC ERYTHEMA NODOSUM)

Erythema nodosum (EN) is the most common inflammatory panniculitis. It occurs in two forms: acute, which is more common, and chronic, which is rare. Acute EN may occur at any age and in both genders, but most cases occur in young adult women (female/male ratio, 3 : 1–6 : 1). The eruption consists of bilateral, symmetric, deep, tender nodules and plaques 1–10 cm in diameter. Usually, there are up to 10 lesions, but in severe cases many more may be found. Initially, the skin over the nodules is red, smooth, slightly elevated, and shiny (Fig. 23.1). The most common location is the pretibial area and lateral shins.

In general, the lesions should be primarily anterior rather than posterior calf. Lesions may also be seen on the upper legs, extensor arms, neck, and rarely the face. The onset is acute and is frequently preceded by malaise and leg edema. Arthritis or arthralgia, usually of the ankles, knees, or wrists, can occur. Fever, headache, episcleritis, conjunctivitis, and various gastrointestinal (GI) complaints may also be present. EN is a panniculitis that is a reactive response to another disease, therefore some of these symptoms may be related to the associated disease. Over a few days, the lesions flatten, leaving a purple or blue-green color resembling a deep bruise (erythema contusiforme). Ulceration does not occur, and the lesions resolve without atrophy or scarring. The natural history is for the nodules to last a few days or weeks, appearing in crops, and then slowly involute. EN in children affects boys and girls equally.

EN is a reactive process although approximately half of cases are idiopathic. It is frequently associated with a streptococcal infection (especially in children). Tuberculosis (TB) remains an important cause in areas where TB is endemic. Intestinal infection with *Yersinia*, *Salmonella*, or *Shigella* may precipitate EN. Other infectious causes include systemic fungal infections (coccidioidomycosis, histoplasmosis, sporotrichosis, blastomycosis) and toxoplasmosis. EN-like lesions have been described in other infectious diseases such as *Helicobacter* septicemia, brucellosis, psittacosis, and cat-scratch fever. Because these organisms are fastidious, it has not always been possible to exclude the possibility that the EN-like lesions seen in these diseases actually represent septic foci in the fat.

Sarcoidosis may present with fever, cough, joint pains, hilar adenopathy, and EN. This symptom complex, known as Löfgren syndrome, is especially common in Scandinavian, Irish, and Puerto Rican women. Sarcoidosis associated EN has been linked to a tumor necrosis factor–α (TNF-α) polymorphism. It generally responds well to therapy and runs a self-limited course. EN is frequently seen in patients with inflammatory bowel disease (IBD), more often Crohn disease than ulcerative colitis, and has been linked to mutations in genes controlling immune signaling, including *PTGER4*, *ITGAL*, and *IKZF1*. In IBD patients, EN is not associated with overall disease severity but is strongly associated with female gender, eye and joint involvement, and isolated colonic involvement. Fecal calprotectin is a marker of inflammation in the GI tract and can be a sensitive marker for active IBD and thus a useful screening test. EN has been rarely reported in association with various hematologic malignancies, but Sweet syndrome and pyoderma gangrenosum are more commonly neutrophilic dermatoses associated with hematologic malignancy. EN has also been associated with idiopathic granulomatous mastitis, which is usually unilateral and mimics infection and breast carcinoma.

Drugs may also induce EN. The bromides and iodides were once the most frequent causative agents. Currently, oral contraceptives, hormone replacement therapy, sulfonamides, and penicillins are the most common medications inducing EN. Azathioprine has also been implicated in causing neutrophilic dermatoses including EN. Other newer associated medications include lenalidomide, methimazole, and Echinacea. The association with hormonal-based therapy, predominantly in young women, and the occurrence of EN in pregnancy suggest that estrogens may predispose to the development of EN. BRAF targeting therapy with vemurafenib, dabrafenib, or trametinib may also induce EN. Although infliximab has been used to treat EN associated with Crohn disease, it has also produced EN on multiple challenges in the setting of ankylosing spondylitis.

Fig. 23.1 Erythema nodosum.

Fig. 23.2 Chronic erythema nodosum.

Erythema nodosum–like lesions have been described in Behçet syndrome and Sweet syndrome and probably represent these inflammatory processes occurring in the fat, rather than the coexistence of two disorders. Histologically, the subcutaneous lesions of Behçet syndrome show features different from EN: a lobular or mixed lobular and septal pattern and, most important, a vasculitis that may be lymphocytic or leukocytoclastic or that may involve a small arteriole. This vasculitis is proposed to be the primary event producing the subcutaneous lesions in Behçet syndrome.

A more chronic variant of EN, called chronic EN, erythema nodosum migrans, or subacute migratory panniculitis of Vilanova and Piñol, is well described. This form of septal panniculitis is much less common than acute EN. It is distinguished from acute EN because it is unilateral, or asymmetric if bilateral (Fig. 23.2); it tends to occur in older women; and it is not associated with associated systemic symptoms except arthralgias. Additionally, the lesions in chronic EN begin as a single red nodule that tends to resolve but migrates centrifugally, forming annular plaques of subcutaneous nodules with central clearing. The lesions are painless or less tender than acute EN, and they have a prolonged course of months to years. TNF-α antagonists seem to be helpful in some cases.

In the differential diagnosis of EN, other forms of panniculitis must be considered. Erythema induratum is a reactive process due to *Mycobacterium tuberculosis*. It usually affects primarily the posterior calves alone and runs a more chronic course, with the possibility of ulceration and scarring. Syphilitic gummas, as well as the nodules of sporotrichosis, are generally unilateral. Subcutaneous fat necrosis associated with pancreatitis and nodular vasculitis may also occur on the shins, but associated clinicohistologic features allow the differentiation from EN. Subacute infectious processes, such as *Helicobacter* cellulitis and primary atypical mycobacterial infection, may closely mimic EN. In most cases, the classic picture of the acute onset of symmetric, red, tender nodules on the anterior shins of a young woman readily leads to the diagnosis of EN without a biopsy. However, if the case is atypical or does not evolve typically, a biopsy should be performed. When the diagnosis of EN has been made in error, either the clinical features were atypical and a biopsy was not performed or was inadequate (punch biopsy), or the biopsy was misinterpreted by the pathologist.

The histopathology of EN is a septal panniculitis; the inflammatory infiltrate principally involves the connective tissue septa between fat lobules throughout the evolution of the lesion. The infiltrate may be composed of either neutrophils (early) or lymphocytes and other mononuclear cells (later), or a mixture, depending on the stage at which the lesion is biopsied. In older lesions, histiocytes and multinucleate giant cells may predominate. Fat lobules are only secondarily affected by the inflammation, but some foamy histiocytes may be seen in the evolution of the lesions. Meischer radial granulomas, which are aggregates of histiocytes around stellate clefts, are characteristic but not diagnostic of EN. Leukocytoclastic vasculitis is not a histologic feature of EN. In chronic EN, septal fibrosis and septal granulomas composed of epithelioid histiocytes are seen.

The management of EN involves three components: identifying the trigger, rest and elevation of the affected extremities, and antiinflammatory medications. Because streptococcus is a common trigger, throat culture (or perianal culture in young children) and antistreptolysin O (ASO) titer are indicated, especially in children. Some basic laboratory testing is done to rule out pregnancy in women, and stool calprotectin level is determined to evaluate for IBD. A complete history of any preceding illness will often lead to clues; for example, previous diarrhea might suggest *Yersinia* infection and a stool culture can be helpful if warranted based on symptoms. A travel and exposure history is especially important when considering endemic fungal infections. Because 4% of patients with histoplasmosis present with EN, this cause should be excluded in endemic areas, and TB should be excluded in patients who may have had exposure.

Early treatment of the infectious cause does not appear to shorten the duration of the EN, although EN triggered by infections tends to last longer with a more chronic infection, and streptococcal-induced EN tends to be shorter than TB-triggered EN. Bed rest is of great value and may be all that is required in mild cases, especially in children. Gentle support hose are also helpful. Curtailing vigorous exercise during the acute attacks will shorten the course, and restriction of physical activities might prevent exacerbations and recurrences. Aspirin and nonsteroidal antiinflammatory drugs (NSAIDs) such as indomethacin are often helpful. Potassium iodide is a safe and effective treatment for both acute and chronic EN. As a supersaturated solution, 5

drops three times a day, increased by 1 drop per dose per day up to 30 drops three times a day, is one easy-to-remember dose schedule. As a tablet, the dose is one 300-mg tablet three times daily. Induction of hypothyroidism by prolonged iodide therapy may occur and should be monitored for. Once controlled, the therapy is gradually reduced over 2–3 weeks. Intralesional corticosteroid injections will control persistent lesions. Systemic corticosteroids will result in rapid resolution of lesions, if not contraindicated by the underlying precipitating cause. In acute lesions, colchicine is often rapidly effective at a dose of 0.6 mg twice daily. In refractory cases, antimalarials such as hydroxycholoroquine may be tried. TNF-α medications may also be effective, but a paradoxic reaction in which adalimumab may have caused EN has been reported.

The prognosis in patients with acute EN is typically good, with the attack running its course in 3–6 weeks. Recurrences do occur, especially if the underlying condition or infection is still present, or if physical activity is resumed too quickly. Chronic or atypical lesions should suggest an alternative diagnosis and require a biopsy.

LOBULAR PANNICULITIS

Vessel-Based Lobular Panniculitis

Inflammation or thrombosis of blood vessels may lead to fat necrosis caused by ischemia. This can occur in primary forms of vasculitis, such as polyarteritis nodosa and Churg-Strauss syndrome, in metabolic disorders such as oxalosis and calciphylaxis, with atheromatous emboli, with heparin and coumarin necrosis, and with various coagulopathies. These entities are discussed in other chapters.

Fig. 23.3 Nodular vasculitis.

Nodular Vasculitis and Erythema Induratum

Clinically and histologically, nodular vasculitis is identical to erythema induratum (EI). The two differ only by the presence of TB as a precipitating factor in EI. Nodular vasculitis presents as tender, subcutaneous nodules on the calves of middle-aged women (Fig. 23.3). Venous insufficiency may be present. Lesions are bilateral and less red and tender than EN; they often ulcerate, drain oily liquid, and recur over years.

The early lesions may show a suppurative vasculopathy, proposed by various authors to be an arteritis, a venulitis, or both. In some cases, no vasculitis is found, and despite its name, the presence of a vasculitis is not required to establish the diagnosis. Nodular vasculitis results in substantial lobular necrosis of adipocytes with suppuration. Necrosis of the lobule results in loss of the lipocyte membrane and pooling of lipid into variably sized round aggregates. As lesions evolve, the fat becomes increasingly necrotic, forming microcysts, and the disease progresses to the point where it may perforate through the epidermis, forming ulceration. Granulomatous inflammation appears adjacent to areas of fat necrosis, and eventually lesions resolve with fibrosis.

Nontuberculous nodular vasculitis must be distinguished from EI. Nodular vasculitis has many reported causes, including *Chlamydia* infections, Crohn disease, Takayasu arteritis, BCG vaccination, TNF-α antagonist therapy, and non-TB mycobacterial infections. Because clinicopathologic features are identical in EI and nodular vasculitis, the differentiation is made by evaluating for tuberculous infection in the patient. A Quantiferon gold or tuberculin skin test can be administered. If this is positive, the appropriate diagnosis is EI. Polymerase chain reaction (PCR) of the affected tissue may reveal the DNA of *M. tuberculosis* in 50%–70% of cases of EI. As a tuberculid (inflammatory response to tuberculosis), EI is a manifestation of cellular immunity to TB, and the purified protein derivative (PPD) test will always be positive. PCR of the tissue is not recommended in patients who are tuberculin skin test negative. It should be noted that even in areas where TB is prevalent, EI is rare, representing only 1% of cutaneous

manifestations of TB in one study. When present, EI may signal serious genitourinary involvement, including tuberculous epididymo-orchitis.

EI requires antibiotic therapy for the underlying TB. Treatment of nodular vasculitis is usually supersaturated solution of potassium iodide (SSKI) supersaturated solution of potassium iodide, as outlined for EN, and is effective in about half of patients. In the others, trials of colchicine, antimalarials, NSAIDs, mycophenolate mofetil, and systemic corticosteroids have been helpful. Support stockings, elevation, and treatment of associated venous insufficiency may also improve nodular vasculitis.

Lipodermatosclerosis

Lipodermatosclerosis, or sclerosing panniculitis, occurs primarily on the medial lower third of the lower legs of women older than 40 (Fig. 23.4), with an above-average body mass index (BMI). It is often bilateral. In the acute phase, red to purple, poorly demarcated, indurated plaques are present on the lower legs. The lesions are painful and the differential diagnosis includes cellulitis, phlebitis, EN, or inflammatory morphea. In the chronic phase there is marked woody induration in a stocking distribution, resulting in calves that resemble inverted champagne bottles. This thick, tight, hyperpigmented skin results from fibrosis in the subcutaneous fat, which may occur without the primary inflammatory panniculitis ever being clinically observed. Fibrosis occurs multifocally and microscopically throughout the affected area.

Fig. 23.4 Lipodermatosclerosis. (Courtesy Douglas Pugliese, MD.)

The etiology of lipodermatosclerosis is venous insufficiency. These patients may have venous varicosities, superficial thrombophlebitis, deep venous thrombosis, or several of these conditions. Even when venous disease is not clinically evident, evaluation of the venous system of the lower leg will frequently reveal insufficiency. Laboratory evaluation is rarely done but may reveal a genetic mutation in the fibrinolytic system resulting in increased thrombosis in these patients. Venous insufficiency results in hypoxia, necrosis of fat, inflammation, and eventual fibrosis. If hypoxemia is present from other causes, such as pulmonary disease, sclerosing panniculitis may be more severe. Angiosarcoma has been reported as a rare complication in the setting of postphlebitic lipodermatosclerosis.

The histologic features of sclerosing panniculitis are characteristic, but not all features may be seen on every biopsy, because the histologic features change over time within the lesion. The overlying dermis frequently shows changes of stasis with nodular proliferation of thick-walled vessels, hemosiderin deposition, fibrosis, and atrophy. In early lesions, there is ischemic necrosis in the center of the fat lobules manifested as "ghost cells"—pale cell walls with no nuclei along with thickened septae. Pseudomembranous changes in the dermis may also be a clue to early disease. There is a sparse lymphocytic infiltrate in the fat septa. As the lesions evolve, the septa are thickened and fibrosed, and there is a mixed inflammatory infiltrate of lymphocytes, plasma cells, and macrophages. Foamy histiocytes are present around the areas of fat necrosis. Fat microcysts are characteristic (but not diagnostic) and appear as small cysts with feathery eosinophilic remnants of adipocytes lining the cyst cavity and resembling frost on a window, so-called lipomembranous fat necrosis. In lesions later, these microcysts collapse and are replaced by fibrosis. Despite these characteristic features, biopsy should be avoided in these patients. Biopsies heal poorly and may lead to chronic leg ulcers. The diagnosis can usually be made clinically. Noninvasive techniques such as magnetic resonance imaging (MRI) have been used to avoid poorly healing wounds related to a biopsy. If a biopsy must be performed, it should be from the most proximal edge of involvement.

This diagnosis can be clinically confirmed if a careful vascular evaluation is performed. The location on the lower medial calf is unusual for EN. Most other panniculitides favor the posterior midcalf. The gradual progression from the ankles proximally is characteristic of sclerosing panniculitis and not other forms of lobular panniculitis.

The treatment of lipodermatosclerosis may be difficult. The fibrosis may be irreversible. Graded compression stockings with elevation and standard treatments for venous insufficiency are most effective in this condition. Application of pressure dressings, such as an Unna boot, can produce dramatic, if temporary, improvement. Greater compression—Unna boot with Coban and a foam buttress (bolster material to apply extra pressure to the red inflamed area) or the Profore boot—can be beneficial. Unfortunately, some patients cannot tolerate compression because of the pain of the lesions. Intralesional triamcinolone and ultrasound therapy have been used, but this is most effective when used in conjunction with compression. Pentoxiphylline, may be useful, especially in patients not responding to compression and elevation alone, or

in patients who are initially intolerant of compression dressings. The addition of hydroxychloroquine to pentoxiphylline may provide additional improvement. Apparently, by enhancing the fibrinolytic capacity of affected patients, stanozolol, or oxandrolone, may benefit some patients. This is rarely required, however, if appropriate pressure dressings are applied and the patient is able to take full doses of pentoxiphylline. Stanozolol and oxandrolone may be virilizing for women and should be avoided in women of childbearing age. Stanozolol may induce hepatitis. Surgical treatment of varicosities and incompetent perforators may result in dramatic improvement in some patients.

PHYSICAL PANNICULITIS

The category of panniculitis includes processes in the fat that occur from physical factors. Some are characterized by the presence of needle-like clefts: sclerema neonatorum, subcutaneous fat necrosis, and poststeroid panniculitis. Infants and children are most frequently affected likely in part due the higher amount of brown fat in children. Fat is typically in a liquid form in lobules. Brown fat freezes into a solid at higher temperatures than regular fat in adults, so slight cooling can lead to solidification and necrosis.

Sclerema Neonatorum

Sclerema neonatorum is the most severe and rarest disorder of the physical panniculitides. It affects premature neonates who are critically ill for other reasons or have experienced profound hypothermia. With more adequate neonatal intensive care, this disorder has become extremely rare. Neonates affected with sclerema neonatorum usually die, unless the underlying diseases can be reversed. In the first few days of life, the skin begins to harden, usually initially on the buttocks or lower extremities, then rapidly spreads to involve the whole body. The skin on the palms, soles, and genitalia is spared. The skin becomes dry, livid, cold, rigid, and boardlike, limiting the mobility of the parts. The skin in the involved areas cannot be picked up. The skin of the entire body may appear half-frozen and is yellowish white. Visceral fat may also be involved. Therapy is mostly supportive, but some data suggest exchange transfusion may improve survival.

Fig. 23.5 Subcutaneous fat necrosis of the newborn.

Histologically, adipocytes are enlarged and filled with needle-like clefts in a radial array Recently, this unusual histologic finding was documented in a reaction to gemcitabine. Affected fat cells undergo necrosis. There is sparse inflammation, and histiocytes containing needle-like clefts are rare, possibly because most children die before granulomas can form.

Subcutaneous Fat Necrosis of the Newborn

Subcutaneous fat necrosis of the newborn (SCFN) occurs during the first 4 weeks of life (half in the first week) in term or postterm infants. There is often a history of fetal distress such as birth asphyxia, maternal-fetal disproportion, or meconium aspiration. More recently, intensive care unit protocols for neonates with neural depression may initiate hypothermia, which can lead to widespread SCFN that can even involve the viscera. Septicemia, severe neonatal anemia, thrombocytopenia, and maternal cocaine use have also been associated with SCFN.

SCFN is characterized by painful, firm to rubbery, erythematous nodules usually on areas that have significant subcutaneous tissue and are susceptible to crush injury during birth such as the upper back, buttocks, cheeks, or proximal extremities (Fig. 23.5). The arms, shoulders, and back were most common in a recent larger series. Lesions may fuse to form plaques. They heal spontaneously within 3 months with no scarring unless there is ulceration. In general, the infants remain well; however, hypoglycemia, thrombocytopenia, hypertriglyceridemia, lactic acidosis, and potentially life-threatening hypercalcemia may rarely occur. Some degree of hypercalcemia occurred in more than 50% of recently reported cases. The hypercalcemia may appear weeks to months after the appearance and resolution of the skin lesions. Periodic measuring of serum calcium for the first 3–6 months of life or until the lesions resolve has been recommended as the calcium can increase even as the lesions are resolving. Hypercalcemia may result in failure to thrive, irritability, lethargy, hypotonia, seizures, and renal failure. Rarely nephrocalcinosis and calcinosis of the gallbladder were reported. Significant hypercalcemia is treated with hyperhydration, calcium-wasting diuretics (furosemide), and formulas low in calcium and vitamin D. Systemic corticosteroids, calcitonin, and bisphosphonates may also be effective when other methods fail to reduce the hypercalcemia.

Histologically, SCFN is a lobular panniculitis with granular necrosis of adipocytes. Needle-shaped clefts are arranged radially within histiocytes, and multinucleate foamy histiocytes are present. Degranulating eosinophils may also be present. Lesions may resolve with calcification and fibrosis. Fine-needle aspiration and touch preparations can confirm this diagnosis, and a biopsy is diagnostic. Characteristic ultrasound and MRI findings have been reported.

Fig. 23.6 Cold panniculitis.

Cold Panniculitis

Infants and young children are particularly predisposed to cold panniculitis. It has been described in children who suck on ice, use frozen teething rings, or popsicles (popsicle panniculitis); in the scrotum of prepubertal males (Fig. 23.6); and in infants treated for supraventricular tachycardia with the application of cold packs to the face. Lesions occur within a few days of the cold application and appear as slightly erythematous, nontender, firm subcutaneous nodules. Equestrian panniculitis on the upper outer thighs (although it can be medial) of people riding horses in the cold more closely resembles a form of perniosis rather than true panniculitis (see Chapter 3). Overlapping histology may occur in adults using ice packs for pain relief.

The typical patient with fat necrosis of the scrotum is a prepubertal (age 9–14) boy, who is heavyset or even obese, with scrotal swelling, usually bilateral, associated with mild to moderate pain. There is a lack of systemic complaints and no symptoms related to voiding. The scrotal masses are bilateral and symmetric in most cases. However, the lesions may be unilateral, and there may be more than two. The masses are firm and tender and do not transmit light. The overlying scrotal skin is normal or red. The most common location of the lesions is near the perineum, consistent with the area of greatest concentration of scrotal fat in children. The adult scrotum lacks this fatty tissue. Without treatment, lesions resolve over several days to weeks.

Histologically, there is necrosis of adipocytes within lobules of the upper subcutaneous fat adjacent to the lower dermis. A mixed inflammatory infiltrate of lymphocytes, neutrophils, and foam cells is present, and microcysts sometimes occur. This histology is not specific, and the diagnosis of cold panniculitis relies largely on obtaining a history of cold exposure.

Zeb A, et al: Sclerema neonatorum. J Perinatol 2008; 28: 453.

Poststeroid Panniculitis

This rare form of panniculitis occurs predominantly in children treated acutely with high doses of systemic corticosteroids during rapid corticosteroid withdrawal. Substantial weight gain has usually occurred during the corticosteroid therapy. Firm subcutaneous nodules begin to appear within 1 month of tapering the corticosteroids. Areas of abundant subcutaneous fat are favored: the cheeks, trunk, and proximal extremities. Most cases resolve spontaneously within weeks, but if severe, the corticosteroids must be reinstituted and tapered more slowly.

Histologically, the changes are identical to those seen in subcutaneous fat necrosis of the newborn. There is a lobular panniculitis with necrosis of adipocytes and needle-shaped clefts in both adipocytes and histiocytes. Foamy histiocytes are also present.

Sacchidanand SA, et al: Post-steroid panniculitis. Indian Dermatol Online J 2013; 4: 318.

Traumatic Panniculitis

Accidental trauma to the skin may induce necrosis of the fat. The prior history of trauma is frequently not recalled. There may be erythema that develops over top of the area of panniculitis. Lesions present similar to a lipoma, as a firm, mobile subcutaneous mass (formerly reported as mobile encapsulated lipoma). The term *myospherulosis* (spherulocytosis) has been used to describe subcutaneous cystic lesions induced by trauma with hemorrhage into areas of high lipid content. Many cases are caused by exogenous lipids from postoperative packing, often in parasinus tissues or subcutaneous fat. The structures resemble the sporangia of rhinosporidiosis but represent degenerated red blood cells rather than true fungal organisms. Accidental trauma to the upper anterolateral thigh from a desk or chair may result in semicircular bands of atrophy of fat called lipoatrophia semicircularis. Airbag injury may induce fat necrosis.

Histologically, there is a granulomatous lobular panniculitis with foamy histiocytes, membranous fat necrosis, and microcysts. Lesions heal with fibrosis of the septa. In myospherulosis, l arge round structures containing many smaller round eosinophilic bodies are noted. These represent degenerated erythrocytes.

Sacchidanand SA, et al: Post-steroid panniculitis. Indian Dermatol Online J 2013; 4: 318.

Factitial Panniculitis

Self-induced panniculitis is rarely reported, but it does occur. It may be induced by the injection of organic materials, povidone, feces, saliva, vaginal fluid, and oils. In many cases, ulceration will occur. Cupping and other trauma may also induce a panniculitis. Some patients have a medical background because they have ready access to syringes and needles. Pointed, detailed questioning of the patient may identify inconsistencies in the history or the underlying cause for the behavior (e.g., attention seeking, revenge, malingering).

The clinician must have a high index of suspicion with patients in whom the clinical pattern is not characteristic of a known form of panniculitis. Inspection of early lesions for telltale healing injection sites may help confirm the diagnosis. A biopsy is often required. Culture may demonstrate many different microbes representative of fecal, oral, or vaginal flora. Biopsy demonstrates an acute lobular panniculitis with fat necrosis and a neutrophilic infiltrate. Careful evaluation of the biopsy material with polarization may identify foreign material. When the suspicion is high and no foreign material can be seen in the tissue, special evaluation by incineration and mass spectroscopy may identify the injected substance. Electron microscopy with x-ray emission spectrography can identify inorganic substances. Radiographs may demonstrate fractured needles or foreign bodies.

Sanmartín O, et al: Factitial panniculitis. Dermatol Clin 2008; 26: 519.

Sclerosing Lipogranuloma

Sclerosing lipogranuloma describes the granulomatous and fibrotic reaction that occurs in the panniculus from the injection of silicone or mineral oils. In most cases, the injections are intentional and cosmetic. The time from injection to onset of symptoms may be months to more than 10 years. Topical application of an antibacterial ointment to an open wound can rarely result in the formation of lipogranuloma. Exenatide injections for type 2 diabetes may induce such changes as well.

Lesions are usually localized to the penis, scrotum, breasts, nose, and buttocks, often after an attempt to augment the area by injection. The overlying skin is hyperpigmented and erythematous. Lesions are frequently diagnosed initially as cellulitis. On palpation, the skin is indurated and cannot be picked up between the fingers. The subcutaneous tissue is indurated, thickened, and lumpy. Some patients will have focal ulceration. MRI can be helpful in establishing the location and extent of the material, ruling out malignancy, and ensuring normal anatomy underneath. The injected material will frequently migrate locally, extending beyond the sites of implantation. In some cases, it is carried to other tissues, specifically the lymphoreticular system and lungs. Hepatosplenomegaly and pulmonary fibrosis may occur.

Histologically, the panniculus is replaced by the injected material, which is in various-sized vacuoles, giving the affected tissue a "Swiss cheese" appearance. Because the material is usually washed out during the tissue processing, the material itself is not seen, only the spaces it occupied in the tissue in vivo. The vacuoles are surrounded by histiocytes, many of which have ingested the material, giving their cytoplasm a vacuolated appearance. Fibrosis may be prominent. Frozen section can be used to demonstrate the lipid.

ENZYME-RELATED PANNICULITIS

The enzyme-related category includes panniculitis induced by enzymes that damage fat (pancreatic panniculitis) and panniculitis caused by the absence of an enzyme critical in preventing tissue inflammation after injury (α_1-antitrypsin).

PANCREATIC PANNICULITIS (SUBCUTANEOUS FAT NECROSIS)

Subcutaneous fat necrosis is most often associated with pancreatitis or pancreatic carcinoma, and rarely with anatomic pancreatic abnormalities, pseudocysts, hypertriglyceridemia in association with nephrotic syndrome, pancreatic portal fistule, endoscopic retrograde cholangiopancreatography, or drug-induced pancreatitis. Men outnumber women 2:1 in cases of pancreatitis and 7:1 in cases of pancreatic carcinoma. In cases associated with pancreatic carcinoma, acinar cell carcinoma is most common. Even metastatic pancreatic carcinoma with no residual tumor in the pancreas may induce the syndrome. In 40% of patients, the skin lesions are the first symptom of the underlying pancreatic pathology and therefore represent an important clue to the diagnosis.

Skin lesions appear as tender or painless, erythematous subcutaneous nodules 1–5 cm in diameter (Fig. 23.7). The lower leg is the most common location and is affected in more than 90% of cases. Subcutaneous fat elsewhere may also be affected, except rarely on the head and neck. The number of lesions is usually fewer than 10 but may reach the hundreds. In most patients, the lesions involute, leaving an atrophic scar. If the fat necrosis is severe, however, the lesion develops into a sterile abscess that may break down, draining a thick, brown, oily material.

Pancreatic panniculitis is frequently accompanied by a constellation of findings related to fat necrosis in other organs. Importantly, abdominal symptoms may be completely absent. Arthritis is found in 54%–88% of patients and may be monoarticular, oligoarticular, and rarely polyarticular. This has been labeled PPP (pancreatitis, panniculitis, and polyarthritis) syndrome. The arthritis may be intermittent, migratory, or persistent and is usually in joints adjacent

Fig. 23.7 Pancreatic panniculitis.

to the lesions of panniculitis. Examination of the joint fluid reveals the presence of free fatty acids, suggesting it is caused by fat necrosis adjacent to the joint space. Other findings are medullary fat necrosis of bone, polyserositis, and pulmonary infiltrates or embolism.

Laboratory evaluation is useful in establishing the diagnosis. In most patients the amylase or lipase (or both) is elevated. In many cases, however, one of the tests may be normal and the other abnormal, so both tests must be performed. About 60% of patients with pancreatic carcinoma and panniculitis will have a peripheral eosinophilia.

The histologic features of pancreatic panniculitis are diagnostic. These include focal areas of fat necrosis with anucleate "ghost cells"; finely stippled basophilic material, representing calcium, within the residual rim of the necrotic cells and at the periphery of the affected foci; and a dense, inflammatory polymorphous infiltrate at the periphery of the affected fat. The affected necrotic areas are relatively acellular. Several reports have suggested that the early features are those of a septal panniculitis, resembling EN. This may have represented sampling error but does indicate that if the initial sample is not diagnostic, another, perhaps more adequate, sample of a more advanced lesion should be considered. Panniculitis caused by interferon-beta injections can have a histologic appearance similar to pancreatic panniculitis.

The necrosis of fat at all affected sites is at least partly caused by the release of fat-digesting enzymes, lipases, from the affected pancreatic tissue. These lipases spread hematogenously to the affected sites.

EN represents the primary differential consideration, because pancreatic panniculitis may not have abdominal symptoms, also favors the lower legs, and may be accompanied by joint symptoms. The distinction can be made by skin biopsy, serum amylase, and lipase determinations, and especially if eosinophilia is present, a search for a pancreatic neoplasm.

Treatment mainly involves treating the cause of the pancreatitis. Obstruction or stenosis of ducts should be repaired, pseudocysts drained, and in the case of pancreatic carcinoma, surgery or other interventions as indicated.

α_1-ANTITRYPSIN DEFICIENCY PANNICULITIS

α_1-Antitrypsin is the most abundant antiprotease in circulation and a potent and irreversible inactivator of neutrophil elastase. Heterozygous deficiency of this enzyme occurs in 1 in 50 persons and homozygous deficiency in 1 in 2500 persons of European descent. Emphysema and liver disease are the most common manifestations of antitrypsin deficiency. A small percentage of patients with homozygous deficiency and the PiZZ or PiSZ phenotypes will develop panniculitis. It is caused by a mutation in SERPINA1 gene.

The panniculitis usually appears between ages 20 and 40 but can occur in childhood. Both genders are equally affected. Lesions appear after relatively minor trauma and present as painful nodules on the extremities or trunk. They may spontaneously drain an oily, brown liquid. Multiple draining sinus tracts can occur, with lesions coalescing into large, draining plaques.

The histologic findings in this form of panniculitis depend on the stage of the lesion. Early lesions show neutrophils splaying the collagen of the reticular dermis and subcutaneous septa. More fully evolved lesions show dissolution of the septa, with islands of normal fat "floating" in the spaces that represented the destroyed septa. This later finding is considered diagnostic by some. Elastic tissue stains may reveal decreased elastic tissue in the affected areas.

The clinical and histologic differential diagnosis is factitial panniculitis. This is not surprising because trauma produces both lesions, and in the case of α_1-antitrypsin deficiency, the inflammation-produced enzymes are simply not inactivated, leading to more pronounced lesions than would be expected from that degree of trauma.

Replacement of the deficient antitrypsin will lead to resolution of the skin lesions, but is costly. Dapsone, colchicine, and doxycycline can also be effective. These agents can reduce the requirement for enzyme replacement and should be considered as maintenance treatment in affected patients. Systemic corticosteroids may exacerbate the panniculitis. Liver transplantation leads to normal levels of α_1-antitrypsin and resolution of the panniculitis. Gene therapy and stem cell therapy appear promising.

CYTOPHAGIC HISTIOCYTIC PANNICULITIS

Cytophagic histiocytic panniculitis (CHP) is a multisystem disease characterized by widespread erythematous, painful, subcutaneous nodules that may occasionally become ecchymotic or break down and form crusted ulcerations. There is a progressive febrile illness, with hepatosplenomegaly, pancytopenia, hypertriglyceridemia, and liver dysfunction. These result from the proliferation of benign-appearing histiocytes, which have a marked phagocytic capacity and extensively involve the reticuloendothelial system. Some patients progress to a terminal phase characterized by profound cytopenia, liver failure, and a terminal hemorrhagic diathesis. CHP represents a spectrum of disease that occurs in children and adults. Some cases are triggered by viral infections, such as Epstein-Barr virus (EBV) or human immunodeficiency virus (HIV), or viral vaccines, and others represent subcutaneous B-cell or T-cell lymphomas. CHP can also occur in hemophagocytic lymphohistiocytosis and has been associated with *STX 11* gene mutation. The benign cases are EBV negative and the lymphoma-associated cases are EBV positive.

Histologically, there is infiltration of the lobules of subcutaneous fat by histiocytes and inflammatory cells, primarily helper T cells, with fat necrosis and hemorrhage. The characteristic cell is a "beanbag" cell: a histiocyte stuffed with phagocytized red blood cells, lymphocytes, neutrophils, platelets, or fragments of these cells. These beanbag cells are not diagnostic of CHP and can be seen infrequently in other panniculitides, especially lupus profundus. The presence of atypical lymphocytes or the detection of a clonal B-cell or T-cell proliferation supports the diagnosis of subcutaneous lymphoma in patients with CHP.

The treatment of CHP is difficult. If malignancy cannot be detected, cyclosporine has been effective in many patients, and combination treatment with high-dose corticosteroids, cyclosporine, and anakinra has been reported. Tacrolimus is another option that has improved some patients. If malignancy is detected, aggressive chemotherapy and perhaps bone marrow transplantation may be considered.

MISCELLANEOUS FORMS OF PANNICULITIS

GOUTY PANNICULITIS

Uric acid crystals may deposit initially in the subcutaneous fat of patients with gouty panniculitis, leading to lesions resembling other forms of panniculitis. Histologically, there is a lobular panniculitis with necrosis of adipocytes and infiltration of polymorphonuclear leukocytes. Feathery, needle-like crystals in sheaves are present.

LIPODYSTROPHY (LIPOATROPHY)

The lipodystrophies are conditions characterized by a marked reduction in subcutaneous fat. Lipodystrophies can be generalized (total), partial, or localized and may be congenital or acquired. In the congenital types, females are more frequently and more severely affected. Hypertriglyceridemia and diabetes mellitus (DM) with insulin resistance occur in many of the congenital and acquired forms of lipodystrophy. These syndromes were quite rare until the 1990s. With the advent of combination antiviral therapy for HIV infection (highly active antiretroviral therapy [HAART]), acquired lipodystrophy has become common in geographic regions where HIV infection is prevalent. In addition, localized fat loss can be a consequence of therapeutic injections into the fat.

CONGENITAL LIPODYSTROPHIES

Congenital Generalized Lipodystrophy

Congenital generalized (total) lipodystrophy, also known as Berardinelli-Seip syndrome, is a rare autosomal recessive condition that is often due to parental consanguinity. At birth or soon after, there is noted an extreme paucity of fat in the subcutaneous tissue and other adipose tissues, giving affected persons a generalized muscular appearance. The mechanical fat of the palms, soles, joints, orbits, and scalp is often not affected. The children have a voracious appetite. They have increased height and height velocity, advanced bone age, muscular hypertrophy, and a masculine habitus. This habitus plus enlargement of the genitalia in infancy (clitoromegaly) can lead to the misdiagnosis of precocious puberty. Scalp hair is abundant and curly, and there is generalized hypertrichosis and hyperhidrosis. The abdomen is protuberant, and the liver and spleen are enlarged. The overall appearance is acromegalic (Fig. 23.8) from enlargement of the mandible, hands, and feet. Acanthosis nigricans is invariably present and often generalized. Hyperinsulinemia, insulin resistance, and DM appear often at about puberty. Women often have menstrual irregularity. The DM resists insulin and oral hypoglycemic therapy, but ketoacidosis does not occur. Hypertriglyceridemia occurs and can produce eruptive xanthomas, pancreatitis, and fatty liver, which may eventuate in cirrhosis. Hypertrophic cardiomyopathy and mild mental retardation may occur. Life span is shortened, with patients frequently dying in young adulthood from complications of diabetes or from liver or heart disease.

Fig. 23.8 Congenital generalized lipodystrophy.

Mutations in four genes, encoding for 1-acylglycerol 3-phosphate-*O*-acyltransferase 2 *(AGPAT2)*, seipin, caveolin-1 *(CAV1)*, and cavin-1, cause different subtypes of congenital generalized lipodystrophy. Type B mandibuloacral dysplasia from *ZMPSTE24* mutations, proteasome-associated autoinflammatory syndromes caused by beta subunit type 8 mutations (e.g., seemingly acquired lipodystrophies seen in Candle syndrome, and three other subtypes), glycosylation disorders, *FBNI* mutations, and *c-Fos* and *BANF1* mutations are other causes of generalized lipodystrophies that are inherited. A novel subtype with preservation of bone marrow fat, congenital muscular weakness, and cervical spine instability has also been described. Serum leptin and adiponectin levels are extremely low in various types. If leptin levels are low, leptin replacement decreases serum triglycerides and improves hyperglycemia. Metreleptin was approved in 2014 for replacement. Some patients with congenital generalized lipodystrophy do not have mutations in these genes, suggesting that there are other genetic causes.

Familial Partial Lipodystrophy

Familial partial lipodystrophy is a heterogeneous autosomal dominant group of disorders with distinct phenotypes. The most common variant is the Dunnigan type. Patients are normal at birth, but at about puberty, subcutaneous tissue is gradually lost from the arms and legs and variably from the chest and anterior abdomen. Fat gain occurs in the face, neck, and intraabdominally, resulting in a cushingoid appearance. Increased levels of dipeptidyl peptidase-4 involved in glucose metabolism have been found. DM, hypertriglyceridemia, and atherosclerosis occur more frequently in female patients. The hypertriglyceridemia may result in pancreatitis and fatty liver, but cirrhosis has not been reported. The genetic defect in the Dunnigan variant of partial lipodystrophy is in the gene encoding lamins A and C *(LMNA)*. Lamins are intermediate filaments integral to the nuclear envelope. The site of the mutation determines the phenotype expressed. Myopathy, muscular dystrophy, cardiomyopathy, and conducting system disturbances can occur in a minority of patients.

A second characterized form of familial partial lipodystrophy is related to mutations in the *PPAR*-γ gene. This rare syndrome is associated with marked loss of subcutaneous tissue of the forearms and calves, and less prominently on the upper arms and thighs.

The trunk is spared, and there is no excess fat on the neck. DM, hypertriglyceridemia, hypertension, and hirsutism also occur. Other forms of familial partial lipodystrophy not associated with the previous two mutations have been described, suggesting additional genetic causes of this syndrome.

Mandibuloacral dysplasia is an extremely rare autosomal recessive condition with hypoplasia of the mandible and clavicle, acro-osteolysis, joint contractures, mottled cutaneous pigmentation, skin atrophy, alopecia, a birdlike facies, and dental anomalies. Two distinct patterns of lipodystrophy occur. Type A is characterized by loss of subcutaneous fat from the arms and legs, but normal to excess fat of the face and neck. Hyperinsulinemia, insulin resistance, DM, and hyperlipidemia occur in some patients. Mutations in the *LMNA* gene have been reported in type A patients. Mutations in the zinc metalloproteinase *(ZMPSTE24)*, which is involved in the processing of prelamin A, have also been responsible for mandibuloacral dysplasia. Other gene mutations responsible for rarer types include those of *AKT2*, *CIDEC*, and perilipin. Autosomal recessive neonatal progeroid syndrome is characterized by near-total absence of fat from birth, with sparing of the sacral and gluteal areas.

ACQUIRED LIPODYSTROPHY

Most cases of acquired lipodystrophy are related to antiretroviral therapy, and the severity may be related to genetic variations in resistin. Lipodystrophy occurs in up to 80% of HIV-infected patients, most of whom are being treated with combination anti-HIV therapy (HAART). The fat of the face (especially buccal fat pads), buttocks, and limbs is lost. There is increased fat deposition in other areas, especially the neck, upper back (buffalo hump), and intraabdominally. It is related to nonnucleoside reverse transcriptase inhibitors, which also inhibit the γ-DNA polymerase of mitochondria, leading to adipocyte apoptosis. There are elevated levels of FGF21 in HIV patients with lipodystrophy, but it is more elevated in those treated with HAART and this may explain the metabolic abnormalities. As with the other acquired and inherited forms of lipodystrophy, patients may have hypertriglyceridemia, hypercholesterolemia, and insulin resistance, especially if a protease inhibitor is a part of their treatment. Metformin or thiazolidinediones combined with exercise can reduce insulin resistance and waist circumference. Antiretroviral-associated lipoatrophy slowly improves with prolonged rosiglitazone. Growth hormone reduces visceral fat, but the effects are short lived, unlike with the growth hormone–releasing factor analog tesamorelin, which has long-term benefit. Various injectable agents may provide cosmetic improvement.

Acquired lipodystrophy has several idiopathic forms, and it can be partial or generalized. In addition, hyperinsulinemia, hyperlipidemia, and DM may occur in patients with acquired lipodystrophy. Management involves controlling the hyperinsulinemia and its complications.

Acquired Partial Lipodystrophy (Barraquer-Simons Syndrome)

Until HAART-associated lipodystrophy appeared, the acquired partial type was the most common form of lipodystrophy. Affected females outnumber males 4:1. The syndrome presents in the first and second decades of life. This progressive fat disorder is characterized by a diffuse and progressive loss of the subcutaneous fat that usually begins in the face and scalp, progressing downward as far as the iliac crests but sparing the lower extremities. The upper half of the body looks emaciated, and the patient has sunken cheeks (Fig. 23.9A). There is an apparent, and sometimes real, adiposity of the buttocks, thighs, and legs, especially in affected women (Fig. 23.9B). The onset is insidious, with no discomfort or inflammation in the areas of fat loss. A few patients have developed other autoimmune diseases, including systemic lupus erythematosus and juvenile dermatomyositis.

Histologically, the skin is normal except for the absence of fat. Most patients with acquired partial lipodystrophy have reduced levels of C3 resulting from a circulating polyclonal IgG called "C3 nephritic factor." Proteinuria caused by membranoproliferative glomerulonephritis occurs in about 20% of patients, appearing about 8 years after the onset of the lipodystrophy. C3 nephritic

Fig. 23.9 Partial lipodystrophy, acquired. (A) Face. (B) Hypertrophy of subcutaneous fat on lower half of the body.

factor stabilizes C3b,Bb (C3 convertase), leading to unopposed activation of the alternative complement system and excessive consumption of C3.

Acquired Generalized Lipodystrophy

This rare form of lipodystrophy appears during childhood or adolescence. Females with acquired generalized lipodystrophy outnumber males 3 : 1. The fat loss affects large areas of the body, particularly the face, arms, and legs. Mechanical fat of the palms and soles may be lost, but ocular and bone marrow fat are spared. Acanthosis nigricans is present. Hepatic steatosis and voracious appetite may be present. Cirrhosis occurs in about 20% of patients due to hepatitic steatosis or autoimmune hepatitis. DM and hypertriglyceridemia may occur.

About 25% of patients will have a preceding inflammatory panniculitis at the onset of the syndrome. These patients tend to have less severe manifestations. Another 25% of patients with acquired generalized lipodystrophy have an associated connective tissue disease, especially juvenile dermatomyositis. Half the patients give no history of panniculitis and have no connective tissue disease. Other associations include graft-versus-host disease, lymphoma, and glucocorticoid administration.

CENTRIFUGAL ABDOMINAL LIPODYSTROPHY

Most cases of "lipodystrophia centrifugalis abdominalis infantilis," as described by Imamura et al., have been reported nearly exclusively from a single region of Japan. The cause is unknown. It is almost invariably a disease of childhood; 90% of cases begin at age 3. Girls outnumber boys 2 : 1. It is characterized by depression of the skin caused by loss of fat in the groin (80% of patients) or axilla (20%). The atrophic area slowly enlarges centrifugally for 3–8 years in most patients, often stopping with the onset of puberty. In 80% the depressed area was surrounded by a discrete, erythematous border with scale. One third of patients have multiple lesions, and regional lymph nodes are enlarged in 65%. The affected children are otherwise well. When the lesion stops expanding, the erythematous rim and lymphadenopathy disappear. After the progression stops, the skin returns to normal within 1 or 2 years.

LIPOATROPHIA ANNULARIS (FERREIRA-MARQUES SYNDROME)

Lipoatrophia annularis primarily affects women and usually involves the upper extremity. The lipoatrophy may be preceded by erythema, a bracelet-shaped swelling, and tenderness of the entire extremity. This is followed by loss of subcutaneous fat, with the arm divided into two parts by a depressed, atrophic, bracelet-like constriction. The depressed band is usually about 1 cm wide and up to 2 cm in depth. Arthralgias and pain of the affected extremity precede and accompany the process. The band persists for up to 20 years. The histology shows atrophy of the subcutaneous fat. The cause is unknown.

LOCALIZED LIPODYSTROPHY

A few months after subcutaneous injections, localized atrophy of fat may develop. Many different medications have been implicated, including insulin (more commonly nonhumanized), antibiotics, and vaccinations, and the reports are more frequent in children and women than in men. Acupuncture has also been associated. Localized lipodystrophy may also be a manifestation of connective tissue disease. Pegvisomant and insulin have also been associated with lipohypertrophy.

ACROMEGALY

Excess growth hormone (GH) in prepubertal children leads to gigantism, whereas once the epiphyseal growth plates close, such excess leads to acromegaly. In acromegaly, changes in the soft tissues and bones form a characteristic syndrome. In association with the well-known changes in the facial features caused by gigantic hypertrophy of the chin, nose, and supraorbital ridges, there is thickening, reddening, and wrinkling of the forehead and exaggeration of the nasolabial grooves. The lips and tongue are thick. Cutis verticis gyrata is present in approximately 30% of patients. The hands and feet enlarge (Fig. 24.1), and there is gradual growth of the fingertips until they resemble drumsticks. There is diffuse hypertrophy of the skin, which is at least partly caused by deposition of colloidal iron-positive material in the papillae and reticular dermis. This increased skin thickness can be demonstrated in lateral radiographs of the heel, with reversal toward normal after treatment. Skin thickness does not correlate well with GH levels at the time of diagnosis. Skin tags are often present and the skin has an oily feel. Hypertrichosis, hyperpigmentation, and hyperhidrosis occur in many patients. The viscera also enlarge and patients may develop a variety of rheumatologic, cardiovascular, metabolic, and respiratory complications.

The clinical changes may suggest the leonine facies of Hansen disease, as well as Paget disease, myxedema, and pachydermoperiostosis. Acromegaloid facial appearance syndrome is an inherited condition in which only the facial changes are present, and no abnormality of GH exists. Pseudoacromegaly is an acquired condition that may be seen in patients with severe insulin-resistant diabetes, which appears to be a fibroblast defect, in patients receiving long-term minoxidil.

The cause of 98% of acromegaly is hypersecretion of GH by a pituitary adenoma. Rare cases of ectopic GH-releasing hormone (GHRH) producing tumors of the lung and pancreas have been reported. The peak age of diagnosis is in the forties. Measurement of serum insulin-like growth factor (IGF, somatomedin C), measurement of serum GH after a glucose load, and magnetic resonance imaging (MRI) of the pituitary are diagnostic tests. It may occur as one of the manifestations of Carney complex, McCune-Albright syndrome, or multiple endocrine neoplasia (MEN) type I.

The currently preferred treatment is a transsphenoidal microsurgical excision of the tumor. Medical therapy may be used as a primary treatment for those unsuitable for surgery, as a preoperative treatment, or as secondary therapy after failed surgery. Octreotide and lanreotide are potent, long-acting inhibitors of GH (somatostatin analogs) that are given as once-monthly or biweekly intramuscular (IM) depot injections. Fatigue, paresthesias, and headaches improve rapidly. With continuous treatment, soft tissue swelling and facial coarsening improve as GH levels decline in almost all patients. After 18–24 months of therapy, 50% of patients will completely normalize, with the exception of hyperhidrosis, which persists in most patients. The dopamine agonists bromocriptine and cabergoline suppress GH secretion and are used as an adjuvant medical therapy in some cases. The GH receptor antagonist pegvisomant is another medical option to normalize GH secretion. Radiation is generally reserved for recalcitrant cases.

CUSHING SYNDROME

Chronic excess of glucocorticoids leads to a wide variety of signs and symptoms. The most prominent features of Cushing syndrome include central obesity, affecting the face, neck, trunk, and especially the abdomen, but sparing the limbs. There is classically deposition of fat over the upper back, referred to as a buffalo hump. This may be treated with liposuction. The face becomes moon shaped, being wide and round. The peak age of onset is in the twenties and thirties.

The striking and distressing skin changes include hypertrichosis, dryness, acne, susceptibility to superficial dermatophyte and *Pityrosporon* infections, a plethora over the cheeks, anterior neck, and V of the chest, and the characteristic purplish, atrophic striae that may involve the abdomen (Fig. 24.2), buttocks, back, breasts, upper arms, and thighs. Skin fragility and thinning occur such that easy bruising and a cigarette paper–type wrinkling are present. The skin may easily pull off when adhesive tape is removed (Liddle sign). The thinning of the skin can be demonstrated and measured in lateral radiographs of the heels. There is reversal with treatment. Women, who are affected four times more frequently than men in noniatrogenic cases, develop facial lanugo hypertrichosis, with thinning of the scalp hair. Occasionally, there may be livedo reticularis, purpura, ecchymosis, or brownish pigmentation. Poikiloderma-like changes have been observed. Opportunistic fungal infections occur, either with organisms that are not normally pathogenic or as uncommon presentations of common infections.

Patients with Cushing syndrome usually have hypertension and marked generalized arteriosclerosis, with progressive weakness, prostration, and pains in the back, limbs, and abdomen; kyphosis of the dorsal spine also occurs, accentuating the buffalo hump appearance. Osteoporosis occurs, and there is generally a loss of libido. In 20% of patients, a disturbance in carbohydrate metabolism develops, with hyperglycemia, glycosuria, and diabetes mellitus.

These varied symptoms indicate a marked and widespread disturbance caused by the hyperactive adrenal cortex. When

microadenomas of the pituitary gland produce these clinical findings, it is referred to as Cushing disease; this accounts for only 10% of patients. Between 40% and 60% of additional cases are caused by increased adrenocorticotropic hormone (ACTH, corticotropin) production by the pituitary, but no adenoma is identified. Adrenal adenomas and carcinomas, with ectopic production of ACTH by other tumors, account for the remainder of cases of noniatrogenic Cushing syndrome. Iatrogenic Cushing syndrome is usually secondary to systemic administration of corticosteroids; however, absorption from topical corticosteroids to the skin, nasal mucosa, the conjunctiva, or the gingiva may occur, especially in children. Primary pigmented nodular adrenocortical disease leading to Cushing syndrome occurs in 30% of patients with Carney complex. It is a rare feature of McCune-Albright and MEN type I syndrome. With alcohol abuse, the clinical findings of Cushing syndrome may be mimicked, producing the pseudo–Cushing syndrome.

A rapid screening test for Cushing syndrome consists of oral administration of 1 mg of dexamethasone at 11 PM, followed at 8 AM by a fluorometric determination of plasma cortisol. A cortisol level below 50 nmol/L essentially rules out Cushing syndrome, except for the iatrogenic variety, in which there is adrenocortical hypoplasia, and the serum cortisol level is very low, even without dexamethasone suppression. If this test is positive, it must be confirmed by doing a 24-hour urinary free cortisol test. A value of at least three times the upper limit of normal is 95%–100% sensitive and specific. A serum ACTH is then obtained to determine whether the source is the adrenal glands or whether it is a pituitary tumor or an ectopic tumor (low, normal or high, and very high, respectively). Treatment is primarily surgical removal of the tumor; however, radiation, chemotherapy, or medication that blocks steroid synthesis is occasionally used.

ADDISON DISEASE

Adrenal insufficiency is manifested in the skin primarily by hyperpigmentation (Fig. 24.3). It is diffuse but most prominently observed in sun-exposed areas and sites exposed to recurrent trauma or pressure. The axillae, perineum, and nipples are also affected. Palmar crease darkening in patients of lighter skin type, scar hyperpigmentation, and darkening of nevi, mucous membranes, hair, and nails may all be seen. Multifocal oral melanoacanthoma, a reactive mucosal hyperpigmentation, may occur. An eruptive onset of multiple new nevi may be an early sign of Addison disease. Occasionally, pigmentation may not occur; this is referred to as white Addison disease. Decreased axillary and pubic hair is seen in women, because their androgen production primarily occurs

Fig. 24.3 Hyperpigmentation in Addison disease. (Courtesy Steven Binnick, MD.)

in the adrenals. Fibrosis and calcification of the pinnae of the ears are rare complications.

Systemic signs such as weight loss, nausea, vomiting, diarrhea, weakness, fatigue, and hypotension add specificity to the cutaneous abnormalities. Addison disease is usually the result of autoantibody destruction of adrenocortical tissue; however, infection, hemorrhage, or infiltration may be the cause of adrenal insufficiency. In young boys suspected of having Addison disease, adrenoleukodystrophy, a peroxisomal disease, must be considered. Hyperpigmentation associated with adrenocortical insufficiency usually occurs in childhood, and precedes the adult onset of neurologic signs, so very-long-chain fatty acid levels should be determined and analysis for a mutation of the *ABCD1* gene done. Addison disease may be part of polyglandular autoimmune syndrome types I, II, and IV, in which various combinations of hypoparathyroidism, chronic candidiasis, vitiligo or autoimmune thyroiditis, and diabetes may occur.

Diagnosis of Addison disease is made by obtaining a paired serum cortisol and plasma ACTH, followed by stimulation with cosyntropin. Failure to see an elevation above 550 nmol/L in 1 hour is diagnostic. Plasma ACTH is elevated in primary insufficiency but normal to low in patients with secondary adrenal insufficiency, in whom the damage is in the hypothalamic-pituitary axis. The adrenals should be imaged with computed tomography (CT) to exclude infiltration or infection.

Treatment of Addison disease is replacement of the glucocorticoids and mineralocorticoids.

COMBINED PITUITARY HORMONE DEFICIENCY AND GROWTH HORMONE DEFICIENCY

Pituitary failure results in many changes in the skin, hair, and nails because of the absence of pituitary hormone action on these sites. Pale, thin, dry skin is seen. Hypohidrosis is present. Diffuse loss of body hair occurs, with axillary, pubic, and head hair being especially thin. The nails are thin, fragile, and opaque and grow slowly. Compromise of the pituitary gland is usually caused by a pituitary tumor, although infiltration, autoimmunity and other inflammatory processes, infection, genetic mutations, trauma, radiation, hemorrhage, or hypothalamic tumors may be the etiology. Isolated GH deficiency is the most common sporadic form of hypopituitarism; however, thyroid hormone, glucocorticoids, and sex steroids may be low and require replacement in combined pituitary hormone deficiency (or panhypopituitarism). A pituitary MRI will screen for tumors or infiltrative processes. Mutations in a large number of genes encoding transcription factors and specific autoantibodies such as anti-pit-1 may also be responsible.

ANDROGEN-DEPENDENT SYNDROMES

The androgen-dependent syndromes are caused by the excessive production of adrenal or gonadal androgens by adrenal adenomas, carcinoma, or hyperplasia, Leydig cell tumors in men, and arrhenoblastomas and polycystic ovarian syndrome (PCOS) in women.

PCOS is defined as the association of polycystic ovaries with biochemical (the best screening laboratory test is free testosterone) or clinical signs of hyperandrogenism and chronic anovulation (less than nine periods per year), without specific underlying disease of the adrenal or pituitary glands. The cutaneous signs of excessive androgen in women include acne, hirsutism, and androgen-induced patterned scalp hair loss. Hyperpigmentation of the skin, areolae, genitalia, palmar creases, and buccal mucosa develops in some patients. Acanthosis nigricans is common in PCOS, reflecting insulin resistance. Women who meet the criteria of PCOS have more severe truncal hirsutism and axillary acanthosis nigricans. Diabetes mellitus, cardiovascular complications, and sleep apnea are associated comorbidities of PCOS. In patients who are obese, weight loss is a prime target of therapy to prevent morbidity and mortality from the associated metabolic syndrome. An association of endometrial cancer is suggested but remains unproven.

In the congenital adrenogenital syndrome (Fig. 24.4), excess androgen is produced by an inherited defect in any of the five enzymatic steps required to convert cholesterol to cortisol. The formation of inadequate amounts of cortisol stimulates the pituitary to secrete excessive ACTH, which leads to excess androgen production. In boys, precocious puberty results. In girls, masculinization occurs, with the prominent cutaneous signs of excess androgen production. These signs may include acne. Acne with onset between ages 1 and 7 with physical findings suggestive of a hormonal disorder, such as sexual precocity, virilization, and growth abnormalities, should be referred to a pediatric endocrinologist. Acne that begins from ages 7 to 12 often manifests primarily as comedonal lesions in the central face. Unless there are other signs of androgen excess, these patients do not need a workup. Accelerated bone growth with early closure of the epiphyseal plates results in short stature. Early appearance of pubic and axillary hair is also seen.

Testing includes serum total testosterone and dehydroepiandrosterone sulfate (DHEA-S) levels. If the total testosterone concentration is greater than 200 ng/dL, ovarian imaging is indicated to assess for an ovarian tumor. If the DHEA-S level is

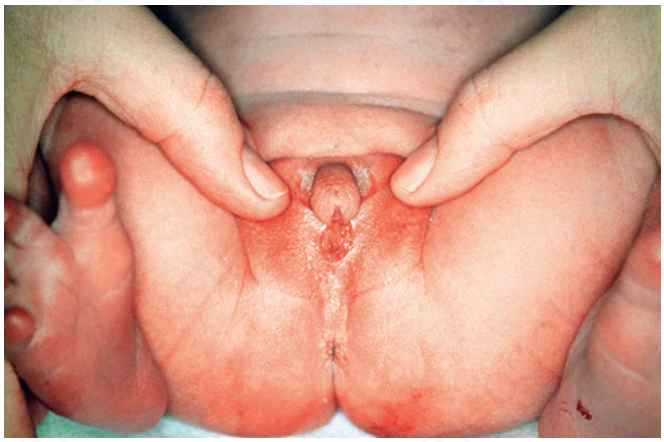

Fig. 24.4 Adrenogenital syndrome.

two to three times the upper limit, an adrenal mass should be suspected, and CT scan of the adrenals is required. Tumors causing such elevations in serum androgens often cause more dramatic masculinization with clinical findings such as a deepening voice, increased muscle mass, enlargement of the clitoris, decreased breast size, galactorrhea, and absent periods. In congenital adrenal hyperplasia, testing should include levels of cortisol, aldosterone, and precursor hormones, and in some patients, cosyntropin (Cortrosyn) stimulation tests. Nonclassic adrenal hyperplasia is most often related to 21-hydroxylase deficiency and may present as PCOS. It is best diagnosed by a corticotropin-stimulated 17-hydroxyprogesterone (17-HP) level greater than 10 ng/mL (30.3 nmol/L). The diagnosis can be confirmed by genotyping of the *CYP21* gene. The question remains whether treatment with corticosteroid replacement results in better outcomes than empiric antiandrogen therapy.

Treatment of the cutaneous signs of androgen excess is successful with an oral contraceptive and often also an androgen-blocking agent such as cyproterone acetate, flutamide, or finasteride. Spironolactone, which competes for the androgen cytosol receptors, has proved useful as a systemic antiandrogen in the treatment of hirsutism and acne. Laser hair removal and standard acne therapy are also effective. Adrenal-androgenic female pattern alopecia may improve with topical minoxidil or spironolactone. Metformin is frequently used to improve insulin responsiveness. Chorionic villous biopsy may identify homozygous adrenogenital female fetuses and allow for dexamethasone therapy to prevent intrauterine virilization of the external genitalia.

HYPOTHYROIDISM

Hypothyroidism is a deficiency of circulating thyroid hormone, or rarely, peripheral resistance to hormonal action. Deficiency may be caused by iodine deficiency, late-stage Hashimoto autoimmune thyroiditis, or pituitary or hypothalamic disease causing central hypothyroidism, or it may be iatrogenic secondary to surgery, radioactive iodine treatment, or drug therapy with lithium, interferon, multikinase inhibitors, ipilimumab alone or particularly if given in combination with nivolumab, valproic acid, or bexarotene. It may also complicate anticonvulsant and minocycline hypersensitivity syndromes, appearing approximately 2 months after the eruption has resolved. The endothelium in infantile hemangiomas may produce elevated type 3 iodothyronine deiodinase, leading to consumptive hypothyroidism. Hypothyroidism produces various clinical manifestations, depending on the age when it occurs and on its severity. Middle-aged women are the adults most often affected. Patients with Turner and Down syndrome are predisposed to hypothyroidism and the production of thyroid autoantibodies. A wide array of immunologic conditions are associated with Hashimoto thyroiditis, including polyglandular autoimmune syndrome types II and III, vitiligo, connective tissue disease, and autoimmune urticaria.

An autosomal recessive variant of ectodermal dysplasia has been described as ANOTHER syndrome: alopecia, nail dystrophy, ophthalmic complications, thyroid dysfunction, hypohidrosis, ephelides and enteropathy, and respiratory tract infections. Other associations with hypothyroidism include lichen planopilaris and cutaneous sarcoidosis.

Congenital Hypothyroidism

Thyroid deficiency in fetal life produces the characteristic picture of cretinism at birth and in the next few months of life. Various mutations in the thyroglobulin gene, the thyroid peroxidase gene, and the thyroid-stimulating hormone (TSH) receptor may be causative. True absence of the gland may occur, as was documented in a patient with PHACE syndrome. Depending on the degree of thyroid deficiency, a wide variety of signs and symptoms may be evident. The main consequence of extreme thyroid deficiency is cretinism and its attendant mental retardation, but much more prevalent are lesser degrees of intellectual and neurologic deficits seen in areas of the world where iodized salt is still not routinely available.

The person with cretinism has cool, dry, pasty-white to yellowish skin. Disturbances in the amount, texture, and distribution of the hair with patchy alopecia are common. Pigmentation is less than normal after exposure to sunlight. Sweating is greatly diminished. The lips are pale, thick, and protuberant. The tongue is usually enlarged, and there is delayed dentition. Wide-set eyes, a broad, flat nose, and periorbital puffiness characterize the face. A protuberant abdomen with umbilical hernia; acral swelling; coarse, dry, brittle nails; a clavicular fat pad; and hypothermia with cutis marmorata are also seen. Mandatory screening programs for congenital hypothyroidism (as in the United States) has led to dramatically improved cognitive outcomes.

Myxedema

When lack of secretion of thyroid hormone is severe, myxedema is produced. The skin becomes rough and dry, and in severe cases of primary myxedema, ichthyosis vulgaris may be simulated. The facial skin is puffy; the expression is often dull and flat; macroglossia, swollen lips, and a broad nose are present; and chronic periorbital infiltration secondary to deposits of mucopolysaccharides frequently develops (Fig. 24.5A). Such infiltrate can lead to a cutis verticis gyrata appearance of the scalp. Carotenemia may cause a yellow tint in the skin that is especially prominent on the palms and soles. Diffuse hair loss is common, and the outer third of the eyebrows is shed (Fig. 24.5B). The hair becomes coarse and brittle. The free edges of the nails break easily, and onycholysis may occur.

Mild Hypothyroidism

Lesser degrees of thyroid deficiency are common and much less easily diagnosed. Coldness of hands and feet in the absence of vascular disease, sensitivity to cool weather, lack of sweating, tendency to put on weight, need for extra sleep, drowsiness in the daytime, and constipation all suggest possible hypothyroidism and the need for appropriate tests. Palmoplantar keratoderma may be a sign of hypothyroidism and will resolve after thyroid hormone replacement is given.

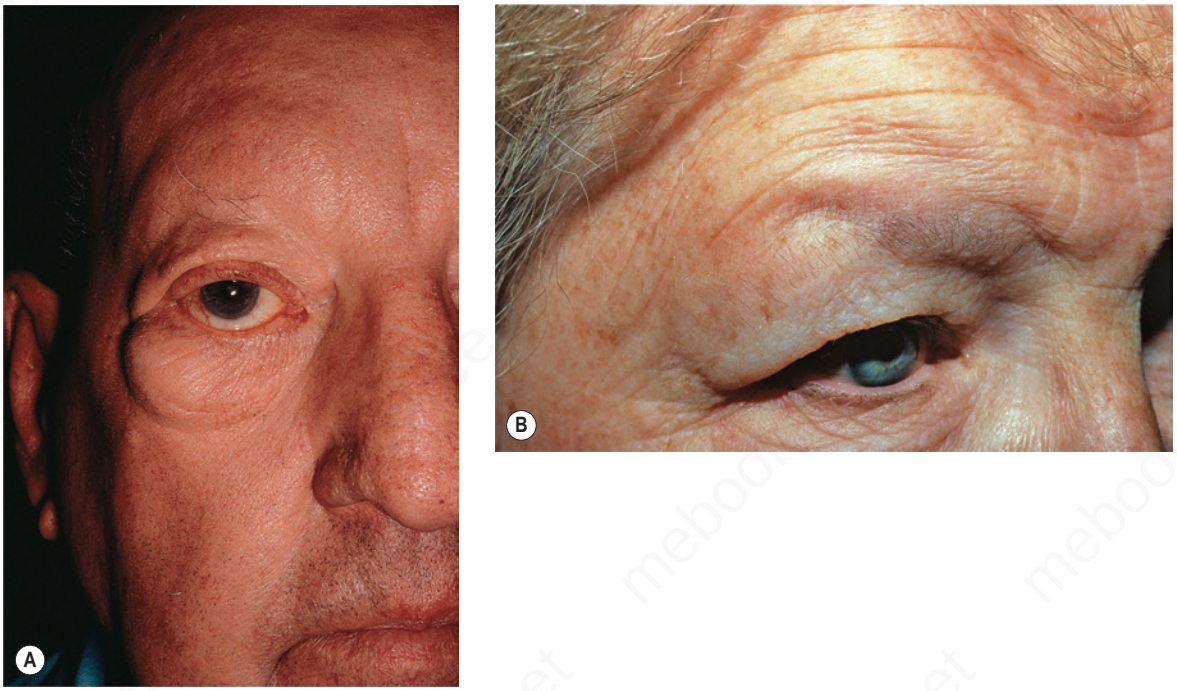

Fig. 24.5 (A) Periorbital infiltration with mucopolysaccharides. (B) Loss of lateral eyebrow.

Diagnosis and Treatment

An elevated TSH is the best diagnostic test for primary hypothyroidism. Triiodothyronine (T_3) and thyroxine (T_4) are low. In Hashimoto thyroiditis, the most common cause of hypothyroidism in the United States, thyroid peroxidase antibodies are present in 95% of patients and antithyroglobulin antibodies in 65%. In those with positive antibodies but normal thyroid function, hypothyroidism will develop at a rate of 5% per year. Thyroid hormone replacement will reverse the skin findings of hypothyroidism.

HYPERTHYROIDISM

Excessive quantities of circulating thyroid hormone may be caused by Graves thyroiditis (diffuse toxic goiter), a multinodular toxic goiter (Plummer disease), or a single, toxic thyroid nodule, early Hashimoto autoimmune thyroiditis, a TSH-secreting pituitary adenoma, pituitary resistance to thyroid hormone, metastatic thyroid cancer, or excessive human chorionic gonadotropin. The most common etiology is Graves disease, which accounts for about 55% of cases; it is mediated by thyroid-stimulating antibodies that bind to the TSH receptor, mimic the effects of TSH, and induce hyperthyroidism. Many skin changes are common to all forms of hyperthyroidism. The cutaneous surface is warm, moist, and smooth. Palmar erythema or facial flushing may be seen. The hair is thin and has a downy texture, and nonscarring diffuse alopecia may be observed. The skin may darken to produce a bronzed appearance or melanoderma; melasma of the cheeks is seen is some cases. Nail changes are present in approximately 5% of patients with Plummer nails, a concave contour of the plate with characteristic distal onycholysis. Hyperhidrosis may be noted.

Graves disease has a female/male ratio of 7:1, and the peak age of onset is 20–30 years. Ophthalmopathy, pretibial myxedema, and thyroid acropachy are findings almost always limited to patients with Graves disease (Fig. 24.6). Thyroid acropachy, seen in approximately 0.1%–1% of patients with Graves disease, is characterized by digital clubbing, soft tissue swelling of the hands and feet, and diaphyseal proliferation of the periosteum in acral and distal long bones (tibia, fibula, ulna, radius). It usually occurs after treatment of hyperthyroidism and is frequently associated with exophthalmos and pretibial myxedema. It may, however, occasionally precede the thyrotoxicosis and has been recognized in euthyroid and hypothyroid patients. It can be confused clinically with acromegaly, pachydermoperiostosis, pulmonary osteoarthropathy, or osteoperiostitis, but the radiologic findings are pathognomonic.

Pretibial myxedema, consisting of bilateral, localized, cutaneous accumulations of glycosaminoglycans, occurs in 4% of patients who have or have had Graves disease. The morphology may vary from a nonpitting infiltration to nodules, plaques, and even an

Fig. 24.6 (A) Thyroid acropachy and pretibial myxedema. (B) Pretibial myxedema.

elephantiasic form where the skin is thickened, firm, and hyperpigmented from just below the knees to the feet. It may also occur infrequently during the course of Hashimoto thyroiditis and primary hypothyroidism. Patients with pretibial myxedema regularly have associated ophthalmopathy and occasionally thyroid acropachy. Although usually not clinically apparent, approximately half of patients with Graves disease have mucopolysaccharide deposition in the preradial area of the extensor aspects of the forearms. Lesions of the shoulder, hands, thigh, and scalp have been reported.

Improvement in the plaques of pretibial myxedema has resulted from intralesional injections of triamcinolone acetonide and with high-potency topical corticosteroids under occlusion. Systemic corticosteroids may also be helpful. Compression stockings or complete decongestive physiotherapy, and a combination of manual lymphatic drainage, bandaging, and exercise, are useful and safe. With intravenous immune globulin (IVIG) administration, improvement of the skin, eye, and immunologic parameters has been reported in small series of patients. Pentoxifylline, octreotide, plasmapheresis, and cytotoxic drugs have all been reported to help in small numbers of patients, but negative reports also exist.

Vitiligo is present in 7% of patients with Graves disease and occurs with an increased frequency in Hashimoto thyroiditis. Urticaria may be seen in patients with thyroid autoantibodies and may clear with the administration of thyroid hormone, even in euthyroid patients. A wide range of other autoimmune disorders may be seen in patients with Graves disease or Hashimoto autoimmune thyroiditis.

The TSH level is low in all patients except those with a TSH-secreting pituitary adenoma. Free T_3 and T_4 are elevated. Anti-TSH antibodies are present in almost all patients with Graves disease. A 24-hour radioiodine scan will also help define the etiology. Treatment is with radioactive iodine or antithyroid drugs such as methimazole or propylthiouracil.

HYPOPARATHYROIDISM

Varied changes in the skin and its appendages may be evident in parathyroid hormone (PTH, parathormone) deficiency. Most pronounced is faulty dentition when hypoparathyroidism is present during development of the permanent teeth. The skin is dry and scaly. A diffuse scantiness of the hair and complete absence of axillary and pubic hair may be found. The nails are brittle and malformed. Onycholysis with fungal infection may be present. Of patients with idiopathic hypoparathyroidism, 15% develop mucocutaneous candidiasis. Hypoparathyroidism is the most frequent endocrine abnormality present in patients with the APECED (autoimmune polyendocrinopathy, candidiasis, ectodermal dystrophy) syndrome. In this syndrome caused by mutations in the autoimmune regulator (*AIRE*) gene, hypoparathyroidism is present in association with Addison disease and chronic candidiasis. Hypoparathyroidism may also occur in DiGeorge syndrome, or with parathyroid infiltration or their inadvertent surgical removal during thyroid surgery. The causative genetic defects and specific autoantibodies responsible for PTH deficiency and pseudohypoparathyroidism are well defined. Hypoparathyroidism with resultant hypocalcemia may trigger bouts of impetigo herpetiformis or pustular psoriasis.

Pseudohypoparathyroidism (PH) is an autosomal dominant or X-linked inherited disorder characterized by end-organ unresponsiveness to PTH. The PTH and phosphorus levels are high, whereas the serum calcium is low. The typical clinical findings include short stature; obesity; round face; prominent forehead; low nasal bridge; attached earlobes; short neck; short, wide nails; delayed dentition; mental deficiency; amenorrhea; blue sclerae; and cataracts. Brachycephaly, microcephaly, and shortened metacarpals or metatarsals, especially of the fourth and fifth digits (Fig. 24.7), occur because of premature epiphyseal closure. This results in short, stubby fingers and toes, with dimpling over the metacarpophalangeal joints (Albright sign). Subcutaneous calcification and ossification occur frequently in PH, as they may in pseudopseudohypoparathyroidism (PPH), which has the same phenotype, but patients have normal serum and calcium levels. Mutations or epigenetic changes in the complex GNAS locus in the mother

Fig. 24.7 Pseudohypoparathyroidism.

result in PH, whereas if present in the father PPH results. PH and PPH are two types of Albright hereditary osteodystrophy.

Tafaj O, Jüppner H: Pseudohypoparathyroidism. J Endocrinol Invest 2017; 40: 347.

HYPERPARATHYROIDISM

Whereas PTH regulates calcium levels, calcinosis cutis may develop from excess PTH. This can occur when the serum calcium/phosphorus product is greater than 65 mg/dL. This may manifest as large, subcutaneous nodules or white, often linearly arranged papules centered around joints. Additionally, calciphylaxis, although most common in the patient with secondary hyperparathyroidism and renal failure, may be seen occasionally in primary hyperparathyroidism.

Multiple endocrine neoplasia type I (MEN-1) is characterized by tumors of the parathyroid glands, endocrine pancreas, anterior pituitary, thyroid, and adrenal glands. The most frequently observed abnormality is hypercalcemia from hypersecreting tumors of the parathyroid glands. This autosomal dominant inherited disease usually presents in the fourth decade of life with clinical symptoms related to hypersecretion of hormones specific for the type of tumor present. Skin findings in MEN-1 include multiple angiofibromas (Fig. 24.8), collagenomas, café au lait macules, lipomas, confetti-like hypopigmentation, and gingival macules. The angiofibromas are smaller and less numerous than those present in tuberous sclerosis. MEN-1 is caused by *MENIN* mutations. MEN types 2A and 4 also may manifest parathyroid tumors. The latter is caused by mutations of *CDNK1B*.

Vidal A, et al: Cutaneous lesions associated to multiple endocrine neoplasia syndrome type 1. J Eur Acad Dermatol Venereol 2008; 22: 835.

ACANTHOSIS NIGRICANS

Acanthosis nigricans (AN) is characterized by hyperpigmentation and velvet-textured plaques, which are symmetrically distributed.

Fig. 24.8 Multiple endocrine neoplasia type 1 angiofibromas. (Courtesy Thomas Darling, MD, PhD.)

Fig. 24.9 Acanthosis nigricans.

The regions affected may be the face, neck (Fig. 24.9), axillae, external genitals, groin, inner aspects of the thighs, flexor and extensor surface of the elbows and knees, dorsal joints of the hands, umbilicus, nasal crease, and anus. With extensive involvement, lesions can be found on the areolae, conjunctivae, lips, and buccal mucosa, and around the umbilicus. Rarely, the involvement may be almost universal. The color of the patches is grayish, brownish, or black. The palms or soles may show thickening of the palmar or plantar skin with exaggeration of the dermatoglyphs. In severe cases, a rugose hypertrophy occurs and can be a sign of malignancy. Small, papillomatous, nonpigmented lesions and pigmented macules may occasionally be found in the mucous membranes of the mouth, pharynx, and vagina. Acrochordons are a frequent accompaniment in the axillae and groin. There is a clear predisposition for certain racial groups, independent of obesity, to manifest AN, with Native Americans most often affected, followed by African Americans and Hispanics, all above the rates in Caucasians.

Acanthosis nigricans can best be understood by grouping the associations in the following manner.

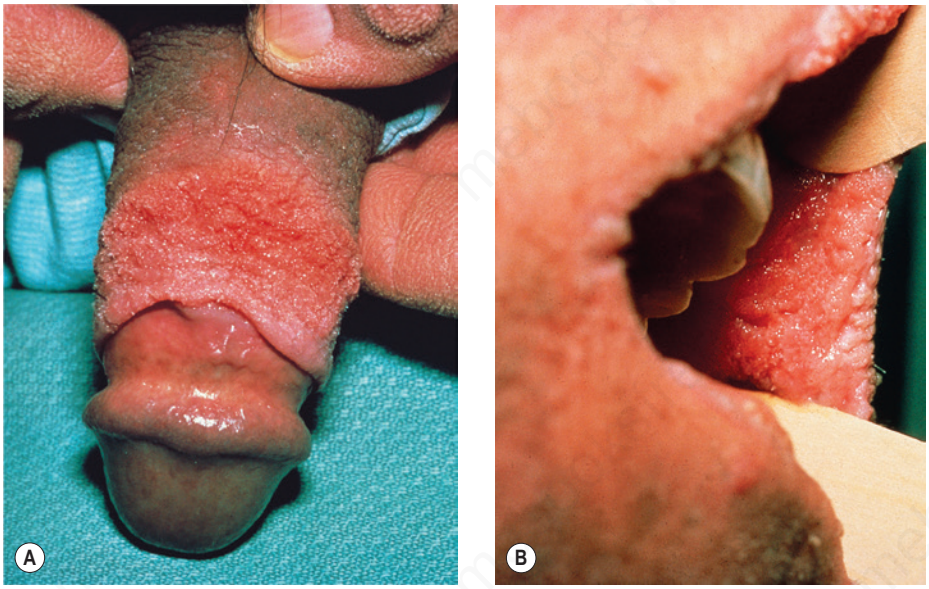

Fig. 24.10 (A and B) Extensive acanthosis nigricans in patient with stomach cancer.

Fig. 24.11 Tripe palms.

Acanthosis Nigricans Associated With Malignancy

The rare type I AN may either precede (18%), accompany (60%), or follow (22%) the onset of the internal cancer. It is generally the most striking type clinically, from both the extent of involvement and the pronounced nature of the lesions (Fig. 24.10). Most cases are associated with adenocarcinoma, especially of the gastrointestinal tract (60% stomach), lung, and breast, or less often the gallbladder, pancreas, esophagus, liver, prostate, kidney, colon, rectum, uterus, and ovaries. Other types of cancer and lymphoma may be seen as well. A few cases have been observed in childhood, but most begin after puberty or in adulthood. Type I AN should be highly suspected if widespread lesions develop in a nonobese man over age 40.

Tripe palms (acanthosis palmaris) are characterized by thickened, velvety palms with pronounced dermatoglyphics; 95% occur in patients with cancer, and 77% are seen with AN (Fig. 24.11). In 40% of these patients, tripe palms are the presenting sign of an undiagnosed malignancy. If only the palms are involved, lung cancer is most common, whereas in tripe palms associated with AN, gastric cancer is most frequent.

Familial Acanthosis Nigricans and *Fgfr* Gene Mutation Syndromes

The exceedingly rare type II AN is present at birth or may develop during childhood. It is commonly accentuated at puberty. It is not associated with an internal cancer and is inherited in an autosomal dominant manner. Some patients will have a mutation in a fibroblast growth factor receptor gene, as also occurs in Cruzon and other syndromes with associated AN such as Beare-Stevenson cutis gyrata syndrome, severe achondroplasia with developmental delay and AN (SADDAN), and thanatophoric dysplasia.

Acanthosis Nigricans Associated With Insulin-Resistant States and Syndromes

This is the most common variety of AN. It presents as a grayish, velvety thickening of the skin of the sides of the neck, axillae, and groins. It occurs in obese persons with or without endocrine disorders. When AN accompanies obesity there is more severe hyperinsulinemia and hyperuricemia and lower serum testosterone in men than in obese patients without AN.

It also occurs in acromegaly and gigantism, pseudoacromegaly, PCOS, Cushing syndrome, diabetes mellitus, MORFAN syndrome (mental retardation, overgrowth, remarkable face, and AN), Addison disease, Prader-Willi syndrome, Alström syndrome, ataxia-telangiectasia, hyperandrogenic states, hypogonadal syndromes, and the various well-recognized insulin-resistant states. These states include lipoatrophic diabetes, leprechaunism, Rabson-Mendenhall syndrome, pineal hypertropic syndrome, and acral hypertrophy syndrome, as well as type A syndrome, with a defect in the *INSR* (insulin receptor) gene and postreceptor pathways, or a lamin A mutation, and type B syndrome, with the presence of autoantibodies to the insulin receptor. Whereas both type A and type B syndromes occur most often in black females, type A predominates in young children with hyperandrogenic manifestations. Many of the conditions associated with insulin resistance and AN manifest as hyperandrogenism and have been called the HAIR-AN syndrome. In one group of women with hirsutism, obesity, and hyperandrogenism, vulvar AN was present in all patients, with other sites less frequently involved. Type B syndrome is seen in middle-aged patients with autoimmune disease (Fig. 24.12). Most, if not all, patients with this type of AN may

Fig. 24.12 Diffuse acanthosis nigricans in type B syndrome.

have either clinical or subclinical insulin resistance, and patients should have a glucose and insulin level drawn simultaneously. In adults a glucose-to-insulin ratio of less than 4.5 is abnormal, and in prepubertal children less than 7 is abnormal. Fasting glucose and lipoprotein profile, hemoglobin A1c, body weight, blood pressure, and an alanine transaminase (ALT) test for evaluation for fatty liver are other investigations that are useful in assessing patients with suspected insulin-resistant states.

Drug-Induced Acanthosis Nigricans

Drugs known to induce AN include nicotinic acid, niacinamide, somatotrophin, testosterone, triazinate, diethylstilbestrol, oral contraceptives, insulin, protease inhibitors, and glucocorticoids.

Miscellaneous Associations

Other syndromes and conditions not mentioned previously that may manifest AN include Bloom syndrome, Costello syndrome, Wilson disease, benign encephalopathy, Hirschowitz syndrome, Capozucca syndrome, Down syndrome, Hermansky-Pudlack syndrome, Kabuki syndrome, hypothyroidism, Rud syndrome, Lelis syndrome, and primary biliary cirrhosis. Approximately 10% of renal transplant patients have AN.

Diagnosis and Treatment

The histopathology of AN shows papillomatosis without thickening of the malpighian layer. "Acanthosis" was applied here to indicate the clinical bristly thickening of the skin and not as a histologic term. Hyperkeratosis and slight hyperpigmentation of the basal layer is present in most cases; it appears, however, that the clinically observed hyperpigmentation is caused by hyperkeratosis and clinical thickening rather than by melanin.

The differential diagnosis includes intertriginous granular parakeratosis and several disorders of reticulated hyperpigmentation, including confluent and reticulated papillomatosis (Gougerot-Carteaud syndrome), Dowling-Degos disease, Haber syndrome, and acropigmentation reticularis of Kitamura. Granular parakeratosis presents as erythematous to brownish hyperkeratotic papules and plaques of the intertriginous regions. It is most often seen in middle-aged women in the axillae; however, the inguinal folds and submammary areas may be involved. Histology reveals a thickened stratum corneum, severe compact parakeratosis with retention of keratohyalin granules, and vascular proliferation and ectasia. The cause is likely to be an irritant response to rubbing or to antiperspirants or deodorants. Dowling-Degos disease is a familial nevoid anomaly with delayed onset in adult life. There is progressive, brown-black hyperpigmentation of flexures with associated soft fibromas and follicular hyperkeratoses. Pitted acneiform scars occur periorally.

Treatment of type I AN, associated with malignancy, consists of finding and removing the causal tumor. Early recognition and treatment may be lifesaving. AN occurring with obesity (type III) usually improves with weight loss. If there is associated endocrinopathy, it must be treated as well. One patient with lipodystrophic diabetes improved during dietary supplementation with fish oil. Etretinate, metformin, or other medications to control insulin resistance, as well as tretinoin, calcipotriol, urea, salicylic acid, glycolic acid peels, CO_2 laser ablation, and long-pulsed alexandrite laser therapy, have been reported as successful treatments in individual cases.

25 Abnormalities of Dermal Fibrous and Elastic Tissue

Bonus images for this chapter can be found online at expertconsult.inkling.com

COLLAGEN

Many types of collagen have been identified in tissues of vertebrates (Table 25.1). Collagens help form the support structure and scaffolding for many parts of the body, including tissues, blood vessels, and bones. Fibrillar collagens (types I, II, III, V, and XI) form fibrils that are among the most abundant proteins in the body. Type I collagen accounts for 60%–90% of the dry weight of skin, ligaments, and demineralized bone. Type III collagen is abundant in fetal skin and blood vessels. It comprises 35% of the collagen in normal adult skin, but up to 40% in inflamed skin in the setting of contact dermatitis. Basement membrane–associated collagen is made up of types IV and VII. Fiber-associated collagens (types VIII, IX, and XIV) are found on the surface of type I and II collagens and are believed to serve as flexible spacers among fibrils. Fibril-associated collagens with interrupted triple helices (FACITs) do not form fibrils themselves but are found attached to the surfaces of preexisting fibrils of the fibril-forming collagens. FACITs are composed of types IX, XII, XIV, XVI, XIX, XX, and XXI. Network-forming collagens are sheets formed from types VIII and X. Studies on types XV, XVII, and XIX demonstrate their widespread presence in basement membranes, particularly vascular endothelium, which may represent a new subgroup of collagens associated with angiogenic and pathologic processes. Type XVII collagen is also known as BP180, and contains the target antigens for several immunobullous diseases. Type VII collagen contains the target antigens for bullous lupus and epidermolysis bullosa acquisita. Type II collagen contains the target antigens for relapsing polychondritis. Genetic mutations leading to defects in or absence of various collagens (VII and XVII) can lead to epidermolysis bullosa.

The regulation of collagen synthesis and degradation is complex. Dermal fibrosis is largely related to increases in type I collagen mediated by proα1 and proα2 collagen genes. Transforming growth factor–beta (TGF-β) results in increased type I procollagen synthesis. Angiotensin II type 1 receptor stimulation increases collagen production and inhibits collagen degradation, whereas type 2 receptor stimulation exerts the reverse effects. Mutations in collagens or disruption of their function due to autoimmunity or medications can lead to disease.

ELASTOSIS PERFORANS SERPIGINOSA

In 1953 Lutz described a chronic papular keratotic eruption in an arciform shape located on the sides of the nape of the neck. The papules range from 2–5 mm in diameter and are grouped in a serpiginous or horseshoe-shaped arrangement (Fig. 25.1). The papules have a keratotic top that extrudes elastic fibers likely by binding to an elastin receptor on keratinocytes. Although the lesions typically occur on the neck, other sites may be involved, such as the upper arms, face, lower extremities, and rarely the trunk. Disseminated lesions may occur in Down syndrome. The disease runs a variable course, with spontaneous resolution often occurring from 6 months to 5 years after onset. Often, atrophic scarring remains. Progressive vasoocclusive disease with stroke has been reported.

Elastosis perforans serpiginosa (EPS) is most common in young adults. Men outnumber women 4:1. Approximately one third of EPS cases occur in patients with associated diseases; the most common concomitant disorder is Down syndrome. Approximately 1% of patients with Down syndrome have EPS, and the lesions are likely to be more extensive and persistent than in other patients. EPS has also been reported in Ehlers-Danlos syndrome, osteogenesis imperfecta, Marfan syndrome, Rothmund-Thomson syndrome, acrogeria, systemic sclerosis, morphea, XYY syndrome, and renal disease. Reports of EPS associated with pseudoxanthoma elasticum have occurred with penicillamine administration. EPS can also be idiopathic. Evaluation for associated disease should be driven by associated signs and symptoms.

The distinctive histopathologic changes of EPS consist of elongated, tortuous channels in the epidermis into which eosinophilic elastic fibers perforate. The fibers are extruded from the dermis. There is degeneration and alteration of the elastic tissue in the adjacent papillary dermis with an accompanying inflammatory response. In penicillamine-associated disease, the fibers may have an irregular (bramble bush) contour when examined with electron microscopy.

Treatment of EPS is difficult, but individual lesions may resolve after liquid nitrogen cryotherapy. Some cases have responded to carbon dioxide (CO_2) (fractional in some reports), erbium:yttrium-aluminum-garnet (Er:YAG), or pulsed dye laser therapy. Topical retinoids and imiquimod have been reported to be of benefit.

REACTIVE PERFORATING COLLAGENOSIS

In 1967 Mehregan reported a rare, familial, nonpruritic skin disorder characterized by papules that grow to a diameter of 4–6 mm and develop a central area of umbilication in which keratinous material is lodged. The discrete papules may be numerous (Fig. 25.2) and involve sites of frequent trauma, such as the backs of the hands, the forearms, elbows, and knees. The lesion reaches a maximum size of about 6 mm in 4 weeks and then regresses spontaneously in 6–8 weeks. The lesions are broader than those of EPS, and a broad crust containing collagen fibers is extruded centrally. Koebnerization is often observed. Young children are most frequently affected. Most reports support an autosomal recessive mode of inheritance, although apparent autosomal dominant inheritance was reported in one family but

TABLE 25.1 Collagen Types

Collagen Type	Gene*	Chromosome	Tissue Distribution
I	*COL1A1–2*	17q21.3–q22	Skin, bone, tendon
I-trimer			Tumors, cell cultures, skin, liver
II	*COL2A1*	7q21.3–q22	Cartilage, vitreous
III	*COL3A1*	12q13–q14	Fetal skin, blood vessels, intestines
IV	*COL4A1–6*	13q34, 2q35–q37, Xq22	Basement membranes

the genetics have not been elucidated. Acquired reactive perforating collagenosis is discussed further in Chapter 33.

No specific treatment is typically indicated for reactive perforating collagenosis because the lesions involute spontaneously. Topical retinoids may be helpful in patients who require treatment.

PSEUDOXANTHOMA ELASTICUM

Pseudoxanthoma elasticum (PXE) is an inherited disorder involving the connective tissue of the skin, eye, and cardiovascular system. Many cases are sporadic. In familial cases, both a recessive and a dominant inheritance pattern have been reported, with the recessive form apparently more common. The skin changes generally present as small, circumscribed, yellow to cream-colored papules on the sides of the neck and flexures, giving the skin a "plucked chicken skin" appearance (Fig. 25.3). Lax, redundant folds of skin may be present (Fig. 25.4). Nuchal comedones and milia en plaque may also be seen. Characteristic exaggerated nasolabial folds and mental creases are common. Mental creases (horizontal creases across the chin) appearing in patients under age 30 are highly suggestive of PXE. In addition, the inguinal, periumbilical, and periauricular skin, as well as the mucosa of the soft palate, inner lip, tonsils, stomach, rectum, and vagina, may be involved.

The characteristic retinal change is the angioid streak, which is the result of breaks in Bruch's elastic membrane. PXE can be demonstrated in more than half of patients with angioid streaks, and 85% of PXE patients will have retinal findings. The angioid streaks appear earlier than the skin changes, so most cases are discovered by ophthalmologists. Angioid streaks may be the only sign of the disease for years. Biopsies of the midportions of old scars may be diagnostic of PXE. Angioid streaks may also be seen in Ehlers-Danlos syndrome, Paget disease of bone, diabetes, hemochromatosis, hemolytic anemia, hypercalcinosis, solar elastosis, neurofibromatosis, Sturge-Weber syndrome, tuberous sclerosis, myopia, sickle cell anemia, trauma, lead poisoning, hyperphosphatemia, pituitary disorders, and intracranial disorders. PXE, Paget disease of the bone, and sickle cell disease account for the vast majority of patients with angioid streaks.

On funduscopic examination, a reddish brown band is evident around the optic disk, from which glistening streaks extend. In addition, there may be hemorrhages and exudates. Progressive loss of vision often starts after minor trauma to the eye. Drusen-like spots are often present and show increased autofluorescence, unlike age-related drusen.

Vascular involvement frequently leads to hemorrhage. These vascular events are caused by the degeneration of the elastic fibers in the vascular media. Gastric hemorrhage occurs in 10% of patients, and on gastroscopy, diffuse bleeding is common. Epistaxis occurs frequently, but hematuria is rare. PXE affects the elastic tissue of the cardiac valves, myocardium, and pericardium. In one study, mitral valve prolapse was found in 71% of 14 patients examined. Hypertension occurs in many patients older than age 30. Any patient with hypertension at a young age should be examined for stigmata of PXE. Leg cramps and intermittent claudication occur prematurely, and peripheral pulses are diminished or absent. Calcification of peripheral arteries is seen in many patients over age 30 and may be detected by radiography. Accelerated coronary artery disease (CAD) can occur, especially in association with hypertension. Extensive cutaneous calcification and renal and testicular stones may occur.

Mutations in the adenosine triphosphate (ATP)–binding cassette transporter protein subfamily C member 6 gene *(ABCC6)* have been implicated in the pathogenesis of PXE in a majority of patients, who also have a higher incidence of CAD. Defective release of ATP leads to less inorganic pyrophosphate (PPi), which is important

Fig. 25.3 (A and B) Pseudoxanthoma elasticum.

Fig. 25.4 Pseudoxanthoma elasticum.

in inhibiting mineralization; thus the mineralization goes unchecked. Although the most prominent manifestations of the disease are in the skin, eye, gut, and heart, mineralization of elastic fibers can be found in many organs.

Histologically, elastic fibers are fragmented and mineralized with calcium. The fibers stain gray-blue with hematoxylin and eosin (H&E) and are twisted, curled, and broken, suggesting "raveled wool." Blind biopsies of scars or axillary skin in patients with a family history of PXE or with angioid streaks may show early changes of PXE. Calcium stains are helpful in identifying early disease.

The differential diagnosis includes PXE-like papillary dermal elastolysis, perforating calcific elastosis, connective tissue nevus with elastorrhexis, and cutis laxa. Patients with PXE-like papillary dermal elastolysis may have cobblestoned, yellow papules on the neck, similar to PXE, but lack any retinal or vascular alterations and the typical fragmentation of elastic fibers with calcium deposition on histology. Patients described with connective tissue nevus with elastorrhexis have tiny white papules coalescing into a plaque on the upper chest and lower neck that are not associated with any internal findings. Penicillamine may induce similar clinicohistologic features in patients with Wilson disease or homocystinuria.

No definitive therapy is available to treat the skin disease. Some data suggest that PXE patients benefit from limiting dietary calcium and phosphorus to the minimal daily requirement. Intravitreal bevacizumab has been used to treat choroidal neovascularization. Atorvastatin treatment appears promising in a mouse model. Therapeutic trials of magnesium and a bisphosphonate are ongoing.

PERFORATING CALCIFIC ELASTOSIS

Also known as periumbilical perforating PXE and localized acquired cutaneous PXE, perforating calcific elastosis is an acquired, localized cutaneous disorder most frequently found in obese, multiparous, middle-aged women. Lax, well-circumscribed, reticulated, or cobblestoned plaques occur in the periumbilical region with keratotic surface papules. It is a distinct disorder that shares some features of PXE. As in PXE, patients may have calcific elastosis in the middermis; however, hereditary PXE rarely causes perforating channels. None of the systemic features of PXE occurs in perforating calcific elastosis.

It is suggested that repeated trauma of pregnancy, obesity, and abdominal surgery promote elastic fiber degeneration, resulting in localized disease. PXE can cause periumbilical lesions, and in the absence of documented perforation, evaluations to exclude PXE should be performed as patients with angioid streaks and periumbilical perforating PXE clinical findings have been reported. There is no effective therapy for perforating calcific elastosis.

EHLERS-DANLOS SYNDROMES

Ehlers-Danlos syndromes (EDSs) are a group of genetically distinct connective tissue disorders characterized by excessive stretchability and fragility of the skin (Fig. 25.5), with hyperextensibility of the joints (Fig. 25.6) and a tendency toward easy scar formation and formation of fibrous or calcified pseudotumors. The dermatologist's role is to help identify people who may have EDS and guide them to workup by a geneticist and if necessary other specialties including cardiology.

Recently EDS was reclassified into 13 subtypes. Type IX EDS, an allelic variant of Menkes disease, is now reclassified as the occipital horn syndrome and is identical to X-linked cutis laxa. It is related to mutations in an X-linked gene, *ATP7A*. The most clinically relevant features of EDS (for a dermatologist) are reviewed in Table 25.2. For a full review of the symptoms the reader is referred to the Malfait et al. review.

Fig. 25.5 Ehlers-Danlos syndrome.

TABLE 25.2 Features of Ehlers-Danlos Syndromes Based on 2017 Classification

Ehlers-Danlos Type and Clinical Name	Gene (Protein) and Inheritance	Selected Clinical Features[a]	
		Major Criteria	*Minor Criteria*
1 Classical	*COL5A1* (type 5 collagen) AD *COL1A1* (type I collagen) AD	Skin hyperextensibility Joint hypermobility Atrophic scars	Easy bruising Soft doughy skin Molluscoid pseudotumors Epicanthal folds
2 Classical-like	*TNXB* (tenascin XB) AR	Skin hyperextensibility Velvety skin but no atrophic scars Joint hypermobility Easy bruising	Broad forefoot Pes planus Polyneuropathy Edema Vaginal/rectal prolapse
3 Cardiac Valvular	*Col1A2* (type I collagen) AR	Aortic and mitral valve disease Skin hyperextensibility Atrophic scars Joint hypermobility Easy bruising	Inguinal hernia Pectus excavatum Joint dislocations
4 Vascular	*COL3A1* (type III collagen) *Col1A1* (type I collagen) AD	Arterial rupture Colon perforation Uterine rupture	Easy bruising Thin translucent skin Congenital hip dislocation
5 Hypermobile	Unknown AD	Joint hypermobility Velvety skin Hyperextensiblity Striae Piezogenic papules Abdominal hernia	Joint dislocations or laxity Musculoskeletal pain
6 Arthrochalasia	*Col1A1–2* (type I collagen) AD	Congenital hip dislocation (bilateral) Severe joint hypermobility Skin Hyperextensibility	Hypotonia Easy bruising
7 Dermatosparaxis	*ADAMTS2 (ADAMTS-2)* AD	Fragile skin with tears Skin laxity Easy bruising Short limbs, hands, and feet	Doughy skin Skin hyperextensibility Atrophic scars Joint hypermobility Bladder rupture/diaphragm rupture
8 Kyphoscoliosis	PLOD1 (LH1) FKBP14 (FKBP22) AR	Congenital hypotonia Kyphoscoliosis Joint hypermobility	Skin hyperextensibility Easy bruising Rupture of arteries Blue sclerae Marphanoid Pectus deformity PLOD1 (skin more fragile, scleral rupture, microcornea) FKBP14 (hearing impairment, follicular hyperkeratosis, muscle atropy)
9 Brittle Cornea Syndrome	ZNF469 (ZNF469) PRDM5 (PRDM5) AR	Thin cornea Keratoconus Blue sclerae	Hypotonia Hypermobile joints Finger contractures Velvety translucent skin
10 Spondylodysplastic	*B4GALT7 (B4GalT7)* *B3GALT6 (B3GalT6)* *SLC39a13 (ZIP13)* AR	Short stature Muscle hypotonia Bowing limbs	Skin hyperextensibility Cognitive impairment *B4GALT7* (elbow contractures, clouded cornea) *B3GALT6* (joint contractures and hypermobility, tooth discoloration) *SLC39a13* (protuberant eyes, blue sclerae, atrophy of thenar eminences and wrinkled palms)
11 Musculocontractural	CHST14 (D4ST1) DSE (DSE) AR	Congenital contractures, skin hyperextensibility Easy bruising Fragile skin	Dislocations Finger anomalies Spinal deformities Pneumothorax nephrolithiasis
12 Myopathic	*COL12A1* (type XII collagen) AD or AR	Congenital hypotonia Proximal contractures Hypermobility of joints	Doughy skin Atrophis scars
13 Periodontal	*C1R (C1r)* *C1S (C1s)* AD	Severe periodontitis Pretibial plaques Lack of attached gingiva	Easy bruising Joint hypermobility Skin hyperextensibility

AD, Autosomal dominant; *AR,* autosomal recessive.
[a]Not all criteria listed; see full classification from Malfait et al.

Joint hypermobility, skin hyperextensibility, and tissue fragility are the hallmark cutaneous findings of EDS. There are multiple clinical tests to help evaluate for these. Remvig et al. described that if the skin can be pinched and stretched over 1.5 cm on the dorsal hand or volar forearm or over 3 cm at the neck, this is defined as hyperextensible. In hyperextensible skin the integument may be stretched like a rubber band and snaps back with equal resilience. This rubbery skin is most pronounced on the elbows, neck, and sides of the abdomen. The skin may be velvety in appearance and feel like wet chamois cloth.

The Beighton score grades joint hypermobility; a point is given for each side of the body that can do the following: if the fifth digit can be pulled back more than 90 degrees with the palm on a flat surface, with the arm stretched out and the palm pronated if the thumb can be pulled to touch the forearm, if the elbows can bend more than 10 degrees with the arms outstretched and hands supinated, if the knees extend more than 10 degrees while standing with knees locked, with knees locked if the patient can lean over and put the palms flush on the floor. A score of 5 to 9 is positive.

Other prominent features in many forms of EDS include easy bruising and scarring. Minor trauma may produce a gaping "fish-mouth" wound with large hematomas underneath. Two types of nodules occur in patients with EDS. Molluscoid pseudotumors are soft, fleshy nodules seen in easily traumatized areas such as the ulnar forearms and shins. From 2–8 mm oval subcutaneous calcifications can occur, mostly on the legs, and probably result from fat necrosis. Trauma over the shins, knees, hands, and elbows produces cigarette paper–thin scars. Atrophic scarring on the distal fingers and wide atrophic "fish-mouth" scars are typical. Patients demonstrate reduced thickness of the dermis. The reduction in thickness is most marked on the chest and distal lower leg. Approximately 50% of these patients can touch the tip of the nose with their tongue (Gorlin sign), compared with 10% of persons without the disorder. Aortic root dilation is seen in up to 20% of patients with EDS and patients should be referred to cardiology to consider an echocardiogram.

Patients must be counseled to avoid trauma and may need physical therapy. Unfortunately, invasive cardiovascular procedures have generally not improved outcomes for patients with severe disease, but echocardiograms are generally recommended. Matrix metalloproteinase (MMP) inhibitors produce changes in connective tissue and are being evaluated as possible therapeutic agents.

Fig. 25.7 Marfan syndrome.

MARFAN SYNDROME

Marfan syndrome is an autosomal dominant disorder of connective tissue caused by mutations in the gene encoding fibrillin-1. It is one of the more common inherited diseases, with estimated incidence rates of 1 in 10,000 in the United States. Important clinical findings include tall stature, loose-jointedness, a dolichocephalic skull, high-arched palate, arachnodactyly (Fig. 25.7), pigeon breast, pes planus, poor muscle tone, and large, deformed ears. The aorta, chordae tendineae, and aortic and mitral valves are often involved. Ascending aortic aneurysm and mitral valve prolapse are frequently seen. Ectopia lentis (typically upwardly displaced), extensive striae over the hips and shoulders, dental anomalies, and rarely EPS have been reported. Several cases document the occasional occurrence of spontaneous pneumothorax and congenital lung abnormalities.

Marfan syndrome is caused by a gene defect in fibrillin-1 (aorta adventitia, suspending ligaments of lens and skin). Fibrillin-2 mutations are associated with congenital contractural arachnodactyly (arachnodactyly, camptodactyly and contractures, crumpled-appearing ears, and pectus carinatum).

In Marfan syndrome, echocardiography is helpful for early detection of cardiovascular involvement. Surgical intervention may be required for aneurysms of the aortic root or for aortic dissection. Death may result from aortic root aneurysm rupture or dissection. Long-term administration of propranolol may significantly reduce the rate of aortic dilation, as does angiotensin II blockade with losartan. Long-term doxycycline may be helpful to inhibit MMPs. Some evidence suggests that doxycycline may be more effective than atenolol in preventing progression of thoracic aortic aneurysms. Antisense ribozymes are promising for gene therapy.

LOEYS DIETZ SYNDROME

Loeys Dietz is a syndrome caused by mutations in the TGF-β pathway that clinically resembles Marfan syndrome without the tall stature. Affected individuals have pectus abnormalities, flat feet, and arachnodactyly, along with arterial tortuosity and risk of aortic dissection. Their skin is translucent, with easy bruising, and they get striae and atrophic scars with impaired wound healing. They have a higher rate of atopic disease and they have joint hypermobility and hypotonia.

HOMOCYSTINURIA

Homocystinuria, an inborn error in the metabolism of methionine, is characterized by the presence of homocysteine in the urine and deficiency of the enzyme cystathionine synthetase or methylenetetrahydrofolate reductase. Cystathionine β-synthase is a heme-containing enzyme that catalyzes pyridoxal 5′-phosphate–dependent conversion of serine and homocysteine to cystathionine. The defect results in increased levels of homocysteine and methionine and decreased levels of cysteine. The incidence of the disorder varies from 1 in 344,000 worldwide to 1 in 65,000 in Ireland, where homocystinuria is more common.

Signs of homocystinuria include ectopia lentis, genu valgum, kyphoscoliosis, pigeon breast deformity, and frequent fractures. The facial skin has a characteristic flush, especially on the malar areas, and the color tends to become violaceous when the patient is reclining. Elsewhere, the skin is blotchy red, suggestive of livedo reticularis. The hair is typically fine, sparse, and blond, and the teeth are irregularly aligned. Generalized osteoporosis, arterial and venous thrombosis, and mental retardation are features of homocystinuria not found in Marfan syndrome. Half of all patients will have a serious vascular event before age 30, and 25% experience a serious event before age 16. Downward dislocation of the lens, unlike the upward displacement seen in Marfan syndrome, is a prominent feature.

Treatment with pyridoxine, folic acid, and vitamin B_{12} produces variable results in homocystinuric patients. A methionine-restricted, cysteine-supplemented diet is generally recommended. Betaine supplementation has been shown to be effective. Some recommend that methionine-free formulas be supplemented with 150 mg/dL of betaine. Alfalfa and bean sprouts contain ample homocysteine, and excessive amounts should be avoided. Other vegetables do not contain large amounts of homocysteine. Vitamin C ameliorates endothelial dysfunction, and the effect appears to be independent of homocysteine concentration. Some of the beneficial effects of folate are also independent of homocysteine reduction. In an animal model of homocystinuria, 5-methyltetrahydrofolate decreased mortality rate, but folic acid did not.

CUTIS LAXA (GENERALIZED ELASTOLYSIS)

Cutis laxa is characterized by inelastic, loose, redundant skin. Around the eyelids, cheeks, and neck, the drooping skin produces a "bloodhound-like" facies. Usually, the entire integument is involved. The shoulder girdle skin may resemble that of a St. Bernard dog. The abdomen is frequently the site of large, pendulous folds. There are two well-described genetic forms of cutis laxa, the autosomal dominant and autosomal recessive types, and there is also acquired cutis laxa as described later. The dominant form is primarily a cutaneous, cosmetic form, with a good prognosis. The recessive form is more common and associated with significant internal involvement, including hernias, diverticula, pulmonary emphysema, cor pulmonale, aortic aneurysm, dental caries, large fontanelles, and osteoporosis. Pulmonary emphysema, cor pulmonale, and right-sided heart failure are often seen already in infancy. Frameshift and splicing mutations in the elastin gene have been reported in autosomal dominant disease. Both homozygous and heterozygous missense mutations in the gene for fibulin 5 have been reported in some patients with the disease, especially in families with the recessive form. Gene mutations in fibulin 4 may cause autosomal recessive cutis laxa associated with emphysema, vascular tortuosity, ascending aortic aneurysm, inguinal and diaphragmatic hernia, joint laxity, and pectus excavatum. X-linked recessive cutis laxa is now known as the occipital horn syndrome (formerly type IX EDS). It is caused by a mutation in the copper-binding ion-transporting ATPase, *ATP7A*, and is allelic to another X-linked disorder, Menkes disease.

Acquired cases have been associated with urticaria, Sweet syndrome (Marshall syndrome), lupus erythematosus, glomerulonephritis, plasma cell dyscrasias, and systemic amyloidosis. These acquired cases may have a preceding inflammatory phase with large numbers of interstitial neutrophils, eosinophils, or macrophages engulfing elastic fibers. Isolated acral disease has been associated with myeloma and rheumatoid arthritis. Middermal elastolysis is an acquired, noninherited condition that usually affects young women. Wide areas of skin demonstrate atrophic wrinkling. Histologically, elastic tissue is absent from the middle dermis. Many cases appear to be induced or aggravated by ultraviolet light exposure.

There are a few genetic disorders that have cutis laxa as a component. Costello syndrome is characterized by increased prenatal growth, postnatal growth retardation, coarse facies, loose skin that resembles cutis laxa, cardiomyopathy, and gregarious personality. Patients are predisposed to abdominal and pelvic rhabdomyosarcoma in childhood. The disorder appears to be inherited as an autosomal dominant trait. De Barsy syndrome is associated with severe cutis laxa, mental and growth retardation, joint laxity, ocular abnormalities, and skeletal disease.

BLEPHAROCHALASIS

In blepharochalasis, the eyelid skin becomes lax and falls in redundant folds over the lid margins. The condition may affect young adults, in whom a preceding inflammatory phase presents with episodes of lid swelling, such as from allergies or bee stings, that lead to disruption of elastin. Most cases are bilateral, but unilateral involvement may occur. Rarely, elastolysis of the earlobes may accompany blepharochalasis. It is generally sporadic, but a dominantly inherited form has been described. Biopsy shows lack of elastic fibers, and abundant IgA deposits have been demonstrated in some cases, possibly binding to fibulin and fibronectin. Sequelae include excess thin skin, fat herniation, lacrimal gland prolapse, ptosis, blepharophimosis, pseudoepicanthic fold, proptosis, conjunctival injection and cysts, entropion, and ectropion.

Ascher syndrome consists of progressive enlargement of the upper lip and blepharochalasis (Fig. 25.8). The minor salivary

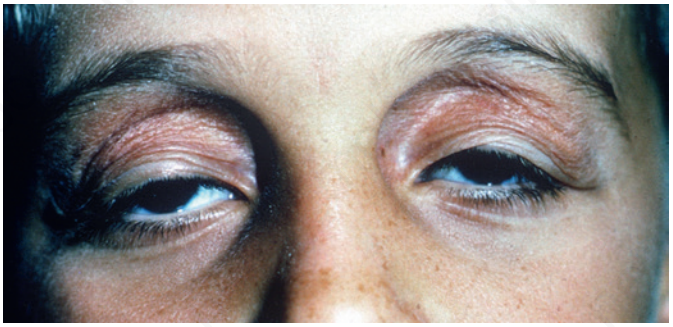

Fig. 25.8 Blepharochalasis in Ascher syndrome. (Courtesy Ken Greer, MD.)

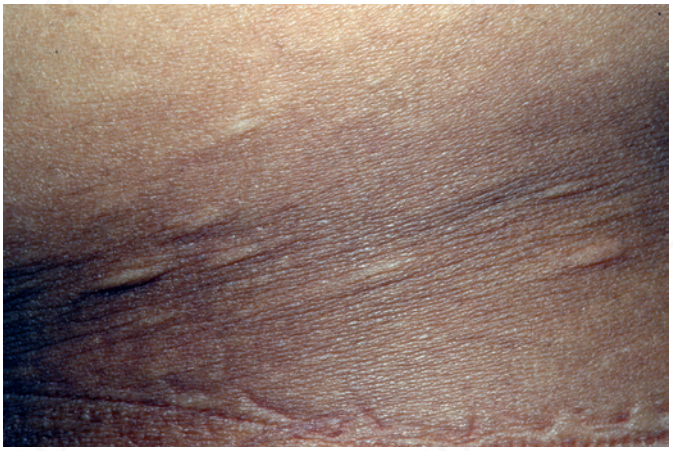

Fig. 25.9 Anetoderma.

glands of the affected areas are inflamed, resulting in superfluous folds of mucosa, giving the appearance of a double lip. There is a superficial resemblance to angioedema.

Treatment is generally by surgical correction, although successful medical treatment has been reported with systemic acetazolamide in combination with topical hydrocortisone cream. Doxycycline has also been reported as effective, presumably through MMP inhibition.

ANETODERMA (MACULAR ATROPHY)

Anetoderma is characterized by localized loss of elastic tissue resulting in herniation of subcutaneous tissue. The lesions protrude from the skin (Fig. 25.9) and on palpation have less resistance than the surrounding skin, producing the "buttonhole" sign identical to a neurofibroma. The surface skin may be slightly shiny, white, and crinkly. The usual locations are the trunk, especially on the shoulders, the upper arms, and thighs. The intervening skin is normal.

Up to half of patients with anetoderma have an accompanying abnormality, such as lupus, antiphospholipid antibodies, Graves disease, scleroderma, hypocomplementemia, hypergammaglobulinemia, autoimmune hemolysis, or human immunodeficiency virus (HIV) infection. Screening for antiphospholipid antibodies is of particular importance because these may produce a prothrombotic state, and some patients fulfill criteria for the antiphospholipid syndrome. The antibodies may be detected as anticardiolipin antibodies, anti-β_2-glycoprotein-I antibodies, or a lupus anticoagulant. Patients may experience recurrent fetal loss, recurrent strokes, or recurrent deep vein thrombosis. Thrombosis-associated anetoderma with ulceration has been related to antithrombin III deficiency. Some cases of anetoderma may be related to borreliosis. Rare familial cases have been noted. Secondary anetoderma may be associated with previous lesions of acne, secondary syphilis, measles, lupus erythematosus, Hansen disease, sarcoidosis, tuberous xanthoma, varicella, granuloma annulare, mastocytosis, and lymphoreticular malignancy.

Anetoderma of prematurity (congenital anetoderma) occurs in premature infants who have immature epidermis. This is almost always caused by direct damage to the epidermis from the lifesaving care necessary to keep these infants alive; much more rarely, intrauterine borreliosis has also been implicated. Application of adhesives to keep indwelling lines and catheters in place, aggressive epidermal cleansing in preparation for procedures, or pressure from medical equipment can lead to areas of anetoderma. Typical locations include periumbilical due to fastening of umbilical artery lines and on extremities around locations of intravenous access. Recommendations to avoid this include using silicone-based tapes, avoiding stronger adhesives, washing with cleansers that are pH neutral, and avoiding baby wipes in infants under 28 weeks. Chlorhexadine cleansers typically come in 70% isopropyl alcohol and may be an irritant as well and should never be allowed to collect in skinfolds. Some advocate for using 10% povidone-iodine solution preparation for medical procedures for the first 2 weeks of life in infants born before 26 weeks.

Histologically, loss of elastic tissue is noted with special stains. In the late stage, the skin looks normal in H&E sections. In the acute stage, a neutrophilic, lymphoid, or granulomatous response may be noted. Ablative laser treatment has been reported as helpful in some adult patients with anetoderma but treatment is general unsatisfactory.

STRIAE DISTENSAE (STRETCH MARKS)

Striae distensae are depressed lines or bands of thin, reddened skin (Fig. 25.10), which later become white, smooth, shiny, and depressed. Elastotic striae have a yellow-gold iridescent appearance. Striae occur in response to changes in weight or muscle mass and skin tension, such as that induced by weightlifting. They are common on the abdomen during and after pregnancy (striae gravidarum) and breasts due to pregnancy as well. They also occur on the buttocks and thighs, the inguinal areas, and more rarely over the knees and elbows in children during the growth spurt of puberty. Horizontal striae on the midback are common in adolescent males and although the cause is unknown, they are typically not associated with any systemic disease and in various studies have been seen in approximately 25%–50% of young adult males. People with Cushing syndrome have much more purple and

Fig. 25.10 Striae distensae.

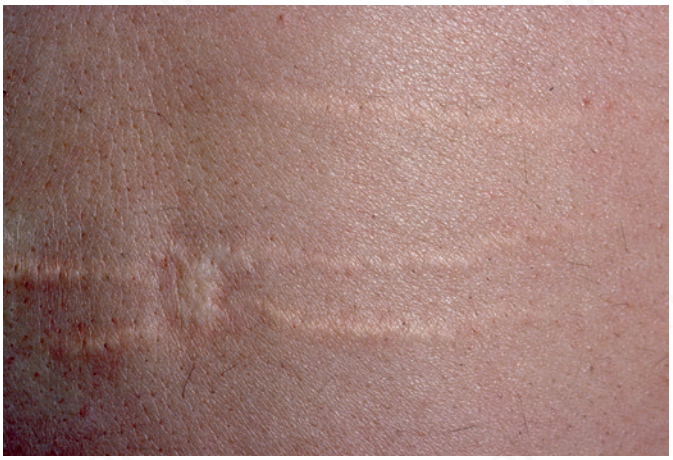

Fig. 25.11 Elastotic striae.

wide (greater than 1 cm) striae. They will also often have other signs of Cushing syndrome, including "cigarette paper" skin on the elbows and knees that tears easily, acanthosis nigricans, and decreased linear but increased weight growth. An important cause of striae is either endogenous or induced by systemic corticosteroid treatment. They may occur after application of potent topical corticosteroid preparations, especially under occlusion or in skinfolds. Striae are common in patients with Marfan syndrome.

The histologic findings are variable and depend on the stage of development. In some early lesions, perivascular and interstitial infiltration of lymphocytes and sometimes eosinophils is noted. In older lesions, the primary changes are in the connective tissue. The collagen of the upper dermis is decreased, and thin collagen bundles lie parallel to the overlying epidermis, as in a scar. Elastic tissue often appears increased, but this may result from a loss of collagen in many cases. Dilated upper dermal vessels may be prominent.

A Cochrane review found no high-quality evidence to support the use of any topical preparation for the prevention of stretch marks during pregnancy. Over time, striae become less noticeable without treatment. Both silicone gel and placebo have demonstrated some positive effects in clinical studies, complicating interpretation of results. Topical tretinoin and vascular lasers may produce some improvement in appearance, although the benefits are more marked in the early erythematous phase and tretinoin should be avoided during pregnancy. Pulsed dye lasers (585 nm) result in a moderate decrease in erythema in striae rubra. Although the total collagen per gram of dry weight increases in striae treated with pulsed dye laser, this change may not result in a clinically evident change in striae alba. Pulsed dye laser has also been used in conjunction with a radiofrequency device. Intense pulsed light has also demonstrated potential for improvement in the appearance of some striae, although with greater risk and lower efficacy in darker skin types. Some data suggest that 590-nm light is more effective than 650-nm light. Fractional photothermolysis has been used in a variety of skin types for both rubra and alba types of striae.

LINEAR FOCAL ELASTOSIS (ELASTOTIC STRIAE)

This elastosis variant presents with asymptomatic, palpable, or atrophic, yellow lines of the middle and lower back, thighs, arms, and breasts (Fig. 25.11). Linear focal elastosis can be differentiated from striae because they are more yellow and raised but may just be the end stage of striae. They are often reported after a sudden increase in exercise. Linear focal elastosis is more common in males. Histologically, increased elastic fibers are seen, characterized by thin, wavy, and elongated as well as fragmented bundles. Electron microscopy reveals thin, elongated, irregularly shaped, swollen elastic fibers with degenerative changes.

ACRODERMATITIS CHRONICA ATROPHICANS

Patients with acrodermatitis chronica atrophicans present with diffuse thinning of the skin on the extremities, sometimes associated with fibrous bands. This condition is reviewed with bacterial infections in Chapter 14, because it results from *Borrelia* infection.

OSTEOGENESIS IMPERFECTA

Osteogenesis imperfecta (OI), also known as Lobstein syndrome, affects the bones, joints, eyes, ears, and skin. It is estimated to affect approximately 10,000 persons in the United States (4–5 in 100,000 population). There are seven recognized forms based on differences in clinical presentation and bone architecture. Types I and IV have only an autosomal dominant inheritance, whereas types II and III have both autosomal dominant and autosomal recessive forms. Fifty percent of OI patients have the type I form. The type II form is lethal, and deaths usually occur within the first week of life.

The brittle bones result from a defect in the collagenous matrix. Fractures occur early in life, sometimes in utero. Children with unexplained fractures are often referred to rule out child abuse and therefore it is vital to recognize OI to avoid emotionally

Fig. 25.12 Osteogenesis imperfecta with blue sclera. (Courtesy Scott Norton, MD.)

traumatic workups for parents. Loose-jointedness may be striking, and dislocation of joints can be a problem. Blue sclerae, when present, are a valuable diagnostic clue (Fig. 25.12). Scoliosis and defective teeth may be present. Deafness develops in many patients by the second decade of life and is audiologically indistinguishable from otosclerosis. The skin is thin and translucent, and healing wounds result in spreading atrophic scars. EPS may occur. Some patients experience unusual bruisability, probably from a structural defect in either the blood vessel wall or the supporting dermal connective tissue.

The basic defect is abnormal collagen synthesis, resulting in type I collagen of abnormal structure. Most forms of OI result from mutations in the genes for the proα1 or proα2 chains of type I collagen. Types V, VI, and VII are not associated with type I collagen gene defects. In type I (blue scleral dominant) there is diminished type I collagen with a mutation of *COL1A1* gene; in type II (perinatal lethal) there is diminished type I collagen synthesis and decreased integrity of the helical domain of the α1(I) gene; in type III (progressive deforming) there is delayed secretion of type I collagen with altered mannosylation; and in type IV (white sclerae dominant) there is a defective proα1(I) gene. A distinct subset of type IV with clinical improvement over time has been mapped to chromosome 11q.

The major causes of death attributed to OI are respiratory failure secondary to severe kyphoscoliosis and head trauma, mostly observed in type III disease. Aortic dissection has also been described. Patients with type I and type IV disease have a normal life span. Brack syndrome is a combination of OI and arthrogryposis multiplex.

Treatment includes surgical intervention, such as intramedullary stabilization. Bisphosphonates and calcitriol are the most effective pharmacologic agents. Specifically, cyclic pamidronate therapy has been shown to suppress bone turnover, reduce bone pain and fracture incidence, and increase bone density and level of ambulation. Gene therapy is promising but is complicated by the genetic heterogeneity of the disease.

AMYLOIDOSIS

Amyloid is a material deposited in the skin and other organs that is eosinophilic, homogeneous, and hyaline in appearance. It represents beta-pleated sheet forms of various host-synthesized molecules processed into this configuration by host cells.

Amyloidosis can be classified as systemic, localized, and heredofamilial types. The systemic types can deposit amyloid in multiple organs due to an overproduction of a host protein that cannot be adequately excreted or metabolized by the host. The excess protein is metabolized into amyloid precursors that interact with tissue proteoglycans/glycosaminoglycans, forming soluble amyloid oligomers. These oligomers complex with serum amyloid P (SAP), forming amyloid deposits in the affected organ. Over 30 proteins have been associated with amyloidosis, including immunoglobulin light chains (myeloma associated amyloid), tranthyretin (senile amyloid), beta-2 microglobulin (diabetic amyloid), and alpha natriuretic protein. In all forms of amyloid, the pattern of deposition is characteristic, although there can be overlap between various forms. The diagnosis of a specific type of amyloid should only be made if the clinical features are characteristic and if the deposited protein is identified histochemically. Primary localized amyloidosis (also called primary cutaneous amyloidosis when the skin is affected) is very common. Rare familial syndromes may be complicated by secondary systemic amyloidosis or may have genetic defects that lead to amyloid deposition (heredofamilial amyloidosis). Classification of cutaneous amyloidoses is as follows:

I. Systemic amyloidosis
   A. Primary (myeloma-associated) systemic amyloidosis
   B. Secondary systemic amyloidosis
   C. Dialysis-related amyloidosis
   D. Senile systemic amyloidosis
II. Cutaneous amyloidosis
   A. Macular amyloidosis
   B. Lichen amyloidosis
   C. Nodular amyloidosis
   D. Secondary (tumor-associated) cutaneous amyloidosis
   E. Familial primary cutaneous amyloidosis
   F. Pharmaceutical amyloidosis
III. Heredofamilial amyloidosis

All forms of amyloid have relatively identical histologic and electron microscopic findings. The amyloid in all forms is made up of three distinct components: protein-derived amyloid fibers, amyloid P component (about 15% of amyloid), and ground substance. The protein-derived amyloid fibers are those that differ among the various forms of amyloid.

Amyloid is weakly periodic acid–Schiff (PAS) positive and diastase resistant, Congo red positive, purple with crystal violet, and positive with thioflavin T. Amyloid stained with Congo red exhibits apple-green birefringence under polarized light. Secondary systemic amyloid (AA amyloid) loses its birefringence after treatment with potassium permanganate, whereas primary and localized cutaneous forms do not.

Amyloid stains an intense, bright orange with cotton dyes such as Dylon, Pagoda red, RIT Scarlet No. 5, or RIT Cardinal Red No. 9. Ultrastructurally, amyloid has a characteristic fibrillar structure that consists of straight, nonbranching, nonanastomosing, often irregularly arranged filaments 60–100 nm in diameter. In most cases, specific antibodies against the protein component should be used to confirm the type of amyloidosis. Because amyloid substance P is present in all forms of amyloid, immunoperoxidase staining against this component will stain all forms of amyloid. In addition, because SAP is avidly bound to amyloid, radiolabeled, highly purified SAP can be used to localize amyloidosis, determine the extent of organ infiltration, study progression of disease, and determine whether therapy reduces the amount of amyloid in various organs. Radiolabeled SAP scintigraphy and identification of specific amyloid proteins immunohistochemically can be done at some specialized centers, although the amount of deposition is not directly correlated with organ dysfunction.

SYSTEMIC AMYLOIDOSES

Primary Systemic Amyloidosis (AL Amyloidosis)

Primary systemic amyloidosis typically involves the kidneys, liver, heart, gastrointestinal (GI) tract, peripheral nerve tissue, and skin. Myeloma-associated amyloidosis is included in this category. The amyloid fibril proteins in primary systemic amyloidosis are composed of the protein AL amyloid, a portion of the immunoglobulin (Ig) light chain. It is usually of the lambda (λ) subtype, and certain germline Ig light-chain V chains (6aVλVI and 3rVλIII) are responsible for AL amyloidosis in 40% of patients.

Cutaneous manifestations occur in approximately 40% of patients with primary systemic amyloidosis. The cutaneous eruption usually begins as shiny, smooth, firm, flat-topped, or spherical papules of waxy color that have the appearance of translucent vesicles. These lesions coalesce to form nodules and plaques of various sizes and, in some cases, bandlike lesions. The regions around the eyes, nose, mouth, and mucocutaneous junctions are frequently involved (Fig. 26.1). Vulvar lesions may resemble giant condylomata. Lesions may also be uniform small papules resembling milia or even microcystic lymphatic malformations. Follicular plugging may occur, resulting in milia.

Purpuric lesions and ecchymoses occur in about 15% of patients and are the most common cutaneous manifestation of primary systemic amyloidosis. There are several mechanisms by which AL amyloid leads to purpura. Amyloid may infiltrate blood vessels, making them fragile. AL amyloid may also bind factor X, inhibiting its function and thus leading to pupura. Last, amyloid infiltration of the liver may lead to reduced production of fibrinogen and factor X, adversely affecting clotting. Purpura chiefly involves the eyelids, limbs, and oral cavity. It typically occurs after trauma (pinch purpura) and can be reproduced by the physician by rubbing a pen or dull instrument over the skin, analogous to trying to demonstrate dermatographism. Purpuric lesions also classically appear after actions or procedures that result in increased pressure in the vessels of the face, such as after vomiting, coughing, proctoscopic examination, or pulmonary function testing.

Glossitis, with macroglossia, occurs in at least 20% of patients, may be an early symptom, and can lead to dysphagia. The tongue becomes greatly enlarged, and furrows develop. The lateral aspects show indentations from the teeth. Papules or nodules, sometimes with hemorrhage, occur on the tongue (Fig. 26.2).

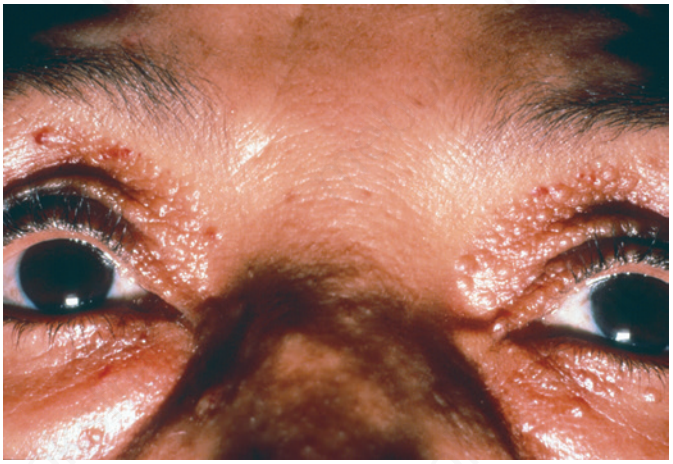

Fig. 26.1 Amyloidosis.

Fig. 26.2 Amyloidosis of the tongue.

Bullous amyloidosis is a rare but important clinical manifestation of amyloidosis. Skin fragility and tense, hemorrhagic or clear, noninflammatory bullae appear at areas of trauma, usually the hands, forearms, and feet. Lesions heal with scarring and milia. The esophagus and oropharyngeal mucosae may also be involved. Histologically, the lesions are subepidermal and pauci-inflammatory. Epidermolysis bullosa acquisita and porphyria cutanea tarda are in the differential diagnoses because they both cause blisters that heal with milia. Amyloid staining may yield negative results, and direct immunofluorescence (DIF) may be falsely positive because of AL protein deposition at the dermoepidermal junction (DEJ). The diagnosis is confirmed by evaluation of the patient's serum and urine for Ig fragments and by amyloid stains or electron microscopy of the skin biopsies.

A diffuse or patchy alopecia, cutis verticis gyrata, and a scleroderma-like, scleromyxedema-like, or a cutis laxa–like appearance have also rarely been described. Cutis laxa–like findings may be generalized or localized to the acral parts. Lesions in the flexors and lateral neck may resemble pseudoxanthoma elasticum (PXE). At times, lesions with cutis laxa–like or PXE-like appearance may show amyloid bound to elastic fibers. The nail matrix may be infiltrated, resulting in atrophy of the nail plate, presenting as longitudinal striae, partial anonychia, splitting, and crumbling of the nail plate. Cordlike thickening along blood vessels can also occur. Bilateral stenosis of the external auditory canals has been reported. Patients with systemic amyloidosis are at increased risk for skin cancer.

Patients may present with or develop a plethora of systemic findings. Most characteristically, they develop carpal tunnel syndrome, other peripheral neuropathies, a rheumatoid arthritis (RA)–like arthropathy of the small joints, orthostatic hypotension, GI bleeding, nephrotic syndrome, and cardiac disease.

About 90% of patients will have the Ig fragment detectable in the serum or urine; in the other 10%, the serum free light-chain assay will detect a clear excess of one of the light chains (κ or λ), confirming the diagnosis. Also, reduction of the urine free light chains by more than 50% correlates with substantial benefit from treatment. Cardiac troponins are elevated and are powerful prognostic determinants in AL amyloidosis. Elevated troponins are associated with a 6-month survival. AL patients may appear to have prominent deltoid muscles as a result of deposition of amyloid in the muscles (shoulder pad sign). Cardiac arrhythmias and right-sided congestive heart failure are common causes of death.

The prognosis for patients with primary systemic amyloidosis is poor, and therapy is targeted toward decreasing the production of the initial protein that makes the amyloid. Those presenting with neurologic findings survive longer than patients presenting with cardiac disease. Approximately 15% of patients with AL amyloidosis will have myeloma, and 15% of patients with myeloma will have AL amyloidosis.

Secondary Systemic Amyloidosis (AA Amyloidosis)

Secondary systemic amyloidosis is caused by a chronic infectious or inflammatory process. In these conditions, the precursor protein, serum amyloid A (SAA), an acute-phase reactant, is chronically elevated and cannot be adequately cleared from the body. It is processed to AA amyloid in affected tissues. With more effective treatment for chronic infections (especially tuberculosis, schistosomiasis, osteomyelitis, bronchiectasis, pyelonephritis, and decubitus ulcer), infection-related AA amyloid is much less common. Most cases are now related to chronic inflammatory conditions, especially RA, juvenile idiopathic arthritis, ankylosing spondylitis, adult Still disease, inflammatory bowel disease, and Behçet disease. Amyloidosis has also been reported in alkaptonuria. The newer and more aggressive management strategies for these inflammatory conditions have led to reduced numbers or delayed onset of AA amyloidosis in these patients. Maintaining SAA below 4 mg/L is associated with a good outcome in AA amyloidosis. The organs involved most commonly by AA amyloidosis are the kidneys, adrenals, liver, and spleen. The skin is not involved, but biopsy of skin in patients with AA amyloidosis will detect amyloid deposits in the dermis perivascularly. Certain skin conditions, such as hidradenitis suppurativa, stasis ulcers, psoriatic arthritis, and dystrophic epidermolysis bullosa, may be complicated by AA amyloidosis. Many inherited conditions associated with elevated SAA may be complicated by AA amyloidosis as well. These include familial Mediterranean fever, cryopyrin-associated periodic syndromes, and tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS).

Dialysis-Associated Amyloidosis (β_2-Microglobulin Amyloidosis)

β_2-Microglobulin is excreted primarily by the kidneys. In patients with severe renal failure on dialysis or predialysis, the excess β_2-microglobulin may be processed to amyloid in certain tissues.

Almost 100% of patients receiving dialysis for 15 years or more will develop this form of amyloidosis. It primarily affects the synovium, causing musculoskeletal symptoms, carpal tunnel syndrome, and, less often, triggers finger, bone cysts, and spondyloarthropathy. Rarely subcutaneous tumors can arise often of the buttocks overlying the sacrum. Pedunculated sacral masses, lichenoid papules, and localized hyperpigmentation can also be seen. The diagnosis is confirmed by biopsy, which demonstrates that the amyloid material is β_2-microglobulin on immunohistochemical stains. The treatment is high-flux dialysis or kidney transplantation.

Senile Systemic Amyloidosis

Senile systemic amyloidosis is increasingly recognized as an important cause of cardiac disease in the elderly population (>70 years). Carpal tunnel syndrome can also occur. Senile systemic amyloidosis is caused by deposition of normal transthyretin, a transporter protein, in tissue. Skin lesions have not been reported, but vascular deposition has led to tongue necrosis. The diagnosis can be confirmed in about three quarters of patients with a deep abdominal fat biopsy.

CUTANEOUS AMYLOIDOSIS

Primary Localized Cutaneous Amyloidosis

The primary localized cutaneous amyloidoses have been divided into four forms: macular, lichen, nodular, and familial. Macular and lichen forms of amyloidosis are also called "keratinocyte-derived" amyloidosis, frictional amyloidosis, and frictional melanosis. Some cases of these two forms of cutaneous amyloidosis are familial, but the relationship between these and cases of familial primary localized cutaneous amyloidosis is unclear. Patients with macular and lichen amyloidosis often have coexistent atopic dermatitis and the scratching is likely the cause of the amyloid. Nodular and familial cases of cutaneous amyloidosis are rare and have a unique pathogenesis.

Nonfamilial macular and lichen amyloidosis have the same pathogenic basis (rubbing and friction), and overlap cases (biphasic cutaneous amyloidosis) can be seen. Individuals of Asian, Hispanic, or Middle Eastern ancestry seem to be predisposed and use of abrasive devices during bathing is a precipitant. In cases of acquired macular and lichen amyloidosis, the deposited amyloid material contains keratin (primarily keratin 5) as its protein component, strongly suggesting that traumatic damage to basal keratinocytes results in the deposits. A rare form localized to the conchae has been described. Many pruritic skin conditions such as primary biliary cirrhosis and chronic renal failure have been associated.

The histologic picture of acquired macular and lichen amyloidosis is similar; the only difference is the size of the amyloid deposits and the extent of the overlying epidermal changes. The overlying epidermis is frequently hyperkeratotic and focally acanthotic, as a result of the chronic rubbing. Focal necrotic keratinocytes may be observed in the basal cell layer. Microscopic and rarely macroscopic bullae (analogous to those in lichen planus) may be seen. Dermal papillae are expanded by amorphous deposits of amyloid that abut immediately below the epidermis. Melanin deposits are classically present in the amyloid. In cases of postinflammatory hyperpigmentation with incontinence of pigment, the architecture of the areas of dermal melanosis should be examined carefully to exclude amyloidosis. Systemic amyloidosis is excluded by the absence of amyloid deposits around blood vessels. Special stains may be used to confirm the diagnosis, but this is rarely required if the classic histology is found. In difficult cases, immunoperoxidase for keratin will stain the amyloid deposits and confirm the diagnosis of primary cutaneous amyloidosis. DIF may demonstrate immunoglobulin (usually IgM) in a globular pattern in the keratin-derived cutaneous amyloidoses, but this is caused by passive absorption rather than specific deposition. This phenomenon is seen in all disorders with prominent apoptosis of keratinocytes.

Fig. 26.3 Macular amyloid. (Courtesy Dr. Debabrata Bandyopadhyay.)

Macular Amyloidosis

Typically, patients with macular amyloidosis exhibit moderately pruritic, brown, rippled macules characteristically located in the interscapular region of the back (Fig. 26.3). Women outnumber men by 5:1 and the disease is chronic. Pigmentation is generally not uniform, giving the lesions a "salt and pepper" or rippled appearance. Many cases of macular amyloid between the scapulae probably result from rubbing dysesthetic areas of notalgia paresthetica. Occasionally, the thighs, shins, arms, breasts, and buttocks may be involved, and these more diffuse cases are usually associated with diffuse pruritus.

Lichen Amyloidosis

Lichen amyloidosis is characterized by the appearance of paroxysmally itchy lichenoid papules, virtually always appearing bilaterally on the shins (Fig. 26.4). Some patients may deny itching but there is still chronic rubbing. Men outnumber women 2:1. Lichen amyloidosis may be found in approximately one third of patients with multiple endocrine neoplasia type IIA (see later discussion). The primary lesions are small, brown, discrete, slightly scaly papules that group to form large, infiltrated plaques. Less frequently, these may occur on the thighs, forearms, face, and even the upper back.

Treatment

Treatment of lichen and macular cutaneous amyloidosis is frequently unsatisfactory. Reducing friction is critical. Identifying the cause of the rubbing, and whether it is habit, pruritus, or neuropathy (as in notalgia paresthetica), directs treatment. Occlusion of therapy is helpful because it both enhances topical treatments and provides a physical block to prevent trauma to the skin. High-potency topical corticosteroids can be beneficial, as can intralesional corticosteroid therapy when small areas are involved. Topical tacrolimus 0.1% ointment, psoralen plus ultraviolet A light (PUVA) and with retinoids (Re-PUVA), ultraviolet B (UVB) light, tar, and calcipotriol benefit individual patients. Amitriptyline (for itching), oral retinoids, thalidomide, and systemic immunosuppressants, including corticosteroids, may be used in refractory cases. The pigmentation of macular amyloidosis reportedly has been improved by laser therapy, especially the 532-nm Q-switched neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser.

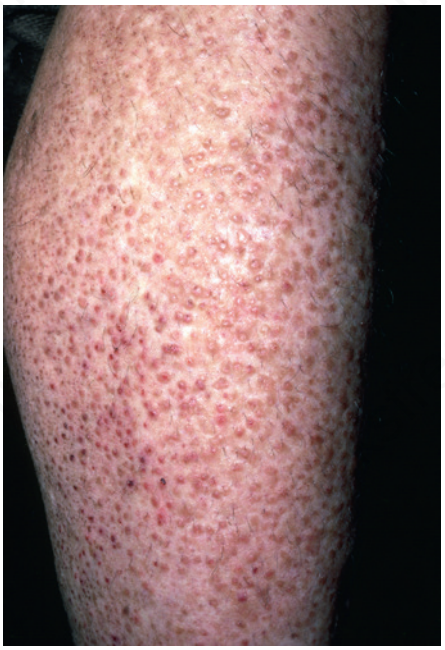

Fig. 26.4 Lichen amyloidosis.

Fig. 26.5 Nodular amyloidosis.

Nodular Amyloidosis

Nodular amyloidosis is a rare form of primary localized cutaneous amyloidosis in which single or, less often, multiple nodules or tumefactions preferentially involve the acral areas (Fig. 26.5). However, trunk, genital, or facial lesions may be seen as well. The lesions are asymptomatic, vary in size from several millimeters to several centimeters, and may grow slowly after their initial appearance. The overlying epidermis may appear atrophic, and lesions may resemble large bullae. Numerous conditions have been associated with nodular primary localized cutaneous amyloidosis (NPLCA), especially Sjögren syndrome, but also systemic sclerosis (including CREST) and RA. In Sjögren syndrome the nodular amyloidosis typically appears around age 60, more frequently in females, and may precede the diagnosis of Sjögren syndrome by many years. The dermis and subcutis may be diffusely infiltrated with amyloid. The lesions may contain numerous plasma cells and may be early MALT lymphomas. The amyloid in these patients is Ig-derived AL, as is seen in primary systemic amyloidosis, and is unrelated to keratinocyte-related amyloid or to AA amyloid. Progression to systemic amyloidosis may occur in about 7% of cases, so they should be regularly evaluated for progression. Treatment is physical removal or destruction of the lesion with shave removal and destruction of the base.

Secondary Cutaneous Amyloidosis

After PUVA therapy and in benign and malignant cutaneous neoplasms, deposits of amyloid may be found. Most frequently, the associated neoplasms are nonmelanoma skin cancers or seborrheic keratoses. Discoid lupus, dermatomyositis (DM), and graft-versus-host disease (GVHD), as interface dermatoses with apoptosis of keratinocytes, can occasionally demonstrate amyloid in the upper dermis. In all cases, this is keratin-derived amyloid.

Hereditary Cutaneous Amyloidosis Syndromes

Familial primary localized cutaneous amyloidosis (FPLCA) is an autosomal dominant syndrome associated with chronic itching (although some deny it) and cutaneous lesions resembling macular and lichen amyloidosis. It is seen most often in Japan, Brazil, China, and Taiwan. The age of onset is 5–18 years. In some families, sun exposure may be an exacerbating factor. Lesions are often widespread on the limbs, chest, and upper and lower back. The buttocks, conchae, and dorsal feet and hands may also be involved. Mutations in the *OSMRβ* or interleukin-31 receptor A *(IL-31RA)* genes that code for proteins that form the two subunits of the transmembrane receptor for IL-31. IL-31 induces the secretion of monocyte chemotactic protein 1 (MCP-1), and levels of MCP-1 expression are very low in FPLCA. MCP-1 recruits monocytes to clear the cellular debris resulting from keratinocyte damage. In the absence of this signal, cellular debris accumulates, and the keratin is processed to amyloid. There is hypersensitivity of small nerve fibers leading to itching. Rare cases of macular amyloidosis in a blaschkoid distribution suggest that mosaicism for FPLCA can be seen, giving this unusual cutaneous distribution. Some FPLCA cases demonstrate extensive poikilodermatous lesions, and less frequently a patient may have multiple morphologies of lichen amyloid, poikiloderma, and dyschromica and even small bullous lesions.

Amyloidosis cutis dyschromica is a distinct type of FPLCA with onset in childhood, no pruritus, a dotted reticular hyperpigmentation with hypopigmented spots without papulation covering almost all the body, and small foci of amyloid just below the epidermis. The nature of the amyloid is unclear. Most affected families are from Japan, Taiwan, and India. UVB hypersensitivity is often reported by these patients.

Multiple endocrine neoplasia type IIA (MEN-2A) syndrome and familial medullary thyroid carcinoma (FMTC) are both caused by mutations in the *RET* proto-oncogene. Cutaneous amyloidosis, most often keratin-derived macular amyloidosis, may be seen in these patients. The macular amyloid may be restricted to the upper back and also unilateral (associated with notalgia paresthetica), or it may be bilateral and more extensive. Age of onset is usually before 20. Thirty of 31 patients with MEN-2A had cutaneous amyloidosis before the diagnosis of MEN-2A was made. In a patient with macular amyloidosis of early onset (before age 20), a careful family history should be taken for endocrine neoplasias,

the skin and mucosa examined for neuromas, the blood pressure taken (checking for pheochromocytoma), and the thyroid palpated. A serum calcitonin level should be ordered and, if elevated, a thyroid ultrasound performed.

Pharmaceutical Amyloidosis

When injected into the skin, insulin can create deposits of amyloid composed of the A and B subunits of insulin. This is termed *AIns*. Lesions present as deep subcutaneous nodules, usually on the lower abdomen. If patients inject into these sites, their glucose control may be impaired as their insulin is less effective. Injecting into new areas or surgically removing the nodules improves glucose control. Enfuvirtide, a human immunodeficiency virus (HIV) fusion–inhibiting peptide administered subcutaneously, can produce similar lesions.

FAMILIAL SYNDROMES ASSOCIATED WITH AMYLOIDOSIS (HEREDOFAMILIAL AMYLOIDOSIS)

Most forms of familial amyloidosis are caused by abnormal host proteins that cannot be adequately processed, resulting in their deposition in various tissues in the form of amyloid. Only 50% of patients with hereditary amyloidosis will have a positive family history. Liver, kidney, heart, eye, and nervous system may be involved. Several types of hereditary amyloidosis have been identified; some forms are caused by genetic defects in transthyretin. These are autosomal dominant syndromes, and most affected patients are heterozygotes. Others are caused by a genetic defect in apolipoprotein A-I or A-II, by a defect in gelsolin, fibrinogen A-α, cystatin C, or lysozyme. These syndromes must often be diagnosed by genetic testing or immunohistochemical identification of the deposited pathogenic protein.

PORPHYRIAS

Porphyrinogens are the building blocks of all the hemoproteins, including hemoglobin and the cytochrome enzymes, and are produced primarily in the liver and bone marrow. Each form of porphyria has now been associated with a deficiency in an enzyme in the metabolic pathway of heme synthesis. These enzyme deficiencies lead to accumulation of the precursor molecules before the mutation. The precursors are porphyrins, and the diseases are called porphyrias. Many of the porphyrins lead to severe photosensitivity that accounts for most of the cutaneous findings.

Understanding the biosynthetic pathway of heme has clarified the biochemical basis of the porphyrias. Delta-aminolevulinic acid (dALA) is synthesized in the mitochondria by dALA synthetase. From it are formed, successively, porphobilinogen (PBG), uroporphyrin III, coproporphyrin III, and protoporphyrin IX. Protopoyphyrin IX reenters the mitochondrion, to be acted on by ferrochelatase to produce heme. Each step in this process is catalyzed by a specific enzyme. The final product, heme, by negative feedback, represses the production, or activity, of dALA synthetase. If the amount of heme produced is inadequate due to a missing enzyme, dALA synthetase activity may be increased, leading to the production of more porphyrins. Because this enzyme system is inducible, medications that increase the cytochrome drug-metabolizing system in the liver can lead to exacerbation of the porphyrias by increasing the production of the porphyrin intermediates.

The current grouping of the porphyrias is based on the primary site of increased porphyrin production, either liver or bone marrow—the hepatic or erythropoietic porphyrias, respectively. Some include a hepatoerythropoietic category. Congenital erythropoietic porphyria (CEP), X-linked dominant protoporphyria (XLDPP), and erythropoietic protoporphyria (EPP) are the erythropoietic forms. Acute intermittent porphyria (AIP), ALA dehydratase deficiency (ADP), hereditary coproporphyria (HCP), variegate porphyria (VP), and porphyria cutanea tarda (PCT) are the hepatic forms. Hepatoerythrocytic porphyria (HEP) has been classified as either a hepatic or a hepatoerythropoietic type.

Another way to classify the porphyrias is by their symptomatology. This system divides those diseases that have acute episodes, called the acute porphyrias, and those that have skin findings, called the cutaneous porphyrias. Some conditions have both skin disease and acute episodes. The acute porphyrias are ADP, AIP, HCP, and VP. The cutaneous porphyrias are PCT, CEP, XLDPP, and EPP. VP and HCP can have both acute attacks and skin lesions. The acute attacks are induced by conditions that activate the heme biosynthesis pathway. Due to the enzymatic "blocks" as the pathway is activated, large amounts of the heme precursors (specifically, dALA and PBG) are produced by the liver and dumped into the bloodstream. These substances are neurotoxic and affect primarily the autonomic and peripheral nerves. In the cutaneous porphyrias, photosensitivity is observed. The photosensitivity is caused by the absorption of UV radiation in the Soret band (400–410 nm) by the porphyrins, primarily in the blood vessels of the upper dermis. These activated porphyrins are unstable, and as they return to a ground state, they transfer energy to oxygen, creating reactive oxygen species. These unstable oxygen species interact with biologic systems, primarily plasma and lysosomal membranes, causing tissue damage. Mediators released from mast cells and polymorphonuclear leukocytes, acting through complement and metalloproteinase, eicosanoids, or factor XII pathways, may augment tissue effects. The skin lesions are determined by the biochemical nature of the excess porphyrin. Hydrophobic protoporphyrin has more affinity to lipid membranes, specifically endothelial cells. This correlates with acute burning and purpura exhibited in EPP, as well as the prominent reduplication of the basement membranes (seen as perivascular hyaline deposits) of the upper dermal vessels from constant repair of the phototoxic damage to the endothelial cells. The more water-soluble porphyrins (uroporphyrin and coproporphyrins) diffuse into and accumulate in the dermis and along the DEJ. The resulting skin lesions, subepidermal blisters, are caused by the phototoxic damage in this region.

The porphyrias have classically been diagnosed by identifying characteristic clinical and biochemical abnormalities, typically elevated levels of porphyrins in the urine, serum, red blood cells (RBCs), or stool. Because there is some clinical overlap, biochemical testing should be performed to confirm any diagnosis of porphyria. In the acute porphyrias, patients are often asymptomatic between attacks. During attacks, porphyrin assays will be abnormal in all forms of porphyria. Between attacks, some patients with AIP may have normal porphyrin assays so genetic testing is necessary to make the diagnosis. The genetic defect and the points of the most common mutations for each gene are now known for most forms of the porphyrias. Genetic testing is now recommended in most porphyrias, except PCT and EPP. There is considerable clinical overlap in these rarer porphyrias; dual porphyrias exist, with mutations in two different heme synthesis genes; and low-level mutations causing atypical presentations are now well described. Accurate diagnosis in such cases requires genetic testing and allows for genetic counseling and prenatal diagnosis.

PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda (PCT) is the most common type of porphyria. Patients with PCT present most often in midlife, averaging 45 years of age at disease onset. The disease is characterized by photosensitivity resulting in skin fragility and bullae, especially on sun-exposed parts. The dorsal hands and forearms, ears, and face are primarily affected. The bullae are noninflammatory and rupture easily to form erosions or shallow ulcers (Fig. 26.6). These heal with scarring, milia, and dyspigmentation. Lesions on the legs, especially the shins and dorsal feet, occur primarily in women. There is hyperpigmentation of the skin, especially of the face, neck, and hands. Hypertrichosis of the face, especially over the cheeks and temples. The face and neck, especially in the periorbital area, may show a pink to violaceous tint. Sclerodermatous thickenings may develop on the back of the neck, in the preauricular areas, or on the thorax (Fig. 26.7), fingers, and the scalp, with associated alopecia. There is a direct relationship between the levels of uroporphyrins in the urine and sclerodermatous changes.

Liver disease is frequently present in patients with PCT. A history of alcoholism is common. PCT is a well-recognized cutaneous complication of hepatitis C virus (HCV) infection. All

Fig. 26.8 Porphyria cutanea tarda with hemochromatosis. (Courtesy Curt Samlaska, MD.)

Fig. 26.7 Sclerodermoid lesions in a patient with porphyria cutanea tarda.

PCT patients should be screened for HCV infection especially with new therapeutics so effective for HCV. A recent report documented clearance of PCT with cure of the Hep C. Iron overload in the liver is frequently found in patients with PCT as a result of chemical or viral liver damage, or because a significant number of patients with PCT have a *C282Y* mutation (and a few with *H63D* mutation), the genetic cause of hemochromatosis (Fig. 26.8). The net result of all these liver and iron metabolism abnormalities is an increase in ferritin, with hepatic iron overload. Hepatocellular carcinoma may rarely present with PCT, and PCT patients are at 3.5 times the risk of developing hepatocellular carcinoma.

PCT has been frequently associated with other diseases. It is estimated that adult-onset (type 2) diabetes mellitus occurs in 15%–20% of patients with PCT usually about a decade after the PCT diagnosis. Type 2 diabetes and the metabolic syndrome are associated with hyperferritinemia. It has been proposed that in some patients, nonalcoholic steatohepatitis (NASH) of diabetes may contribute to the development of PCT. In one patient, weight reduction led to improvement of PCT and antimalarial treatment of PCT has lead to enhanced glucose control. Moderate smoking (>10 cigarettes/day) may lead to earlier presentation of PCT by almost a decade. Numerous cases of lupus erythematosus (systemic of purely cutaneous) concomitant with PCT have been reported.

PCT can occur in patients with HIV infection. This is not only accounted for by coexistent HCV infection, which is increased in some risk groups of HIV-infected persons. Subtle porphyrin abnormalities (typically below concentrations capable of inducing disease) are found in HIV disease due to interference with normal porphyrin metabolism. Other risk factors, such as alcoholism, should be evaluated, and the existence of PCT should not be attributed to the HIV disease alone. However, effective anti-HIV therapy has led to improvement of PCT in one HIV/HCV-infected patient.

Estrogen treatment is associated with the appearance of PCT by an unknown mechanism. Before oral contraceptives were introduced, PCT cases occurred predominantly among men, but in most recent series, 60% of cases occurred in men and 40% in women. Men treated with estrogens for prostate cancer may develop PCT.

PCT is caused by a deficiency in the enzyme uroporphyrinogen decarboxylase (UROD). Several types have been described. The most common is the sporadic, nonfamilial form, which represents about 75%–80% of cases. Enzymatic activity of UROD is abnormal in the liver but normal in other tissues. This is the form associated with the cofactors previously listed. The enzyme deficiency is related to loss of enzyme activity caused by the liver damage or estrogens triggering the PCT. The enzyme UROD is inhibited by iron, so conditions that lead to iron overload in the liver (cirrhosis, alcoholism, HCV infection, type 2 diabetes, hemochromatosis) can all induce the clinical signs and symptoms of PCT. Removal of this iron in the liver may result in improvement in PCT. With remission, the enzyme activity in the liver may return to normal.

The second, or familial, type of PCT is an autosomal dominant inherited deficiency of UROD in the liver and RBCs of patients and of clinically unaffected family members. Both the activity and the concentration of the enzyme decrease by about 50%. Multiple genetic defects have been reported that produce the same phenotype. Familial PCT tends to present at an earlier age because it does not require a second insult to the liver to decrease enzyme activity further, and development of PCT before age 20 strongly suggests familial PCT.

A third form, acquired toxic PCT, is associated with acute or chronic exposure to hepatotoxins, specifically, polyhalogenated hydrocarbons such as hexachlorobenzene and dioxin. These patients have biochemical and clinical features identical to those of patients with sporadic and familial PCT.

A diagnosis of PCT can be strongly suspected on clinical grounds. A useful confirmatory test that can be performed in the office is the characteristic pink or coral-red fluorescence of a random urine specimen under Wood's light. A 24-hour urine specimen usually contains less than 100 μg of porphyrins in a

normal individual, whereas in the PCT patient it may range from 300 μg to several thousand. The ratio of uroporphyrins to coproporphyrins in PCT is typically 3 : 1 to 5 : 1, distinguishing PCT from variegate porphyria. Plasma porphyrins will also be abnormal and may be detected by peak plasma fluorescence at less than 623 nm. The diagnosis of hereditary PCT is made by demonstrating reduced UROD activity in erythrocytes. There are a few reference laboratories in the United States that have special expertise in evaluation of porphyrins and they often recommend shielding the sample from light after it is collected.

Biopsy of a blister reveals a noninflammatory subepidermal bulla with an undulating, festooned base. PAS-positive thickening of blood vessel walls in the upper and middle dermis is present. A useful and highly characteristic, but not diagnostic, feature is the presence of the so-called caterpillar bodies. These eosinophilic, elongated, wavy structures are present in the lower and middle epidermis and lie parallel to the basement membrane zone (BMZ). They stain positively with PAS and are positive for type IV collagen and laminin, suggesting they represent BMZ material present in the epidermis. DIF of involved skin shows IgG and C3 at the DEJ and in the vessel walls in a granular-linear pattern.

Initial treatment of PCT involves removal of all precipitating factors, such as alcohol, medications, and therapy for HCV and metabolic syndrome if present. This may lead to sufficient improvement so that further therapy is not required. Chemical sunscreens are of little value because they do not typically absorb radiation in the near-visible UVA range. Barrier sunscreens such as titanium dioxide and zinc oxide with nonionized zinc oxide being superior. Physical barriers such as hats and gloves should be used.

Phlebotomy is a highly effective treatment for PCT. UROD is inhibited by iron, and removal of hepatic iron may therefore lead to recovery of enzyme activity. Typically, phlebotomy of 500 mL at 2-week intervals is performed until the hemoglobin reaches 10 g/dL or the serum iron 50–60 μg/dL. Ideally, serum ferritin will become normal as well. Urinary porphyrin excretion initially increases, but gradually, 24-hour uroporphyrin levels are greatly reduced, with most patients able to achieve normal levels. This process takes several months, usually requiring a total of 6–10 phlebotomies. As the porphyrins fall, the skin lesions also involute. Initially, blistering improves, then skin fragility decreases, and finally the cutaneous sclerosis and hypertrichosis can eventually reverse. A common error in management is coadministration of oral iron supplementation during the phlebotomies to treat the anemia.

Antimalarial therapy is an alternative to phlebotomy and may be combined with phlebotomy in difficult cases. Antimalarials complex the excess porphyrins, enhancing their excretion. Full doses of antimalarials may produce a severe hepatotoxic reaction. The initial dose is 125 mg of chloroquine or 100–200 mg of hydroxychloroquine twice weekly. Improvement is gradual and parallels the reduction in porphyrins.

The duration of treatment to reach a biochemical remission is the same for phlebotomy and antimalarial therapy, about 6–7 months. This remission may last many years. If the patient relapses, these treatments can be repeated. Alternative treatments, which are rarely required, include desferrioxamine or deferasirox (iron chelation) and erythropoietin treatment. Erythropoietin may be combined with phlebotomy. PCT in renal failure may respond to erythropoietin and low-volume phlebotomy, desferrioxamine given at the end of dialysis, or renal transplantation. If HCV infection coexists, interferon alfa treatment of the HCV infection may lead to improvement of the PCT. The management of PCT associated with hemodialysis is much more difficult. High-flux, high-efficiency hemodialysis should be instituted. *N*-acetylcysteine, 400 mg of powder dissolved in orange juice twice daily, can be added to augment dialysis. Erythropoietin, at times at very high dose, in combination with miniphlebotomy can be used in anuric patients with PCT not controlled by other methods.

Fig. 26.9 Pseudoporphyria cutanea tarda in a 16-year-old girl who was taking tetracycline for acne.

PSEUDOPORPHYRIA

In certain settings, patients develop blistering and skin fragility identical to PCT, with the histologic features of PCT but with normal urine and serum porphyrins. Hypertrichosis, dyspigmentation, and cutaneous sclerosis do not occur. This pseudoporphyria is most often caused by medications, typically a nonsteroidal antiinflammatory drug (NSAID), usually naproxen. Other NSAIDs, such as nabumetone, diclofenac, and rofecoxib, as well as voriconazole, tetracycline (Fig. 26.9), tolterodine, imatinib mesylate and sunitinib, metformin, finasteride, estrogen, chlorophyll, and multiple other medications, can cause a similar clinical picture. Tanning bed use can also produce pseudo-PCT. Some patients on hemodialysis develop a similar PCT-like picture. Less frequently, dialysis patients develop true PCT. In the anuric dialysis patient, true PCT and pseudo-PCT are distinguished by analysis of serum porphyrins in a laboratory knowledgeable in the normal porphyrin levels in patients undergoing hemodialysis. The treatment of pseudoporphyria is physical sun protection and discontinuance of any inciting medication. Ibuprofen is a safer alternative NSAID that usually does not cause pseudoporphyria. In medication-induced PCT, blistering resolves over several months once the medication is stopped. Skin fragility may persist for much longer. *N*-acetylcysteine and glutamine have been reported to improved dialysis-associated pseudo-PCT.

HEPATOERYTHROPOIETIC PORPHYRIA

Hepatoerythropoietic porphyria (HEP) is the homozygous form of PCT. It is caused by a homozygous or compound heterozygous deficiency of UROD, which is about 10% of normal in both the liver and the erythrocytes. The biochemical abnormalities are similar to but more marked than those in PCT, although the clinical features are similar to CEP. Dark urine is usually present from birth. In infancy, vesicles occur in sun-exposed skin, followed by sclerodermoid scarring, hypertrichosis, pigmentation, red fluorescence of the teeth under Wood's light, and nail damage. Neurologic disease has been reported. The diagnosis of HEP is confirmed by abnormal urinary uroporphyrins (as seen in PCT),

elevated erythrocyte protoporphyrins, and increased coproporphyrins in the feces. In CEP uroporphyrins are elevated in the erythrocytes, allowing differentiation from HEP. Sun protection is necessary, but often inadequate. Bone marrow transplantation, as in CEP, may be required for HEP patients.

VARIEGATE PORPHYRIA

Variegate porphyria (VP) is also known as mixed porphyria, South African genetic porphyria, and mixed hepatic porphyria. VP has an autosomal dominant inheritance with a high penetrance. It results from a decrease in activity of protoporphyrinogen oxidase (PPOX). Between 40% and 70% of patients with VP have skin symptoms, 27% have acute attacks, and only 14% have both acute attacks and skin symptoms. Many affected relatives have silent VP, in which there is reduced enzyme activity but no clinical lesions. Such persons should be identified and evaluated.

VP is characterized by the combination of the skin lesions of PCT and the acute GI and neurologic disease of AIP. In 50% of VP patients, skin lesions are the presenting finding. Vesicles and bullae with erosions, especially on sun-exposed areas, are the chief manifestations. In addition, hypertrichosis is seen in the temporal area, especially in women. Hyperpigmentation of sun-exposed areas is also a feature. Facial scarring and thickening of the skin may give the patient a prematurely aged appearance. The visceral attacks include hypertension, fever and paralysis of the respiratory system.

The presence of VP should be suspected in a patient when findings indicate both PCT and AIP, especially if the patient is of South African ancestry. Fecal coproporphyrins and protoporphyrins are always elevated, and during attacks, urine PBG and ALA are elevated. Normal levels of fecal protoporphyrin in adulthood predicts lack of both skin symptoms and acute attacks. Urinary coproporphyrins are increased over uroporphyrins, distinguishing VP from PCT. Urinary coproporphyrin level greater than 1000 nmol/day predicts increased risk for acute attacks and skin symptoms and indicates the need for preventive treatment to reduce porphyrins. A finding in the plasma of a unique fluorescence at 626 nm is characteristic of VP and distinguishes it from all other forms of porphyria. Lymphocyte PPOX can be measured, but because of the profound founder effect in this condition, genetic testing should be used to confirm the diagnosis.

Treatment of the skin lesions is symptomatic, because antimalarials and phlebotomy are not effective in modifying cutaneous disease in VP. Gonadotropin-releasing hormone (GnRH) analogs may prevent premenstrual attacks, and "hemin" and glucose loading can be used for acute attacks. VP patients, as well as those with other acute porphyrias (HCP and AIP), are at increased risk for hepatocellular carcinoma, and regular liver imaging should be performed after age 50. Education of patients and unaffected PPOX-deficient relatives is essential to avoid triggering medications.

Homozygous VP is a very rare autosomal recessive condition that presents in childhood with PCT-like acral blistering, vermiculate scarring of the cheeks, finger shortening, and developmental delay. Brain myelin is completely absent.

HEREDITARY COPROPORPHYRIA

Hereditary coproporphyria (HCP) is a rare, autosomal dominant porphyria resulting from a deficiency of coproporphyrinogen oxidase (CPO). About one third of patients are photosensitive, with blistering similar to but less severe than in VP. About 35% have acute attacks with GI and neurologic symptoms similar to those seen in AIP and VP. Fecal coproporphyrin III is always increased; urinary coproporphyrin, ALA, and PBG are increased only during attacks. Plasma fluorescence at 619 nm is seen. Mutation screening can be used to confirm the diagnosis and identify unaffected but CPO-deficient relatives. Homozygous hereditary coproporphyria, or harderoporphyria, is caused by a homozygous defect of CPO, with patients having 10% or less of normal activity. Harderoporphyrin is the natural intermediate between coproporphyrinogen and protoporphyrinogen. There is a report of HCP induced by efavirenz and liver failure in a patient who used "hydroxycut" over-the-counter weight loss therapy. Children present with photosensitivity, hypertrichosis, and hemolytic anemia, and a neonatal form was recently described. The biochemical findings in plasma, feces, and urine are identical to HCP, but more marked.

ERYTHROPOIETIC PROTOPORPHYRIA

Erythropoietic protoporphyria (EPP) is caused by decreased ferrochelatase (FECH) activity. There is a wild-type allele that has low function (hypomorphic) and when this is combined with a mutated allele leading to dysfunction. Therefore it is usually inherited in an autosomal dominant pattern with only one gene being truly mutated (pseudodominant). Autosomal recessive EPP from inheritance of 2 loss of function mutations is much more severe and typically requires bone marrow transplantation. FECH activity below 35% will lead to disease and most affected patients have 10%–25% of normal function. In Europe, up to 10%–15% of the population carries the low-expression (hypomorphic) allele that is only 50% as active as the wild-type enzyme.

Typically, EPP presents early in childhood (3 months to 2 years), although presentation late in adulthood can occur. The diagnosis of EPP in children is frequently delayed because of its rarity. Older children at times are referred to psychiatrists until the diagnosis is suspected.

Unique among the more common forms of porphyria is an immediate burning of the skin on sun exposure. Because the elevated protoporphyrin IX absorbs both in the Soret band and at 500–600 nm, visible light through window glass, in the operating room, or during neonatal exposure to a bili-light (Fig. 26.10) may precipitate symptoms. Infants cry when exposed to sunlight. Erythema, plaquelike edema, and wheals such as those seen in solar urticaria can be seen. These lesions appear solely on sun-exposed areas. In severe cases, purpura is seen in the sun-exposed areas.

With repeated exposure, the skin develops a weather-beaten appearance. Shallow linear or elliptical scars, waxy thickening and pebbling of the skin on the nose and cheeks and over metacarpophalangeal joints, and atrophy of the rims of the ears have been described. Perioral furrow-like scars are characteristic. The dorsal

Fig. 26.10 Erythropoietic protoporphyria in a neonate after bili-light exposure.

hands and face of EPP patients appear much older than their chronologic age.

About 2.5% of patients with EPP have a seasonal palmar keratoderma. It is worse in the summer and resolves in winter or with occlusion of the palm by a plaster cast. The keratoderma is waxy and may cover the whole palm or may be localized to the first web space. It is sharply demarcated at the wrist and has no red border. The thickening is moderate in severity. The nails are usually unaffected but may show minimal onycholysis. Patients with nail changes all have true autosomal recessive EPP, with lower levels of erythrocyte protoporphyrin but increased levels of fecal total porphyrin compared with pseudodominant EPP patients. In fact, their erythrocyte protoporphyrin may be near normal. About 45% of patients with autosomal recessive EPP have this keratoderma.

Between 20% and 30% of EPP patients have liver complications because of excessive porphyrin deposits in hepatocytes. This can occur anywhere along the spectrum, from mild elevation of liver function tests to cirrhosis. Only 5% of patients with EPP and liver disease develop hepatic failure, or 0.5%–1% of all EPP patients. Liver transplantation may be required. It is extremely important during liver transplantation to use filters on the operating room lights. A yellow filter that only emits below 470 nm has been reported to be safe. Autosomal recessive inheritance of EPP may be a risk factor for the development of liver failure. There is currently no marker for progressive liver disease (not laboratory porphyrins or genetic defect), so all patients must be monitored. Ten percent of patients develop gallstones, often in childhood. A mild microcytic anemia is present in 25% of patients with EPP, but therapy with iron should be used only if iron deficiency is detected, because it may exacerbate symptoms. Because of sun avoidance, vitamin D deficiency can occur.

The rare syndrome of EPP appearing de novo in adults has been reported multiple times. These cases are associated with a myeloproliferative disorder or myelodysplastic syndrome. The malignant cells in the bone marrow, caused by a translocation, lose the *FECH* gene on chromosome 18, and the patient "acquires" a FECH deficiency. Bone marrow transplantation is associated with resolution of this form of EPP.

Histologically, there is prominent ground-glass, PAS-positive material in the upper dermis, mostly perivascularly. This material is type IV collagen. On DIF, IgG and C3 may be found perivascularly. If an acute purpuric lesion is biopsied, the features of a leukocytoclastic vasculitis may be seen.

A diagnosis of EPP can usually be suspected on clinical grounds, especially if both the acute symptoms and the chronic skin changes are found. Because protoporphyrin IX is not water soluble, urine porphyrin levels are normal. Erythrocyte protoporphyrin is elevated and can be detected by RBC fluorescence. Erythrocyte, plasma, and fecal protoporphyrin can also be assayed to confirm the diagnosis. Erythrocyte protoporphyrin levels in affected persons may range from several hundred to several thousand micrograms per 100 mL of packed RBCs (normal values, <35 μg/100 mL of packed RBCs). Plasma fluorescence shows a peak at 634 nm.

The differential diagnosis of EPP includes hydroa vacciniforme, pseudoporphyria, xeroderma pigmentosa, and solar urticaria. In infancy, before the appearance of the chronic skin changes, erythrocyte porphyrins may need to be screened to confirm the diagnosis. Once chronic changes are present, a skin biopsy will confirm the diagnosis.

The treatment of EPP patients consists of protection from exposure to sunlight with clothing and barrier sunscreens containing titanium dioxide or zinc oxide. Beta carotene, 60–180 mg/day in adults and 30–90 mg/day for children, to maintain a serum level of 600 μg/100 mL, provides some modest protection. As the child grows, the dose must be increased to maintain adequate tissue levels. Early-spring hardening with narrow-band UVB or PUVA (wavelengths below the action spectrum of the incriminated porphyrins) is being increasingly used. Preliminary trials of colestipol, 2 g daily, and oral zinc sulfate, 600 mg daily, have led to substantial increases in light tolerance in EPP patients. Alpha melanocyte stimulating hormone analogs (alfamelanotide) can help increase photoprotection by inducing melanin production. Alfamelanotide has been demonstrated to increase light tolerance in patients with EPP, in a 20-mg sustained-release form implanted every 2 months. There are reports of increased pigmentation and number of nevi.

X-LINKED DOMINANT PROTOPORPHYRIA

X-linked dominant protoporphyria (XLDPP) is caused by deletions in the dALA synthetase 2 (*ALAS2*) gene. These mutations result in gain of function of the *ALAS2* gene, with increased production of protoporphyrin. Erythrocyte protoporphyrins are elevated from this overproduction of protoporphyrin, which exceeds the capacity of the ferrochelatase to incorporate the protoporphyrin into heme, resulting in excess protoporphyrin. Patients present with symptoms identical to EPP. About 10% of patients in North America with "EPP" actually have XLDPP. More severe photosensitivity and more frequent liver disease (15%) occur in XLDPP due to higher levels of protoporphyrins, about two times higher than in EPP patients. One case of late-onset XLDPP associated with myelodysplasia has been reported. Intravenous iron therapy has improved skin symptoms.

CONGENITAL ERYTHROPOIETIC PORPHYRIA

Congenital erythropoietic porphyria (CEP) is a very rare form of porphyria that is inherited as an autosomal recessive trait. It is caused by a homozygous defect of the enzyme uroporphyrinogen III synthase (UROS). The coinheritance of a gain-of-function mutation in *ALAS2* can lead to a more severe phenotype. One family with a *GATA1* mutation also developed CEP.

CEP presents soon after birth with the appearance of red urine (noticeable on diapers). Severe photosensitivity occurs and may result in immediate pain and burning, so that the affected child screams when exposed to the sun. The laser used in pulse oximeters may lead to skin lesions of the nail bed. Redness, swelling, and blistering occur and result in scarring of the face (Fig. 26.11), dorsal hands, and scalp (with subsequent alopecia). Ectropion can occur, with subsequent corneal damage and loss of vision. Erythrodontia of both deciduous and permanent teeth is also characteristic

Fig. 26.11 Congenital erythropoietic porphyria. (Courtesy Dr. Debabrata Bandyopadhyay.)

(see Fig. 26.11). This phenomenon is demonstrated by the coral-red fluorescence of the teeth when exposed to Wood's light. Mutilating scars, especially on the face, and hypertrichosis of the cheeks, with profuse eyebrows and long eyelashes, occur. Other features seen in CEP include growth retardation, hemolytic anemia, thrombocytopenia, porphyrin gallstones, osteopenia, and increased fracturing of bones.

A diagnosis of CEP can be easily suspected when an infant has dark urine and is severely photosensitive. There is a direct correlation among the severity of the disease, the levels of plasma porphyrins, and the residual activity of UROS. Abnormally high amounts of uroporphyrin I and coproporphyrin I are found in urine, stool, and RBCs. There is stable red fluorescence of erythrocytes. On biopsy, a subepidermal bulla is seen, identical to that in PCT.

Treatment of CEP patients is strict avoidance of sunlight and, in some cases, splenectomy for the hemolytic anemia. Oral activated charcoal is efficacious, presumably impairing the absorption of endogenous porphyrins. Repeated transfusions of packed RBCs are given at volumes sufficient to maintain the hematocrit level at 33%, turn off the demand for heme, and reduce porphyrin production. A report of using deferasirox to induce iron deficiency also reduced symptoms. Bone marrow transplantation should be considered in severely affected children, typically those with transfusion requiring anemia or thrombocytopenia, but also those with progressive photomutilation and genotypes associated with poor outcome. Proteosome inhibitors and induced pluripotent stem cells are newer treatment opportunities.

Adult-onset CEP is extremely rare, presenting as a mild, photosensitive blistering disease resembling PCT. Usually, patients with CEP live into adulthood. Preauricular fibrosis with loss of earlobes occurs. A corticobasal syndrome resembling Parkinson disease can also occur.

ACUTE INTERMITTENT PORPHYRIA

Acute intermittent porphyria (AIP), the second most common form of porphyria after PCT, is characterized by periodic attacks of abdominal pain (up to 95% of patients), GI disturbances (up to 90% of patients), pain and paresis (50%–70%), seizures (10%–20%), and mental symptoms (40%–60%), including agitation, hallucinations, and depression. Skin lesions do not occur because the elevated porphyrin precursors are not photosensitizers. AIP is inherited as an autosomal dominant trait and is caused by a deficiency in PBG deaminase, which has 50% activity in affected persons. Only 10% of those with the genetic defect develop disease, but all may be at risk for primary liver cancer. AIP is particularly common in Scandinavia, especially Lapland. AIP usually presents after puberty in young adulthood, and women outnumber men 1.5 : 1 to 2 : 1.

Severe abdominal colic is most often the initial symptom of AIP. Patients usually have no abdominal wall rigidity, although tenderness and distention are present. Nausea, vomiting, and diarrhea or constipation accompany the abdominal pain. Peripheral neuropathy, mostly motor, is present. Severe pain in the extremities occurs. Optic atrophy, diaphragmatic weakness, respiratory paralysis, flaccid quadriplegia, facial palsy, and dysphagia are some of the many neurologic signs.

Attacks of AIP are triggered by certain medications and other conditions. These triggers frequently require increased hepatic heme synthesis (e.g., to make the cytochrome P450 enzymes required for metabolism of medications). Progesterone is one trigger, explaining the increased prevalence of AIP in women and the relationship to menses. Anticonvulsants, griseofulvin, rifampin, and sulfonamides are common drugs implicated in triggering AIP. The implicated medication list is constantly being modified as new drugs enter the market. The website of the European Porphyria Initiative is the best source for an up-to-date list of both patients and health care providers (www.porphyria-europe.com). Crash dieting, cigarette smoking, infections, and surgery are additional triggers.

A diagnosis of AIP is established by finding elevated levels of urinary PBG and increased dALA in the plasma and urine during attacks. During remissions, the diagnosis can be confirmed in 88% of patients by detecting elevated urinary PBG. A normal test between attacks suggests less likelihood of subsequent attacks. Erythrocyte and fecal porphyrin levels are normal. AIP must be distinguished from VP, CP, and ALA dehydratase deficiency porphyria (ALAD), an autosomal recessive condition presenting in an almost identical manner to AIP. Increased dALA in the urine is found in ALAD patients and those with lead poisoning.

No specific treatment is available for AIP. It is important for the patient to avoid such precipitating factors as a wide variety of medications, including sex steroid hormones, and to maintain adequate nutrition. Glucose loading has been used extensively and appears to be beneficial in many cases. Hematin infusions, in the form of heme arginate, result in clinical improvement and a marked decrease in ALA and PBG excretion. Early treatment may ameliorate attacks. The phenothiazines (e.g., chlorpromazine) may be helpful for pain; opiates and propoxyphene are also useful for analgesia. Because 10% of patients with AIP die of hepatoma (without the development of cirrhosis), yearly ultrasound and alpha-fetoprotein determination should be undertaken in all AIP patients over age 50.

TRANSIENT ERYTHROPORPHYRIA OF INFANCY (PURPURIC PHOTOTHERAPY-INDUCED ERUPTION)

Paller et al. reported seven infants exposed to 380–700 nm blue lights for the treatment of indirect hyperbilirubinemia who developed marked purpura in skin exposed to UV light. Extensive blistering and erosions occurred in one patient. Biopsies of the skin showed hemorrhage without epidermal changes in the cases associated with purpura, and a pauci-inflammatory, subepidermal bulla in the patient with blistering. The infants had all received transfusions. Elevated plasma coproporphyrins and protoporphyrins were found in the four infants examined. The pathogenesis is unknown.

CALCINOSIS CUTIS

Cutaneous calcification results from deposits of calcium and phosphorus in the skin. Calcinosis cutis is divided into five forms. Dystrophic calcinosis includes conditions in which calcification occurs in damaged tissue, usually collagen or elastic tissue. Serum calcium and phosphorus levels are normal. DM is a classic example of a disease in which the inflamed skin can have dystrophic calcinosis. Metastatic calcification refers to deposition of calcium resulting from elevated serum levels of calcium or phosphorus. Hyperparathyroidism can cause this form of calcification. Iatrogenic and traumatic calcinosis is associated with medical procedures or occupational exposures that may involve both tissue damage and local elevated calcium concentrations. Idiopathic calcinosis cutis refers to the forms of cutaneous calcification of unknown cause with normal serum calcium. In osteoma cutis, true bone is formed in the skin. Calciphylaxis is discussed in Chapter 35.

DYSTROPHIC CALCINOSIS CUTIS

The dystrophic type occurs in a preexisting lesion or inflammatory process. Systemic calcium metabolism is normal, and lesions affect the skin only. Dystrophic calcinosis cutis presents as small deposits of chalky granular material around the fingers and on the elbows, at areas of trauma. The deposits may spontaneously extrude from the skin. The dystrophic form often occurs in limited scleroderma (the CREST syndrome: calcinosis cutis, Raynaud phenomenon, esophageal disorders, sclerodactyly, and telangiectasia) (Fig. 26.12), as well as polymyositis systemic sclerosis overlap. Pancreatic and lupus panniculitis typically demonstrate dystrophic calcification, but the process tends to remain microscopic. Dystrophic calcification of facial lesions of systemic lupus erythematosus and GVHD have also been reported. Patients with Werner syndrome and PCT may also develop calcifications within the scleroderma-like lesions.

Calcinosis cutis occurs in about 10% of patients with DM, especially juvenile cases. Fingertip ulcers and disease duration are associated with calcinosis cutis. Autoantibodies to NXP-2 increase the risk for cutaneous calcinosis in DM by 15-fold. MDA-5 antibodies are associated with fingertip ulcers but don't seem to be independently associated with calcification. Calcification in DM can occur in multiple forms, including hard nodules or plaques in the subcutaneous or periarticular areas; large tumors; deposits in the intermuscular fascia leading to decreased mobility; and as an exoskeleton.

Various benign and malignant neoplasms may develop calcification or ossification, with pilomatrixomas and pilar cysts most frequently reported. Nephrogenic systemic fibrosis, Hutchinson-Gilford progeria, and poikiloderma with neutropenia (Clericuzio type) may all be complicated by calcinosis cutis.

The treatment of dystrophic calcification is determined by the location, size/extent, and underlying condition. Limited surgical removal, as needed to control discomfort, can be very beneficial. Curetting out the calcium deposits around the fingers can bring dramatic relief to the patients with CREST and DM. Systemic therapies have not been consistently beneficial, with some patients having dramatic response, and the same treatment for the same disease having no effect in other patients. Bisphosphonates (alendronate, etidronate, pamidronate), diltiazem (30–180 mg/day), warfarin, antiinflammatory agents, TNF inhibitors, intravenous immune globulin (IVIG), thalidomide, and colchicine have all been used as single agents or in combination. Sodium thiosulfate, 10%–25% by topical application and 12.5 mg/50 mL by injection, has reduced dystrophic calcifications in various areas. Eight patients with dystrophic calcification treated with lithotripsy had a decrease in size of the calcium deposits and a dramatic reduction in pain.

Fig. 26.12 Dystrophic calcinosis cutis.

METASTATIC CALCINOSIS CUTIS

Metastatic calcinosis cutis is a rare entity characterized by calcifications in the skin due to elevated serum calcium, and sometimes hyperphosphatemia. It is often associated with bone loss or destruction, with the bone providing the source of the elevated serum calcium. Conditions associated with metastatic calcinosis include parathyroid neoplasms, primary hyperparathyroidism, chronic renal failure, hypervitaminosis D, sarcoidosis, and excessive intake of milk and alkali. Destruction of bone by osteomyelitis, leukemia, Paget disease of the bone, myeloma, and metastatic carcinoma may lead to elevated serum calcium and metastatic calcification. In calcinosis cutis with hyperparathyroidism, many skin manifestations are seen, with small, firm, white papules, about 1–4 mm in diameter, occurring symmetrically in the popliteal fossae, over the iliac crests, and in the posterior axillary lines. At times, metastatic calcinosis cutis localizes to areas of damaged elastic tissue (e.g., striae, solar elastosis).

The most common metabolic condition associated with metastatic calcification is renal failure. Usually, there is an elevated phosphorus level and secondary hyperparathyroidism, resulting in high calcium and phosphorus production and deposition of calcium phosphate in tissues. Less often, cutaneous calcification in renal disease can occur with normal serum calcium and phosphorus levels. Three forms of cutaneous calcification in renal

disease have been described: tumoral calcinosis, calcifying panniculitis, and calciphylaxis. Tumoral calcinosis is a rare complication of renal disease. Managing the metabolic abnormalities may lead to resolution of the large deposits of calcium.

Often, calcifying panniculitis and calciphylaxis occur in the same patient at the same time, suggesting a common pathogenesis. Isolated, firm, indurated nodules, usually on the legs or thighs in the subcutaneous fat, have been called calcifying panniculitis. Usually these are seen with the most severe complication of the abnormal calcium and phosphorus metabolism of renal disease, calciphylaxis. This life-threatening condition leads to livedo reticularis and ischemic tissue necrosis (see Chapter 35).

IATROGENIC AND TRAUMATIC CALCINOSIS CUTIS

Medical procedures that may inadvertently introduce calcium into tissue, in association with tissue trauma, may lead to cutaneous calcification. This has been reported after extravasation of calcium chloride or calcium gluconate infusion and after electroencephalography or electromyography. Electrode paste is high in calcium, and the skin is traumatized during the procedure, leading to calcifications at the sites of electrode insertion. The most common setting is on the scalp of children. Performing frequent heel sticks in neonates has led to similar lesions that are characteristically on the side of the heel. Injections of low-molecular-weight calcium–containing heparins in patients with renal failure may result in calcification at the sites of injection. Frequent subcutaneous injection of interferon beta in the abdomen has resulted in localized calcification in the fat. Lesions spontaneously resolve over months. Topical thiosulfate has also been reported to help speed resolution.

During liver transplantation, hypocalcemia can result from calcium chelation by the citrate in transfused blood products. Intravenous calcium infusions are regularly given. Calcifications on the upper extremities have been reported, occurring 1–3 weeks after transplantation and resolving over 6 months.

Traumatic calcinosis may occur as a result of occupational exposure to calcium-containing materials, as in the cases reported in oil-field workers and coal miners. Exposure of the skin to cloth sacks of calcium chloride, limewater compresses, and refrigerant calcium chloride can all cause calcinosis cutis.

IDIOPATHIC CALCINOSIS CUTIS

Idiopathic Scrotal Calcinosis

Idiopathic scrotal calcinosis is the most common form of idiopathic calcinosis cutis. Lesions present in young to middle-aged adult men as multiple, asymptomatic, firm, round, yellow papules from several millimeters up to 1 cm in diameter (Fig. 26.13). The papules resemble infundibular follicular cysts. Similar lesions, usually 1 mm to several millimeters in size, may be seen rarely in girls or women on the labia majora. In men with scrotal lesions, similar lesions rarely will be found on the shaft of the penis, termed idiopathic calcinosis cutis of the penis. Calcinosis of the areola can have a similar appearance and is extremely rare. Histologically, localized deposits of calcium are surrounded by a foreign body reaction. At least some are calcified scrotal infundibular cysts. Why they have such a high proclivity to calcification at this anatomic location is unclear. Treatment is not required, but surgical removal cures individual lesions.

Subepidermal Calcified Nodule and Milia-Like Idiopathic Calcinosis Cutis

These two similar conditions are uncommon but distinct types of idiopathic calcinosis. Subepidermal calcified nodule occurs most frequently as one or a few lesions on the eyelid, scalp, or face of children (Fig. 26.14) and occasionally adults. Males outnumber females by almost 2:1, and the average age at onset is 7 years. Lesions present as fixed, noninflamed papules that closely resemble those of molluscum contagiosum with a central umbilication. The affected children usually do not have an underlying medical condition. The differential diagnosis includes pilomatrixomas, which also commonly occur on the head and neck, including the eyelids.

A similar condition, milia-like idiopathic calcinosis cutis, has a wider distribution; eyelids, hands, feet, elbows, and knees are common sites. Two thirds of patients have Down syndrome. Treatment is not required, but surgical removal will cure any individual lesion.

Fig. 26.13 Scrotal calcinosis.

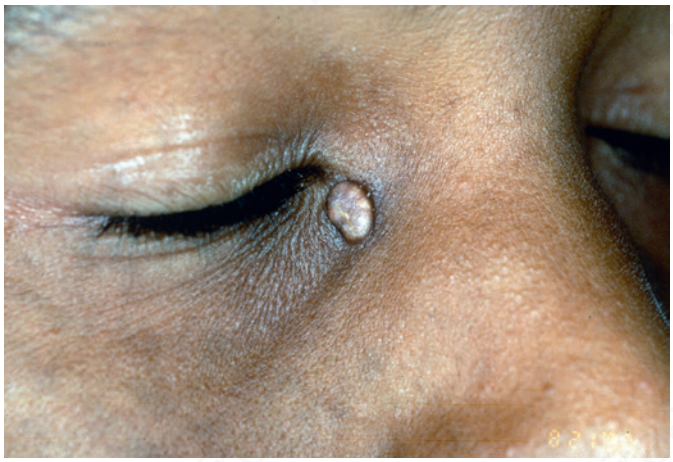

Fig. 26.14 Subepidermal calcified nodule.

Tumoral Calcinosis

Investigation of the rare cases of tumoral calcinosis, discovery of the causal genes, and development of animal models have led to improved understanding of the mechanisms of ectopic mineralization. Familial tumoral calcinosis has two genetic causes.

Normophosphatemic familial tumoral calcinosis (NFTC) is seen in young adults, primarily of African descent. Lesions are associated with antecedent trauma. The genetic cause is mutation in *SAMD9*. Hyperphosphatemic familial tumoral calcinosis (HFTC) is characterized by periarticular calcifications. Mutations in three genes have been described as causing this syndrome: fibroblast growth factor 23 (*FGF23*), *GALNT3*, and *KLOTHO*. Most patients present before the second decade of life. Three quarters of these individuals have affected siblings. Multiple lesions predominate, and there is no preceding history of trauma. The serum calcium level is normal, but serum phosphorus and calcitriol levels are elevated.

Lesions in both types present as large subcutaneous masses of calcium overlying pressure areas and large joints, usually the hips, elbows, shoulders, or knees. Skin involvement, apart from the tumoral masses, is extremely rare but may occur as localized calcinosis cutis. The internal organs are not involved, and serum calcium levels are generally normal. Surgical excision has been the mainstay of therapy; however, recurrences are frequent after incomplete removal. Various dietary restrictions to lower calcium and phosphorus intake have shown some success. The combination of a phosphate binder and a carbonic anhydrase inhibitor (acetozolamide), along with a low-phosphorus diet, has been reported to lead to significant improvement.

OSTEOMA CUTIS

Bone formation within the skin may be primary, occurring in cases with no preceding lesion; metastatic, in cases associated with abnormalities of parathyroid metabolism; or dystrophic, in which ossification occurs in a preexisting lesion or inflammatory process.

Primary osteoma cutis occurs in several clinically distinct disorders: Albright's hereditary osteodystrophy (AHO), pseudohypoparathyroidism (PHP), progressive osseous heteroplasia (POH), and widespread or single, platelike osteoma cutis (PLOC). Mutations in all four of these conditions occur in the *GNAS* gene.

Progressive osseous heteroplasia is a rare form of cutaneous ossification initially seen between birth and 6 months of age, often in the first month of life. Females are preferentially affected. Lesions begin as small papules that can coalesce to large plaques. Sometimes these plaques will have small, firm, calcified papules overlying them. Lesions are randomly distributed and may be unilateral or may involve only one anatomic area. There is no preceding trauma or inflammatory phase. Serum calcium, phosphorus, parathyroid hormone (PTH), and calcitriol are normal, but alkaline phosphatase (ALP), lactate dehydrogenase (LDH), and creatine phosphokinase (CPK) may be elevated, indicating increased bone formation (ALP) or muscle destruction (CPK and LDH). Histologically, the lesions reveal intramembranous bone formation and can affect the soft tissues as well as skin. Only calcification without ossification may be found in superficial dermal biopsies, so a deep biopsy, including subcutaneous fat, may be required to confirm the diagnosis. The condition is progressive and can lead to serious sequelae, including ulceration, infection, and severe pain. Plate-like osteoma cutis occurs in newborns or young children, but also in adults. It is not associated with dysmorphic features or abnormalities of calcium or phosphorus metabolism, but shows intramembranous bone formation histologically. These disorders are most likely polar ends of a spectrum of disease; one family has been described with members having either condition. AHO is characterized by childhood development of intramembranous bone formation in the dermis and subcutaneous tissue (see Chapter 24). The cutaneous ossifications may be noted soon after birth and are usually multiple, small, superficial plaques that favor the scalp, hands, feet, periarticular regions, abdomen, and chest wall. Small lesions are of little consequence, but large subcutaneous masses may disrupt underlying structures. The patient may have characteristic dysmorphic features and pseudohypoparathyroidism or pseudopseudohypoparathyroidism. AHO also is associated with mutations of the *GNAS1* gene.

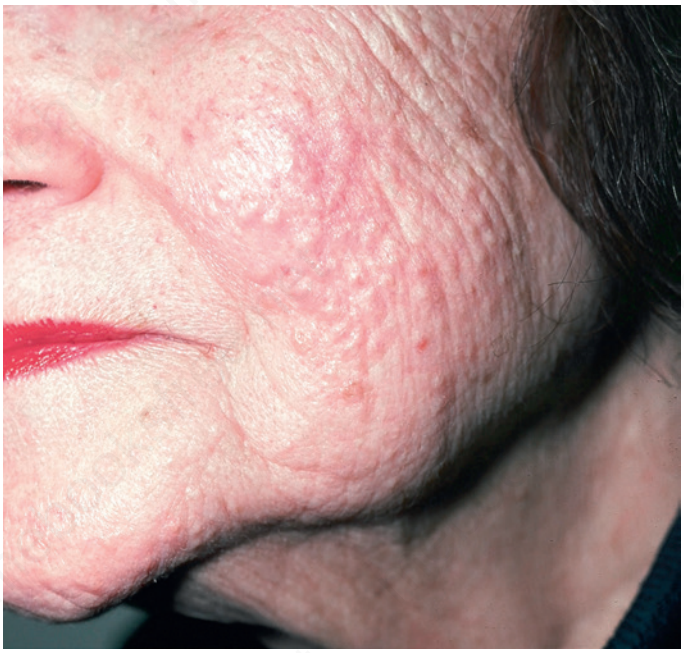

Fig. 26.15 Osteoma cutis. (Courtesy Dr. Don Adler.)

Multiple miliary osteomas of the face are clinically the most common form of osteoma cutis. These are usually seen in women (Fig. 26.15). The osteomas probably represent dystrophic ossification because they occur in patients with acne, are localized to the face, and are associated with acne scars. If oral tetracycline or minocycline is taken to treat the acne, the cutaneous osteomas may be pigmented or may fluoresce under Wood's light. Improvement with topical tretinoin, erbium:YAG laser, or incision, curettage, and primary closure has been reported.

LIPID DISTURBANCES

XANTHOMAS

Xanthomas are deposits of lipids in tissue. For the dermatologist, the important areas to look for lipid deposits are on the skin, tendon, and eyes. Xanthomas appear when abnormalities of lipid amount or processing occur in the body and thus are important markers of underlying dyslipidemia and potentially increased cardiovascular risk. The histologic features in all varieties of xanthoma are similar, characterized by the presence of numerous large, xanthoma or foam cells, that are phagocytes (fat-laden histiocytes). The cells may be multinucleated. In addition to the foam cells, touton giant cells can occur. Clefts representing cholesterol and fatty acids dissolved by processing agents may be noted. Generally, a connective tissue reaction occurs around the nests of foam cells, and in old lesions, most of the foam cells are replaced with fibrosis. CD68 and adipophilin immunoperoxidase may aid in identifying foam cells.

In addition to inherited genetic defects of molecules involved in lipid homeostasis, systemic diseases (e.g., diabetes mellitus) and medications (e.g., systemic retinoids) can also cause hyperlipidemias and result in xanthomas especially in people who have some genetic predisposition. The names of the various forms of cutaneous xanthomas are based on clinical morphology. Numerous genetic mutations that result in hyperlipidemias have been identified. Several different genetic diseases may present with similar cutaneous xanthoma patterns, so referral to a "lipid" clinic is recommended for xanthoma patients with familial patterns of hyperlipidemia, as well as for those without an obvious medical cause for their dyslipidemia. The morphologies are relatively specific for the associated elevated lipid, or triglycerides. The clinical phenotype of the lesions will be discussed first and then the syndromes associated with each type of xanthoma are reviewed.

Lipids can either be endogenous or exogenous (ingested). Exogenous lipids in the diet are absorbed and incorporated into triglyceride-rich chylomicrons. These are hydrolyzed by the action of lipoprotein lipase and certain cofactors, including apoprotein CII. The resulting remnants are taken up by the liver. Endogenously produced very-low-density lipoproteins (VLDLs) are synthesized in the liver and, again through the action of lipoprotein lipase. They are converted to cholesterol-rich IDLs and eventually into low-density lipoproteins (LDLs). These are then available for uptake by peripheral tissues, as well as by the liver. Specific receptors in different tissues guide uptake of LDL, IDL, and chylomicron remnants. Abnormalities of lipoprotein lipase, the apolipoproteins, cofactors, receptors, or stimulators or retarders of endogenous production or catabolism, whether on a genetic or a sporadic basis, may accelerate or block the pathway in different areas. If blockade occurs early and results in elevation of triglyceride-rich particles, eruptive xanthoma may result. If a defect occurs later in the pathway and cholesterol-rich particles accumulate, xanthelasma, tuberous xanthomas, and tendinous xanthomas should be expected, along with premature atherosclerotic cardiovascular disease.

Xanthoma Tuberosum

Tuberous xanthomas are variously found as flat or elevated and rounded, grouped, yellowish or orange nodules located over the joints, particularly on the elbows and knees (Fig. 26.16). The lesions are indurated and tend to coalesce. They may also occur over the face, knuckles, toe joints, axillary and inguinal folds, and buttocks. Solitary lesions may be found. Early lesions are usually

Fig. 26.16 Tuberous xanthomas.

Fig. 26.17 Tendinous xanthomas.

bright yellow or erythematous; older lesions tend to become fibrotic and lose their color. Pedunculated, fissured, and suppurative nodules may also be seen.

Xanthoma Tendinosum

Papules or nodules 5–25 mm in diameter are found in the tendons, especially in extensor tendons on the backs of the hands and dorsa of the feet and in the Achilles tendons (Fig. 26.17). These predominate in conditions with elevated LDL cholesterol (see later discussion) and can be seen in association with tuberous xanthomas and xanthelasma. The lesions also occur in obstructive liver disease, diabetes, myxedema, cerebrotendinous xanthomatosis, and phytosterolemia.

Palmar Xanthomas

Palmar xanthomas consist of nodules and irregular yellowish plaques involving the palms and flexural surfaces of the fingers. Striated

Fig. 26.18 Palmar xanthomas in biliary cirrhosis. (Courtesy Steven Binnick, MD.)

Fig. 26.19 Plane xanthoma. (Courtesy Dr. Debabrata Bandyopadhyay.)

xanthomas appear as yellowish streaks that follow the distribution of creases of the palms and soles (Fig. 26.18). These lesions are seen in familial dysbetalipoproteinemia, multiple myeloma, and primary biliary cirrhosis. In patients with primary hyperlipoproteinemias, palmar xanthomas have been proposed to be pathognomic of familial dysbetalipoproteinemia.

Xanthoma Planum (Plane Xanthoma)

Plane xanthomas appear as flat macules or slightly elevated plaques with a yellowish tan or orange coloration of the skin spread diffusely over large areas. Characteristically, plane xanthomas may occur around the eyelids, neck, trunk, shoulders, or axillae (Fig. 26.19). These well-defined macular patches may be situated on the inner surface of the thighs and antecubital and popliteal spaces. Although these can be seen as a complication of elevated lipid levels, as in primary biliary cirrhosis, they are the one form of xanthoma that may not be associated with increased lipids. Normolipemic plane xanthomas are most frequently seen in patients with myeloma or a monoclonal gammopathy and less often in other myelodysplasias, such as mycosis fungoides, lymphoma, leukemia, and adult T-cell lymphoma/leukemia caused by human lymphotropic virus type 1 (HTLV-1). In myeloma and monoclonal gammopathy,

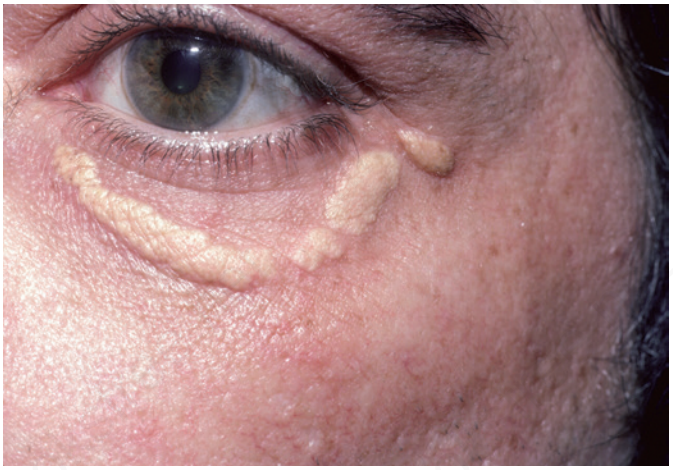

Fig. 26.20 Xanthelasma.

Fig. 26.21 Eruptive xanthomas.

the paraprotein complexes with LDL, and these complexes are phagocytosed by histiocytes in tissue, forming the plane xanthomas. In patients with monoclonal gammopathy–associated xanthoma, a reduced CH50 and reduced C4 (both in 80% of patients) are also usually detected, as well as a decreased C1 inhibitor level (50%) and the presence of a cryoglobulin (30%). Treatment of the underlying myelodysplasia may lead to resolution of the xanthomas.

A rare form of normolipemic xanthomatosis can occur in childhood termed *normolipemic papuloeruptive xanthomatosis.* Yellowish papules 2–5 mm in diameter occur on the face. They can coalesce to form large confluent plaques, especially on the face, nape of the neck, and axillae. Spontaneous involution occurs. It is unclear whether this is a rare disease in its own right or a variant of benign cephalic histiocytosis or papular xanthoma of childhood.

Xanthelasma Palpebrarum (Xanthelasma)

Xanthelasma is the most common type of xanthoma. It occurs on the eyelids and is characterized by soft, chamois-colored or yellowish orange oblong plaques, usually near the inner canthi (Fig. 26.20). They usually appear between ages 40 and 60. The xanthelasmas vary from 2–30 mm in length and are usually symmetric. Xanthelasmas are typically seen without other forms of xanthomas and often with "normal" lipids. In 60% of xanthelasma patients, however, dyslipidemia is detected. New patients with xanthelasma should be evaluated with a full lipoprotein profile, as well as a careful history and physical examination. Consultation with a lipid clinic may be appropriate. Early (childhood) onset of xanthelasma should suggest a hereditary lipid abnormality, especially familial hypercholesterolemia. Xanthelasma has been reported after injection of hyaluronic acid and polymethacrylate collagen fillers.

Treatment of xanthelasma is discussed here because of its uniqueness among the xanthomas, in that surgical therapy is often successful. The best method is surgical excision. The anesthetized lesion is grasped with mouse-tooth forceps and clipped off with scissors, and the skin edges are undermined and sutured. Excellent cosmetic results are obtained, even if the wound is not closed. Fulguration, trichloroacetic acid cauterization, and carbon dioxide (CO_2), erbium:YAG, or Nd:YAG laser therapy are other methods. Complete removal of the lesions does not preclude the possibility that other new lesions will develop.

Eruptive Xanthoma

Xanthoma eruptivum consists of small, yellowish orange to reddish brown papules that appear in crops over the entire body (Fig. 26.21). The papules may be surrounded by an erythematous halo and may be grouped in various favored locations, such as the buttocks, extensor surfaces of the arms and thighs, knees, inguinal and axillary folds, and oral mucosa. Koebnerization may occur. Pruritus is variable. Eruptive xanthomas strongly suggest the presence of elevated triglyceride levels. Eruptive xanthomas are seen most often in poorly controlled type 2 diabetes mellitus but can also be seen in chronic renal failure, hypothyroidism, and treatment with estrogens, corticosteroids, or systemic retinoids.

PRIMARY HYPERLIPOPROTEINEMIAS

Lipoproteins are responsible for carrying fat molecules in the blood, and the β-lipoproteins (VLDL, LDL, IDL, and chylomicron) have ApoB on their surface so they can invade into the intima of blood vessels and lead to artherosclerotic plaques. α-Lipoproteins (HDL) are antiartherogenic. Frederickson classified hyperlipoproteinemias into six types on the basis of electrophoretic patterns, now called the World Health Organization International Classification of Diseases (WHO ICD) hyperlipoprotein (HLP) phenotypes, as follows.

- HLP1/type I (chylomicronemia): excess chylomicrons (triglycerides).
  - Clinical: There are monogenic as well as polygenic forms. The monogenic familial forms present in childhood and the polygenic forms typically require a secondary illness such as diabetes to unmask the predisposition toward hypertriglyceridemia. Familial monogenic chylomicronemia (hypertriglycerideamia) is caused by many different gene mutations including lipoprotein lipase deficiency. With levels of triglycerides above 1000 mg/dL, a high risk of pancreatitis and eruptive xanthomas exists (Fig. 26.22). This monogenic familial version often manifests in early childhood with xanthomas, pancreatitis, lipema retinalis, abdominal pain and failure to thrive. Alipogene tiparvovec is a gene therapy available to treatment.
- HLP2A/type IIa (familial hypercholesterolemia): excess β-lipoprotein (LDL predominantly).
  - Familial hypercholesterolemia (FH) has an HLP2A (Frederickson type IIa) lipid profile. It is caused by mutations in multiple genes, most often the LDL receptor. One in 500 persons carry a mutation in this gene, and these heterozygotes present with planar, tendon, or tuberous xanthomas from age 30–60. Their LDL cholesterol is two to three times normal, and they have a twofold to threefold increase in cardiovascular disease. People with homozygous recessive

Fig. 26.22 Eruptive xanthomas in lipoprotein lipase deficiency.

Fig. 26.23 Homozygous hypercholesterolemia with intertriginous xanthomas.

defects in LDL receptor gene will present in childhood (teens or early twenties) with xanthomas, LDL cholesterol four to six times normal, and cardiovascular disease with aortic stenosis. Homozygous FH patients may have large xanthelasmas (xanthomatous pseudospectacles) and xanthomas of the interdigital web spaces and the gluteal cleft (Fig. 26.23). Statin medications have less effect due to the lack of LDL receptor, but a medication (evinacumab) that targets angiopoietin-like 3 (a liver-secreted protein that increases LDL and VLDL in blood) was effective in a small series.

- HLP2B/type IIb (familial combined hyperlipidemia): excess β-lipoprotein (VLDL and LDL).
  - Clinical: similar to the polygenic HLP1 there is typically a secondary event such as diabetes or metabolic syndrome that leads to artherosclerosis but xanthomas are less common.
- HLP3/type III (familial dysbetalipidemia): increased IDL and chylomicron remnants.
  - Clinical: eruptive or tuberous xanthomas. Planar and palmar crease xanthomas also noted and the latter have been deemed pathognemonic for HLP3
- HLP4/type IV: increased pre–β-lipoprotein (VLDL).
  - Clinical: increased cardiovascular risk along with hypertension and hyperuricemia.
- HLP5/type V (mixed dyslipidemia): increased pre–β-lipoproteins (VLDL) and chylomicrons.
  - Clinical: Presentation typically in adults. Risk for pancreatitis due to eruptive xanthoma, hepatosplenomegaly, or lipema retinalis.

Familial Apoprotein CII Deficiency

Patients with the rare familial apoprotein CII deficiency lack lipoprotein lipase activator and have very high triglyceride levels, up to 10,000 mg/dL. They are at risk for pancreatitis and eruptive xanthomas.

SECONDARY HYPERLIPOPROTEINEMIA

Obstructive Liver Disease (Xanthomatous Biliary Cirrhosis)

Lipoprotein X is an aberrant protein formed when there is biliary obstruction of multiple different etiologies including primary biliary cirrhosis and Alagille syndrome. Lipoprotein X has the ability to carry large quantities of free cholesterol and phospholipids, but when oxidized in the periphery and taken up by macrophages it leads to foamy macrophages that can be detected in xanthomas. The xanthomatous lesions are plane xanthomas, with lesions on the face, flexor surfaces of the extremities, and trunk. Striate palmar and plantar lesions and xanthelasmas can also be seen. Tuberous xanthomas may occur. Pruritus is extremely severe. Hepatomegaly and jaundice are present. Cholestyramine can help in allaying pruritus. The triglycerides are not elevated, and the plasma is clear, showing no chylomicrons, giving a type II lipoprotein pattern.

Alagille syndrome is a congenital disorder characterized by intrahepatic bile ductular atresia, patent extrahepatic bile ducts, a characteristic facies (prominent forehead, deep-set eyes, straight nose, and small, pointed chin), cardiac murmur, vertebral and ocular abnormalities, low intelligence, and hypogonadism. It is an autosomal dominant inherited condition. There is persistent cholestasis early in life, with pruritus and hyperbilirubinemia. Lipid levels increase by age 2 years, and planar or papular xanthomas may occur. Alagille syndrome is treatable with cholestyramine and fat-soluble vitamins leading to long-term improvement.

Pancreatitis

Hyperlipidemia in the hyperchylomicronemic syndromes (HLP types I and V) may cause pancreatitis; it may be recurrent, and pancreatic necrosis and death may occur. Alternatively, pancreatitis may cause type I or V hyperlipoproteinemia by inducing insulin deficiency and a relative lack of lipoprotein lipase activity. A triglyceride level of 1000 mg/dL is required for pancreatitis to occur in the setting of hypertriglyceridemia. The amylase may be normal, but the lipase will be elevated.

Medication-Induced Hyperlipoproteinemia

Estrogens, by decreasing lipoprotein lipase activity and increasing VLDL synthesis, may cause HLP1 or HLP5 patterns. Eruptive xanthomas may occur. Oral prednisone may induce insulin resistance and cause HLP4 or HLP5 patterns to develop. Oral retinoids, indomethacin, protease inhibitors for HIV, and olanzapine may also cause eruptive xanthomas through hypertriglyceridemia.

Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis is a rare autosomal recessive disease caused by an accumulation of cholestanol in plasma lipoproteins, brain, and xanthomatous tissue. The underlying abnormality is a mutation in the sterol 27-hydroxylase gene

(*CYP27A1*) in the mitochondria, leading to incomplete oxidation of cholesterol to bile acids. As a result, cholestanol, an intermediate, accumulates in tendons, brain, heart, lungs, and the lens of the eye. The disorder is characterized by prominent tendinous xanthomas, especially of the Achilles tendons (not present in all patients), macroglossia, progressive neurologic dysfunction in many forms, infantile diarrhea, developmental cataracts, and atherosclerotic coronary artery disease. Plasma cholestanol is elevated and can exceed more than 10 times normal levels. Patients with cerebrotendinous xanthomatosis are treated with chenodeoxycholic acid, and early treatment can prevent the progressive neurologic impairment.

Sitosterolemia (Phytosterolemia)

In sitosterolemia, a rare autosomal recessive disorder, plasma plant sterols are extremely elevated (>30 times normal). This disorder is caused by mutations in the genes encoding the ABCG5 and ABCG8 transporters, which are expressed only in the intestine and liver. In the intestine, they pump plant sterols and cholesterol out of intestinal cells back into the lumen of the gut, limiting sterol and cholesterol absorption. In the liver, they pump plant sterols into the bile, aiding in their excretion. Absence of either of these genes results in increased absorption and decreased excretion of plant sterols, leading to their accumulation in the body. There is also excess absorption of cholesterol leading to somewhat elevated LDL levels. Patients develop tendinous xanthomas, xanthelasma, and tuberous, intertriginous, and palmar xanthomas (similar to HLP IIa familial hypercholesterolemia). The diagnosis of sitosterolemia should be considered in any child or adolescent with xanthomas and an LDL less than 130–400 (thus lower than would be expected with homozygous LDL receptor mutation). It can also present as dietary-responsive hypercholesterolemia in infancy. Phytosterolemia can also mimic FH in the adult because most patients also have type IIa hyperlipoproteinemia and accelerated atherosclerosis due to the enhanced absorption of cholesterol. Treatment is dietary restriction of plant sterols, cholesterol, and some shellfish (clam, oysters, scallops) whose sterols are also hyperabsorbed. In addition, bile sequestrants (chenodeoxycholic acid) can be used. Ezetimibe, an inhibitor of NPC1L1 (Niemann-Pick C1-like 1), inhibits absorption of plant sterols and can be effective in reducing plasma sterol levels.

Verruciform Xanthoma

Verruciform xanthoma (VX) is an uncommon lesion that occurs as a reddish or light orange hyperkeratotic plaque or papillomatous growth with a pebbly or verrucous surface. The most common site is the oral mucosa. VX has also been reported on other mucosal surfaces, genitalia (Fig. 26.24), lower extremities, and elsewhere. On the external genitalia in men, the lesions frequently resemble condylomata acuminata and are not associated with any other condition. Disorders with damage of the papillary dermis have been associated with VX, including recessive dystrophic epidermolysis bullosa, lymphedema, and GVHD. Similarly, vulvar VX have been associated with lichen sclerosus, lichen planus, Paget disease, and radiodermatitis. Additionally, VX has been reported in a patient with psoriatic lesions undergoing PUVA therapy and in psoriasiform skin lesions in an HIV-positive patient. Histologically, there is acanthosis without atypia, parakeratosis, and xanthoma cells in the papillary dermis. In CHILD syndrome (congenital hemidysplasia with ichthyosiform erythroderma and limb defects) the blaschkoid epidermal lesions have histologic characteristics of VX. In a small percentage of VX patients, a mutation in the *NSDHL* gene (3β-hydroxysteroid dehydrogenase) has been found. This gene is also mutated in CHILD syndrome, explaining why it and VX share the same histology. In one child, a genital VX responded to topical imiquimod treatment.

Fig. 26.24 Verruciform xanthoma.

Familial α-Lipoprotein Deficiency (Hypoalphalipoproteinemia, Tangier Disease)

Tangier disease is caused by mutations in the cell membrane protein ABCA1, which mediates the secretion of excess cholesterol from cells into the HDL metabolic pathway. This results in a profound deficiency of HDL and accumulation of cholesterol in tissue macrophages. The characteristic clinical finding is enlarged yellow tonsils from accumulation of lipid in this localized area. Xanthomas do not occur, but there is diffuse accumulation of cholesterol esters in the skin, as well as in the intestines, thymus, bone marrow, lymph nodes, and spleen. Peripheral neuropathy, splenomegaly (with thrombocytopenia), and premature coronary artery disease are other features of Tangier disease.

NIEMANN-PICK DISEASE

Niemann-Pick disease is a rare autosomal recessive condition originally described in people of Ashkenazi Jewish descent that has three recognized subtypes. Type A and type B are both caused by mutations in the acid sphingomyelinase gene (*SMPD1*). There can be hyperlipidemia with rarely associated xanthomatous lesions, including xanthomas and xanthogranulomas, in addition to waxy yellow-brown skin. Type A is more severe, presents in infancy with neurovisceral disease, and is often fatal, and skin manifestations may arise. Type B is purely visceral (nonneurologic), and survival into adulthood is characteristic and lichen nitidus has been reported. Histologically, foamy histiocytes are found, which on electron microscopy have characteristic cytoplasmic inclusions. Niemann-Pick disease type C is caused by mutations in the *NPC1* and *NPC2* genes, which are involved in endosomal-lysosomal cholesterol trafficking. Type C is a neurovisceral disease with a variable age of onset and neurodegenerative course. Patients may present from the perinatal period to adulthood. Cholestatic jaundice is characteristic.

GAUCHER DISEASE

Although rare, Gaucher disease is the most common lysosomal storage disease and occurs most frequently among people of Ashkenazi Jewish descent. It is an autosomal recessive disorder caused by insufficient activity of the lysosomal enzyme acid β-glucosidase (glucocerebrosidase, GBA, glucosylceramidase). Lysosomal accumulation of glucosylceramide, the substrate of GBA in macrophages, causes the disease manifestations. In rare cases, Gaucher disease is caused by mutations in the prosaposin gene, which encodes the saposin C activator protein that is necessary for optimal activity of β-glucosidase. Gaucher cells are identified histologically as large macrophages, 20–100 μm in diameter, with one nucleus or a few small nuclei, and pale cytoplasm that stains faintly for fat but is PAS positive.

Gaucher disease occurs at any age, but three types are recognized: type 1 (adult form), without neurologic involvement; type 2, the infantile form, with acute early neurologic manifestations;

Fig. 26.25 Pigmentation of the lower leg in Gaucher disease.

and type 3, the juvenile chronic neuropathic form. The diagnosis is confirmed by genetic testing. Some type 2 patients are born with a collodion membrane, and there is one report of blueberry muffin lesions. The collodion can transition into and ichthyosis that precedes neurologic manifestations thus can be helpful in diagnosis. Epidermal ultrastructural and biochemical abnormalities occur in all type 2 patients. Hepatosplenomegaly, osteopenia/osteoporosis of the long bones, pingueculae of the sclera, and a distinctive bronze coloration of the skin from melanin characterize the adult type. A deeper pigmentation may extend from the knees to the feet (Fig. 26.25). This is often caused by hemosiderin and may be accompanied by thrombocytopenia and splenomegaly.

Therapy for Gaucher disease types 1 and 3 now consists of enzyme replacement therapy (ERT) with intravenous mannose-terminated glucocerebrosidase; ERT does not benefit type 2 patients. ERT is successful in treating some of the manifestations of the adult form (Gaucher disease type 1). Substrate reduction therapy using the glycolipid synthesis inhibitor *N*-butyldeoxynojirimycin (miglustat) is also available.

Adult patients with Gaucher disease can develop monoclonal gammopathy, myelodysplasia (myeloma or lymphoma). Heterozygous carriers of GBA mutations are frequently found in patients with Parkinson disease. Parkinson disease is associated with certain "pathogenic" variant GBA mutations.

LIPOID PROTEINOSIS

Also known as Urbach-Wiethe disease and hyalinosis cutis et mucosae, lipoid proteinosis is a rare autosomal recessive condition that usually presents in infancy with a hoarse cry or voice (99%). Mucosal lesions include yellowish white infiltrative deposits on the inner surface of the lips (Fig. 26.26), undersurface of the tongue, buccal mucosa, fauces, and uvula. Inability to protrude the "woody" tongue because of frenulum shortening is characteristic. Xerostomia may occur. In childhood, beaded eyelid papules are seen in over 90% (Fig. 26.27). Uveitis and hyaline deposits on and in the eye may develop. Waxy, yellow papules and nodules with generalized skin thickening occur. Mechanical friction leads to hyperkeratosis of the hands, elbows, knees, buttocks, and axillae. Acral hyperkeratotic papules occur in about 20% of patients and

Fig. 26.26 Lipoid proteinosis.

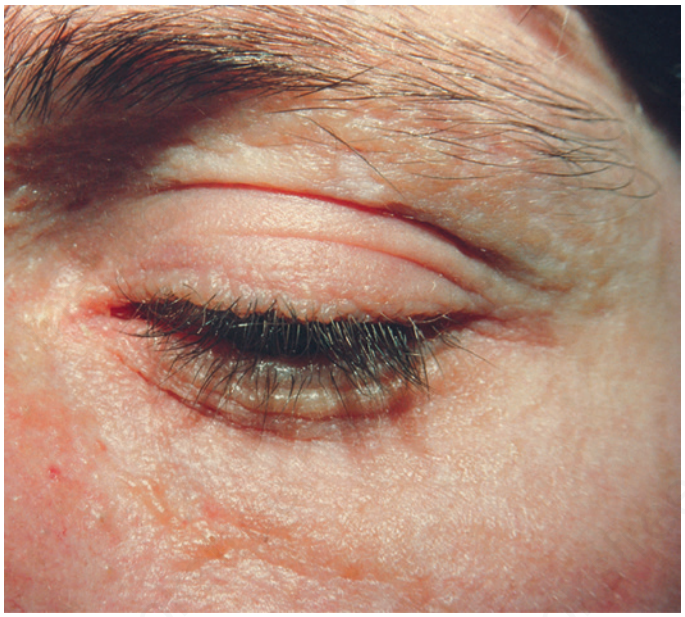

Fig. 26.27 Papules of the eyelid in lipoid proteinosis. (Courtesy Dr. Eric Krause.)

have been described as "verrucous." In fact, in some patients these lesions are induced by human papillomavirus (HPV). In one patient with lipoid proteinosis, epidermodysplasia verruciformis was diagnosed. Minor trauma leads to bullae that heal with pocklike or acnelike scars, especially on the face. This may be related to the increased risk for bacterial skin infections in these patients. Scalp involvement may lead to mild loss of hair. Neurologic sequelae include epilepsy, dystonia, and cognitive impairments.

Distinctive histologic features include extreme dilation of the blood vessels, thickening of the vessel walls, progressive hyalinization of sweat glands, and infiltration of the dermis and subcutaneous tissue with extracellular hyaline deposits. Normal skin and mucous membranes also show changes of endothelial proliferation of the subpapillary vessels and a homogeneous thickening of the walls of the deeper vessels. Type IV collagen and laminin are increased around blood vessels.

Lipoid proteinosis is caused by mutations in the extracellular matrix protein 1. This protein binds to heparin sulfate proteoglycans, which are also the binding substances for HPV, perhaps explaining the frequency of HPV infection. Differentiation from erythropoietic protoporphyria may be difficult, especially histologically.

Numerous patients with lipoid proteinosis have been treated with systemic retinoids with positive results. A dose of about 0.5 mg/kg of acitretin is well tolerated and effective. Hoarseness improves in most patients, palmar and plantar hyperkeratosis is reduced, and patients may note reduction in skin blisters. Oral ulcerations improve. Earlier treatment (before age 11) was associated with a better response. Histologically, the epidermis is less thick, but the hyaline deposition is unchanged. Although death from respiratory obstruction occasionally occurs in infancy, the disease is otherwise compatible with a normal life span.

ANGIOKERATOMA CORPORIS DIFFUSUM (FABRY DISEASE)

Fabry disease (FD) is a rare X-linked lysosomal storage disease. It is caused by mutations in the α-galactosidase A gene (*GLA*), leading to a deficiency in α-galactosidase A. This results in the inability to catabolize glycosphingolipids, and globotriaosylceramide accumulates in lysosomes in many tissues, including endothelial cells, erector pili muscles, dorsal root ganglion nerves, and visceral organs. Males are affected more severely and earlier. Female heterozygotes (carriers of the defective gene) can have a broad spectrum of disease, from asymptomatic to disease as severe as males, depending on patterns of lyonization. This can make confirming the diagnosis of FD in a female with limited cutaneous and visceral disease quite difficult.

Skin lesions are common, and in about one quarter of male patients a dermatologist makes the diagnosis. The most characteristic skin lesions are widespread punctate telangiectatic vascular papules that on first inspection suggest purpura, but are actually angiokeratomas. Some show hyperkeratotic tops, but these are less prominent than in other forms of angiokeratoma. Angiokeratomas occur in 66% of male and 36% of female patients with FD. The average age of onset in males is about age 20 and in females, about 10 years later. Lesions can be present as early as age 1 year. Lesions tend to occur in the "bathing trunk" area, from the umbilicus to the genitalia, where they may be present in large numbers (Fig. 26.28). Smaller "macular angiomas" are seen, especially on the proximal limbs, palms, and soles, around the nailfolds of the digits, and on the vermilion border of the lips. Telangiectasias occur in about 25% of men presenting about age 25 and in women about age 40. Vascular tortuosities of the upper eyelid are seen in 95% of FD patients, with 40% showing microaneurysms. The ophthalmologist should examine for these lesions when screening for the characteristic corneal opacities.

Other skin manifestations of FD include lower limb edema and lymphedema. Leg ulceration can occur. Hair growth is scanty. Lack of sweating can lead to overheating. Hypohidrosis is reported

Fig. 26.28 Fabry disease. (Courtesy Ken Greer, MD.)

by 50% or more of male and about one third of female patients, starting in their twenties. Anhidrosis occurs in 25% of male patients. About 12% of female and 6% of male patients complain of hyperhidrosis.

Visceral disease is common, especially of the kidneys, cardiovascular system, nervous system, and GI tract, although only one organ may be involved. Abdominal pain, nausea, vomiting and diarrhea can all occur. Proteinuria followed by renal failure may begin as early as the second decade and typically presents around age 40. Cardiovascular events (myocardial infarction, arrhythmia, angina, congestive heart failure) typically appear around age 40, contributing to premature death. About 5% of men and women have a cerebrovascular accident (stroke) around age 40 that is often "cryptogenic."

Neuropathic pain is the most common initial presentation, affecting about two thirds of FD patients. It may begin in childhood, but its nonspecific nature and the lack of physical findings delay the diagnosis, usually by more than a decade, until other stigmata appear. Thermohypesthesia is often present. The acroparesthesia or burning pain affects primarily the longest nerves and is severest on the hands and feet. This is similar in distribution to erythromelalgia. The pain in fabrys may be transient or may last for hours. Treatment is as for neuropathy, with tricyclics, gabapentin, capsaicin, and anticonvulsants. About 25% of FD patients develop carpal tunnel syndrome. Cramps and fasciculation may be the presenting neurologic symptoms. Female patients may be misdiagnosed as having multiple sclerosis.

Distinctive whorl-like opacities of the cornea occur in 90% of patients, and 50% develop characteristic spokelike cataracts in the posterior capsular location. Telangiectasias may be present on the conjunctiva and in the eye.

The diagnosis of FD may be confirmed by finding diminished levels of α-galactosidase A in leukocytes, serum, fibroblasts, or amniotic fluid cells. Less than 10% enzyme activity is usually detected in affected males. In females, the diagnosis requires the identification of a genetic mutation in the *GLA* gene. This can be quite difficult if an affected male relative is not identified, because hundreds of *GLA* mutations have thus far been described that cause FD.

Histologically, there is dilation of capillaries in the papillary dermis, resulting in endothelium-lined lacunae filled with blood and surrounded by acanthotic and hyperkeratotic epidermis. Electron microscopy reveals characteristic electron-dense bodies in endothelial cells, pericytes, erector pili muscles, and fibroblasts. They are also present in normal skin of affected adults and children.

Enzyme replacement therapy is safe and can reverse substrate storage in the lysozyme. ERT leads to a reduction in neuropathic

pain, relief of GI symptoms, and stabilization of cardiomyopathy; left ventricular mass decreases. Stroke and vascular coronary disease still occur, but perhaps at a lower rate. Early treatment may be more effective in preventing progression of FD.

Although widespread angiokeratomas are typical of FD, patients with other rare autosomal recessive lysosomal storage diseases, such as galactosialidosis, aspartylglycosaminuria, GM1 gangliosidosis (β-galactosidase deficiency, which may also manifest extensive dermal melanocytosis), and α-*N*-acetylgalactosaminidase deficiency (Kanzaki disease), have been reported to have Fabry-like angiokeratomas. Also, several patients with no detectable enzyme deficiency have been reported, including a family with autosomal dominant inherited Fabry-like angiokeratomas associated with arteriovenous malformations. It should be emphasized that there are many normal patients who have widespread small, petechia-like lesions that erupt in adulthood, a variant of cherry angiomas.

FUCOSIDOSIS

Angiokeratomas identical to those of FD occur in types II and III of this rare lysosomal storage disease. Fucosidosis can be distinguished clinically by the frequent presence of facial dysmorphism, severe mental retardation, weakness, spasticity, and seizures. The most severely affected patients die in childhood (type I), without the development of typical angiokeratomas. Patients with type II disease have severe spondyloepiphyseal dysplasia and normal intelligence. The adolescent type III patient can also have angiokeratomas. Fucosidosis is autosomal recessive and is caused by a deficiency in α-L-fucosidase, usually detected in leukocytes.

SIALIDOSIS

Sialidosis (mucolipidosis type I) is an autosomal recessive lysosomal storage disease caused by mutations in the sialidase gene *NEU1*. Two types are described, the severest of which is the infantile form (type II), in which the children die within the first 2 years of life. Type I sialidosis is less severe and is characterized by mental retardation, myoclonus, cerebellar ataxia, hypotonia, skeletal abnormalities, and facial dysmorphism. Angiokeratoma can occur.

β-MANNOSIDASE DEFICIENCY

This rare autosomal recessive lysosomal storage disease of glycoprotein metabolism is caused by a deficiency of β-mannosidase that results in the accumulation of a characteristic disaccharide in the lysosomes, which may also be found in the urine. In addition to the Fabry-like angiokeratomas, mental retardation, hearing loss, aggressive behavior, peripheral neuropathy, recurrent infections, epilepsy, coarse facies, and skeletal abnormalities are often present.

SKIN DISORDERS IN DIABETES MELLITUS

Skin lesions are common in diabetic patients, with two thirds or more having at least one skin finding. Xerosis appears to be particularly common, affecting 50% of those with type 1 diabetes. Keratosis pilaris is also common. Other specific cutaneous findings of diabetes are discussed next.

NECROBIOSIS LIPOIDICA/NECROBIOSIS LIPOIDICA DIABETICORUM

Necrobiosis lipoidica (NL) is characterized by well-circumscribed, firm, depressed, waxy, yellow-brown plaques, usually of the anterior shin. Although NL can occur in persons without diabetes mellitus, 60% of cases of NL occur in insulin-dependent (type 1) diabetic patients, and 20% occur in persons at risk for the development of diabetes (who have glucose intolerance or a family history of diabetes). If NL occurs in the setting of diabetes, it is called necrobiosis lipoidica diabeticorum (NLD). In diabetics who have NL they tend to have worse hyperglycemia but also more associated autoimmune disease such as celiac. Women are affected three times more often than men; the condition usually appears between ages 20 and 40 but may occur in children or elderly people as well. The average age of onset is 34 for all diabetic patients, but 22 years, on average, in insulin-dependent patients, and 49 in non–insulin-dependent patients. Although NL is reported to affect only 0.3% of diabetic patients, the prevalence was much higher (>2%) in series of patients with type 1 diabetes. In 15%, NL precedes the onset of frank diabetes by an average of 2 years. Control of the diabetes does not influence the course of the NL.

The earliest changes are small, sharply bordered, red papules that may be capped by a slight scale and that do not disappear under diascopic pressure. Later, the lesions develop into irregularly round or oval lesions with well-defined borders and a smooth, glistening (glazed) surface. The center becomes depressed and sulfur yellow, so that a firm yellowish lesion forms, surrounded at times by a violet-red or pink border. In the yellow portion, numerous telangiectases and ectatic veins are evident. Ulceration occurs in one third of NLD patients. In an unusual case, the plaques were studded with exophytic nodules resembling tuberous xanthomas. This patient had marked hyperlipidemia, perhaps contributing to the morphology. Rarely, squamous cell carcinoma may occur in chronic ulcers.

The most common location of the lesions is the shins (Fig. 26.29). Much less often, lesions will appear on the forearms, and rarely, lesions have been reported on the trunk, face, scalp, palms, and soles.

Histologically, well-developed lesions of NL demonstrate a superficial, deep, and interstitial inflammatory process that involves the whole reticular dermis and often the panniculus. Because the dermis is firm, punch biopsy specimens appear rectangular rather than tapered. The inflammatory cells include lymphocytes, histiocytes, multinucleate giant cells, and plasma cells. At low magnification, there are layered palisaded granulomas with pale-pink degenerated collagen alternating with amphophilic-staining histiocytes. In contrast to granuloma annulare, mucin is not increased in the centers of the granulomas, and there is no normal dermis in NL lesions. Between granulomas in granuloma annulare, the collagen pattern is relatively normal, although inflammatory cells may be present. In NL, the overlying epidermis tends to be thinned, with loss of the normal rete ridge pattern.

Fig. 26.30 Bullous eruption of diabetes.

Treatment of NLD, after control of the diabetes is achieved, is not completely satisfactory. Initial therapy is superpotent topical corticosteroids with occlusion. Topical calcineurin inhibitors can also be effective. Intralesional injections of triamcinolone suspension into the inflammatory papules and active advancing edges can be quite effective. Injection into the yellow center is of little benefit and may result in ulceration. It had been proposed that NLD is caused by the microangiopathy of diabetes. For this reason, agents designed to improve circulation have been used, at times with success. These include low-dose aspirin, nicotinamide, pentoxifylline, and dipyridamole. The blood flow in lesions of NLD is normal, however, suggesting that this is better considered as an inflammatory dermatosis. Phototherapy, including PUVA and UVA1, has been effective in select patients. Oral immunomodulatory therapy should be considered in patients unresponsive to topical treatment. Antimalarial treatment and thalidomide are nonimmunosuppressive options that would not alter blood sugar control. Systemic antiinflammatories reported to be effective in select cases include systemic corticosteroids, mycophenolate mofetil (MMF), and cyclosporin A. TNF inhibitors (specifically infliximab and etanercept) have been effective in refractory cases, either systemically or by intralesional injection. However, patients being treated with TNF inhibitors for other conditions have developed NLD, similar to the paradox of patients who take TNF inhibitors developing psoriasis. Hyperbaric oxygen may be used for patients with chronic ulceration. Intense pulse light has also been reported to be effective. In severe cases with persistent ulceration, excision and skin grafting have been effective, although the NLD may recur in or at the edges of the grafts. Despite initial reports of success, photodynamic therapy only improves about one third of treated patients. Pioglitazone treatment may be beneficial. Pancreas-kidney transplantation led to resolution in one case, but the patient also received MMF, prednisone, and tacrolimus orally.

Diabetic Dermopathy (Shin Spots)

Dull-red papules that progress to small, well-circumscribed, round, atrophic, hyperpigmented lesions on the shins are a common cutaneous sign of diabetes, occurring in up to 40% of diabetic patients. Lesions begin on the lower extremities as crops of four or five dull-red macules 0.5–1 cm in diameter. As the lesions resolve, they become shallow, depressed, and hyperpigmented scars. The lesions are twice as common in men; 70% of diabetic men over age 60 have diabetic dermopathy. Although shin spots occur individually in people who do not have diabetes, if four or more are present, the specificity is high for diabetes. Patients with diabetic dermopathy have a higher risk of nephropathy and retinopathy.

Diabetic Bullae

Noninflammatory, spontaneous, painless blistering, most often in acral locations, is characteristic of diabetic bullae (Fig. 26.30). Lesions tend to involve the lower legs and to be 10 cm or more in diameter. The incidence is 0.16% per year. In many cases, lesions heal spontaneously in 4–5 weeks, usually without scarring. However, lesions may be complicated at times by chronic ulceration. Aggressive and cautious management with dressings and diabetic foot care is required. Lesions appear after periods of relative hypoglycemia, perhaps explaining the clinical resemblance of diabetic bullae to pressure bullae.

The blisters are subepidermal. Electron microscopic studies show separation at the lamina lucida level. DIF is negative. Treatment is diabetic control, aspiration of the bulla to prevent expansion by hydrostatic pressure, and aggressive wound management to optimize healing and prevent infection.

Carotenosis

Carotenosis is a yellowish discoloration of the skin, especially of the palms and soles (Fig. 26.31), which is sometimes seen in diabetic patients and patients with trisomy 21.

Limited Joint Mobility and Waxy Skin

Limited joint mobility and waxy skin are important not only because of the 30%–50% prevalence of these conditions in diabetic patients with long-standing disease, but also because they are associated with microvascular complications, such as nephropathy and retinopathy. Joint symptoms begin with limitation of joint mobility in the fifth finger at the metacarpophalangeal and proximal joints and progress radially to the other fingers. The condition is bilateral,

Fig. 26.31 Carotenemia, yellow palm shown next to normal palm.

symmetric, and painless. Dupuytren contractures and palmar fibrosis may occur. Involvement of the feet also occurs and is thought to contribute to the development of chronic ulcerations. Such open sores on the neuropathic, microvascularly compromised, infection-prone diabetic foot pose a constant threat to life and limb.

Other Associated Conditions in Patients With Diabetes

Various abnormalities associated with diabetes are erysipelas-like erythema of the legs or feet; sweating disturbances; paresthesias of the legs; mal perforans ulcerations; a predisposition to certain infections such as mucormycosis, group B streptococcal infections, nonclostridial gas gangrene, and malignant external otitis resulting from *Pseudomonas;* disseminated granuloma annulare; eruptive xanthomas; clear cell syringomas; rubeosis of the face; lipoatrophy or lipohypertrophy at sites of insulin injection; acquired perforating disorders; acanthosis nigricans; skin tags; and finger pebbling. Pruritus is common in adult diabetic patients, typically of the central trunk. It is associated with evidence of diabetic neuropathy and probably represents a form of neuropathic pruritus. Treatment is similar to that for neuropathy, starting with gabapentin.

OTHER METABOLIC DISORDERS

CITRULLINEMIA

Citrullinemia occurs in two forms. Type I is caused by a deficiency of the enzyme argininosuccinic acid synthetase (*ASS1* gene). This enzyme converts citrulline and aspartic acid to argininosuccinic acid, as a part of the urea cycle. Low plasma arginine levels result, and the hypothesis is that, because keratin is 16% arginine, dermatitis may occur. Neonates who present with severe deficiencies and hyperammonemic crises may develop erosive, erythematous, scaling patches and plaques prominent in the perioral, lower abdominal, diaper, and buttock regions or erythroderma similar to psoriasis. Short, sparse hair may also be present. This eruption clears with arginine supplementation. Citrullinemia type II is caused by a defect in the *SCL25A13* gene and is seen primarily in East Asia, usually presenting in adolescence or adulthood.

In carbamoyl phosphate synthetase deficiency, low plasma arginine levels may also occur, and similar cutaneous findings have been reported in this second metabolic defect of the urea cycle.

Diets high in arginine will heal the skin lesions.

HARTNUP DISEASE

Hartnup disease is an inborn error of tryptophan excretion named after the Hartnup family, in whom it was first noted. It is the second most common inherited aminoaciduria after phenylketonuria. The characteristic findings are a pellagra-like dermatitis following exposure to sunlight, intermittent cerebellar ataxia, psychosis, and constant aminoaciduria.

The dermatitis occurs on exposed parts of the skin, chiefly the face, neck, hands, and legs. The erythematous scaly patches flare up into a hot, red, exudative state after exposure to sunlight, followed by hyperpigmentation. Stomatitis and vulvitis also occur. The disease becomes milder with increasing age. Rarely, an acrodermatitis enteropathica–like eruption with normal zinc levels may occur in patients with Hartnup disease.

Hartnup disease is an autosomal recessive trait caused by mutations in the *SLC6A19* gene coding an enzyme that transports neutral amino acids across the apical membrane of epithelial cells in the gut and kidneys. Large amounts of neutral amino acids, including tryptophan, are present in the urine, establishing the diagnosis. The skin lesions respond to niacinamide, but the neurologic disease may not improve.

PROLIDASE DEFICIENCY

Prolidase deficiency (PD) is an autosomal recessive inherited inborn error of metabolism caused by mutations in the *PEPD* gene. Prolidase cleaves dipeptides containing C-terminal proline or hydroxyproline. When this enzyme is deficient, the normal recycling of proline residues obtained from collagen degradation is impaired. A buildup of iminodipeptides results, with disturbances in connective tissue metabolism and excretion of large amounts of iminodipeptides in the urine. Clinically, 85% of patients have some dermatologic manifestations. The most important cutaneous signs, which almost always appear before the affected person is 12 years old, are skin fragility; ulceration and scarring of the lower extremities; photosensitivity and telangiectasia; poliosis; scaly, erythematous, maculopapular, and purpuric lesions; and thickening of the skin with lymphedema of the legs. Systemic signs and symptoms include mental deficiency, splenomegaly, recurrent infections and facial dysmorphism with low hairline, frontal bossing, and saddle nose. About 10% of patients with PD meet American Rheumatology Association (ARA) criteria for the diagnosis of systemic lupus erythematosus. Antinuclear antibodies, extractable nuclear antigen, and anti-dsDNA may be positive; C3 and C4 are low; and cytopenias are present. Because C1q has a high proline content, a relative deficiency of functional C1q may explain the high frequency of lupus erythematosus in these patients.

PD is confirmed by determining prolidase activity in erythrocytes, leukocytes, or fibroblasts in culture or by sequence analysis of the *PEPD* gene. In long-standing ulcerations, squamous cell carcinomas may occur.

Butbaul Aviel Y, et al: Prolidase deficiency associated with systemic lupus erythematosus (SLE). Pediatr Rheumatol 2012; 10: 18.

PHENYLKETONURIA

Phenylketonuria (PKU) is an autosomal recessive disorder of phenylalanine metabolism caused by a deficiency in the enzyme phenylalanine hydroxylase. Phenylalanine is not metabolized to tyrosine. PKU is the most common form of inherited aminoaciduria, affecting 1 in 15,000 live births in the United States. It is characterized by mental deficiency; epileptic seizures; pigmentary dilution of skin, hair, and eyes; pseudoscleroderma; and dermatitis (Fig. 26.32). It is most common in white persons.

Affected children are blue-eyed, with blond hair and fair skin. They are usually extremely sensitive to light, and about 50% have an eczematous dermatitis. It is clinically similar to atopic dermatitis, with a predilection for the flexures. The dermatitis is worst in the youngest patients, may improve with dietary treatment, and has been exacerbated by phenylalanine challenge in a carrier of the recessive gene. Indurations of the thighs and buttocks are present early in infancy and increase with time. After many years, the lesions soften and become atrophic.

Fig. 26.32 Light-skinned, light-haired phenylketonuria patient with dermatitis. (Courtesy Dr. Jeff Miller.)

Blood levels of phenylalanine are high. The presence of phenylpyruvic acid in the urine is demonstrated by a characteristic deep-green color when a few drops of ferric chloride solution are added. Green diapers occur in histidinemia as well as in PKU.

In developed countries, universal screening for PKU is practiced, so dietary therapy with phenylalanine restriction is instituted. Sapropterin dihydrochloride may also be given. This prevents the manifestations of the disease. If compliance is poor, the manifestations, including eczema, may develop at any age, followed by improvement of the skin with reinstitution of the diet.

ALKAPTONURIA AND OCHRONOSIS

Alkaptonuria (endogenous ochronosis), inherited as an autosomal recessive trait, is caused by the lack of renal and hepatic homogentisic acid oxidase, the enzyme necessary for the catabolism of homogentisic acid (HGA), a product of tyrosine and phenylalanine metabolism. Excess HGA is excreted in the urine and deposited in connective tissues throughout the body, especially the cartilage leading to a dark color. The urine is dark and becomes black on standing. Men with alkaptonuria outnumber women by 2:1.

For many years, the dark urine may be the only indication of the presence of alkaptonuria. In the meantime, large amounts of HGA accumulate in the body tissues. By the third decade of life, the deposition of pigment becomes apparent. The early sign is the pigmentation of the sclera (Osler sign; Fig. 26.33) and the cartilage of the ears (Fig. 26.34). Later, the cartilage of the nose and tendons, especially those on the hands, becomes discolored.

Blue or mottled brown macules appear on the skin. The bluish macules have a predilection for the fingers, ears, nose, genital regions, apices of the axillae, and buccal and vaginal mucosae. Palmoplantar pigmentation may occur and may be accentuated along the thenar and hypothenar eminences as pigmented pitted areas some with hyperkeratosis. The transgradience of the index

Fig. 26.33 Osler sign.

Fig. 26.34 Alkaptonuria.

Fig. 26.35 Exogenous ochronosis.

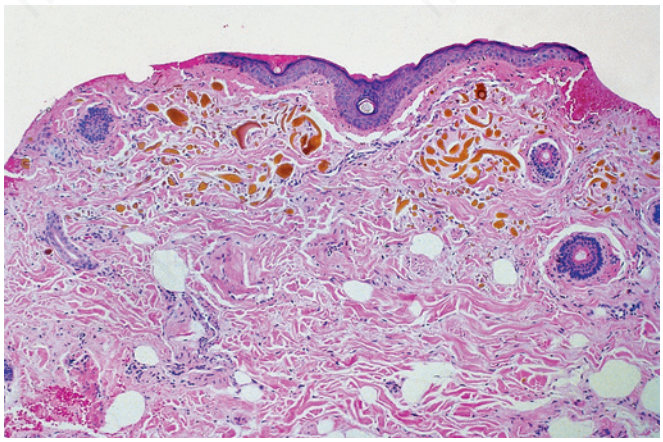

Fig. 26.36 Exogenous ochronosis.

fingers is also affected, closely resembling degenerative collagenous plaques the hand and acrokeratoelastoidosis. The apocrine sweat glands are rich in ochronotic pigment granules, and the intradermal injection of epinephrine into the skin of the axillary vault will yield brown-black sweat droplets in the follicular orifices. The cerumen is often black. Histologically, there are large, irregular ochre bodies within the reticular dermis. These represent degenerated elastic fibers with deposition of ochronotic pigment and stain black with crystal violet or methylene blue.

Ochronotic arthropathy first involves the axial spine joints, followed by the knees, shoulders, and hips. Radiographs show a characteristic appearance of early calcification of the intervertebral disk and later narrowing of the intervertebral spaces with eventual disk collapse. Tendon rupture may occur. Heart disease results from HGA deposition in the aortic and mitral valves. Renal disease is caused by HGA stones in the urinary system and can progress to renal failure.

There is no effective treatment for alkaptonuria. Dietary restriction of tyrosine and phenylalanine is recommended but may not prevent progression of disease. Joint and cardiac valve replacement may be necessary. Nitisinone can greatly reduce HGA excretion but does not appear to be effective once joint disease is present. Tyrosine keratopathy can result from nitisinone treatment. Life span is generally unaffected.

Exogenous Ochronosis

Topically applied phenolic intermediates, such as hydroquinone, carbolic acid (phenol), picric acid, and resorcinol, may produce exogenous ochronosis. Even 2% over-the-counter hydroquinone can produce ochronosis if used regularly for a long period. Hydroquinone specifically inhibits the enzyme HGA oxidase locally instead of the systemic inhibition of alkaptonuria. This results in accumulation of the blue discoloration on the collagen fibers where hydroquinone is applied. All skin types can be affected, but ethnic groups with the highest prevalence of melasma and hydroquinone use are primarily reported: African Americans, Africans, and Asians. Because most patients use the hydroquinone to treat melasma, findings of melasma may overlay the skin findings of exogenous ochronosis. The typical findings are gray-brown or blue-black macules, usually over the zygomatic regions (Fig. 26.35). Hyperchromic pinpoint papules may occur, that on dermoscopy can be seen associated with follicular openings. Confetti-like depigmentation (from the hydroquinone) may be admixed with the hyperpigmentation. Histologically, exogenous ochronosis and alkaptonuria show identical changes (Fig. 26.36). Treatment is challenging but stopping the application of hydroquinone may lead to improvement. Q-switched lasers and IPL have shown some inconsistent improvement.

WILSON DISEASE (HEPATOLENTICULAR DEGENERATION)

Wilson disease is an autosomal recessive derangement of copper transport. The disease is caused by dysfunction of a copper-transporting enzyme, P-type adenosine triphosphatase (ATP7B), which is required to excrete copper into the bile. This leads to accumulation of copper in the liver, brain, cornea, and kidney. Affected persons develop hepatomegaly, splenomegaly, and neuropsychiatric changes. Slurred speech, a squeaky voice, salivation, dysphagia, tremors, incoordination, and spasticity may all occur. There is progressive, fatal, hepatic and central nervous system degeneration.

Azure lunulae ("sky-blue moons") of the nails occur in 10% of patients, and the smoky, greenish brown Kayser-Fleischer rings develop at the edges of the corneas. Hyperpigmentation develops on the lower extremities in most patients. A vague greenish discoloration of the skin on the face, neck, and genitalia may also be present. An idiopathic blistering eruption that ceased with treatment of Wilson disease has been reported. Lipomas can occur in approximately 25% of patient with Wilson disease. Skin changes of cirrhosis (vascular spiders and palmar erythema) may occur. Low ceruloplasmin level in the serum leads to the suspected diagnosis, along with elevated 24-hour urinary copper excretion and elevated free serum copper. Ten percent of carriers for Wilson disease have a low ceruloplasmin level, so additional tests should be performed to confirm the diagnosis.

The treatment is a low-copper diet, often with agents that bind copper and enhance its excretion from the body. D-Penicillamine, 1 or 2 g/day orally, removes copper by chelating it. Potential side effects include pemphigus, cutis laxa, and elastosis perforans serpiginosa, which has been reported repeatedly in Wilson patients receiving penicillamine. Trientine, another copper chelator, enhances copper excretion. It has less toxicity, but is somewhat less effective than D-penicillamine. Zinc supplementation leads to increased metallothionein in the gut and liver. This leads to more copper excretion in the stool. Zinc can be given at the same time as D-penicillamine. Treatment must be continued for life.

TYROSINEMIA II (RICHNER-HANHART SYNDROME)

Tyrosinemia is an autosomal recessive syndrome resulting from a deficiency of hepatic tyrosine aminotransferase, an important enzyme in the degradation of tyrosine and phenylalanine caused by mutations in the *TAT* gene. Clinical features are mild to severe keratitis and painful hyperkeratotic, erosive lesions of palms and soles, often with mild mental retardation. Photophobia and tearing usually occur as the keratitis begins, and ultimately, neovascularization is seen; occasionally only the eye findings are present or they are totally absent. Painful palmar and plantar hyperkeratosis are usually on weight-bearing areas and the keratosis can track along dermatoglyphs. Bullae can also be present. The skin manifestations, although usually present in the first year, can first present in the second decade. Initially, only the soles may be affected, with hyperkeratosis mainly over the tips of the digits and on weight-bearing surfaces. The fingertips and the hypothenar and thenar eminences are primarily affected on the palms. In any child presenting with palmoplantar keratoderma, the diagnosis of tyrosinemia type II must be considered, especially if there is tearing and photophobia (which is usually present by age 1). The diagnosis is confirmed by identifying elevated levels of serum tyrosine. A low-tyrosine, low-phenylalanine diet may improve or prevent the eye and skin lesions, but it may or may not benefit established mental retardation.

Peña-Quintana L, et al: Tyrosinemia type II. Clin Genet 2017; 92: 306.

HURLER SYNDROME (MUCOPOLYSACCHARIDOSIS I)

Hurler syndrome is an autosomal recessive lysosomal storage disease of mucopolysaccharide metabolism caused by a deficiency of α-iduronidase. This enzyme is responsible for the breakdown of heparan sulfate and dermatan sulfate. All patients have undetectable enzyme activity, yet there is significant polymorphism in the severity and age of onset. In general, cases are divided into severe mucopolysaccharidosis (MPS-I, Hurler syndrome) and attenuated MPS-I (Hurler-Scheie syndrome, Scheie syndrome).

Hurler syndrome is characterized by mental retardation, hepatosplenomegaly, umbilical and inguinal hernia, genital infantilism, corneal opacities, and skin abnormalities. Patients with Hurler syndrome have facial dysmorphism, with a broad saddle nose, thick lips, and a large tongue. The skin is thickened, with ridges and grooves, especially on the upper half of the body. Fine lanugo hair is profusely distributed all over the body. Large, coarse hair is prominent, especially on the extremities. Dermal melanocytosis (Mongolian spots), characterized by extensive blue pigmentation with both a dorsal and a ventral distribution, indistinct borders, and a persistent or progressive course, occurs in approximately 15% of patients with lysosomal storage disease, including patients with Hurler syndrome, Hunter syndrome, and GM1–gangliosidosis type 1. Because the dermal melanocytosis is prominent in infancy, this may be the initial clinical manifestation. The skeletal system is deformed, with hydrocephalus, kyphosis, and gibbus (cat-back shape). The hands are broad and have clawlike fingers.

The diagnosis of MPS-I is made by demonstrating elevated urinary glycosaminoglycan levels and deficient enzyme activity in fibroblasts, leukocytes, serum, or blood spots. Prenatal diagnosis is possible. Hematopoietic stem cell transplantation (HSCT) is the most effective treatment for Hurler syndrome. It can prevent mental deterioration if performed early enough (before age 2 and before developmental quotients fall below 70). ERT with recombinant human α-iduronidase (Aldurazyme) is an option in patients who are not candidates for HSCT.

Kiely BT et al: Early disease progression of Hurler syndrome. Orphanet Journal of Rare Diseases 2017 Feb 14; 12(1): 32.

HUNTER SYNDROME (MUCOPOLYSACCHARIDOSIS II)

Hunter syndrome is X-linked recessive lysosomal storage disease caused by deficiency of the enzyme iduronate-2-sulfatase. The initial

Fig. 26.37 Hunter syndrome papules.

presentation of Hunter syndrome may be to the dermatologist due to the extensive dermal melanocytosis (Mongolian spots) that are large and located in atypical locations (not just along the back and buttocks) seen in infancy. Often these children are otherwise asymptomatic. The pebbly lesions of MPS-II in the skin of the upper back, neck, chest, proximal arms, or thighs occur in approximately 10% of patients. The lesions are firm, flesh-colored to white papules and nodules that coalesce into a cobblestone or reticular pattern as a connective tissue nevus (Fig. 26.37). At time of these skin lesions (around age 10), patients will typically have large head circumference, high body mass index, and short stature. Histologically, the lesions demonstrate increased dermal mucin and metachromatic granules in the cytoplasm of dermal fibroblasts and at times in eccrine sweat glands and epidermal keratinocytes.

Dermatan sulfate and heparan sulfate are excreted in the urine in large amounts, and the diagnosis of Hunter syndrome can be confirmed by absent iduronate-2-sulfatase in leukocytes. HSCT and ERT can be useful in appropriately evaluated patients.

LAFORA DISEASE

Lafora disease is an autosomal recessive form of progressive myoclonic and tonic-clonic epilepsy beginning at puberty that is caused by a mutation in EPM2A or NHLRC1. The products of these two genes form a complex critical to the regulation of neuronal function. It is characterized by myoclonic jerks followed by progressive ataxia, dysphagia, dysarthria, dementia, and death in early adulthood. Diagnosis is established in the proper clinical setting by demonstration of characteristic PAS-positive cytoplasmic inclusion bodies in the eccrine ducts, axillary apocrine myoepithelial cells (Fig. 26.38), and peripheral nerves. The best site to biopsy is the axilla. Other conditions in which similar polyglucosan inclusions can be seen include normal aging (amyloid bodies),

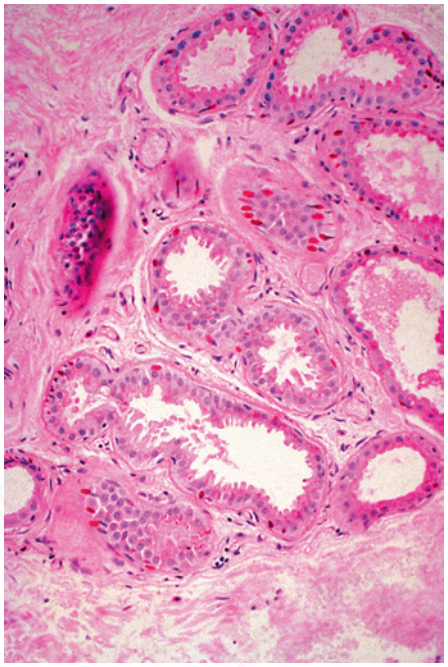

Fig. 26.38 PAS-stained inclusions in Lafora disease.

double-athetosis syndrome, amyotrophic lateral sclerosis, and glycogen storage disease type IV.

Cutaneous manifestations are rare in Lafora disease. Papulonodular lesions on the ears and indurated, thickened plaques on the arms have been reported. Large amounts of acid mucopolysaccharides were demonstrated histologically in these lesions.

CADASIL SYNDROME

Cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) is a neurovascular disease of young and middle-aged people caused by mutations in NOTCH3. It is the most common heritable cause of stroke and vascular dementia in adults, but, due to the characteristic skin findings on histology, skin biopsies can aid in diagnosis. Children have cognitive impairment; young adults have depression and migraine with aura; and patients in their forties and fifties experience apathy, executive dysfunction, mood disturbances, and motor disability followed by dementia. The diagnosis should be confirmed by genetic testing, which will identify most but not all patients with CADASIL. When genetic testing is negative, a skin biopsy can be done showing deposition of a granular osmophilic material in the media of arterial walls with an electron-lucent halo on electron microscopy or demonstrated by a specific immunostain.

FARBER DISEASE

Also known as Farber lipogranulomatosis, Farber disease is characterized by periarticular nodules; joint swelling and deformation (usually the initial presentation); a weak, hoarse cry (from laryngeal involvement); pulmonary failure; and motor and mental retardation. It is caused by deficiency of lysosomal acid ceramidase resulting from mutations in the *ASAH1* gene. Progressive accumulation of ceramide in affected tissues results in the complications. Testing for C26-ceramide is the most sensitive.

The rubbery subcutaneous nodules have a distinct yellowish hue and are 1–2 cm in diameter. They are usually located over the joints, lumbar spine, scalp, and weight-bearing areas. Histologically, these are granulomas. Farber disease presents with a highly variable spectrum, with the most severely affected children dying by age 2 years and mildly affected children reaching their teens. There is no correlation between the genotype or the residual ceramidase level and the phenotype. In more mildly affected cases that have not been diagnosed in infancy, the periarticular swellings and predominant joint disease, in about one third of patients, leads to the incorrect diagnosis of juvenile idiopathic arthritis. An animal model has allowed treatment strategies to be tested.

ADRENOLEUKODYSTROPHY (SCHILDER DISEASE)

Adrenoleukodystrophy (X-ALD) is an X-linked disorder in which cerebral white matter becomes progressively demyelinated and serious adrenocortical insufficiency usually occurs. X-ALD is caused by mutations in the *ABCD1* gene. The gene defect results in impaired degradation of very-long-chain fatty acids (>22 carbons). Skin hyperpigmentation including the buccal mucosa and palmar creases often calls attention to the adrenal disease (Addison disease), and mental deterioration indicates the even graver diagnosis of X-ALD. A mild ichthyotic appearance to the skin of the trunk and legs and sparse hair with trichorrhexis nodosa–like features may occur. Although males are most severely affected, female heterozygote carriers can, in adulthood, develop Addison disease and chronic myelopathy and peripheral neuropathy, often with fecal incontinence. Skin biopsies may show characteristic vacuolization of eccrine secretory coils (duct cells being spared), and biopsies of the skin and conjunctiva may show diagnostic clefts in Schwann cells surrounding myelinated axons. Lorenzo's oil and pioglitazone are potential therapies. Bone marrow transplantation may benefit X-ALD patients, but gene therapy trials are in progress and show promise.

Fig. 26.39 Gout.

GOUT

Classic gout presents as an acute monoarthritis, usually of the great toe or knee, in a middle-aged to elderly man with hyperuricemia. In such patients with chronic disease, usually present for more than 10 years, monosodium urate monohydrate may be deposited in the dermal or subcutaneous tissues, forming papules or nodules called tophi. Rarely, tophi may be the initial presentation of gout, even with normal serum uric acid levels. Gouty tophi vary from pinhead to pea sized or rarely even baseball sized. Tophi are typically found on the pinna (Fig. 26.39) or outer helix of the ears and over the distal interphalangeal articulations. Tophi are of a yellow or cream color. Over time, tophi tend to break down and discharge sodium urate crystals, afterward healing and perhaps breaking down again. Atypical locations for gout include nasal bridge tophi, gouty panniculitis (inflammatory subcutaneous nodules mimicking other forms of panniculitis, possibly with normal serum uric acid), disseminated gout not associated with joints and finger pad tophi. When urate crystal deposition occurs in the dermis, the lesions have been described as "pustular" or "intradermal" tophi.

The diagnosis of gout is verified histologically by finding the characteristic long, needle-shaped crystals of monosodium urate. Because routine processing dissolves these deposits, fixation in absolute ethanol or freezing is optimal for their demonstration, but this is rarely done because most specimens are submitted in formalin. Rather, 10-μm unstained sections from formalin-fixed specimens can demonstrate characteristic crystals under polarized light. Atypical gout occurs as a polyarticular chronic arthritis, often of the hands. It occurs equally in women and men, and there may be tophi, frequently overlying Heberden nodes, at presentation. Another risk group is organ transplant patients, 10% of whom develop gout. Treatment with certain medications has been associated with the appearance of tophi. These include diuretics, methotrexate, cyclosporine, and etanercept. Treatment with allopurinol can result in disappearance of the tophi.

LESCH-NYHAN SYNDROME

Also known as juvenile gout, Lesch-Nyhan syndrome is a rare X-linked recessive inherited disorder characterized by childhood

Fig. 26.40 Lesch-Nyhan syndrome.

hyperuricemia, gout, tophi (Fig. 26.40), choreoathetosis, progressive mental retardation, and self-mutilation. The cutaneous lesions are distinctive. Massive self-mutilation of lips with the teeth occurs. The fingers are also severely chewed. The ears and nose are occasionally mutilated. An early diagnostic clue is orange crystals in the diaper. The blood uric acid is increased, and allopurinol, 200–400 mg/day, is given. There is a marked deficiency in an enzyme of purine metabolism, hypoxanthine guanine phosphoribosyltransferase.

27 Genodermatoses and Congenital Anomalies

Bonus images for this chapter can be found online at **expertconsult.inkling.com**

The genetic basis for common diseases such as atopic dermatitis and psoriasis, in addition to rare diseases, has been partially elucidated. Some genetic disorders are explained by mutations in a specific gene or genes that lead to a specific clinical phenotype that can be recognized based in part on the skin manifestations. These are termed *genodermatoses*, and recognizing the skin features can lead to earlier diagnosis and management, potentially preventing disease. Genetic disorders are often grouped into three categories: chromosomal, single gene, and polygenic. The advancement of genetic testing has allowed the discovery of postzygotic mutations that only affect a small area of the body. Many segmental patterns of congenital lesions are due to postzygotic mutations. These postzygotic mutations leading to congenital lesions of the vascular system and epidermal nevi are discussed in their respective chapters. Chromosomal disorders can be numeric, such as trisomy and monosomy, or structural, resulting from translocations or deletions. Most genodermatoses show single-gene or mendelian inheritance (autosomal dominant, autosomal recessive, or X-linked recessive genes). Polygenetic syndromes often involve complex interactions of genes. Occasionally a second genetic hit is required to manifest skin findings.

Autosomal dominant conditions require only a single gene to produce a given phenotype. Usually the patient has one affected parent or is affected by a new mutation. The disease is transmitted from generation to generation. Autosomal recessive traits require a homozygous state to produce the abnormality. The pedigree may reveal parental consanguinity. Parents will be clinically unaffected or have mild manifestations but often have affected relatives. X-linked conditions occur when the mutated gene is carried on the X chromosome. If a disease is X-linked recessive, the loss is evident in males (XY), who do not have a second X chromosome to express the normal allele. Therefore X-linked recessive traits occur almost exclusively in males. They cannot transmit the disease to sons (who inherit their Y chromosome), but all their daughters will be carriers. Carrier females who are heterozygous (having one normal and one abnormal X chromosome) occasionally show some evidence of the disease. This occurs as a result of lyonization, the physiologic inactivation of one of the X chromosomes. X-linked dominant disease states are usually lethal in males. Survival is possible in females who retain a normal allele. Because the mutation is lethal in many affected cell lines, females typically demonstrate loss of normal tissue in the affected segments (narrow Blaschko segments, loss of digits, microphthalmia, loss of teeth). X-linked dominant traits result in pedigrees in which more than one female is affected but no males express the disease. Rarely, males may survive, especially if they have Klinefelter syndrome (XXY) or a postzygotic mutation leading to mosaicism such that only some cells are affected.

Mosaicism is the presence of two or more genetically distinct cell lines in a single individual. It may occur as a result of physiologic inactivation of one X chromosome (lyonization) or as the result of a postzygotic somatic mutation. Mosaicism often presents in a linear and whorled pattern along the lines of Blaschko. In mosaic states, genes that are detrimental to a cell population during fetal development (e.g., incontinentia pigmenti) typically result in thin segments because they are overgrown by the adjacent normal tissue. Conversely, genes that confer a growth advantage during fetal development (e.g., mutated tumor suppressor gene in segmental neurofibromatosis) may result in broad, plaque-type lesions that have grown beyond the boundaries of a typical Blaschko segment.

In autosomal dominant conditions, a normal allele remains but is not enough to prevent disease. Loss of heterozygosity (LOH) is a second genetic mutation leading to a defect in the remaining normal allele that explains why a lesion is only in a limited part of the skin. LOH may give rise to segments of the body with an exaggerated presentation of the syndrome. The affected area corresponds to a Blaschko segment or plaque. The forehead plaque of tuberous sclerosis is related to a mutation in a tumor suppressor gene. The loss of the tumor suppressor gene imparts a growth advantage, and LOH leaves no suppressor gene product in the segment. As a result, the affected segment grows beyond its Blaschko boundaries, forming a broad plaque.

When a patient presents with segmental distribution of a disorder, it is critical to determine whether the disorder is a result of mosaicism or LOH. In LOH, the abnormal allele is present throughout the body, including gonadal tissue. In a patient who presents with segmental neurofibromatosis but has Lisch nodules or axillary freckling, LOH rather than mosaicism is likely to account for the segmental presentation. The risk of passing the gene to a child is about 50/50. A genetic counselor should be involved to discuss risk of transmission to offspring because the mechanisms may be complex. Patients with mosaicism based on postzygotic somatic gene mutation may have gonadal mosaicism and may be capable of passing on the gene. Gonadal mosaicism is more likely when more than one segment is present on different regions of the body. Before gastrulation, when a cavity forms in the embryo, every cell is pluripotent and can give rise to an entire organism, or it can contribute to multiple sites of the body. At gastrulation, cells become dedicated to produce specific segments of the body. Blaschko segments in different regions suggest a mutation that occurred before gastrulation, when the involved cell lines could contribute to different parts of the body, including the gonads. Polygenetic disorders, such as psoriasis, may also present with limited and linear forms that may relate to segmental LOH or postzygotic mutation.

Online Mendelian Inheritance in Man (OMIM.org) contains a comprehensive database of known genetic disorders and has a search function that allows the clinician to match clinical manifestations with possible diagnoses. When a patient has more than one very unusual finding OMIM can help determine whether the patient may have a genetic disorder linking the findings. PubMed's clinical query function can also be used to match manifestations with syndromes, and Genetest.org lists sources for genetic testing.

X-LINKED, MOSAIC AND RELATED DISRODERS WITH ABNORMAL PIGMENT

INCONTINENTIA PIGMENTI

Also known as Bloch-Sulzberger disease, incontinentia pigmenti is an X-linked dominant condition characterized by whorled pigmentation on the trunk, preceded by vesicular and verrucous changes. It appears in girls during the first weeks after birth (Fig.

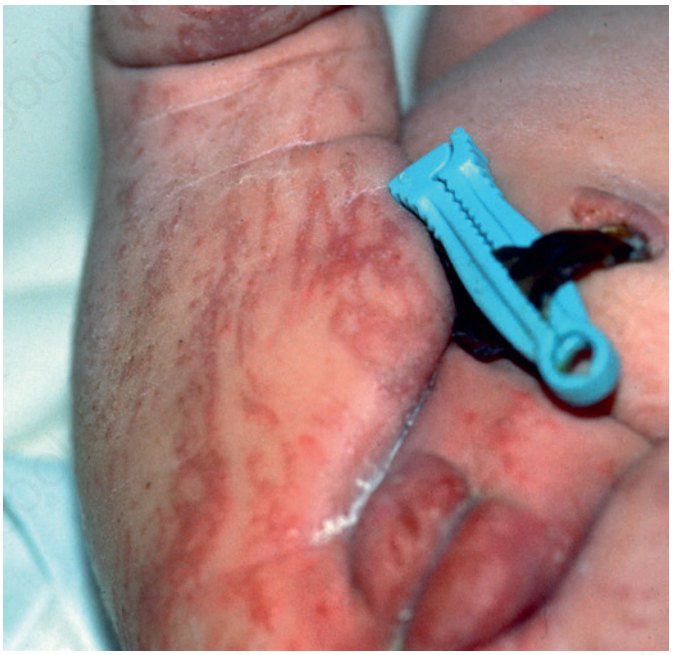

Fig. 27.1 Incontinentia pigmenti, early inflammatory phase.

27.1). Most lesions are evident by the time the infant is 4–6 weeks old. A vesicular phase is present in nearly all cases. This first stage begins in most individuals before 6 weeks of age and is replaced by verrucous lesions after several weeks to months in two thirds of patients. Although these usually resolve by 1 year of age, lesions may persist or recurr for many years. In the third, or pigmentary, phase, pigmented macules in streaks, sprays, splatters, and whorls follow the lines of Blaschko. The pigmentary stage may last for many years and then fade away, leaving no sequelae. The stages are not mutually exclusive. Therefore it is not uncommon for a young child to have some areas still in a verrucous stage while others are hyperpigmented. A fourth stage may be seen in some adult women, manifesting subtle, faint, hypochromic or atrophic linear lesions, most often on the extremities.

Histologically, the vesicular stage is characterized by spongiosis with eosinophils. As the lesions mature, clusters of dyskeratotic cells appear within the epidermis. Dyskeratotic cells predominate in the verrucous stage, and pigment incontinence (dermal melanophages) predominates in hyperpigmented lesions.

Other cutaneous changes include patchy alopecia at the vertex of the scalp, atrophic changes simulating acrodermatitis chronica atrophicans on the hands, onychodystrophy, late subungual tumors that resemble subungual keratoacanthoma and may have underlying lytic bone lesions, and palmoplantar hyperhidrosis. Extracutaneous manifestations occur in 70%–90% of patients. Most frequently involved are the teeth (up to 90%), bones (40%), central nervous system (CNS; 33%), and eyes (35%). Immune dysfunction with defective neutrophil chemotaxis and elevated immunoglobulin E (IgE) has been reported. Eosinophilia is common. Incontinentia pigmenti is an important cause of neonatal seizures and encephalopathy.

Dental abnormalities usually manifest by the time the individual is 2 years old. Dental defects may be the only stigmata still present in the mother and thus can be helpful in the diagnosis of an affected child. Dental defects include delayed eruption, partial anodontia (43%), microdontia, and cone- or peg-shaped teeth (30%). The most common CNS findings are seizures in approximately 10% followed by mental retardation, spastic paralysis, microcephaly, destructive encephalopathy, and motor impairment. The eye changes include strabismus, cataracts, retinal detachments, optic atrophy, vitreous hemorrhage, blue sclerae, and exudative chorioretinitis. Skeletal abnormalities include syndactyly, skull deformities, dwarfism, spina bifida, clubfoot (talipes), supernumerary ribs, hemiatrophy, and shortening of the legs and arms. Rarely, tricuspid insufficiency, right ventricular hypertrophy, and pulmonary hypertension have been described.

Incontinentia pigmenti is caused by a mutation in the nuclear factor-κB (*NEMO)* gene on the X chromosome, localized to Xq28. Therefore it is typically passed from mother to daughter although there are reports of germline mosaic males giving birth to affected daughters. The gene is generally lethal in male fetuses, although males with Klinefelter syndrome (47,XXY) may survive. Mosaicism may also account for some cases in males. *NEMO* mutations also cause X-linked ectodermal dysplasia with immunodeficiency, characterized by alopecia, hypohidrosis, dental anomalies, and defects in humoral immunity. Osteopetrosis and lymphedema may be present.

Incontinentia pigmenti achromians is a term that has been replaced with the term *pigmentary mosaicism* (see section on pigmentary mosaicism). Mendelian susceptibility to mycobacterial disease is a rare syndrome predisposing to infection with weakly virulent mycobacteria, such as *Mycobacterium avium* complex, *Mycobacterium bovis*, bacille Calmette-Guérin (BCG), and environmental nontuberculous mycobacteria. The causative mutations in *NEMO* selectively affect the CD40-dependent induction of interleukin-12 (IL-12) in mononuclear cells. These patients typically clinically manifest with hypohidrotic ectodermal dysplasia or rarely incontinentia pigmenti.

Use of ruby lasers to treat pigmented lesions in infants and young children may worsen the condition. Usually, the end stage of streaks of incontinentia pigmenti start to fade at age 2 years, and by adulthood, there may be minimal residual pigmentation.

NAEGELI-FRANCESCHETTI-JADASSOHN SYNDROME

Naegeli-Franceschetti-Jadassohn syndrome differs from incontinentia pigmenti in that the pigmentation is reticular, with no preceding inflammatory changes, vesiculation, or verrucous lesions. Vasomotor changes and hypohidrosis are present. There is reticulate pigmentation involving the neck, flexural skin, and perioral and periorbital areas. Diffuse keratoderma and punctiform accentuation of the palms and soles may occur. Dermatoglyphics are abnormal, producing atrophic or absent ridges on fingerprints. Congenital malalignment of the great toenails may be found. Dental abnormalities are common, and many patients are edentulous. Both genders are equally affected, and the syndrome appears to be transmitted as an autosomal dominant trait related to mutations in keratin 14, causing increased susceptibility to tumor necrosis factor (TNF)-α–induced apoptosis. The syndrome is allelic to dermatopathia pigmentosa reticularis (DPR), which manifests with similar cutaneous findings but DPR patients have absent dermatoglyphs.

PIGMENTARY MOSAICISM

Pigmentary mosaicism is a term that encompasses congenital hypopigmentation and hyperpigmentation in multiple patterns that is due to alterations in genetic pathways responsible for pigmentation. Pigmentation changes can be either hypopigmentation or hyperpigmentation and are often manifested along lines of Blaschko. Some of the affected genes are also important in other tissues and thus markers of systemic disease. For example, if there are defects in neural crest cells that are programmed to form both the skin and the CNS or eye there can be manifestations in all of the tissues. Genetic mutations that occur in earlier in development lead to a more widespread pattern of pigmentation changes and likely a greater chance that some of those cells with mutations were the progenitors for other tissues, thus increasing the risk for systemic disease associations. Many patients with localized pigmentary mosaicism especially when unilateral and blocklike have no associated systemic findings (segmental pigmentary disorder). There are many historical descriptive terms for different types of pigment but because the pathophysiology is the same, the term *pigmentary mosaicism* is more correct. Pigmentary mosaicism can result from chromosomal abnormalities, with most demonstrating mosaicism for aneuploidy or unbalanced translocations. There is no treatment for pigmentary mosaicism although the pigment may normalize over time in some.

PIGMENTARY MOSAICISM WITH HYPOPIGMENTATION

Incontinentia pigmenti achromians (IPA) and *hypomelanosis of Ito* (HI) are terms that have historically been used, but because most people with HI have been described as having seizures and/or developmental delay whereas many people with blaschkoid hypopigmentation do not have these manifestations, it is favored to use the term *pigmentary mosaicism* to avoid the assumption that children with hypopigmentation will have poor prognosis. The hypopigmentation typically follows the lines of Blaschko (Fig. 27.2). If there are system findings, which may be more likely in children with more diffuse cutaneous involvement, affected individuals can have associated anomalies of the CNS, eyes, hair, teeth, skin, nails, musculoskeletal system, or internal organs, including polycystic kidney disease. Patients may manifest psychomotor or mental impairment, autism, microcephaly, coarse facies, and dysmorphic ears.

Because there are many different types of mutations that can lead to hypopigmentation, these patients should not be considered to have one syndrome but instead multiple rare syndromes many of which have not been named. Some patients have had associated Sturge-Weber syndrome–like leptomeningeal angiomatosis. A recent group of patients was described mammalian target of rapamycin (mTOR) with pigmentary mosaicism of the hypopigmented type with megalencephaly and focal cortical dysplasia due to mosaic mTOR mutations. Several patients have demonstrated trisomy 13 with hypopigmented mosaicism.

Fig. 27.2 Incontinentia pigmentary mosaicism.

Hogeling MI, Frieden IJ: Segmental pigmentation disorder. Br J Dermatol 2010; 162: 1337.

PIGMENTARY MOSAICISM WITH HYPERPIGMENTATION

Linear and whorled nevoid hypermelanosis is the term historically used to describe blaschkoid distribution of hyperpigmented streaks without preceding bullae or verrucous lesions. Sparing of mucous membranes, eyes, palms, and soles is noted. Congenital anomalies, such as mental retardation, cerebral palsy, atrial septal defects, dextrocardia, auricular atresia, hemiatrophy, and patent ductus arteriosus, may be present but seem to be less prevalent with hyperpigmentation than with hypopigmented mosaicism. Bilateral giant cerebral aneurysms have been reported. Biopsy of pigmented areas demonstrates increased pigmentation of the basal layer and prominence of melanocytes without incontinence of pigment. Again, patients who have localized pigmentation especially in blocklike unilateral patterns seem to be less likely to have systemic manifestations. Most cases appear to be sporadic, although familial cases have been reported. The differential diagnosis includes other causes of blaschkoid hyperpigmentation such as incontinentia pigmenti, verrucous epidermal nevi that have not proliferated yet, and McCune-Albright syndrome.

DISORDERS DUE TO SEX CHROMOSOMES

X-Linked Reticulate Pigmentation Disorder

X-linked reticulate pigmentation disorder with systemic manifestations that presents with reticulate hyperpigmentation due a mutation that leads to amyloid buildup. In males, cutaneous involvement is characterized by reticulate hyperpigmentation of the skin, characteristic facies, and severe systemic involvement. In the carrier females, manifestations are limited to the skin.

Anderson RC, et al: X-linked reticulate pigmentary disorder with systemic manifestations. Pediatr Dermatol 2005; 22: 122.

Klinefelter Syndrome

Klinefelter syndrome, the most common sex chromosome disorder, consists of hypogonadism, gynecomastia, eunuchoidism, small or absent testicles, and elevated gonadotropins. The patient may have a low frontal hairline, sparse body hair with only a few hairs in the axillary and pubic areas, scanty or absent facial hair in men, and shortening of the fifth digit of both hands.

Thrombophlebitis and recurrent or chronic leg ulcerations may be a presenting manifestation; these may be more common than previously reported. The cause of the hypercoagulable state is believed to be an increase in plasminogen activator inhibitor 1 levels. Patients are at an increased risk of lupus erythematosus and a variety of cancers, especially male breast cancer, hematologic malignancies, and sarcomas (retinoblastoma and rhabdomyosarcoma).

Many of these patients are tall; some are obese. Psychiatric disorders occur in about one third of patients and patients can have decreased mental capacity. Klinefelter syndrome is most frequently associated with an XXY sex chromosome pattern, although other variations occur as the number of X chromosomes increases. Androgen therapy may result in improvements in appearance and function.

XXYY Genotype

The XXYY genotype is considered to be a variant of Klinefelter syndrome. In addition to the changes seen in Klinefelter, vascular changes occur in XXYY patients, such as cutaneous angiomas, acrocyanosis, and peripheral vascular disease leading to stasis dermatitis. Hypertelorism, clinodactyly, pes planus, and dental abnormalities are common. Systemic manifestations include asthma, cardiac defects, radioulnar synostosis, inguinal hernia, cryptorchidism, CNS defects, attention-deficit disorder, autism, and seizures.

XYY Genotype

Patients with an XYY karyotype can have very severe acne with onset in childhood and be more aggressive and have cognitive delays, although these studies were performed on prisoners so there may be a selection bias.

Turner Syndrome

Turner syndrome, also known as gonadal dysgenesis, is characterized by a webbed neck, low posterior hairline margin, increased carrying angle at the elbow (cubitus valgus), congenital lymphedema, and a triangular mouth. Patients may demonstrate alopecia of the frontal area on the scalp, koilonychia, cutis laxa, cutis hyperelastica, mental retardation, short stature, infantilism, impaired sexual development, primary amenorrhea, numerous melanocytic nevi, angiokeratomas, and an increased risk of melanoma, pilomatricoma, and thyroid disease. Coarctation of the aorta is frequently found. There may be an increased incidence of alopecia areata and halo nevi in these patients.

Patients with Turner syndrome are females who have only one X chromosome. Mosaic Turner syndrome exists in which only some cells are missing the other X. Loss of long-arm material (Xq) can result in short stature and ovarian failure, but deletions distal to Xq21 do not appear to affect stature. Loss of the short arm (Xp) produces the full phenotype. Patients with very distal Xp deletions usually have normal ovarian function.

No specific treatment is available for Turner syndrome. Human growth hormone (hGH) has been used to treat the short stature. A review of the Cochrane Central Register of Controlled Trials determined that hGH increases short-term growth, but few data exist regarding its effects on final height.

Multiple pterygium syndrome (Escobar syndrome) is a rare autosomal recessive disorder characterized by multiple congenital joint contractures and multiple skin webs that may mimic Turner syndrome.

RASOPATHIES

The Ras-Map kinase pathway (including Raf, ERK, and MEK) is critical for cellular growth. Many different genetic disorders involving mutations in the genes controlling various parts of this pathway present with similar features. Historically as these diseases were described they had significant clinical overlap and this is due to the defects involving the same pathway. These disorders are now grouped under the category of RASopathies.

Neurofibromatosis Type 1

The four types of neurofibromatosis are neurocutaneous syndromes that are manifested by developmental changes in the nervous system, bones, and skin.

Patients with neurofibromatosis type I (NF-1, von Recklinghausen disease), which accounts for more than 85% of cases, typically present in infancy. NF-1 is either inherited autosomal dominantly or occurs due to de novo mutations. The most common initial manifestations are a large head circumference along with six or more café au lait macules. The typical café au lait macules of NF-1 should have a smooth margin and are oval or round and typically very clinically apparent (Fig. 27.3). Most often, these macules are present at birth and almost always present by 1 year of age. The finding of six or more of these lesions measuring at least 1.5 cm in diameter is diagnostic, usually indicating NF-1. In children, the minimum diameter for a significant lesion is 0.5 cm. There are many children who have brown patches with jagged margins that appear splattered onto the skin or arranged in blaschkoid pattern and these are not typical for NF-1. Histologically, basilar hyperpigmentation is noted, and giant melanosomes may be seen. Axillary freckling (Fig. 27.4) and/or inguinal freckling (Crowe sign) may also be present at birth and can extend to the neck and involve the inguinal, genital, and perineal areas.

Neurofibromas (Fig. 27.5) develop later in childhood and continue to develop into adulthood but are rarely present in infants unless there is a plexiform neurofibroma. Neurofibromas of the areolae

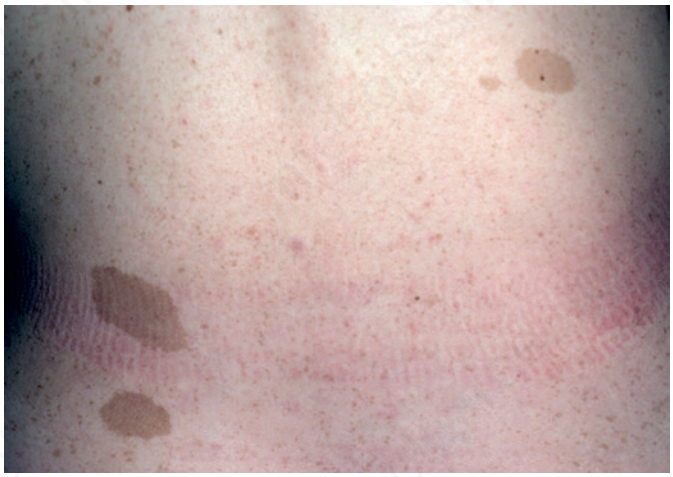

Fig. 27.3 Neurofibromatosis with café au lait macule.

Fig. 27.4 Axillary freckling.

Fig. 27.5 Neurofibromatosis type 1.

Fig. 27.6 Plexiform neurofibroma.

occur in more than 90% of women with NF-1. Neurofibromas are soft tumors that can be pushed down into the panniculus by light pressure with the finger ("buttonholing") and spring back when released. Histologically, these are well-circumscribed, but rarely encapsulated, spindle cell proliferations with an amphophilic myxoid stroma and many mast cells. The spindle cells have a wavy appearance. Neurofibromas result from proliferation of all supporting elements of the nerve fibers, including Schwann, perineurial, endoneurial, and mast cells and blood vessels. Axon stains demonstrate individual axons spread randomly throughout the tumor, in contrast to a schwannoma, where a nerve trunk is compressed at one edge of the tumor, but no axons are present within its bulk.

Subcutaneous plexiform neurofibromas are virtually pathognomonic of NF-1 and are often a manifestation of LOH. On palpation, these resemble a "bag of worms." The overlying skin is usually hyperpigmented and may resemble a giant café au lait macule (Fig. 27.6). Because the plexiform neurofibromas can take time to grow and manifest the larger café au lait may be the only marker of its presence in infancy. Plexiform neurofibromas within the spine can cause paralysis. Histologically, plexiform neurofibromas demonstrate numerous elongated encapsulated neurofibromas, often embedded in diffuse neurofibroma that involves the dermis and subcutaneous fat.

Many organ systems may be involved. Optic gliomas can be present in infancy and patients should be referred to an ophthalmologist immediately. Lisch nodules are found in the irides of about one quarter of patients under 6 years of age and in 94% of adult patients. Acromegaly, cretinism, hyperparathyroidism,

myxedema, pheochromocytoma (<1%), or precocious puberty may be present. Patients with NF-1 can present with hypertension either due to renal artery stenosis or aortic coarctation (early in life) or a pheochromocytoma usually manifested later, and thus all patients with NF-1 should have their blood pressure closely monitored. Bone changes (usually erosive) may produce lordosis, kyphosis, and pseudoarthrosis, as well as spina bifida, dislocations, and atraumatic fractures. The pseudoarthrosis (pseudojoints) can be seen on imaging of long bones in childhood in some patients.

Patients with NF-1 are four times more likely to develop malignancies than the general population. Cutaneous neurofibromas rarely develop into malignant, peripheral nerve sheath tumors. A painful, growing or hardening lesion is an indication for biopsy. An increased incidence of breast carcinoma, Wilms tumor, rhabdomyosarcomas, gastrointestinal (GI) malignancies, and chronic myelogenous leukemia (CML) has also been reported. Children with NF-1 are 200–500 times more likely to develop malignant myeloid disorders than age-matched controls, and the risk for juvenile chronic myelomonocytic leukemia (JCMML) may be higher for those with juvenile xanthogranulomas (JXGs). Therefore some experts advocate for regular complete blood counts for the first few years in patients with NF-1 who have JXG.

Mental retardation, dementia, epilepsy, and a variety of intracranial malignancies may occur. Hypertelorism heralds a severe expression of neurofibromatosis with brain involvement. Diffuse interstitial lung disease occurs in 7% of patients.

Approximately 50% of cases of NF-1 represent new mutations. The gene for NF-1 codes for neurofibromin, a protein that negatively regulates signals transduced by Ras proteins. There is a high rate of spontaneous postzygotic mutation of this gene. Both alleles must be affected for the individual to grow a neurofibroma. In patients with the syndrome, there is germline loss of one allele, and each neurofibroma that develops represents a late spontaneous mutation knocking out the remaining allele.

Segmental neurofibromatosis (also called mosaic neurofibromatosis) arises from postzygotic somatic mutation (Fig. 27.7). Early postzygotic mutation affecting the second allele in fetal life results in LOH affecting an entire Blaschko segment. Within this affected lesion any of the other features of NF-1 could occur, but in one series 29% of the patients were found to have features of NF-1 affecting other tissues and thus patients with segmental NF-1 should be monitored similarly to patients with nonsegmental NF-1. Diagnosis is by biopsying affected tissues for genetic testing because the peripheral blood may be negative.

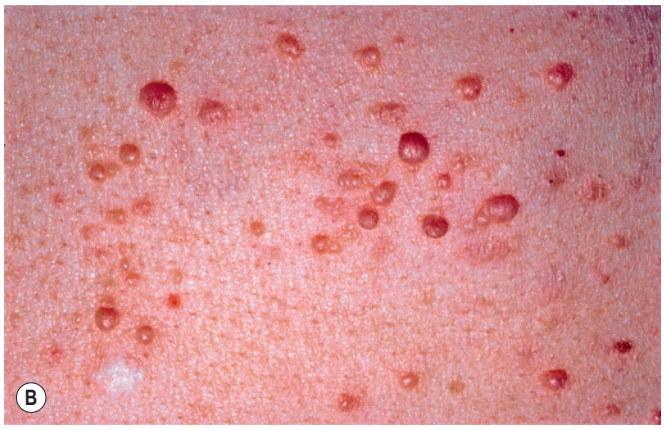

Fig. 27.7 (A and B) Segmental neurofibromatosis.

Diagnosis

The diagnosis of NF-1 requires two or more of the following criteria to be fulfilled:

1. Six or more café au lait macules with a greatest diameter of more than 5 mm in prepubertal individuals, and a greatest diameter of more than 15 mm in postpubertal individuals
2. Two or more neurofibromas of any type or one plexiform neurofibroma
3. Freckling in the axillary or inguinal regions
4. Optic gliomas
5. Two or more Lisch nodules
6. Distinctive osseous lesion, such as a sphenoid dysplasia or thinning of the long-bone cortex with or without pseudarthrosis
7. First-degree relative (parent, sibling, or offspring) with the disease

A diagnosis of NF-2 requires either of the following:

1. Bilateral eighth cranial nerve masses, as demonstrated on computed tomography (CT) or magnetic resonance imaging (MRI)
2. First-degree relative with NF-2 and either unilateral eighth nerve mass or two of the following: a neurofibroma, meningioma, glioma, schwannoma, and juvenile posterior subcapsular lenticular opacity

Although not listed in the previous criteria, the presence of nevus anemicus, xanthogranuloma, and glomus tumors is strongly associated with a diagnosis of NF-1, and the prevalence is high during the first 2 years of life, when other diagnostic criteria may be absent so they are vital to recognize. Nevus anemicus is usually found on the neck and upper chest, whereas the xanthogranulomas tend to be cephalic or genital.

Screening and Monitoring for Complications

In one study of 93 asymptomatic patients with NF-1 who underwent cerebral imaging, 12 optic gliomas were detected, suggesting that screening MRI or CT may be of value. Positron emission tomography (PET) scanning has shown some value in discriminating between benign and malignant tumors. The National Institutes of Health (NIH) consensus panel concluded that studies should be dictated by findings on clinical evaluation. It concluded that laboratory tests in asymptomatic patients are unlikely to be of value. In the majority of patients with NF-1,

imaging studies should only be performed as indicated by signs or symptoms.

Therapy for individual symptomatic lesions is with surgical removal, but sirolimus has shown some efficacy for plexiform neurofibromas that are causing morbidity. Trials of targeted therapy to reduce the growth of cutaneous neurofibromas are ongoing and are likely to result in better treatment options for severely affected patients.

Type 2 neurofibromatosis (NF-2), central or acoustic neurofibromatosis, is distinguished by bilateral acoustic neuromas, usually in the absence of cutaneous lesions, although neurofibromas and schwannomas may occur. The gene for NF-2 encodes for merlin (schwannomin), a protein that links the actin cytoskeleton to cell surface glycoproteins and functions as a negative growth regulator. NF-2 patients, in contrast, often require imaging studies. Screening studies should include an audiogram and brainstem auditory evoked responses. MRI is the best imaging procedure for patients with evidence of hearing impairments or abnormal evoked responses. Tests of vestibular function may be useful, because eighth cranial nerve tumors develop on the vestibular division. A screening MRI should be performed by puberty. Other tests should be performed as dictated by signs and symptoms. Pediatric patients with NF-2 have a worse prognosis, with 75% demonstrating hearing loss, 83% visual impairment, and 25% abnormal ambulation. Type 3 (mixed) and type 4 (variant) forms resemble type 2 but have cutaneous neurofibromas. Patients with these types are at greater risk for developing optic gliomas, neurilemmomas, and meningiomas. These forms are inherited as autosomal dominant traits.

SPRED1 (Legius Syndrome)

Germline loss-of-function mutations in the *SPRED1* gene have been associated with an NF-1–like phenotype with café au lait macules and axillary or inguinal freckling but no neurofibromas or lisch nodules (Legius syndrome). Patients present with similar café au laits and increased head circumference to NF-1, and most laboratories that do genetic testing for NF-1 will do *SPRED1* reflexively if NF-1 testing is negative because the diseases match each other so closely. Developmental delay in patients with mosaic *SPRED1* has now been reported as well.

Noonan Syndrome

Noonan syndrome is an autosomal dominant RASopathy associated with a webbed neck that mimics Turner syndrome but affects males and females equally. The other major features are a characteristic facies with hypertelorism, prominent ears, short stature, undescended testicles, low posterior neck hairline, cardiovascular abnormalities (e.g., pulmonary stenosis), and cubitus valgus. From 25%–40% of patients have dermatologic findings: lymphedema, short curly hair, dystrophic nails, tendency toward keloid formation, soft elastic skin, keratosis pilaris atrophicans (ulerythema of eyebrows), multiple granular cell tumors, and abnormal dermatoglyphics. Growth hormone can help patients achieve more normal stature.

Genetic changes in Noonan affect the RAS/MAPK pathway. The majority of Noonan cases are caused by defects in *PTPN11*. Patients with *PTPN11* have more café au lait macules. Patients with Noonan syndrome may have *SOS1* mutations associated with normal cognition and stature along with keratosis pilaris, *RAF1* mutations entailing a high risk of hypertrophic cardiomyopathy. *PTPN11* mutations predispose to juvenile myelomonocytic leukemia. When differentiating RAsopathies, feeding difficulties and developmental motor delay are the most common features with the cardiofaciocutaneous syndrome and Costello syndrome. Noonan-associated RASopathies appear to have an increased risk of lupus erythematosus.

Noonan Syndrome–Like Disorder With Loose Anagen Hair (NSLAH)

Recently a group of patients with Noonan-like features (short stature, typical facies, and pectus excavatum) along with loose anagen have been documented. They also have more hyperactive behavior, a hoarse voice, and more severe developmental delay. This is caused by a *SHOC2* mutation (or more recently described with *PPP1CB*). The hair demonstrates an anagen hair bulb (hockey stick or tube sock at the end) on dermoscopy, but recently trichorrhexis nodosa and trichoptilosis along with darkened or hairless skin have been described.

Noonan Syndrome With Lentigines (LEOPARD)

The LEOPARD syndrome—multiple lentigines, electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormal genitalia, retardation of growth, and sensorineural deafness—also known as multiple lentigines syndrome, cardiocutaneous syndrome, lentiginosis profusa syndrome, or progressive cardiomyopathic lentiginosis has been renamed Noonan syndrome with lentigines. The lentigines occur in nearly all patients and are small, dark-brown, polygonal, and irregularly shaped macules, usually measuring 2–5 mm in diameter that start around age 5 and increase dramatically over time. There are none in the mucosa. Individual lesions may be larger, even up to 1–1.5 cm. Melanoma has been described in these patients, so atypical lesions should be biopsied.

The LEOPARD syndrome shares many clinical features with Noonan syndrome. These are allelic disorders; patients with both syndromes (Fig. 27.8) demonstrate mutations in the Noonan syndrome gene, *PTPN11*, although patients with *BRAF*, *RAF1*, and *MAP2K1* mutations are described. Although the "R" in LEOPARD indicates growth retardation, some patients with the syndrome also exhibit mild mental retardation or speech difficulties. Many cases appear sporadically; however, inheritance as an autosomal dominant genetic trait has also been reported. Patients should be referred for cardiovascular and hearing evaluation and screened for cryptorchidism.

Costello Syndrome

Costello syndrome is characterized by growth retardation; failure to thrive in infancy; coarse facies; redundant velvety skin on the neck, palms, soles, and fingers; acanthosis nigricans; and nasal papillomata caused by HRAS mutations. Ventricular dilation

Fig. 27.8 Noonan syndrome with multiple lentigines (previously LEOPARD syndrome). (Courtesy Paul Honig, MD.)

is observed in more than 40% of cases. Hydrocephalus, brain atrophy, Chiari malformation, and syringomyelia may occur. Mild to moderate mental deficiency is frequently discovered, and most patients exhibit a characteristic sociable and friendly personality.

CARDIOFACIOCUTANEOUS SYNDROME

Cardiofaciocutaneous (CFC) syndrome is characterized by a distinctive facial appearance, heart defects, and mental retardation. Facial characteristics include high forehead with bitemporal constriction, downslanting palpebral fissures, hypoplastic supraorbital ridges, a depressed nasal bridge, and posteriorly angulated ears with prominent helices. The heart defects include pulmonic stenosis, atrial septal defect, and hypertrophic cardiomyopathy. Patients may have ectodermal abnormalities. The most frequent dermatologic findings in CFC patients involve the hair, which may be sparse, curly, fine or thick, or woolly or brittle. In the majority reported cases, the patient had dry, scaly, ichthyotic skin with follicular hyperkeratosis (keratosis pilaris, or keratosis pilaris atrophicans faciei). Other cutaneous findings include sparse or absent eyebrows and eyelashes, low posterior hairline, patchy alopecia, scant body hair, seborrheic dermatitis, eczema, lymphedema, hemangiomas, café au lait spots, pigmented nevi, hyperpigmented macules or stripes, cutis marmorata, and sacral dimples. Nail dystrophy, koilonychia, and dysplastic teeth have also been reported.

Most cases occur sporadically, but autosomal dominant transmission has been reported. Various subtypes relate to different genes in the RAS/MAPK pathway, including *KRAS*, *BRAF*, and *MEK1 or MEK2* mutations.

EPIDERMAL NEVUS SYNDROMES

Epidermal nevi are overgrowths of specific epidermal structures and can be isolated to skin findings or if more widespread or extensive can be a marker for a syndrome. Important clues to the diagnosis of specific epidermal nevus (EN) syndromes include linear lesions following blaschkoid lines because the lesions and syndromes are caused by postzygotic mutations leading to mosaicism. Many of the following syndromes are reviewed in other chapters: linear nevus sebaceous (NS) in Schimmelpenning syndrome, NS and papular nevus spilus in phacomatosis pigmentokeratotica, soft white hair in angora hair nevus syndrome (Schauder syndrome), breast hypoplasia in Becker nevus syndrome, mosaic R248 C mutation in fibroblast growth factor receptor 3 EN syndrome (characterized by soft velvety EN and CNS abnormalities), and acral strawberry papillomatous lesions on tips of fingers or toes in CHILD syndrome (see Congenital Hemidysplasia with Ichthyosiform Erythroderma and Limb Defects [CHILD] Syndrome, later in this chapter). Other EN syndromes include nevus trichilemmocysticus (cysts in blaschkoid distribution), didymosis aplasticosebacea (NS with aplasia cutis congenita), SCALP syndrome (NS, CNS malformations, aplasia cutis, limbal dermoid, and pigmented nevus), Gorbello syndrome (systematized linear velvety EN with bone defects), NEVADA syndrome (nevus epidermicus verrucosus with angiodysplasia and aneurysms), and CLOVE syndrome (congenital lipomatous overgrowth [see Chapter 28], vascular malformations, and EN with nonprogressive proportionate overgrowth).

Proteus Syndrome

Proteus syndrome is an overgrowth syndrome caused by an *AKT1* mutation. The mutation appears to be mosaic and activating leading to overgrowth. Proteus shares many features with other syndromes such as PTEN hamartoma syndrome and CLOVE syndrome (see Chapter 28) because they are within a common cellular pathway. Proteus syndrome is named after the Greek god Proteus. The syndrome has protean manifestations that include disproportionate, asymmetric, and distorting segmental overgrowth; cerebriform plantar hyperplasia (Fig. 27.13); epidermal nevi; patchy dermal hypoplasia; macrocephaly; hyperostosis; muscular hypoplasia; hypertrophy of long bones; vascular malformations of the capillary, venous, or lymphatic types; lipomas, lipohypoplasia; fatty overgrowth; bullous lung alterations; intellectual disability; seizures; brain malformations; and deep vein thrombosis. The cerebriform hyperplasia is histopathologically a connective tissue nevus made of collagen and can occur most commonly on the plantar foot but also the palm, abdomen, and nose and is a major diagnostic criterion of Proteus syndrome and very suggestive if present. The vascular lesions are capillary malformations and tend to be darker purple and geometric. Patients with a greater number of cutaneous lesions also have the most extracutaneous abnormalities. There is a high risk of deep vein thrombosis. The vascular stains and epidermal nevi may be the first manifestations because the overgrowth can take time to present (different from CLOVE syndrome) that has similar features. There is progressive severe bony overgrowth in Proteus syndrome that can be extremely distorting.

PHAKOMATOSES

The phakomatoses are the various inherited disorders of the CNS associated with cutaneous and often ocular involvement. The term was more helpful in organizing genodermatoses before the current genetic pathophysiologic classifications. Phakomatoses include tuberous sclerosis, neurofibromatosis, von Hippel–Lindau disease, ataxia-telangiectasia, nevoid basal cell carcinoma syndrome, nevus sebaceous, and Sturge-Weber syndrome. Many of these disorders have been grouped into more specific groups in this book due to more specific understanding of the pathogenisis of each syndrome.

TUBEROUS SCLEROSIS

Tuberous sclerosis was first described by Desiree-Magloire Bourneville in 1880. The classic triad of adenoma sebaceum (Fig. 27.9), mental deficiency, and epilepsy, however, is present in only a minority of patients. Other associated features include periungual fibromas, shagreen plaques (collagenoma), oral papillomatosis, gingival hyperplasia, ash-leaf hypomelanotic macules, skin fibromas, and café au lait spots.

The first cutaneous lesions are typically the white patches that are oval and shaped like an "ash leaf" (Fig. 27.10). These congenital white, leaf-shaped macules, also called hypomelanotic macules, are found in 85% of patients with tuberous sclerosis and range in number from 1 to 100, although 3 lesions greater than 5 mm must be present to satisfy the criteria. Occasional patients may not develop the macules until 6–8 years of age. These may be

Fig. 27.10 Ash-leaf macules.

Fig. 27.9 Angiofibromas (adenoma sebaceum).

Fig. 27.11 Tuberous sclerosis with shagreen plaque.

Fig. 27.12 Tuberous sclerosis with periungual fibromas.

shaped like an ash leaf, but linear and confetti-type white macules may also be present. Wood's light examination will highlight these lesions because they can be subtle. Focal poliosis (localized tufts of white hair) may be present at birth. Solitary ash-leaf macules can occur in the general population and may be difficult to distinguish from pigmentary mosaicism and nevus depigmentosus.

Adenoma sebaceum lesions (angiofibromas) are 1–3 mm, yellowish red, translucent, discrete, waxy papules that are distributed symmetrically, principally over the cheeks, nose, and forehead. These lesions are present in 90% of patients older than 4 years, persist indefinitely, and may increase in number. A fibrous forehead plaque (newly named "fibrous cephalic plaque" because they can be anywhere on the head) is usually on the forehead and histopathologically appears to be an angiofibroma. Angiofibromas have also been reported in patients with multiple endocrine neoplasia (MEN-1) and the Birt-Hogg-Dube syndrome.

Shagreen plaque is named after a type of leather tanned to produce knobs on the surface, resembling shark skin. Patches of this type of "knobby" skin, varying from 1–8 cm in diameter, are found on the trunk, most often on the lumbosacral area (Fig. 27.11). These are connective tissue nevi composed almost exclusively of collagen, occur in 40% of patients, and develop in the first decade of life.

Koenen tumors (periungual angiofibromas) occur in 50% of patients (Fig. 27.12). The tumors are small, digitate, protruding, asymptomatic, and periungual/subungual. They appear at puberty. Similar lesions may occur on the gingiva. Nails may also demonstrate longitudinal grooves, long leukonychia, and short red streaks.

Gingival fibromas in the mouth can occur on the buccal mucosa, the labial mucosa, and the tongue.

Mental deficiency, usually appreciated early in life, is present in 40%–60% of patients, varying widely in its manifestations. Epilepsy also occurs, is variable in its severity, and usually also presents early in life. Between 80% and 90% of patients have seizures or nonspecific electroencephalographic abnormalities. Hamartomatous proliferations of glial and neuronal tissue produce potato-like nodules in the cortex. X-ray evaluation will reveal these once calcified, but CT, cranial ultrasonography, and MRI may define these lesions as early as 6 weeks of age and thus are useful in making an early diagnosis. These brain tumors may progress to gliomas. Subependymal nodules ("candle drippings") are similar lesions in the ventricular walls. Astrocytomas may also occur. Forehead plaques may be a marker for more serious intracranial involvement.

Retinal tumors (phakomas) are optic nerve or retinal nerve hamartomas. Various ophthalmologic findings, such as pigmentary changes, nystagmus, and angioid streaks, occur in 50% of patients. Renal hamartomas (angiomyolipomas, cystic disease, fibroadenomas, or mixed tumors) and cardiac tumors (rhabdomyomas in 43%) may also occur. Renal angiomyolipomas are bilateral and cause renal failure. The cardiac rhabdomyomas may only be seen prenatally and regress after birth but are highly specific for tuberous sclerosis (TS). Pulmonary lymphangioleiomyomatosis is more common in women, especially in their thirties and forties, and can lead to progressive respiratory failure or spontaneous pneumothorax. The condition is characterized by diffuse proliferation of smooth muscle cells and cystic degeneration of the pulmonary parenchyma, associated with the perivascular epithelioid cells ("PEC" cells) implicated in various PEComas. Almost half of patients with TS have bony abnormalities such as bone cysts and sclerosis, which can be seen on x-ray evaluation. Five or more pits in the enamel of permanent teeth are a marker for this disease.

Tuberous sclerosis is a common inherited autosomal dominant disease with highly variable penetrance. Prevalence estimates range from 1 in 5800 to 1 in 15,000. Up to 50% of cases may result from spontaneous mutations. There are two genes, the mutations of which produce indistinguishable phenotypes *TSC1* and *TSC2*. These are tumor suppressor genes. *TSC2* encodes for tuberin, a putative guanosine triphosphatase (GTPase)–activating protein for rap1 and rab5. *TSC1* encodes for hamartin, a novel protein with no significant homology to tuberin or any other vertebrate protein. Hamartin and tuberin associate physically in vivo, suggesting that they function in the same complex rather than in separate pathways. This interaction of tuberin and hamartin explains the indistinguishable phenotypes caused by mutations in either gene. Hamartomas frequently demonstrate loss of the remaining normal allele (loss of heterozygosity).

Diagnosis

The major criteria for TS are three or more hypomelanotic macules, three or more angiofibromas or a fibrous cephalic plaque, two or more periungual fibromas, shagreen patch, retinal hamartomas, cortical dysplasia, subependymal nodules, subependymal giant cell astrocytoma, cardiac rhabdomyoma, lymphangioleiomyomatosis, and angiomyolipomas.

The minor criteria are confetti-like macules, three or more dental enamel pits, two more intraoral fibromas, retinal achromic patch, multiple renal cysts, and nonrenal hamartomas.

A diagnosis of TS is made either with positive TSC 1 or 2 testing or with two major or one major and two or more minor criteria. A possible diagnosis is with one major or two or more minor criteria.

Workup should include a full skin examination for cutaneous features including a Wood's light examination. If x-ray examination fails to show calcified intracranial nodules, ultrasonography, CT, or MRI should be performed. Funduscopic examination, hand and foot x-ray evaluation, and renal ultrasonography are often revealing in a patient with few clinical findings; up to 31% of asymptomatic parents have been identified using these tests.

Treatment

Adenoma sebaceum can be treated by shaving, dermabrasion, or laser therapy, but topical rapamycin ranging from 0.1%–1% applied to the lesions can eradicate them noninvasively. Lesions are likely to recur, requiring maintenance treatment. Everolimus was the first mTOR inhibitor approved in the United States and Europe as a treatment for subependymal giant cell astrocytomas. Clinical evidence also supports the use of mTOR inhibitors, including sirolimus, in a variety of tuberous sclerosis complex–associated disease manifestations, including facial angiofibromas, renal angiomyolipoma, and epilepsy. Cranial irradiation of astrocytomas should be avoided because this may result in the subsequent development of glioblastomas.

VON HIPPEL–LINDAU SYNDROME

Von Hippel–Lindau syndrome is an autosomal dominant disorder consisting of retinal angiomas, cerebellar medullary angioblastic tumors, pancreatic cysts, and renal tumors and cysts. Ocular lesions may lead to retinal detachment. Pheochromocytoma has been associated in several kindreds with von Hippel–Lindau disease. Usually, the skin is not involved, although capillary malformations on the head and neck and café au lait macules have been described.

Patiroglu T, et al: Cerebellar hemangioblastoma associated with diffuse neonatal hemangiomatosis in an infant. Childs Nerv Syst 2012; 28: 1801.

ATAXIA-TELANGIECTASIA

Also known as Louis-Bar syndrome, ataxia-telangiectasia (AT) consists of cerebellar ataxia, oculocutaneous telangiectasia, and sinopulmonary infections. Patients may have a marked IgA deficiency, with decreased lymphocytes and a small to absent thymus. In 80% of cases, IgA is absent or deficient; in 75%, absent or deficient IgE is seen; and in 50%, IgG is very low. There also can be T-cell lymphopenia. AT is caused by a mutation in the ATM gene. It is usually first noted when the child begins to walk. There is awkwardness and a swaying gait, which results in the child needing to use a wheelchair by about 10 years of age. Choreic and athetoid movements and pseudopalsy of the eyes are other features. Fine telangiectases appear on the exposed surfaces of the conjunctiva at about age 3. Telangiectases also appear later on the butterfly area of the face, inside the helix and over the backs of the ears, in the roof of the mouth, in the necklace area, in the flexures, and over the dorsa of the hands and feet. The skin tends to be dry and coarse and over time becomes tight and inelastic, as in scleroderma. Atrophic, granulomatous, scarring plaques may occur. Granulomatous plaques occur in various immunodeficiency syndromes including cartilage hair hypoplasia, combined variable immunodeficiency and DNA ligase deficiency. Rubella virus has been documented by PCR in the granulomatous lesions and likely is a result of the immune system not being able to handle the killed virus that is introduced during vaccination that occurs with the live vaccine at age 1 before knowing the child has immunodeficiency.

Other cutaneous stigmata are café au lait patches, hypopigmented macules, melanocytic nevi, hypertrichosis, seborrheic dermatitis, premature graying and sparsity of the hair, and progeroid features. The most common types of malignancy are lymphomas, usually of the B-cell type, and leukemias. It has been shown that homozygous patients also have a higher risk of breast cancer—100 times higher than age-matched controls. Heterozygous carriers share the defective repair of radiation-induced damage, and there is a threefold to fivefold higher risk for development of neoplasms, especially breast cancer, in heterozygotes under age 45. The ovaries and testicles do not develop normally. There is deficient thymus development, with absence of Hassall's corpuscles and a lack of T-helper cells. Suppressor T cells are normal.

Early death from bronchiectasis occurs in more than half these patients, most of whom have recurrent sinus and lung infections that begin between 3 and 8 years of age.

Ataxia-telangiectasia is transmitted as an autosomal recessive trait, and heterozygotes, although they lack clinical findings, are cancer prone. The ATM gene is involved in cell cycle control, meiotic recombination, telomere length monitoring, and DNA damage response. Affected cells are hypersensitive to ionizing radiation.

Early diagnosis can be difficult and the most frequent misdiagnosis is cerebral palsy. The ataxia, along with telangiectasias, persistently elevated levels of α-fetoprotein, and carcinoembryonic antigen, along with the immunodeficiency, are useful in early diagnosis. Genetic testing is diagnostic.

EPIDERMOSYSIS BULLOSA

Epidermolysis bullosa (EB) is a group of rare genetic disorders characterized by skin fragility with formation of blisters from minor physical injury. EB occurs due to congenital absence of proteins involved in keeping the epidermis together or connected to the dermis. Autoimmune blistering diseases often target similar proteins but are acquired. EB has been reclassified based on where the splitting of the skin occurs. The severity of EB subtypes is associated with the location of blistering, extent of loss of the skin, and other abnormalities associated with the protein that is defective or absent. The split in EB simplex (EBS) is within the epidermis (and is further divided into suprabasal and basal), junctional EB (JEB) splits within the basement membrane, and dystrophic EB (DEB) splits below the basement membrane. There are mixed pattern as well (Kindler). The inherited types of EB are classified as listed in Box 27.1.

Some of the mutations leading to EB are in genes that expressed in other tissues and therefore have extracutaneous manifestations. Esophageal and laryngeal complications are seen primarily in recessive dystrophic EB but may be present in JEB (Herlitz). Pyloric atresia can occur in JEB. Ocular lesions may be severe in dystrophic EB, and mild lesions have been reported in simplex and junctional disease. Congenital absence of the leg skin (Bart syndrome) presents with geometric loss of large areas of skin often on the medial legs extending to the calves possibly from one leg rubbing on the other in utero. This phenotype can be seen in multiple different forms of EB although it is most commonly reported with dystrophic EB.

Clinical findings and routine histologic features overlap in EB. Electron microscopy (EM) studies and immunofluorescent mapping can be used to determine the location of the split and the presence or absence of certain proteins. Immunofluorescent mapping may define the level of the split without resorting to EM. By staining biopsy specimens for normal components of the basement membrane zone (BMZ), such as bullous pemphigoid antigen, laminin, type IV collagen, or LDA-1 antigen, the level of the split may be determined by whether the antigen localizes at the roof or base of the blister. Biopsy should be done by inducing a new blister (usually with a pencil eraser) in clinically normal skin and sending to a specialized laboratory. EM and immunofluorescence do not always fully differentiate between various phenotypes that can be caused by mutations in the same genes, and genetic testing can be done to confirm a diagnosis. Now that genetic panels are available that include nearly all described EB mutations and are less expensive and faster than previously, it is reasonable to start with genetic testing because it will avoid a procedure and give a more definitive diagnosis. However, caution is advised predicting severity from genetic testing because not all patients with the same mutation will have the same clinical symptoms.

BOX 27.1 Inherited Types of Epidermolysis Bullosa

INTRAEPIDERMAL

- Epidermolysis bullosa (EB) simplex, generalized intermediate, *KRT5* or *KRT14* mutation
- EB simplex, localized, *KRT5* or *KRT14* mutation
- EB, generalized severe, *KRT5* or *KRT14* mutation
- EBS with muscular dystrophy, pyloric atresia and Ogna are caused by Plectin mutations
- EB simplex-migratory circinate is caused by keratin 5 mutations
- EB simplex with mottled pigmentation, *KRT5* mutation
- EBS with muscular dystrophy, pyloric atresia and Ogna (above) are caused by Plectin mutations)
- EB superficialis
- Acantholytic EB simplex, *DSP* or *JUP* mutations
- Acral peeling skin syndrome is caused by TGM5 mutation
- Skin fragility syndromes
  - **Skin fragility–wooly hair syndrome (desmoplakin mutation)**
  - **Skin fragility (plakoglobin mutation)**
  - **Skin fragility–ectodermal dysplasia syndrome (plakophilin mutation)**
- EB simplex autosomal recessive–BP230 mutation
- EB simplex autosomal recessive–exophilin 5 mutation
- EB simplex autosomal recessive–*K14* mutation

JUNCTIONAL (INTRALAMINA LUCIDA)

- Junctional epidermolysis bullosa (JEB), generalized severe, *LAMA3, LAMB3,* or *LAMC2* mutations
- JEB, generalized intermediate, *LAMA3, LAMB3, LAMC2,* or *COL17A1* mutations
- JEB localized
- JEB with pyloric atresia (α6β4-integrin)
- JEB, late onset (Collagen XVII mutation)
- JEB with respiratory and renal involvement (α3-integrin subunit)
- JEB inversa

DERMOLYTIC OR DYSTROPHIC (SUBLAMINA DENSA)

Dominant Forms

- Dystrophic EB, generalized, *COL7A1* mutation
- EB pruriginosa
- Pretibial EB
- Bullous dermolysis of the newborn

Recessive Forms

- Generalized severe, collagen VII absent, *COL7A1* mutations
- Generalized intermediate, *COL7A1* mutations
- Bullous dermolysis of the newborn, *COL7A1* mutations
- Localized (various types, including EB pruriginosa and pretibial EB)

Intraepidermal Forms (Epidermolysis Bullosa Simplex)

Suprabasal Epidermolysis Bullosa Simplex

Suprabasal forms of EBS are caused by defects in transglutaminase 5, plakophilin, desmoplakin, and plakoglobin. They present with skin fragility and peeling.

Acral peeling skin syndrome is caused by transglutaminase 5 mutations and leads to superficial peeling, especially on the palms and soles, and heals without scarring.

EBS superficialis presents with superficial blisters and has no causal known mutation.

Skin fragility syndromes include EBS desmoplakin skin fragility and woolly hair syndrome, skin fragility–ectodermal dysplasia syndrome, and skin fragility–plakoglobin deficiency. Mutations in the genes that encode the plakin family (desmoplakin, plakoglobin, and plakophilin) can present with widely variable phenotypes, including with systemic findings.

Skin Fragility (Plakoglobin Mutation)

Plakoglobin mutations can affect skin, hair and heart. Different mutations can lead to isolated skin findings of fragility or isolated cardiac findings. The phenotype of wooly hair,

palmoplantar keratoderma and cardiomyopathy is called Naxos disease.

Skin Fragility and Woolly Hair Syndrome (Desmoplakin Mutation)

Mutations in desmoplakin can lead to multiple different phenotypes depending in part on the specific mutation because desmoplakin is expressed in skin, hair, nails, and cardiac tissue. Skin fragility with wooly hair is isolated to the skin. Desmoplakin mutations can also cause a striate PPK in isolation, a striate PPK with wooly hair and cardiomyopathy (Carvajal syndrome), cardiac disease in isolation, or a lethal acantholytic EB with complete alopecia.

Skin Fragility–Ectodermal Dysplasia Syndrome (Plakophilin Mutation)

This syndrome is characterized by inflammation around the mouth with fissuring, nail dystrophy, trauma-induced skin fragility, and defects of the hair, nails, and sweat glands. Trauma-induced blisters are generalized with skin tearing noted on the pressure points, especially after prolonged standing or walking. Plakophilins are not expressed in cardiac tissue so there are no cardiac findings thus far reported.

Epidermolysis Bullosa Simplex, Basalar

There are multiple forms of EBS caused by mutations in the genes encoding keratins 5 or 14, and the severity and pattern depend on the how much the mutation disrupts function. Basal EBS mutations in Krt5 or Krt14 can cause EBS localized, EBS generalized-severe, or EBS generalized-intermediate. Mutations in Krt5 cause EBS with mottled pigmentation and EBS migratory circinate.

Mutations in K14 can cause an autosomal recessive EBS (EBS autosomal recessive-K14). EBS with muscular dystrophy, pyloric atresia, and Ogna are caused by plectin mutations. Two other types of autosomal recessive EBS are caused by BPAG-1 or exophillin 5 mutations.

Epidermolysis Bullosa Simplex, Localized

Recurrent bullous eruption of the hands and feet is autosomal dominantly determined and appears in a chronic form in early childhood with exacerbations as an adult based on activities that increase friction. The Weber-Cockayne designation has been dropped in recent classification schemes. The lesions worsen during hot weather and when the patient is subjected to prolonged walking or marching, as in military service. Hyperhidrosis may be an associated finding. In localized EBS, the bullae are intraepidermal and suprabasal, and healing occurs without scarring.

Application of aluminum chloride hexahydrate in anhydrous ethanol (Drysol) on the normal skin of hands and feet twice a day has been shown to reduce blistering in this form of EBS. After 2 weeks of daily therapy, the patient can be switched to weekly or twice-weekly applications.

Epidermolysis Bullosa Simplex, Generalized Intermediate

The generalized type of EBS, dominantly inherited with complete penetrance, occurs in 1 in 500,000 births. It is characterized by the development of vesicles, bullae, and sometimes milia over the joints of the hands, elbows, knees, and feet, as well as other sites subject to repeated trauma. The child is affected at birth or shortly thereafter, with improvement within the first few months, but there are more blisters when the child begins crawling. The blistering is worse during the summer and improves during the winter. The lesions are sparse and do not lead to severe atrophy. Usually, the mucous membranes and nails are not involved. EBS is usually milder than other forms of EB.

Inherited as an autosomal dominant trait, EBS is a disease in which keratin gene mutations cause the production of defective intermediate filaments, that lead to epidermal basal cell fragility and subsequent blistering. The genes encoding keratins 5 or 14 (expressed in the basal layer) are mutated. Patients heterozygous for abnormal keratin 14 have blistering limited to the hands and feet, but homozygotes have more severe and widespread blistering of the skin and mucous membranes. Separation occurs through the basal cell layer.

Epidermolysis Bullosa Simplex, Generalized Severe

In this autosomal dominant variant of EBS, active blisters (Fig. 27.14) with circinate configuration occur in infancy. Milia may develop, but there is no scarring. The oral mucosa is involved. Nails are shed but may regrow, sometimes with dystrophy. Blistering lessens with age. Hyperkeratosis of the palms and soles may occur. Histologically, the split is through the basal layer, and tonofilaments are clumped on EM. Point mutations have been shown in keratin 5 and 14 genes.

Epidermolysis Bullosa Simplex With Mottled Pigmentation

Patients have been reported with autosomal dominant EBS with congenital scattered hyperpigmented and hypopigmented macules that fade slowly after birth. The remaining features are similar to those of generalized EBS. Ultrastructural studies show vacuolization of the basal cell layer.

Epidermolysis Bullosa Simplex Migratory Circinate

Affected individuals present with slowly advancing erythema with blisters, and the lesions resolve with pigmentation. The mutation in EBS migratory circinate is the same as mottled pigmentation, so they are likely on a spectrum with some cases showing more erythema in early life and mottled pigmentation later.

Fig. 27.14 Epidermolysis bullosa simplex, generalized.

Epidermolysis Bullosa Simplex With Muscular Dystrophy

A form of EBS is associated with late-onset neuromuscular disease and is caused by plectin mutation. Widespread blistering at birth is associated with scarring, milia, atrophy, nail dystrophy, dental anomalies, laryngeal webs, and urethral strictures. Progressive muscular dystrophy with weakness and wasting begins in childhood or later so patients should be followed over time.

Epidermolysis Bullosa Simplex With Pyloric Atresia

EBS with pyloric atresia is also caused by plectin mutation as well as integrin beta-4 and alpha-6 because integrin beta-4 binds plectin in the hemidesmosome. Late urologic complications have been described in patients with EBS with pyloric atresia.

Epidermolysis Bullosa Simplex (Ogna)

Generalized bruising and hemorrhagic blisters occur. EBS is transmitted as an autosomal dominant trait. At birth there are small, acral, traumatic sanguineous blisters. The basal keratinocytes in this syndrome do not stain with antiplectin antibodies.

Junctional Forms

Junctional epidermolysis bullosa (JEB) presents with severe generalized blistering usually at birth (Fig. 27.15), and in most forms extensive denudation may prove fatal. JEB is caused by mutations in three genes: *LAMA3*, *LAMB3*, or *LAMC2*, that code for polypeptide subunits of laminin 332 (also referred to as laminin 5), COL XVII, and integrins alpha-3 or -6 or beta-4.

Junctional Epidermolysis Bullosa

JEB can classified as localized, generalized, or generalized severe. The more severe phenotypes are characterized by more blisters, scarring, and intraoral involvement. There is little to no GI, ocular genitourinary, or respiratory involvement in the less severe forms. JEB is characteristic perioral and perinasal hypertrophic granulation tissue. Eventually, the lesions heal without scarring or milia formation, but erosions may persist for years. Dysplastic teeth are common. Laryngeal and bronchial lesions may cause respiratory distress and death in more severe forms. Additional systemic complications include GI tract, gallbladder, corneal, and vaginal disease. Patients who survive infancy have growth retardation and, often, moderate to severe refractory anemia.

In addition to good wound care and control of infection, epidermal autographs of cultured keratinocytes, isolated from clinically uninvolved skin and grown on collagen sponges, may be useful for chronic facial erosions.

Fig. 27.15 Junctional epidermolysis bullosa.

Junctional Epidermolysis Bullosa With Pyloric Atresia

This rare autosomal recessive inherited form of JEB presents at birth with severe mucocutaneous fragility and gastric outlet obstruction. Often the ears are crumpled and misshapen. Even if the pyloric atresia is repaired, the neonates may die of the severity of their skin disease. If they survive the neonatal period, the blistering diminishes. Persistent scarring of the urinary tract may occur, however, with stenosis of the ureteral-vesicular junction, requiring numerous urologic procedures. This syndrome is usually caused by a genetic mutation in either the α6- or β4-integrin genes (*ITGA6* and *ITGB4*). This α6β4-integrin complex is uniquely expressed on epithelial surfaces.

Other Forms of Junctional Epidermolysis Bullosa

JEB with late onset is caused by collagen XVII mutations and is generally more mild than typical JEB. JEB with respiratory or renal involvement is caused by mutations in integrin alpha-3.

Dermolytic or Dystrophic Forms of Epidermolysis Bullosa

The cause of dystrophic EB in both autosomal dominant and autosomal recessive inherited forms is mutation in the *COL7A1* gene encoding for type VII collagen. The anchoring fibrils in these patients are defective or deficient. Presumably, because of antigen exposure, anti–type VII collagen, anti-BP180, and anti-BP230 autoantibodies may be detected.

Dominant Dystrophic Epidermolysis Bullosa

Dominant dystrophic EB (DDEB) typically presents at or soon after birth with blisters but the overall course of it is favorable. The blisters are most pronounced over the joints, especially over the toes, fingers, knuckles, ankles, and elbows (Figs. 27.16 and Fig. 27.17). Spontaneous, flesh-colored, scarlike (albopapuloid) lesions may appear on the trunk, often in adolescence, with no previous trauma and may be associated with more severe disease. The nails may be thickened. Usually, Nikolsky sign is present, and frequently the accumulated fluid in a bulla can be moved under the skin several centimeters away from the original site. Healing usually occurs with scarring and atrophy. Milia are often present on the rims of the ears, dorsal surfaces of the hands, and extensor surfaces of the arms and legs.

The mucous membranes are frequently involved. Bullae, vesicles, and erosions are encountered on the buccal mucosa, tongue, palate, esophagus, pharynx, and larynx. The latter involvement is manifested by persistent hoarseness in some of these patients. There may be angular contractures at the gingivolabial sulcus and dysphagia from pharyngeal scarring. Scarring on the tip of the tongue can happen. The teeth are normal. Usually, the conjunctiva is not involved.

EB pruriginosa is a form for DDEB is characterized by extreme pruritus, lichenified plaques, prurigo-like lesions, and violaceous linear scarring often worst on the pretibial area. Nail dystrophy is common.

Bullous dermolysis of the newborn (BDN), also called transient BDN, is a mild form of DDEB in which the blisters dissipate or

Fig. 27.16 Dominant dystrophic epidermolysis bullosa.

Fig. 27.17 Epidermolysis bullosa, dominant dystrophia.

stop forming all together after infancy. The presence of intracytoplasmic collagen VII retention seen on immunofluorescence or stellate bodies on EM has been proposed as a way of distinguishing BDN from DDEB. The mechanism for the transient nature of reduced amounts of type VII collagen along the dermoepidermal junction remains to be defined.

Histologically, in DDEB a noninflammatory subepidermal bulla is generally present. On electron microscopy, cleavage occurs beneath the basal lamina, and anchoring fibrils are rudimentary and reduced in number. In blistered areas, these are not demonstrable.

Recessive Dystrophic Epidermolysis Bullosa, Generalized Severe

All forms of recessive dystrophic EB result from mutations in the gene encoding type VII collagen, *COL7A1*. Generalized recessive dystrophic EB in its mildest form has blisters limited primarily to the hands, feet, elbows, and knees, and limited complications. The more severe variety characteristically begins at birth with generalized cutaneous and mucosal blistering. Digital fusion with encasement of the fingers and toes in scar tissues, forming a "mitten-like" deformity (Fig. 27.18), is characteristic of the severe form of recessive dystrophic EB, occurring in up to 90% of patients by

Fig. 27.18 Epidermolysis bullosa, recessive dystrophic type.

age 25. Dental complications may be severe, including extensive dental caries and microstomia. Esophageal stricture may be present. Anemia and growth retardation are frequently seen in the most severe cases, and progressive nutritional deficiency can result in fatal cardiomyopathy. Monitoring for anemia, hypoproteinemia, zinc deficiency, selenium levels, and carnatine levels is recommended. Fatal systemic amyloidosis (AA type) has also been reported. There is a high risk of developing cutaneous squamous cell carcinomas (SCCs), with up to 50% of patients affected by age 35. These SCCs may be multiple and can metastasize and cause death.

Although gene therapy is promising, treatment remains primarily palliative. Gentle wound care and proper nutrition are critical. Debilitating oral lesions produce pain, scarring, and microstomia. Aggressive dental intervention is recommended. Nutritional support is of critical importance. Autologous meshed split-thickness skin grafts and allogeneic cultured keratinocytes have been useful in treating nonhealing cutaneous defects, or may be used for closure after removal of large cutaneous malignancies. A single injection of allogeneic fibroblasts at the margins can accelerate early healing of chronic recessive dystrophic EB erosions. Family education and referral to DEBRA (Dystrophic Epidermolysis Bullosa Research Association of America, 5 West 36th Street, Room 404, New York, NY 10018, www.debra.org) are strongly recommended.

Kindler Syndrome (Acrokeratotic Poikiloderma, Weary-Kindler Syndrome)

In 1954 Kindler reported a combination of poikiloderma congenitale and traumatic blistering of the feet from minor trauma. The disorder shares some clinical features with dominant dystrophic EB, but in the largest reported familial cluster, inheritance followed an autosomal recessive pattern. Characteristic features include skin fragility with blistering, congenital acral bullae, generalized poikiloderma with prominent atrophy, photosensitivity, acral keratoses, severe periodontal disease, and phimosis. Some patients develop intestinal dysfunction or ulcerative colitis. Pseudoainhum and sclerotic bands were reported in one case. The principal histologic change is absence of elastic fibers in the papillary dermis and fragmented fibers in the middermis. Ultrastructural studies have shown replication of the lamina densa. Acrokeratotic poikiloderma is caused by loss-of-function mutations in fermitin family homolog 1, an actin cytoskeleton-associated protein encoded by the gene *FERMT1*, which plays a role in keratinocyte adhesion, migration, and proliferation. The protein is mainly expressed in basal keratinocytes. It binds to fermitin family homolog 2, as well as beta-1 and beta-3 integrins.

TREATMENT

Treatment consists of prevention of trauma, decompression of large blisters, and monitoring for and treating infection. Denuded areas should be covered with nonadherent dressings such as silicone or petrolatum based dressings as a contact layer and then wrapped with elastic dressings that do not require tape. Application of prophylactic antibiotics may lead to resistance, so topical antibiotics are typically reserved for acute infections and the type of antibiotic (mupirocin, bacitracin, retapamulin) is often rotated to decrease the risk of resistance. In severe forms of EB including JEB and recessive dystrophic epidermolysis bullosa (RDEB), patients are often colonized with *Staphylococcus aureus* or other bacteria, including *Pseudomonas aeruginosa*. Infection with candida species or even herpes simplex can be difficult to differentiate in chronic wounds and blistered areas so there should be a low threshold for culture.

Autologous meshed split-thickness skin grafts and allogeneic cultured keratinocytes may be used in treating nonhealing skin defects. Bone marrow or cord blood transplantation for more severe forms of EB has been tried but the benefits may be transient and there is significant risk related to the transplantation itself. Recently a JEB patient's entire epidermis was regenerated with autologous keratinocytes grown in culture.

OTHER GENETIC BLISTERING DISEASES

Familial Benign Chronic Pemphigus (Hailey-Hailey Disease)

In 1939 Hailey and Hailey described a familial disease characterized by persistently recurrent bullous and vesicular dermatitis of the sides of the neck, axillae, and flexures. The eruption may remain localized or may become widespread. Usually, intact blisters are not evident. Instead, the lesions appear as macerated plaques with a linear or reticulated pattern of fissuring (Fig. 27.19). Lesions may become thickly crusted producing circinate and figurate patterns that resemble impetigo. The onset is usually in the late teens or early twenties. The condition is typically worse during the summer. Lesions tend to recur at sites of prior involvement. There may be tenderness and enlargement of the regional lymph glands caused by secondary bacterial infection. Longitudinal

Fig. 27.19 Hailey-Hailey disease.

leukonychia may occur. Involvement of the esophagus, mouth, and labia majora is rare.

In predisposed persons with Hailey-Hailey disease, skin trauma, sunburn, bacterial or fungal infection, and dermatoses may trigger lesions. Widespread bullous lesions may occur in response to drug eruptions and may be misdiagnosed as toxic epidermal necrolysis. Histopathologically, there is acanthosis and full-thickness acantholysis resembling a dilapidated brick wall. A red band of dyskeratosis is present surrounding the nucleus, with no evidence of the blue or clear bands that occur in Darier disease. Hailey-Hailey disease is caused by a genetic defect in a calcium adenosine triphosphatase *(ATP2C1)*,inherited in an autosomal dominant manner, and 30% of patients express new mutations.

The treatment of Hailey-Hailey disease is difficult. Many patients improve with the use of systemic antibiotics against *S. Aureus*. Topical ckindamycin and mupirocin as well as antifungal agents can be helpful. Corticosteroids, administered topically, systemically, or both, have shown benefit. Cyclosporine, methotrexate, oral retinoids, topical calcineurin inhibitors, topical calcitriol, tacalcitol, botulinum toxin, photodynamic therapy (PDT), narrowband ultraviolet B therapy (NB-UVB), terbinafine, minocycline/niacinamide, and dapsone have been used in severe cases. Low-dose naltrexone was recently reported for pruritus relief. Dermabrasion and carbon dioxide (CO_2) laser vaporization have been effective in refractory disease, as the epidermis heals from uninvolved adnexal structures. Grafting and electron beam therapy have been helpful in the most severe forms of Hailey-Hailey disease.

DISORDERS OF CORNIFICATION (ICHTHYOSES AND ICHTHYOSIFORM SYNDROMES

Ichthyoses are a group of diseases in which the homeostatic mechanism of epidermal cell kinetics or differentiation is altered, resulting in the clinical appearance of scale. The stratum corneum is made of many different proteins, ceramides, and cholesterols, along with keratinocytes, and helps with epidermal barrier function. Disorders that affect cornification and the proper shedding of the cornified layer lead to symptoms of itching, overheating, and increased epidermal infection. Because these disorders manifest as abnormal differentiation of the epidermis, the term *disorders of cornification* is also used. Ichthyoses can be isolated or part of a systemic syndrome. Some ichthyoses start with collodion membranes.

Isolated Ichthyoses

Ichthyosis Vulgaris

Ichthyosis vulgaris is an autosomal dominant ichthyosis caused by mutations in filaggrin. It is characterized by onset in early childhood, usually between 3 and 12 months, with fine scales that appear "pasted on" over the entire body. Varying degrees of dryness of the skin may be evident. The scales are more coarse on the lower extremities than on the trunk and are especially apparent along the shins. The axillary and gluteal folds are usually not affected. Although the antecubital and popliteal fossae are usually spared by ichthyosis vulgaris, atopic changes may be present, because these disorders are frequently associated. Accentuated skin markings, hyperkeratosis of the palms, and keratosis pilaris are frequently associated. The scalp is involved, with only slight scaling. Keratotic lesions may be found on the palmar creases (keratosis punctata). Atopy manifested as seasonal allergies, atopic dermatitis, and asthma are often present. The course is favorable, with limited findings by the time the patient is an adult.

Histologically, there is compact eosinophilic orthokeratosis. The granular layer is reduced or absent, and keratohyalin granules may appear spongy or fragmented on EM. The spinous layer is of normal thickness. Filaggrin is reduced in involved epidermis, and profilaggrin messenger RNA is unstable in keratinocytes. This is a retention hyperkeratosis, with a normal rate of epidermal turnover. Therapy is similar to that for atopic dermatitis with thick emollients and gentle cleansers. Bathing more frequently can help desquamate the extra scaling. The differential diagnosis includes severe xerosis, X-linked ichthyosis, and acquired ichthyosis.

X-Linked Ichthyosis

X-linked ichthyosis is transmitted only to males by heterozygous mothers as an X-linked recessive trait. This condition results from a deficiency of steroid sulfatase (arylsulfatase C) and occurs in 1:2000 to 1:5000 male births. Onset is usually before age 3 months. Cesarean birth is typical, with failure in progression of labor because of a placental sulfatase deficiency. Scales are dark, large, and prominent on the anterior neck, extensor surfaces of the extremities (Fig. 27.20), and the trunk. The sides of the neck are invariably involved, giving the child an unwashed look. The elbow and knee flexures are relatively spared, as are the face and scalp; the palms and soles are almost always spared.

The condition may be confused with ichthyosis vulgaris but typically has darker scales and demonstrates dramatic clearing during the summer months. A diagnosis of X-linked ichthyosis is likely if the abdomen is more involved than the back, and if the ichthyosis extends down the entire dorsum of the leg. Keratosis pilaris is not present, and the incidence of atopy is not increased.

Fig. 27.20 X-linked ichthyosis.

Fig. 27.21 Collodion baby.

Corneal opacities (which do not affect vision) are seen by slit-lamp examination on the posterior capsule or Descemet membrane in about 50% of affected males and female carriers. Another extracutaneous feature is a 12%–15% incidence of cryptorchidism (undescended testicle) and an independently increased risk of testicular cancer. Unlike ichthyosis vulgaris, X-linked ichthyosis does not improve with age, but gradually worsens in both extent and severity.

There is usually a deletion at Xp22.3, and steroid sulfatase is lacking in fibroblasts, leukocytes, and keratinocytes. The diagnosis can be confirmed by genetic testing or lipoprotein electrophoresis, because the increase in cholesterol sulfate makes the low-density lipoproteins (LDLs) migrate much more rapidly, and cholesterol sulfate is elevated in serum, erythrocyte membranes, and keratin. The reduced enzyme activity can be assessed in fibroblasts, keratinocytes, leukocytes, and prenatally in amniocytes.

Autosomal Recessive Congenital Ichthyosis

Biochemical and genetic studies have helped to define the specific ichthyotic subtypes. Clinical features often overlap, and in the past, the severity of the disease determined the classification. Identification of specific defects is the basis for classification of ichthyotic disorders. These disorders typically present with a collodion membrane that is a thin layer that looks like plastic wrap and depending on the severity can be associated with ectropion and eclabium.

Lamellar Ichthyosis

Lamellar ichthyosis usually presents with a collodion membrane with ectropion that then desquamates over the first 2–3 weeks of life (Fig. 27.21). The ensuing ichthyosis is characterized by large (5–15 mm), grayish brown scales, which are strikingly quadrilateral, free at the edges, and adherent in the center (Fig. 27.22). In severe cases, the scales may be so thick that they are like armor plate. Moderate hyperkeratosis of the palms and soles is frequently present. The follicles in most cases have a crateriform appearance.

Fig. 27.22 Lamellar ichthyosis. (Courtesy Dr. Debabrata Bandyopadhyay.)

Lamellar ichthyosis is inherited as an autosomal recessive trait. About half the patients have decreased or absent TGM1 activity. An acral presentation of lamellar ichthyosis was recently described. Patients with no collodion but a lamellar phenotype with erythroderma of the hands and feet is caused by CYP4F22.

Patients should be kept in high humidity isolettes at first with gradual weaning to decrease insensible water losses. In addition to the topical agents recommended for the treatment of other ichthyoses, tazarotene and oral retinoids can improve symptoms. Topical 10% N-acetylcysteine in 5% urea has also been used with excellent success (although it smells of rotten eggs, so rosemary oil is often added). The adverse effects of prolonged oral retinoid therapy make their use for long-term maintenance therapy difficult.

Bathing Suit Ichthyosis

Bathing suit ichthyosis is an ichthyosis caused by a temperature-sensitive mutation in TGM1 that worsens in hot temperature (opposite of most ichthyoses). Therefore the scaling is worse in the bathing suit distribution and the summertime.

Congenital Ichthyosiform Erythroderma

Most infants with congenital ichthyosiform erythroderma (CIE; formerly nonbullous CIE) are born with a collodion membrane often with ectropion. Because the clinical phenotype at birth is similar to lamellar ichthyosis the two cannot be reliably differentiated at birth. Within 24 hours of birth, fissuring and peeling begin, and large, keratinous lamellae are cast off in 10–14 days, coincident with rapid improvement. As the membrane is shed, underlying redness and scaling are apparent (Fig. 27.23). Generalized involvement is the rule, including the face, palms, soles, and flexures. Cicatricial alopecia can occur, and nail dystrophy and some ectropion are common. Scales are more fine on the trunk, face, and scalp.

Histologically, parakeratosis and inflammation are seen more frequently in CIE than in lamellar ichthyoses. The stratum corneum is usually thicker in lamellar ichthyoses and is usually not parakeratotic. Mutations in *ALOXE3*, *ALOX12B*, and ichthyin (NIPAL4) can lead to either CIE or lamellar ichthyoses; the entities are separated largely on the basis of the clinical phenotype.

Harlequin Ichthyosis

Harlequin ichthyosis (HI) is the most severe type of autosomal recessive congenital ichthyosis (ARCI) caused by ABAC12

Fig. 27.23 Nonbullous congenital ichthyosiform erythroderma.

Fig. 27.24 Epidermolytic hyperkeratosis. (Courtesy Dr. Shyam Verma.)

mutations. HI presents with a thick collodion, with thick, horny, armor-like plates covering the entire surface with very severe ectropion and eclabium. The ears are rudimentary or absent. The mortality rate is high but, with aggressive management with emoliation and systemic retinoids, there have been many long-term survivors. Acitretin and isotretinoin have been used with success in infancy. Patients who survive develop features of CIE or lamellar ichthyosis. Absent or abnormal lamellar granules, a lack of extracellular lipid lamellae, and lipid droplets in the stratum corneum have been reported.

Epidermolytic Ichthyosis

Epidermolytic ichthyosis (EI) comprises what used to be called nonbullous congenital ichthyosiform erythroderma, epidermolytic hyperkeratosis (EHK), and ichthyosis bullosa of siemens. EI is usually manifested by blisters at or shortly after birth. Superficial EI (formerly ichthyosis bullosa of siemens) is less severe and typically lacks blisters at birth. In EI, thickened, horny, warty, or spinelike ridged scales predominate (Fig. 27.24). They are particularly prominent at the flexures. There is remarkable heterogeneity, particularly in regard to the degree of hyperkeratosis, extent of body surface involvement, presence or absence of erythroderma, and palm and sole involvement. An association with hypocalcemic vitamin D–resistant rickets has been reported. Keratinocytic epidermal nevi with epidermolysis type are mosaic expressions of epidermolytic ichthyosis. There are reports of people with epidermal nevi that have epidermolysis having offspring with EI. Superficial EI is characterized by a lack of erythema, relatively mild hyperkeratosis usually limited to the flexures, and superficial molting or peeling of the skin (the "mauserung" phenomenon).

Epidermolytic ichthyosis is caused by mutations in the genes for K1 and K10 (or K2e in the case of ichthyosis bullosa of Siemens). Keratin distribution patterns in keratinocytes are abnormal, suggesting an altered assembly process of cornified cell envelopes. A recessive form related to K10 mutation has been described.

Histologically, the lesional skin demonstrates compact hyperkeratosis. The granular layer is greatly thickened and contains coarse, blue and red, keratohyaline granules. Epidermal cells detach in the granular cell layer and may appear vacuolated. EM reveals the formation of perinuclear halos. Epidermolysis has been described as an incidental finding in normal skin, skin adjacent to benign and malignant epidermal tumors, and normal oral mucosa.

Thick emollients are the mainstay of therapy but topical and systemic retinoids can be tried. Pyogenic infection is a common problem, and appropriate antibiotics should be administered. A water solution of 10% glycerin and 3% lactic acid applied to wet skin can result in clinical improvement. The disease tends to become less severe with age.

Acquired Ichthyosis

Ichthyosis clinically similar to ichthyosis vulgaris may develop in patients with several systemic diseases. Acquired ichthyosis has been reported with Hodgkin disease and may be a presenting symptom. It has also occurred in non-Hodgkin lymphoma, mycosis fungoides, multiple myeloma, and carcinomatosis. In hypothyroidism, patients may develop fine scaling of the trunk and extremities, as well as carotenemia and diffuse alopecia. Characteristic ichthyosiform lesions may develop in patients with sarcoidosis, particularly over the lower extremities. Biopsy of the lesion will often show granulomas. Ichthyosiform changes have also been reported in patients with Hansen disease, nutritional deficiency, acquired immunodeficiency syndrome (AIDS), human T-cell lymphotropic virus infection, lupus erythematosus, and dermatomyositis. Drug-induced ichthyosis may occur with nicotinic acid, statins, triparanol, and butyrophenones.

Treatment

Topical keratolytics and retinoids can be used for ichthyosis, but caution is advised in young children because systemic absorption can be assumed given the large body surface area that needs to be covered along with the defective skin barrier. Widespread use of topical salicylic acid in children may lead to salicylism, and lactic acid can lead to lactic acidemia. Symptomatic treatment with α-hydroxy acids, such as lactic acid or 12% ammonium lactate lotion, is helpful, but patients with atopic dermatitis and ichthyosis vulgaris may find that these products sting. Other compounds with hydrating and keratolytic properties are also beneficial. Creams containing 5%–10% urea are effective humectants. Response to topical retinoids has been variable but can be very effective for the face and ectropion in more severe ARCI. Baths may help by hydrating the horny layer, but immediate application of a thick emollient such as white petrolatum is vital. Topical calcipotriene ointment has proved effective in a variety of ichthyoses, and topical

maxacalcitol, a vitamin D_3 analog, has been used successfully in mosaic-type bullous congenital ichthyosiform erythroderma. Application of a 40%–60% solution of propylene glycol in water under an occlusive suit removes the scales, especially on the palms and soles. Propylene glycol can produce renal failure and cardiac toxicity when given systemically, but few reports of adverse effects have been noted with topical use. Many patients benefit from the use of a sauna suit (unless they have bathing suit ichthyosis).

CONGENITAL SYNDROMES WITH ICHTHYOSIS

Chondrodysplasia Punctata

There are four forms of chondrodysplasia punctata, classified by their inheritance patterns and clinical feature of punctiform bone calcification (stippled epiphyses). Chondrodysplasia punctata is characterized by ichthyosis of the skin similar to that of the collodion baby, followed by a blaschkoid pattern of hyperkeratosis on erythematous skin (Fig. 27.25). In addition to reddening, the waxy, shiny skin has hyperkeratotic scales of a peculiar, crushed-eggshell configuration. As the child grows, follicular atrophoderma and pseudopelade develop. Usually, the ichthyosis clears within the first year of life but may leave behind blashckoid hyperpigmentation similar to that seen in incontinentia pigmenti. Additional features are nail findings such as platonychia and onychoschizia.

The Conradi-Hünermann type is caused by autosomal dominantly inherited EBP mutation. Affected individuals present with facial dysmorphia with a low nasal bridge, short stature, mild disease, cataracts, and few skin lesions. The rhizomelic (rhizomelia here means shortening of the long bones of the upper arms and legs) form (caused by PEX7 mutation) has autosomal recessive inheritance, marked shortening of the extremities, cataracts, ichthyosis, and nasal hypoplasia. Patients typically do not survive infancy. The X-linked recessive type has been described as part of contiguous gene deletion syndromes, with short stature, telebrachydactyly, and nasal hypoplasia. The X-linked dominant form (Happle syndrome, Conradi-Hünermann-Happle syndrome, or CDPX2) is lethal in males. Happle syndrome (X-linked dominant chondrodysplasia punctata) has ichthyosiform erythroderma along the lines of Blaschko, cataracts, asymmetric limb shortening, and calcified stippling of the epiphyses of long bones. CDPX2 is caused by a defect in the EBP gene, leading to increase of sterols.

Fig. 27.25 Chondrodysplasia punctata.

The skeletal defects revealed on radiographic evaluation include irregular calcified stippling of the cartilaginous epiphyses in the long bones, costal cartilages, and vertebral diaphysis. The stippling occurs in the fetus and persists until age 3 or 4 years. The humeri and femurs may be shortened, and joint dysplasia may occur. Histologic evaluation of the ichthyotic lesions reveals a thinned, granular cell layer, calcification of keratotic follicular plugs, and focal hyperpigmentation of basal keratinocytes. The keratotic follicular plugs and calcium deposits are characteristic of chondrodysplasia punctata and helpful in establishing the diagnosis in newborns. Various types are related to defects in peroxisomal metabolism, plasmalogen, and cholesterol biosynthesis. X-linked recessive chondrodysplasia punctata (CDPX1) is caused by a defect in arylsulfatase E, located on Xp22.3. There may be an association between the rhizomelic variety and maternal autoimmunity and connective tissue disease. A continguous gene deletion syndrome can affect arylsulfatase E and *KAL1* (the gene defect responsible for Kallman syndrome), leading to anosmia and hypogonadism.

Lambrecht C, et al: Conradi-Hünermann-Happle syndrome. Pediatr Dermatol 2014; 31: 493.

Netherton Syndrome

Netherton syndrome is an inherited autosomal recessive disorder of cornification. It may first appear as severe congenital generalized exfoliative erythroderma in infancy. Then children develop migratory annular and polycyclic patches of ichthyosis linearis circumflexa (Fig. 27.26). Lesions predominate on the trunk and extremities, and appear as a polycyclic serpiginous eruption characterized by constantly changing patterns. Individual lesions grow over about a week and then attain their maximum diameter and involute, leaving no atrophy, scarring, or pigmentation. The lesions may clear almost completely during the summer. Most patients are found to have bamboo hair (trichorrhexis invaginata). The association of ichthyosiform dermatitis, hair abnormality, and atopic diathesis is called Netherton syndrome. Because of coexistent atopic dermatitis, the scalp, face, and eyebrow regions are erythematous and scaly. Hairs may fracture below the surface of the scalp, so that the patient appears bald. Mutations in *SPINK5*, which encodes the serine protease inhibitor Kazal-type 5 protein, have been identified in Netherton syndrome and result in unopposed kallikrein-related peptidase 5 (KLK5) and KLK7 activities and overactivity of elastase 2 (ELA2).

Histologic examination shows hyperkeratosis, parakeratosis, and acanthosis. The granular layer is typically absent.

Acitretin has been effective in some patients but should be avoided in erythrodermic neonates; long-term use is limited by toxicity. Topical tacrolimus has also been reported as effective, but in one report, three patients treated twice with 0.1% tacrolimus ointment were found to have significant tacrolimus blood levels. Although none of these patients developed signs or symptoms of toxic effects, monitoring of blood levels is advised if tacrolimus is used in this setting. NB-UVB has been reported as effective. There is IL-17 activation and thus IL-17 blockade with ustekinumab may be helpful.

Fig. 27.26 Netherton syndrome. (Courtesy Scott Norton, MD.)

Neutral Lipid Storage Disease

Neutral lipid storage disease (Dorfman-Chanarin syndrome) is a rare autosomal recessive disorder characterized by an ichthyosiform erythroderma, myopathy, and vacuolated leukocytes. Affected infants can be born with a collodion membrane. Associated cutaneous disorders include poikiloderma atrophicans vasculare. The ichthyosis is more severe in warmer weather. Lipid vacuoles are present in all circulating granulocytes and monocytes, as well as in dermal fibroblasts, Schwann cells, smooth muscle cells, and sweat gland cells. Other organ systems, such as the CNS, liver, muscles, ears, and eyes, may also have deposits. Neutral lipid storage disease is caused by a regulatory defect that alters the rates of synthesis and degradation of the major cellular phospholipids, particularly triacylglycerol-derived diacylglycerol. EM findings show electron-lucent globular inclusions in lamellar structures. Dietary intervention, with modulation of dietary fats, along with fibrates have been shown to aid in controlling the disease. Recently a report of application of menthol for "cold-sensing" significantly improved the ichthyosis.

Nakajima K, et al: 137 Cold-sensing ameliorated ichthyosis in a patient with Dorfman-Chanarin syndrome likely through reversed lypolysis under thermo-regulation in keratinocytes. J Investig Dermatol 2017; 137: S216.

Van de Weijer T, et al: Effects of bezafibrate treatment in a patient and a carrier with mutations in the *PNPLA2* gene, causing neutral lipid storage disease with myopathy. Circ Res 2013; 112: e51.

Sjögren-Larsson Syndrome

Sjögren-Larsson syndrome is characterized by ichthyosis, spastic paralysis, oligophrenia, mental retardation, and a degenerative retinitis. The ichthyosis is usually generalized, with minimal or no involvement of the scalp, hair, or nails and rarely infants present with a collodion membrane. There is flexural and lower abdominal accentuation. The central face is spared, ectropion is unusual, and palms and soles are involved. Beginning by age 2 or 3 years, there is spastic paralysis consisting of a stiff, awkward movement of the extremities. EM reveals prominent Golgi apparatus and increased numbers of mitochondria in keratinocytes. Usually, a severe mental deficiency with seizures is present. This syndrome is caused by a mutation in fatty aldehyde dehydrogenase (FALDH).

Srinivas SM, et al: Sjögren-Larsson syndrome. Indian Dermatol Online J 2014; 5: 185.

Refsum Syndrome

Refsum syndrome (heredopathia atactica polyneuritiformis) is an autosomal recessive inherited ichthyosis with atypical retinitis pigmentosa, hypertrophic peripheral neuropathy, cerebellar ataxia, nerve deafness, and cardiomyopathy. The ichthyosis resembles ichthyosis vulgaris and presents later in childhood. It may be generalized or localized to the palms and soles. There are lipid vacuoles in the epidermal basal layer with decreased granular cell layer. Biochemically, the disease is a peroxisomal disorder characterized by excessive accumulation of phytanic acid, pristanic acid, and picolinic acid in fatty tissues, myelin sheaths, heart, kidneys, and retinal tissues.

Refsum syndrome is caused by a deficiency of phytanoyl/pristanoyl-CoA-hydroxilase. *PHYH* mutations account for the majority but some patients with mutations in *PEX7* (a gene also

associated with rhizomelic chondrodysplasia punctata type 1) have been identified. Dietary restriction of phytanic acid–containing vegetables can lead to an improvement of neurologic symptoms but does not affect retinal changes. Unfortunately, in many patients, dietary restriction is not sufficient to prevent acute attacks or stabilize the progressive course. The acids are localized within very-low-density lipoprotein (VLDL), LDL, and high-density lipoprotein (HDL) particles and may be removed by extracorporeal LDL apheresis.

Yoneda K: Inherited ichthyosis. J Dermatol 2016; 43: 252.

Rud Syndrome

Rud syndrome is characterized by ichthyosis, hypogonadism, small stature, mental retardation, acanthosis nigricans, epilepsy, macrocytic anemia, and, rarely, retinitis pigmentosa. Most kindreds have shown autosomal recessive inheritance and may be atypical variants of well-described disorders, such as Sjögren-Larsson syndrome or Refsum syndrome, rather than representing a distinct inherited disorder. Some patients have X-linked steroid sulfatase deficiency.

Happle R: Rud syndrome does not exist. Eur J Dermatol 2012; 22: 7.

Keratitis-Ichthyosis-Deafness Syndrome

The keratitis-ichthyosis-deafness (KID or Senter) syndrome is characterized by vascularization of the cornea, an extensive congenital ichthyosiform eruption, neurosensory deafness, reticulated hyperkeratosis of the palms and soles, hypotrichosis, partial anhidrosis, nail dystrophy, and tight heel cords. Distinctive leathery, verrucoid plaques involve the central portion of the face (Fig. 27.27) and ears. These changes, with absent eyebrows and eyelashes and furrows about the mouth and chin, give the children a unique facies. Occasionally, hairs may demonstrate bright and dark bands on polarized microscopy, as seen in trichothiodystrophy. Chronic mucocutaneous candidiasis and superinfection of skin lesions is common. Benign trichilemmal tumors and SCC occur in approximately 15% of patients. The candidal lesions can appear heaped up and mimic SCC, so there should be a low threshold for biopsy.

Some kindreds lack deafness. The disorder is related to missense mutations in the *GJB2* gene that encodes connexin 26 (Cx26). Most cases are sporadic.

Initial therapy with topical retinoids or keratolytics may help some. Isotretinoin treatment may exacerbate and promote corneal vascularization. Treatment with acitretin has been reported to clear the hyperkeratotic ichthyotic lesions with minimal effect on the cornea or hearing. Cyclosporin A eyedrops have been used to treat corneal neovascularization.

Porokeratotic Eccrine Ostial and Dermal Duct Nevus

Porokeratotic eccrine ostial and dermal duct nevus (PEODDN) is a keratotic condition that affects the eccrine ostia keratosis resembling music box spines and typically presents on the palms (Fig. 27.28) or soles. It is caused by a mosaic *GJB2* mutation and PEODDN has been seen in KID syndrome (also caused by *GJB2* mutations), thus PEODDN can be considered a mosaic limited form of KID syndrome.

Congenital Hemidysplasia With Ichthyosiform Erythroderma and Limb Defects (CHILD) Syndrome

Present at birth, congenital hemidysplasia with ichthyosiform erythroderma and limb defects (CHILD) syndrome is characterized by unilateral inflammatory epidermal nevi and ipsilateral limb hypoplasia or limb defects (Fig. 27.29). Features may vary widely, from complete absence of an extremity to defects of internal organs involving the musculoskeletal system, cardiovascular system, or CNS. The condition is X-linked dominant caused by a mutation in the *NSDHL* gene that is involved in cholesterol metabolism. CHILD is lethal in hemizygous males. Survival in males has been reported as a result of mosaicism. In females, lyonization may produce cutaneous patterns following the lines of Blaschko. When unilateral epidermal nevi show features of verruciform xanthoma,

Fig. 27.27 Keratosis ichthyosis deafness syndrome. (Courtesy Paul Honig, MD.)

Fig. 27.28 Porokeratotic eccrine ostial and dermal duct nevus.

Fig. 27.29 Congenital hemidysplasia with ichthyosiform erythroderma and limb defects (child) syndrome. (Courtesy Paul Honig, MD.)

CHILD syndrome should be suspected. The CHILD nevus is distinguished by ptychotropism (flexural involvement), waxy yellowish scaling, lateralization showing both diffuse and linear involvement, and the presence of foamy macrophages in the dermal papillae.

Therapy with a topical formulation of 2% lovastatin/2% cholesterol that bypasses hepatic first-pass metabolism to deliver cholesterol directly to the skin is extremely effective for the cutaneous features.

Paller AS, et al: Pathogenesis-based therapy reverses cutaneous abnormalities in an inherited disorder of distal cholesterol metabolism. J Investig Dermatol 2011; 131: 2242.

Raychaudhury T, et al: A novel X-chromosomal microdeletion encompassing congenital hemidysplasia with ichthyosiform erythroderma and limb defects. Pediatr Dermatol 2013; 30: 250.

Multiple Sulfatase Deficiency

Patients with multiple sulfatase deficiency display an overlap of steroid sulfatase deficiency, mucopolysaccharidosis, and metachromatic leukodystrophy. The scaling is sometimes milder than X-linked recessive ichthyosis. Patients present around age 3 with regressed development, ataxia, hypotonia and the ichthyosis. Histologic examination shows hyperkeratosis with a normal granular cell layer. This autosomal recessive disorder is caused by a lack of or deficiency in all known sulfatases.

Sreekantam S, et al: Clinical features and outcomes in multiple sulfatase deficiency. Mol Genet Metab 2016; 117: S108.

Erythrokeratodermias

The erythrokeratodermias are closely related and have significant clinical overlap but are genotypically distinct. Erythrokeratodermia variabilis (EKV), also called erythrokeratodermia figurata variabilis, is characterized by erythematous patches and hyperkeratotic plaques of sparse but generalized distribution. Progressive symmetric erythrokeratodermia (erythrokeratodermia progressiva symmetrica) manifests soon after birth with erythematous, hyperkeratotic plaques that are symmetrically distributed on the extremities, buttocks, and face, sparing the trunk and palmoplantar keratoderma (often striate). The lesions may regress at puberty. Occipital alopecia, oligodontia, and severe caries have been reported. *Erythrokeratodermia variabilis et progressiva* (EKVP) has been proposed as a term that encompasses the full spectrum of either localized hyperkeratotic plaques to more widespread disease.

Fig. 27.30 Erythrokeratoderma variabilis. (Courtesy Ken Greer, MD.)

The erythematous patches of EKV may assume bizarre geographic configurations that are sharply demarcated (Fig. 27.30). Over time, they change shape or size or involute completely. The keratotic plaques are reddish brown, often polycyclic, and fixed in location. The extensor surfaces of the limbs, buttocks, axillae, groins, and face are most often involved. Approximately 50% of patients display a palmoplantar keratoderma associated with peeling. Hair, nails, and mucous membranes are spared. The onset of EKV is shortly after birth, or rarely at birth, or in early adult life. There may be some improvement with age, particularly after menopause. Exacerbations have been seen during pregnancy. The figurate erythematous component may be accentuated by exposure to heat, cold, or wind. Emotional upsets may also be a factor. Histologically, there is hyperkeratosis and parakeratosis and a diminished granular layer. Acanthosis may occur. Ultrastructurally, epidermal keratinosomes are diminished.

Mutations in *GJB3*, *GJB4*, and *GJA1* have all been associated with EKVP. Recently a mutation in keratin 83 has been shown to cause progressive symmetric erythrokeratodermia. Interestingly, *GJA1* mutations were recently found in inflammatory linear verrucous epidermal nevus (ILVEN), therefore ILVEN may represent mosaic EKV.

Systemic retinoids such as acitretin or isotretinoin alone or combined with psoralens and ultraviolet A (UVA) therapy can restore the deficient keratinosomes and partially clear the hyperkeratotic plaques for severe widespread disease. EKV often relapses when therapy is discontinued. Urea, salicylic acid, and lactic acid have proved useful for the hyperkeratotic plaques.

Colobomas of the Eye, Heart Defects, Ichthyosiform Dermatosis, Mental Retardation, and Ear Defects (CHIME)

Colobomas of the eye, heart defects, ichthyosiform dermatosis, mental retardation, and ear defects (CHIME) syndrome is a neuroectodermal disorder. The ichthyosis is usually congenital and migratory and is most pronounced in the flexural surfaces. Other features may include facial anomalies, epidermal nevi, developmental delay, infantile macrostomia, recurrent infections, acute lymphoblastic leukemia, and duplicated renal collecting system. The inheritance is believed to be autosomal recessive, related to mutations in the glycosylphosphatidylinositol gene *PIGL*.

Richner-Hanhart Syndrome

Richner-Hanhart syndrome (tyrosinemia type 2) is characterized by corneal opacities and keratosis palmoplantaris. The skin manifestations of painful keratotic plaques on the palms and soles usually develop after the first year of life and relate to defects in tyrosine aminotransferase. Newborn screening can allow early intervention with dietary restriction with a low-protein diet that may help the skin as well by lowering tyrosine levels.

Knight Johnson A, et al: Alu-mediated deletion of *PIGL* in a patient with CHIME syndrome. Am J Med Genet A 2017; 173: 1378.

Sidbury R, et al: What syndrome is this? CHIME syndrome. Pediatr Dermatol 2001; 18: 252.

PITYRIASIS ROTUNDA

Pityriasis rotunda (pityriasis circinata) manifests as perfectly circular scaly patches on the torso and proximal portions of the extremities (Fig. 27.31). The scale is adherent and resembles that of ichthyosis vulgaris. There is a strong ethnic predisposition, with a preponderance of reports in black persons, Japanese, Koreans, and Italians suggesting it may have a genetic cause. Two forms of pityriasis rotunda occur. Type I is found in black or Asian persons, usually has fewer than 30 hyperpigmented lesions, is nonfamilial, and may be associated with systemic disease. Type II disease occurs in white persons, has larger numbers of hypopigmented lesions, is often familial, and usually is not associated with internal disease. Some cases are associated with systemic illnesses, especially in darker-skinned patients. Associated illnesses include tuberculosis, other pulmonary disorders, liver disease, malnutrition, leukemia, lymphoma, and carcinoma of the esophagus or stomach. Familial cases with autosomal dominant transmission have also been described.

The differential diagnosis includes tinea versicolor, tinea corporis, erythrasma, Hansen disease, fixed drug eruptions, and pityriasis alba. Some patients note a seasonal improvement during the summer, and some respond to emollients during the winter months. Low levels of steroid sulfatase have been identified, the profilaggrin N-terminal domain is absent in some patients, and filaggrin-2 expression has also been reported to be diminished in some. Topical and systemic retinoids have been used successfully, but pityriasis rotunda often is unresponsive unless the patient has an underlying systemic illness that can be treated.

POROKERATOSIS

Porokeratosis comprises a heterogeneous group of disorders that can be inherited in an autosomal dominant fashion. Except for the punctate type, they are characterized by distinct clinical findings of a keratotic ridge with a central groove that corresponds to the cornoid lamella on histology (Fig. 27.32). The groove may be accentuated by the application of gentian violet, followed by removal with alcohol. The dye remains in the groove. Povidone-iodine has been similarly used. Immunosuppression, UV exposure, and radiation therapy may exacerbate porokeratosis and promote the development of skin cancers within the lesions. The linear type has the greatest risk of malignant transformation. Segmental forms have been reported in a blaschkoid distribution and after radiation therapy.

Topical 5-fluorouracil (5-FU) can be effective in destroying individual lesions; it may need to be applied under occlusion but may result in scarring. In disseminated superficial actinic porokeratosis

Fig. 27.31 Pityriasis rotunda.

Fig. 27.32 Porokeratosis with keratotic ridge. (Courtesy Dr. Curt Samlaska.)

(DSAP), where the risk of malignant transformation is very low, the risks of treatment with 5-FU must be weighed against the generally indolent course of the lesions. PDT has been used with incubation under a heating pad to promote porphyrin conversion. Sun protection, emollients, and observation for signs of malignant degeneration may be the most suitable course of action for many patients with DSAP. Other agents that have been shown to be effective for some patients with DSAP include topical imiquimod, vitamin D_3 analogs, diclofenac gel, and topical retinoids, including tazarotene. Salicylic acid and α-hydroxyl acids may make the lesions less noticeable. Oral retinoids have shown efficacy, but the lesions frequently recur after treatment, and long-term treatment with these agents is impractical. Combinations of oral retinoids and topical 5-FU have been effective for refractory DSAP and porokeratosis plantaris, palmaris, et disseminata, but the side effects of treatment may be considerable. Destructive modalities must extend into the dermis and produce scarring to prevent recurrence. Destructive modalities employed include cryotherapy, electrodesiccation and curettage, CO_2 laser ablation, Q-switched ruby laser, fractional photothermolysis, flashlamp-pumped pulsed dye laser, frequency-doubled neodymium-doped yttrium-aluminum-garnet (Nd:YAG) laser, dermabrasion, and grenz ray radiotherapy.

Plaque-Type Porokeratosis (Mibelli)

Plaque-type porokeratosis is a chronic, progressive disease characterized by the formation of slightly atrophic patches surrounded by an elevated, warty border. The lesion begins as a small keratotic papule, which spreads peripherally and becomes depressed centrally. Eventually, it becomes a circinate or serpiginous, well-defined plaque surrounded by a keratotic wall or collar. This wall is grayish or brownish and frequently is surmounted by a tiny groove or linear ridge running along its summit. The enclosed central portion of the plaque consists of dry, smooth, atrophic skin; the lanugo hairs generally are absent when the patches occur in hairy areas. Linear or zosteriform distribution of the lesions may also occur. If the nail matrix is involved, nail dystrophy may develop. Lesions may appear during chemotherapy for malignancy, after renal transplantation, while on psoralen plus UVA (PUVA) treatment, and in areas of chronic sun damage or chemical exposure, such as benzylhydrochlorothiazide.

Sites of predilection are the surfaces of the hands and fingers, as well as the feet and ankles. The disease also occurs on the face and scalp (where it produces bald patches), on the buccal mucosa (where the ridge becomes macerated by moisture and appears as a milky white, raised cord), and on the glans penis (where it causes erosive balanitis).

Histologically, the principal diagnostic changes are in the area of the cornoid lamella. This area demonstrates a column of parakeratotic keratin extending at about a 45-degree angle from a focus of dyskeratotic cells in the malpighian layer. The column trails behind the focus of dyskeratosis as the focus expands peripherally. The granular cell layer is absent beneath the parakeratotic column. The central portion of the lesion may demonstrate atrophy with loss of the rete ridge pattern, lichenoid dermatitis, or psoriasiform hyperplasia.

Disseminated Superficial Actinic Porokeratosis

Disseminated superficial actinic porokeratosis (DSAP) is characterized by numerous superficial, circinate, keratotic, brownish red macules found on sun-exposed skin (Fig. 27.33). It is more common in women. The distribution of the lesions on the sun-exposed areas indicates that actinic radiation is an important factor in the pathogenesis, and new lesions have been induced by exposure at commercial tanning salons. Exacerbations occur in up to two thirds of patients during summer. Immunosuppression is also well documented as exacerbating the disease. DSAP has been seen in patients with AIDS, cirrhosis, and Crohn disease. Organ transplant patients may develop DSAP. Improvement of the immunosuppression may lead to resolution of the lesions. Gene loci have been localized to chromosomes 12q23.2–24.1 and 15q25.1–26.1, suggesting that DSAP is a genetically heterogeneous disorder. An eruptive form of porokeratosis has been named eruptive disseminated porokeratosis and this may be paraneoplastic (GI, lymphoma, or ovarian), or from an autoimmune or inflammatory disorder or idiopathic.

Fig. 27.33 Disseminated superficial actinic porokeratosis.

Linear Porokeratosis

Linear porokeratosis may be segmental or generalized. It may be identified during the newborn period, and when found in the segmental pattern, may follow the lines of Blaschko. Ulcerations and erosions involving the face or extremities may delay the correct diagnosis, and linear porokeratosis should be included in the differential diagnosis of ulcerative lesions in the neonatal period. This form of porokeratosis has the highest risk of developing cutaneous malignancies, including SCC (Fig. 27.34), Bowen disease, and basal cell carcinoma.

Porokeratosis Palmaris, Plantaris, et Disseminata

In this distinctive form of porokeratosis, lesions first appear on the palms or soles, or more often both. Onset is frequently noted when patients are in their twenties. Slowly, the lesions may extend over the entire body. In porokeratotic eccrine ostial and dermal duct nevus, the presentation clinically appears as a nevus comedonicus of the palm or sole (see Fig. 27.28), but histologic analysis reveals multiple coronoid, lamella-like, parakeratotic columns. In porokeratosis punctata, palmaris, et plantaris or punctate porokeratosis, lesions are limited to the hands and feet.

DARIER DISEASE (KERATOSIS FOLLICULARIS, DARIER-WHITE DISEASE)

Darier disease is an autosomal dominant inherited skin disorder characterized by brown keratotic papules that tend to coalesce into patches in a seborrheic distribution. Early lesions are small, firm papules, almost the color of normal skin. Each papule becomes covered with a greasy, gray-brown crust that fits into a small concavity in the summit of the papule. As the lesions age, their color darkens. Over years, the papules grow and may fuse to form malodorous, papillomatous, vegetating growths.

The neck, shoulders, face, extremities, front of the chest (Fig. 27.35), and midline of the back are sites of predilection for the disease. A frequent site for the earliest lesions is behind the ears. As the eruption spreads, the entire trunk, buttocks, genitals, and other parts of the skin may be involved. Usually, the eruption is symmetric and widespread, but unilateral or segmental involvement may also occur probably representing postzygotic mutations.

Vegetations appear chiefly in the axillae, gluteal crease, and groin and behind the ears. The scalp is generally covered with greasy crusts. Lesions on the face are often prominent about the nose. The lips may be crusted, fissured, swollen, and superficially ulcerated, and there may be a patchy keratosis with superficial erosions on the dorsum of the tongue. Small white papules or pebbling may be present on the gingiva and palate. Involvement of the oropharynx, esophagus, hypopharynx, larynx, and anorectal mucosa has been reported. Punctate keratoses are frequently noted on the palms and soles. A general horny thickening of the palms and soles may be present because of innumerable, closely set, small papules. On the dorsa of the hands and on the shins, the flat verrucous papules may resemble verrucae planae. The nails show subungual hyperkeratosis, fragility, and splintering, with longitudinal alternating white and red streaks, and triangular nicking of the free edges (Fig. 27.36). Cutaneous herpes simplex may be

Fig. 27.35 Darier disease. (Courtesy Dr. Lawrence Lieblich.)

Fig. 27.36 Darier disease.

a complication of the disease. Esophageal involvement, renal anomalies (including agenesis), and gonal hypoplasia have been described. Recently an association with hidradenitis in two patients was proposed.

Darier disease is usually worse in the summer. It may begin after severe sunburn, and in some patients the lesions may be reproduced with suberythema doses of UVB light. Lithium carbonate has been shown to induce Darier disease in some individuals.

Abnormal dissolution of desmosomal plaque proteins is seen, specifically desmoplakin I and II, plakoglobin, and desmoglein. Calcium ion (Ca^{2+})–dependent cell-cell adhesion molecules (epithelial cadherins) are greatly reduced on the acantholytic cells of patients with Darier's disease. The Darier gene *(ATP2A2)* codes for the second isoform of a calcium ATPase of the sarcoplasmic/endoplasmic reticulum (SERCA2) pump, which transports Ca^{2+} from the cytosol into the endoplasmic reticulum. Inhibition of SERCA impairs trafficking of desmoplakin to the cell surface, contributing to acantholysis.

Histology

Darier disease is characterized by acantholytic dyskeratosis with overlying hyperkeratosis. Round, acantholytic dyskeratotic cells (corps ronds) typically demonstrate a pale or blue halo surrounding the nucleus. Grains are flat, deeply basophilic, dyskeratotic cells, seen most frequently in the stratum granulosum and stratum corneum. Formation of a suprabasal cleft (lacuna) is noted and may involve hair follicles as well as the surface epidermis. Dermal papillae covered by a single layer of basal cells project as villi into the acantholytic space.

Treatment

During flares, topical antibacterial agents, oral antibiotics, and short-term application of a corticosteroid may be of benefit. For localized disease, topical retinoids may be effective, but papules often occur at the periphery of the treated region. Topical diclofenac sodium has also been used. Oral retinoids are the drugs of choice for most severe cases. Cyclosporine may control severe flares, and topical sunscreens and ascorbic acid can prevent disease flares in some patients. For hypertrophic lesions, dermabrasion, laser vaporization, or excision and grafting can be considered. PDT using topical 5-aminolevulinic acid produces an initial inflammatory response that lasts 2–3 weeks. In some patients with Darier disease, this is followed by sustained improvement. Because of the initial inflammatory response, it is only appropriate for patients who have failed most other options.

ACROKERATOSIS VERRUCIFORMIS

This rare autosomal dominant genodermatosis is characterized by numerous flat verrucous papules occurring on the backs of the hands, insteps, knees, and elbows. The papules are closely grouped and resemble warts, except that they are flatter and more localized. The verrucous lesions are identical to those in Darier disease, and some, but not all, cases of acrokeratosis verruciformis of Hopf are caused by mutations in the *ATP2A2* gene.

Histologically, hyperkeratosis, thickening of the granular layer, acanthosis, and church spire papillomatosis characterize the disease. Available treatments are liquid nitrogen therapy, shave excision, and CO_2 laser ablation. Recurrence is common. Acitretin has been used successfully.

Serarslan G, et al: Acitretin treatment in acrokeratosis verruciformis of Hopf. J Dermatolog Treat 2007; 18: 123.

PACHYONYCHIA CONGENITA

In 1906 Jadassohn and Lewandowsky described a rare, often familial, anomaly of the nails that they named pachyonychia congenita. It is characterized by thickened nail beds of all fingers and toes, painful palmar and plantar hyperkeratosis, blistering under the callosities, palmar and plantar hyperhidrosis, spiny follicular keratoses, and benign leukokeratosis of the mucous membranes. The nail plates are extremely hard and are firmly attached to the nail beds. The nail bed is filled with yellow, horny, keratotic debris, which may cause the nail to project upward at the free edge (Fig. 27.37). Paronychial inflammation is frequently present. Delayed onset of pachyonychia in young adulthood has been described, as has acro-osteolysis.

On the extensor surfaces of the extremities, buttocks, and lumbar regions, spinelike follicular keratotic papules are found. Removal of these central cores leaves a slightly bleeding cavity. The eruption on the outer aspects of the upper and lower extremities is also follicular, resembling keratosis pilaris. This latter condition is not constant and disappears at times.

Painful friction blisters may develop on the plantar aspects of the toes or heels or along the edges of the feet, and cases have been misdiagnosed as epidermolysis bullosa. In a study of 254 patients, the triad of toenail thickening, plantar keratoderma, and plantar pain was reported by 97% of patients by age 10. Leukokeratosis of the tongue and oral mucosa, as well as occasional laryngeal involvement with hoarseness, may occur. This oral leukokeratosis resembles an oral white sponge nevus histologically and is not predisposed to the development of malignancy.

Pachyonychia congenita was formerly divided into four types but, with more exact genetic diagnosis, patients are now divided based on keratin (KRT6A, KRT6B, KRT6C, KRT16, or KRT17;

Fig. 27.37 Pachyonychia congenita.

e.g., PC-6A). There is overlap in clinical findings even with different genetic mutations so a panel of testing including each gene is usually ordered. There is a higher likelihood of oral leukokeratosis with *KRT6A* mutations, and natal teeth and cysts are strongly associated with *KRT17* mutation. Focal nonepidermolytic PPK is more associated with *KRT6c* and *16*. Homozygous dominant missense mutation in *K17* has been associated with severe pachyonychia congenita and alopecia.

Avulsion of the nails brings about only temporary relief. Vigorous curettage of the matrix and nail bed is the simplest and most effective therapy. Destruction of the nail matrix with phenol may be partially effective, but recurrence of nail bed hyperkeratosis is common. The keratoderma is difficult to treat, but topical lactic acid, ammonium lactate, salicylic acid, or urea may be of some benefit. Isotretinoin has been reported to clear the keratotic papules and the oral leukokeratosis, but not the palms or soles. Acitretin has been shown to be effective in treating the late-onset form.

DYSKERATOSIS CONGENITA (ZINSSER-COLE-ENGMAN SYNDROME)

Dyskeratosis congenita is a rare congenital syndrome characterized by cutaneous poikiloderma, nail dystrophy, premalignant leukoplakia, and bone marrow failure in some. Atrophy and telangiectasia are accompanied by tan-gray, mottled, hyperpigmented and hypopigmented macules or reticulated patches (Fig. 27.38). Commonly affected areas are on the upper torso, neck, and face, although the extremities may also be involved.

The nails may be thin and dystrophic, although only ridging and longitudinal fissuring may be seen in mild cases. This is the first component of the syndrome to appear, becoming apparent between ages 5 and 15. The other cutaneous lesions generally follow within 3–5 years. Leukoplakia occurs mostly on the buccal mucosa, where extensive involvement with verrucous thickening may be present. The anus, vagina, conjunctiva, and urethral meatus can be involved. Malignant neoplasms of the skin, mouth, nasopharynx, esophagus, rectum, and cervix may occur in sites of leukoplakia. Other manifestations of dyskeratosis congenita include hyperhidrosis of the palms and soles, bullous conjunctivitis, gingival disorders, dental caries, hypodontia, thin tooth enamel, periodontitis, dysphagia resulting from esophageal strictures and diverticula, skeletal abnormalities, aplastic anemia, mental deficiency, and hypersplenism. In many cases, a Fanconi type of anemia develops, beginning with leukopenia and thrombocytopenia, and progressing to severe pancytopenia (bone marrow failure). Pulmonary

Fig. 27.38 Dyskeratosis congenita. (Courtesy Dr. Lawrence Lieblich.)

complications include interstitial fibrosis and *Pneumocystis jiroveci* (formerly *P. carinii*) pneumonia.

Patients with dyskeratosis congenita have short telomeres, related to mutations in genes that encode components of the telomerase complex. These include dyskerin, *TERC*, *TERT*, *NHP2*, and *NOP10*. The genetic defect for the X-linked form is caused by a mutation in the *DKC1* gene for dyskerin, a protein implicated in both telomerase function and ribosomal RNA processing. The presence of short leukocyte telomeres can be helpful diagnostically. Autosomal dominant inheritance is often associated with mutations in hTR *(hTERC)*, involved in the RNA component of telomerase. Some autosomal dominant cases have anemia and reticulated pigmentation following the lines of Blaschko. Of interest, some patients with idiopathic aplastic anemia or myelodysplastic syndrome without skin findings demonstrate *hTERC* mutations.

Granulocyte colony-stimulating factor and erythropoietin may provide short-term benefits in treating bone marrow failure. Bone marrow transplantation or hematopoietic stem cell transplantation with nonmyeloablative conditioning affords the best outcomes.

Hoyeraal-Hreidarsson syndrome is a severe variant of dyskeratosis congenita characterized by intrauterine onset with growth retardation, cerebellar hypoplasia, mental retardation, microcephaly, progressive combined immunodeficiency, and aplastic anemia. The syndrome is genetically heterogeneous. Some patients demonstrate *DKC1* gene mutations and are therefore allelic to dyskeratosis congenita.

FANCONI SYNDROME

Also known as familial pancytopenia or familial panmyelophthisis, Fanconi syndrome may be associated with diffuse pigmentation of the skin (hypopigmentation, hyperpigmentation, and café au lait macules), absence of the thumbs, aplasia of the radius, severe hypoplastic anemia, thrombocytopenia, retinal hemorrhage, strabismus, generalized hyperreflexia, and testicular hypoplasia. The syndrome is associated with increased risk of myelomonocytic leukemia, SCC, and hepatic tumors. Human papillomavirus DNA is often found in the SCCs. Both cutaneous and pulmonary manifestations of associated Sweet syndrome have been reported. Some patients manifest short stature, failure to thrive, absent thumbs, short palpebral fissures, and typical skin abnormalities, but no hematologic abnormalities.

Fanconi syndrome is inherited in an autosomal recessive manner. Analysis has shown five complementation groups (FA-A, FA-B, FA-C, FA-D, and FA-E) and therefore five associated genes. The genes play an important role in hematopoiesis, and abnormal gene expression has been shown to increase apoptosis.

ECTODERMAL DYSPLASIAS

The ectodermal dysplasias are a clinically and genetically heterogenous group of genodermatoses in which the cardinal features are the abnormal, absent, incomplete, or delayed development during embryogenesis of one or more of the epidermal or mucosal appendages (hair, sebaceous glands, nails, teeth, or mucosal glands). Well over 100 ectodermal dysplasias have been described; those with the most prominent dermatologic features are reviewed here. Craniofacial reconstruction and dental implants can improve quality of life for some patients with ectodermal dysplasia.

Hypohidrotic Ectodermal Dysplasia (Anhidrotic Ectodermal Dysplasia, Christ-Siemens-Touraine Syndrome)

The classic triad of this disorder consists of hypotrichosis, anodontia, and hypohidrosis or anhidrosis. Patients with the disorder have cheekbones that are high and wide, whereas the lower half of the face is narrow (similar to congenital syphilis). The supraorbital ridges are prominent, and the nasal bridge is depressed, forming a saddle nose. The tip of the nose is small and upturned, and the nostrils are large and conspicuous. The eyebrows are scanty, and the eyes slant upward with prominent darkening around the eyes similar to denny morgan lines in atopic dermatitis. The lips are thickened, with the upper lip particularly protrusive. At the buccal commissures, there may be radiating furrows (pseudorhagades), and on the cheeks there may be telangiectasias. Sebaceous gland hyperplasia may be noted on the cheeks and forehead. Absence of mammary glands and nipples has been reported.

Generalized hypotrichosis is present with thin, sparse hair on the scalp. The skin is soft, thin, dry, and smooth. There is partial or total anodontia with peg shaped/conical teeth similar to those seen in incontinentia pigmenti. The nails may be thinned, brittle, and ridged. Mental retardation has been reported but may be a consequence of hyperthermic episodes in childhood.

The inheritance pattern is almost always X-linked recessive. Three genes, ectodysplasin *(EDA1)*, EDA-receptor *(EDAR)*, and EDAR-associated death domain *(EDARADD)*, have been described. All are involved in nuclear factor (NF)–κB activation. Female carriers may have segmental expression that can be demonstrated with a starch iodide test for sweating. Both autosomal recessive and dominant modes of inheritance have been described.

X-linked anhidrotic ectodermal dysplasia with immunodeficiency is caused by mutations in the gene encoding NF-κB modulator, *NEMO*, or inhibitor of κB kinase (*IKK-γ*). Stop codon mutations are associated with a severe phenotype with associated osteopetrosis and lymphedema. Patients may demonstrate an impaired immunity to mycobacterial infections such as mycobacterium avium complex hyper-IgM syndrome, impaired natural killer cell cytotoxicity, and various associated autoimmune diseases.

Fig. 27.39 Hidrotic ectodermal dysplasia.

Hidrotic Ectodermal Dysplasia

The hidrotic type of congenital ectodermal (Clouston syndrome) manifests with alopecia, nail dystrophy, palmoplantar hyperkeratosis (Fig. 27.39), and eye changes, such as cataracts and strabismus. Some patients have features resembling pachyonychia congenita. Inheritance is autosomal dominant. Eccrine sweat glands function normally, and facial features are normal Widespread poromas and palmoplantar syringofibroadenomas have been described. The defective gene has been identified as *GJB6*, encoding the gap junction protein connexin 30.

AEC Syndrome (Hay-Wells Syndrome)

Ankyloblepharon (fusion or partial fusion of the lids), ectodermal defects, and cleft lip and/or palate constitute the AEC syndrome. It is caused by p63 mutations and inherited autosomal dominantly. Ankyloblepharon is present at birth. Sparse hair, dental defects, cleft palate and lip, dystrophic nails, hypospadias, syndactyly, absent lacrimal puncta, stenotic auditory canals, and short stature may be present. An erosive scalp dermatitis occurs at an early age and can also be seen in KID syndrome (see later in this chapter). The scalp dermatitis is often extensive and difficult to treat, and it persists or recurs (Fig. 27.40). Low-frequency ultrasound has been successful in treating scalp wounds unresponsive to other measures.

EEC Syndrome

Ectodermal dysplasia, ectrodactyly, and cleft lip/palate are defining features of EEC syndrome. The EEC patient lacks scalp dermatitis but has mild hypohidrosis, and ectrodactyly (congenital absence of all or part of a digit, also seen in Goltz syndrome) is a prominent feature (Fig. 27.41). Some patients with EEC also have features of

Fig. 27.40 AEC syndrome with scalp dermatitis.

Fig. 27.41 Ectrodactyly in EEC syndrome.

mucous membrane pemphigoid with mucosal anti-BMZ BP-180 autoantibodies and severe bilateral cicatrizing conjunctivitis with blindness. Folliculitis with scarring may be noted during puberty, and ocular keratitis can be a prominent feature. As with the AEC syndrome, EEC syndrome is associated with mutations in the *p63* gene.

Rapp-Hodgkin Ectodermal Dysplasia Syndrome

Characteristic features of Rapp-Hodgkin ectodermal dysplasia syndrome include anomalies of hair (pili torti, pili canaliculi, alopecia, erosive folliculitis, thinning of eyebrows/lashes), cleft lip/palate, onychodysplasia, dental caries, hypodontia, craniofacial abnormality (Fig. 27.42), hypohidrosis, otitis media (hearing deficits), and hypospadias. It is usually inherited in an autosomal dominant manner. The syndrome is allelic to AEC and EEC, with *p63* mutations demonstrated in all three syndromes.

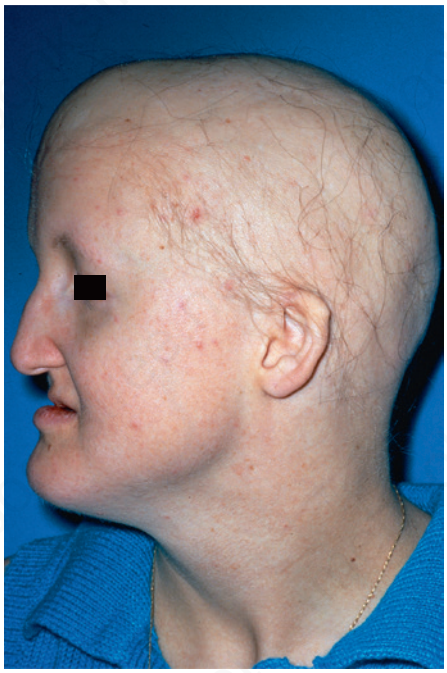

Fig. 27.42 Rapp-Hodgkin syndrome.

Other Ectodermal Dysplasias

Salient features include corkscrew hairs (exaggerated pili torti), scalp keloids, follicular plugging, keratosis pilaris, xerosis, eczema, palmoplantar keratodermia, syndactyly, onychodysplasia, and conjunctival neovascularization. Typical facies, anteverted pinnae, malar hypoplasia, cleft lip/palate, and dental abnormalities may also be found.

Odonto-Tricho-Ungual-Digital-Palmar Syndrome

First described by Mendoza et al., the salient clinical features are natal teeth, trichodystrophy, prominent interdigital folds, simian-like hands with transverse palmar creases, and ungual digital dystrophy, inherited as an autosomal dominant trait. Hypoplasia of the first metacarpal and metatarsal bones and distal phalanges of the toes may also occur.

Lenz-Majewski Syndrome

Lenz-Majewski syndrome is characterized by hyperostosis, craniodiaphyseal dysplasia, dwarfism, cutis laxa, proximal symphalangism, syndactyly, brachydactyly, mental retardation, enamel hypoplasia, and hypertelorism.

Lelis Syndrome

The Lelis syndrome is a form of ectodermal dysplasia with acanthosis nigricans, palmoplantar hyperkeratosis, hypotrichosis, hypohidrosis, nail dystrophy, early loss of adult teeth, and mental retardation.

Nectinopathies

Cleft lip/palate–ectodermal dysplasia and ectodermal dysplasia–syndactyly syndrome are caused by recessive mutations in the *PVRL1* and *PVRL4* genes, respectively. These genes encode nectins 1 and 4, which act in cooperation with cadherins to promote cellular adhesion.

PACHYDERMOPERIOSTOSIS (IDIOPATHIC HYPERTROPHIC OSTEOARTHROPATHY, TOURAINE-SOLENTE-GOLE SYNDROME)

Pachydermoperiostosis is characterized by thickening of the skin in folds and accentuation of creases on the face and scalp, clubbing of the fingers, and periostosis of the long bones. The changes are especially prominent on the forehead, where the horizontal lines are deepened and the skin becomes shiny (Fig. 27.43). The eyelids, particularly the upper lids, are thickened. Likewise, there is thickening of the ears and lips, and the tongue is enlarged. The scalp may be thickened and may show cutis verticis gyrata (pachydermie vorticelle). The extremities, especially the elbows, knees, and hands, are enlarged and spade shaped. The fingers become club shaped. The palms are rough, and the thenar and hypothenar eminences are enlarged. Hyperhidrosis is common. Hyperkeratotic linear lesions of the palms and soles may be present. These lines are rippled, resembling sand of the "wind-blown desert." Movements of the muscles may be painful. An association with gynecomastia and osteoporosis has been described.

There are inherited and acquired forms of pachydermoperiostosis. The acquired form may occur with chronic pulmonary, mediastinal, and cardiac diseases that are associated with chronic hypoxia in peripheral tissues. Some cases have been associated with bronchogenic carcinoma. When such an association occurs, enlargement of the forehead, hands, and fingers may antedate recognition of the tumor or may develop after the tumor is identified as present. Bronchogenic carcinoma–associated pachydermoperiostosis occurs almost exclusively in men over age 40, whereas inherited Touraine-Solente-Gole syndrome usually occurs as an autosomal dominant disorder with onset in late adolescence. It is not associated with malignant disease. More prominent signs are seen in males. Autosomal recessive inheritance with cleft palate and congenital heart defects has been described. Frontal rhytidectomy has been used to treat associated leonine facies, and bone manifestations have shown some response to oral bisphosphonate therapy and arthroscopic synovectomy. *HPGD* gene mutations affecting 15-hydroxyprostaglandin dehydrogenase (15-PGDH) and mutations in the prostaglandin transporter gene *SLCO2A1* have been described.

Fig. 27.43 Pachydermoperiostosis.

CUTIS VERTICIS GYRATA

Cutis verticis gyrata is characterized by folds and furrows on the scalp, usually in an anteroposterior direction. Most frequently, the vertex is involved, but other areas may have the distinctive furrowing. There may be 2–20 folds. The hair itself is normal.

Cutis verticis gyrata has been reported primarily in males, with a male/female ratio of 6:1. Onset is usually at puberty, with more than 90% of patients developing it before age 30. The condition may be familial when it occurs as a component of pachydermoperiostosis. It has been reported to result from developmental anomalies, inflammation, trauma, tumors, nevi, amyloidosis, syphilis, myxedema, Ehlers-Danlos syndrome, Turner syndrome, Klinefelter syndrome, fragile X syndrome, vemurafenib, and the insulin resistance syndrome. Cutis verticis gyrata may be found in patients with mental retardation, seizures, and schizophrenia. Biopsy findings can be normal or may show thick collagen bundles and hypertrophy of adnexal structures. Rarely, a cerebriform intradermal nevus may be mistaken for this disorder. In severely involved cases, excision with grafting or scalp reduction may be indicated.

APLASIA CUTIS CONGENITA

Aplasia cutis congenita (ACC) is a congenital absence of at least the skin but the defect may extend all of the way through the skull if on the scalp. ACC may be from a primary failure of skin formation or from in utero destruction of skin that had formed. The most typical location for ACC is the scalp but there are other stereotypical locations associated with certain syndromes or intrauterine events.

Scalp ACC is divided into membranous and nonmembranous forms. Membranous ACC is notable at birth with a thin membrane often overlying a small nodule that can be filled with clear or serosanguineous fluid. These lesions are usually round or oval and may be due to failed fusion of embryonic planes, because they can also occur off midline and even on the face. Lesions of membranous aplasia cutis may have a "hair collar sign," which refers to a ring of long, dark terminal hair encircling the lesion. Membranous ACC can be a marker of cranial dysraphism or a remnant connection to the CNS such as an atretic encephalocele or meningocele. Therefore midline vertex or posterior scalp lesions and any membranous aplasia cutis with a hair collar sign warrants an MRI to rule out a connection to the CNS and evaluate for a remnant neural lesion.

Nonmembranous aplasia cutis is usually more stellate and then leads to scarring, which may indicate that it was caused by destruction of skin. Imaging is recommended for stellate lesions to rule out bony defects. If large, there can be hemorrhage or infection. Scalp aplasia cutis can be autosomal dominantly inherited.

If there is intrauterine demise of a twin (fetus papyraceus) there can be a resultant cutaneous infarction in the living twin that has a characteristic "H" pattern on the abdomen with aplasia cutis and resultant scarring horizontally across the abdomen with vertical band extending superiorly and inferiorly on the sides forming an "H." Aplasia cutis can occur due to medications such as methimazole. Distal radial epiphyseal dysplasia has been associated with localized ACC.

FOCAL PREAURICULAR DERMAL DYSPLASIA

Focal preauricular dermal dysplasia is a form of ACC not typically associated with any extracutaneous anomalies.

SYNDROMES ASSOCIATED WITH APLASIA CUTIS

Adams-Oliver syndrome includes severe ACC of the scalp, which may involve both skin and skull ossification defects, limb defects (brachydactyly, syndactyly of toes two and three, and hypoplastic toenails), extensive cutis marmorata telangiectatica congenita, cryptorchidism, and cardiac abnormalities, including ventricular septal defects, and tetralogy of Fallot. Adams-Oliver is a rare, autosomal dominant inherited neuroectodermal syndrome caused by *NOTCH-1* mutations although various other mutations have been reported in a minority of patients.

The SCALP syndrome is a syndrome with CNS malformations, ACC, limbal dermoid, and a giant congenital pigmented melanocytic nevus with neurocutaneous melanosis. The 19q13.11 deletion syndrome with microcephaly, scalp defects, and developmental delay was recently found to be from a *UBA2* mutation. Scalp-ear-nipple syndrome is characterized by ACC, ear anomalies, and breast anomalies. Johanson-Blizzard syndrome is characterized by hypoplasia of the nasal ala, scalp defects, and oligodontia.

FOCAL DERMAL HYPOPLASIA (GOLTZ SYNDROME)

Goltz syndrome is an X-linked dominant disorder that presents at birth with a blaschkoid pattern of reddish tan, cribriform, atrophic, plaques (Fig. 27.44). The buttocks, axillae, and thighs are often involved. Adipocytes accumulate in the lesions, resulting in yellowish brown nodules herniate through the atrophic areas. Telangiectases are often present, and segmental presentations have been described. Papillomas may occur around the orifices of the mouth, anus, and vulva. They may be misdiagnosed as condylomata acuminata. An early inflammatory vesicular stage has been described, along with cleft lip and palate although a blaschkoid pattern of vesicles is more typical of incontinentia pigmenti. About 80% of patients have skeletal defects such as ectrodactyly (similar to EEC syndrome), syndactyly, oligodactyly, or adactyly (Fig. 27.45). Scoliosis, spina bifida, and hypoplasia of the clavicle have also been reported. From 40%–50% of patients have ocular or dental abnormalities, with coloboma being the most common ocular defect.

Goltz syndrome is X linked dominant, caused by mutations in *PORCN*, a regulator of Wnt signaling. Females are protected by inactivating the affected X chromosome during lionization (similar to other X linked dominant disorders such as incontinentia pigmenti). Therefore a history of spontaneous male abortions and

Fig. 27.44 Goltz syndrome.

Fig. 27.45 Goltz syndrome.

only female offspring is supportive. Males can have postzygotic mutations that lead to blaschkoid or segmental patterns of Goltz. If males have an extra X chromosome (XXY or XXYY), then they could have the full syndrome. Van Allen–Myhre syndrome appears to represent a severe form of Goltz syndrome with split-foot and split-hand anomalies. Treatment of atrophic erythematous patches has been successful using a flashlamp-pumped pulsed dye laser.

MIDAS SYNDROME

MIDAS (microphthalmia, dermal aplasia, and sclerocornea) is also X-linked dominant (mutation in the *HCSS* gene) and presents with linear facial and neck scarring along with microphthalmia. The clinical lesions are somewhat similar to Goltz syndrome, but the distribution of MIDAS is characteristic.

Stevenson DA, et al: Goltz syndrome and PORCN mosaicism. Int J Dermatol 2014; 12: 1481.

Restrictive Dermopathy

Restrictive dermopathy is a rare, lethal, autosomal recessive inherited laminopathy characterized by abnormal facies, tight skin, sparse or absent eyelashes, and secondary joint changes. Virtually all cases are associated with polyhydramnios, reduced fetal movements, and premature delivery. Infants exhibit a fixed facial expression, with blurring of the groove between nose and cheek, sometimes described as an "Asiatic porcelain doll" appearance. Patients also exhibit micrognathia, mouth in the O position, rigid and tense skin with erosions especially at the flexures, denudations, and multiple joint contractures. Some patients have wide cranial sutures, small pinched nose, low-set ears, microstomia, rocker-bottom feet, scaly skin, and respiratory insufficiency. Pulmonary hypoplasia, microcolon, vessel transposition, natal teeth, ectropion, submucous cleft palate, hypospadias, urethral duplication, dysplasia of clavicles, adrenal hypoplasia, and an enlarged placenta with short umbilical cord may be noted.

Histopathologic features include hyperkeratosis, parakeratosis, abnormal keratohyaline granules, and effacement of the rete ridge pattern. The dermis is attenuated with collagen fibers parallel to the epidermis, resembling a scar or tendon. Elastic fibers are absent. The subcutis demonstrates hypoplastic eccrine and sebaceous glands. The disease is usually caused by mutations in *ZMPSTE24*, causing loss of function of the encoded zinc metalloproteinase STE24 and resulting in accumulation of prelamin A at the nuclear periphery. Dominant and progeroid forms may be related to LMNA mutations.

Starke S, et al: Progeroid laminopathy with restrictive dermopathy–like features caused by an isodisomic LMNA mutation *p.R435C*. Aging (Albany NY) 2013; 5: 445.

WERNER SYNDROME (ADULT PROGERIA)

Werner syndrome is an autosomal recessive, premature aging syndrome characterized by many metabolic and structural abnormalities involving the skin, hair, eyes, muscles, fatty tissues, bones, blood vessels, and carbohydrate metabolism. Cells demonstrate genomic instability. Most of these signs and thus the diagnosis are not fully manifested until age 30. These patients usually die before age 50 from malignant disease or vascular accidents.

The most characteristic findings are premature aging and arrest of growth at puberty, senile cataracts developing in the late twenties and thirties, and premature balding and graying. The skin changes include poikiloderma, scleroderma, atrophy, hyperkeratoses, and leg ulcers. The skin has a diffuse, dark-gray or blackish pigmentation. Painful callosities with ulcerations may occur around the malleoli, Achilles tendons, heels, and toes. The hair thins on the eyebrows, axillae, and pubis. The skin over the cheekbones becomes taut, producing proptosis and beaking of the nose. There is loss of subcutaneous tissue and wasting of muscles, especially the extremities, so that the legs become spindly and the trunk becomes stocky. The vocal cords become thickened, leading to a weak, high-pitched voice. Premature arteriosclerosis and sexual impotence are frequently observed. Hypogonadism in both genders are distinctive in Werner syndrome. Diabetes is common, and areas of calcinosis circumscripta occur. Osteoporosis and aseptic necrosis are frequently found in the small bones of the hands.

A high rate of malignancy is associated with Werner syndrome, including a 50-fold increase in melanoma. Thyroid adenocarcinoma, hepatoma, meningioma, leukemia, carcinoma of the breast, fibrosarcoma, and a variety of sarcomas have been reported. Histologic changes in the skin may include atrophy of the epidermis and fibrosis of the dermis.

Werner syndrome is caused by a mutation in the *WRN* gene that is involved in telomere maintenance and thus loss of function may lead to the age-related changes.

PROGERIA (HUTCHINSON-GILFORD SYNDROME)

Progeria, or Hutchinson-Gilford syndrome, is characterized by accelerated aging, dwarfism, alopecia, generalized atrophy of the skin and muscles, enlarged head with prominent scalp veins, and a high incidence of generalized atherosclerosis, usually fatal by the second decade of life. In affected individuals, their large, bald head and lack of eyebrows and eyelashes are distinctive (Fig. 27.46). The skin is wrinkled, pigmented, and atrophic. Progeroid features can be seen in trichothyodystrophy, neonatal progeroid syndrome, restrictive dermopathy, werner syndrome, bloom syndrome and rothmund thompson. The nails are thin and atrophic. Most patients lack subcutaneous fat, which produces the appearance of premature senility. There are usually sclerodermatous plaques on the extremities. The intelligence remains intact. Arteriosclerosis, anginal attacks,

Fig. 27.46 Progeria.

and hemiplegia may occur, followed by death from coronary heart disease at an early age. Mutations in LMNA and mosaicism have been identified. Treatment is symptomatic, mainly control of diabetes mellitus and treatment of leg ulcerations.

DISORGERS WITH PHOTOSENSITIVITY

Xeroderma pigmentosum, Cockayne syndrome, and trichothiodystrophy are caused by mutations in genes involved in nucleotide excision repair (NER). NER repairs DNA lesions throughout the genome, preventing the accumulation of mutations. Therefore these three syndromes share common features of photosensitivity with or without skin cancer or systemic cancer risk. Mutations in a single gene such as ERCC2/XPB or ERCC3/XPD can actually produce the clinical phenotype of any of the three syndromes depending on how they affect the function of the transcription factor TFIIH that is involved in NER.

XERODERMA PIGMENTOSUM

Xeroderma pigmentosum is an autosomal recessive disorder characterized by defective DNA thymidine dimer excision repair, extreme sun sensitivity, freckling, and skin cancer. Mutations in various different genes involved in DNA repair after UV damage and thus lead to similar phenotypes. Sun sensitivity and lentigines are early skin findings (Fig. 27.47), with median onset before age 2 years. Skin cancers often appear before age 10, and an increase in internal cancer has been noted as well. NIH data suggest a 10,000-fold increase in skin cancer before age 20. In a study of 830 patients, 45% had basal cell carcinoma or SCC, and melanoma was noted in 5%. Most of the tumors occur on the head and neck in sun-exposed areas. Skin tumors in xeroderma pigmentosum patients have sunlight-induced mutations in *RAS*, *p53*, and *PTCH* genes. Ocular abnormalities were found in 40% and included photophobia, ectropion, corneal opacity, blepharospasm and neoplasms. Progressive neurologic degeneration is seen in about 20% of patients. Loss of high-frequency hearing can also occur. Xeroderma pigmentosum patients in complementation group C remain free of neurologic problems. Complementation groups are defined by correction of excision repair when fibroblasts from patients in different groups are fused. A variant type with normal excision repair has also been described.

Fig. 27.47 Xeroderma pigmentosum. (Courtesy Dr. Debabrata Bandyopadhyay.)

The main intervention that is vital is extremely diligent photoprotection. Vitamin D, nicotinamide, and zinc supplementation may help. Retinoids can prevent the appearance of new cancers, but side effects are significant, and a rebound in the number of cancers occurs when the drug is stopped, suggesting that the tumors are merely suppressed. Individual tumors may be excised or destroyed with cryotherapy. Some may be treated with topical imiquimod or 5-FU. Topical application of recombinant liposomal encapsulated T4 endonuclease V repairs UV-induced cyclobutane-pyrimidine dimers and is a promising form of therapy. Gene therapy is also being pursued. Guidelines for evaluation and management from the XP Society can be found at www.xps.org. A publication from the NIH can be found at www.cc.nih.gov/ccc/patient_education/pepubs/xp7_17.pdf.

The De Sanctis–Cacchione syndrome consists of xeroderma pigmentosum with mental deficiency, dwarfism, and gonadal hypoplasia. It occurs most often in patients in complementation group D.

COCKAYNE SYNDROME (NO SKIN CANCER)

Cockayne syndrome is an autosomal recessive syndrome with sun sensitivity and neurologic degeneration related to mutations in five NER genes: *ERCC8* (Cockayne syndrome A), *ERCC6* (Cockayne syndrome B), *XPB*, *XPD*, and *XPG*. Mutations in *XPB* or *XPD* DNA helicase can result in xeroderma pigmentosum, Cockayne syndrome, or trichothiodystrophy. Cockayne differs from xeroderma pigmentosum in the lack of freckling and in the presence of dwarfism, beaked nose, loss of subcutaneous tissue, deafness, basal ganglia calcification, failure of brain growth, and retinopathy. Dermatologic features include photodermatitis with telangiectasia, atrophy, and scarring. The hands and feet are large and cyanotic. Microcephaly, sunken eyes, severe flexion contractures, dorsal kyphosis, cryptorchidism, cataracts, growth retardation, mental retardation, hypothalamic and cerebellar dysfunction, and retinitis pigmentosa with optic atrophy may be seen. There is progressive neurologic disturbance with a shortened life span.

Patients in complementation groups B, D, and G (XPB, XPD, XPG) have skin features of xeroderma pigmentosum and neurologic features of Cockayne syndrome. Mutations in the associated genes may give rise to clinical manifestations of xeroderma pigmentosum, Cockayne syndrome, or the XP-Cockayne syndrome complex. The XP-Cockayne syndrome patients have an elevated skin cancer risk but the other Cockayne patients do not.

TRICHOTHIODYSTROPHY

Trichothiodystrophy (TTD) is an autosomal recessive disorder originally described as photosensitivity, ichthyosis, brittle hair, intellectual impairment, decreased fertility, and short stature (PIBIDS). There are also nonphotosensitive versions caused by other mutations with the acronym IBIDS. A review of 112 patients noted a wide spectrum of clinical features that varied from patients with only hair involvement to those with profound developmental defects. Common features included intellectual impairment (86%),

short stature (73%), ichthyosis (65%), ocular abnormalities (51%), infections (46%), and photosensitivity (42%). More than half the patients had abnormal characteristics at birth, and 19 patients died before age 10.

The hair, with sulfur reduced to 50% of the normal value, has distinctive features under polarizing and light microscopy and scanning EM and can help aid in early diagnosis. With light microscopy, keratin orientation alternates in a Z pattern. With polarizing microscopy, the hair shows alternating bright and dark regions that give a striking striped, or tiger tail, appearance, but the pattern may not be evident at birth, and a similar pattern of bright and dark bands has been described in the keratitis ichthyosis deafness syndrome. Hairs demonstrate heterogeneous deficiency in sulfur, with the greatest loss in areas of trichoschisis (clean fractures). Trichorrhexis nodosa–like fractures may also be seen. In addition, the hair is extremely flattened and folds over itself like a thick ribbon. The hair shaft outline is irregular and slightly undulating, and the melanin granules are distributed in a wavy pattern. With scanning EM, the surface shows marked ridging and fluting, and the cuticle scales may be absent or greatly reduced.

The three genes mutated in TTD are *ERCC2*, *ERCC3*, and *GTF2HF*, which are involved in DNA repair, encoding parts of a transcription repair factor TFIIH. The UV sensitivity and defective NER are similar to those of xeroderma pigmentosum patients, but these patients do not experience an increased incidence of skin cancer. Two of the three described complementation groups match xeroderma pigmentosum groups B and D, with the *XPD* gene accounting for most photosensitive trichothiodystrophy. A combined xeroderma pigmentosum/trichothiodystrophy complex has been described. Patients with trichothiodystrophy without xeroderma pigmentosum do not have an increase in skin cancer formation.

BLOOM SYNDROME (BLOOM-TORRE-MACHACEK SYNDROME)

Bloom syndrome is characterized by photosensitive telangiectatic erythema in the butterfly area of the face (which can be very similar to RTS) along with dwarfism. The earlier onset and the presence of cataracts help differentiate Bloom from RTS. Telangiectatic erythematous patches resembling lupus erythematosous develop in the first 2 years of life (Fig. 27.48). Bullous, crusted

Fig. 27.48 Bloom syndrome.

lesions may be present on the lips. Exacerbation of skin lesions occurs during the summer. Cockayne and EPP display similar photosensitivity. Other changes that may be noted are café au lait spots, ichthyosis, acanthosis nigricans, syndactyly, irregular dentition, lens opacities, prominent ears, hypospadias, and cryptorchidism. Bloom patients have a high-pitched voice. The stunted growth is characterized by normal body proportions, no endocrine abnormalities (except diabetes mellitus), and low birth weight at full term. Dolichocephaly and narrow, delicate facies are present. Immune functions are abnormal, and GI and respiratory infections often occur. Cancer of all cell types and sites is increased in frequency. Leukemia, lymphoma, adenocarcinoma of the sigmoid colon, and oral and esophageal SCC, as well as other malignancies, have been associated with Bloom syndrome. About one quarter of patients under age 20 develop a neoplasm. Regular use of a broad-spectrum sunscreen, as well as photoprotection, is recommended.

Bloom is caused by mutations in *BLM* gene, which codes for a RecQ DNA helicase. *BLM* interacts with WRN, the DNA helicase mutated in Werner syndrome, and is part of a large *BRCA-1*–containing complex containing DNA repair factors. BLM interacts directly with ATM (likely explaining the telangiectasias in each), the protein product of the gene mutated in ataxia-telangiectasia, and together they recognize abnormal DNA structures.

Thomas ER, et al: Surveillance and treatment of malignancy in Bloom syndrome. Clin Oncol (R Coll Radiol) 2008; 20: 375.

ROTHMUND-THOMSON SYNDROME (POIKILODERMA CONGENITALE)

Rothmund-Thomson syndrome (RTS) is a rare autosomal recessive disorder. Poikiloderma begins at 3–6 months of age, with tense, pink, edematous patches on the cheeks, hands, feet, and buttocks, sparing the chest, back, and abdomen (acute phase). Sensitivity to sunlight may be manifested by the development of bullae or intense erythema after brief sun exposure. This is followed by fine, reticulated or punctate atrophy associated with telangiectasia and reticulated pigmentation (chronic phase) (Fig. 27.49). The skin lesions are characteristic. The arms and legs are affected, with sparing of the antecubital and popliteal fossae. Associated cutaneous neoplasms include SCC, Bowen disease, basal cell carcinoma, and melanoma, but the risk for osteosarcoma of bone is particularly high (>30%). Patients with Rothmund-Thomson syndrome may

Fig. 27.49 Rothmund-Thomson syndrome.

have a broad range of noncutaneous lesions. Short stature (66%), small hands with radial ray defects, saddle nose, absence or sparseness of eyebrows and eyelashes (73%), alopecia of the scalp (50%), and numerous bone defects (75%) are often observed. Hypogonadism, dystrophic nails, and defective dentition are seen in a significant proportion of patients (25%–60%). Cataracts occur in a small percentage of patients in childhood or young adult life, and glomerulonephritis has been reported. The syndrome is related to biallelic mutations of the *RECQL4* gene. Thus at least a subset of patients with Rothmund-Thomson syndrome has abnormal DNA helicase activity, as do patients with Werner and Bloom syndromes.

POIKILODERMA WITH NEUTROPENIA

Clericuzio-type poikiloderma with neutropenia (PN) is also characterized by a poikilodermatous eruption that usually starts in the first year and importantly is associated with neutropenia and sinopulmonary infections. They can also have PPK, nail deformities, and skeletal abnormalities. PN should be considered in patients who present with poikiloderma and RTS is being considered. PN is caused by mutations in *USB1*.

HEREDITARY SCLEROSING POIKILODERMA AND MANDIBULOACRAL DYSPLASIA

Hereditary sclerosing poikiloderma is an extremely rare autosomal dominant disorder. The skin changes consist of generalized poikiloderma appearing in childhood (but not at birth), with hyperkeratotic and sclerotic cutaneous bands extending across the antecubital spaces, axillary vaults, and popliteal fossae. In addition, the palms and soles may show sclerosis resembling shiny scotch-grain leather. Aortic stenosis, clubbing of the fingers, and localized calcinosis of the skin have also been noted. The cases described by Weary were subsequently reported later in life as mandibuloacral dysplasia, a rare autosomal recessive syndrome characterized by mandibular hypoplasia, delayed cranial suture closure, dysplastic clavicles, abbreviated club-shaped terminal phalanges, myopathy, lipodystrophy, acro-osteolysis, atrophy of the skin of the hands and feet, and typical facial changes. Mandibuloacral dysplasia must be distinguished from progeria and Werner syndrome.

A distinct subtype has been described in two generations of a South African family. The characteristics included poikiloderma, tendon contracture, and pulmonary fibrosis, with apparent autosomal dominant inheritance. Sparse, fine hairs are present on the scalp, face, and body.

Khumalo NP, et al: Poikiloderma, tendon contracture and pulmonary fibrosis. Br J Dermatol 2006; 155: 1057.
Lombardi F, et al: Compound heterozygosity for mutations in LMNA in a patient with a myopathic and lipodystrophic mandibuloacral dysplasia type A phenotype. J Clin Endocrinol Metab 2007; 92: 4467.

SCLEROATROPHIC SYNDROME OF HURIEZ

Huriez syndrome, a very rare autosomal dominant disorder, is a palmoplantar keratoderma characterized by scleroatrophy of the hands, with sclerodactyly, along with ridging, clubbing, or hypoplasia of the nails. Patients with Huriez syndrome may also have multiple telangiectasias of the lips and face and flexion contractures of the little finger. Aggressive SCCs occur in the scleroatrophic skin, including that of the palms and soles (13% lifetime risk, 5% mortality rate in affected persons). Affected patients have reduced Langerhans cells in affected skin, but normal dermal dendritic cells.

DISORDERS WITH CRANIOFACIAL ABNORMALITIES

Franceschetti-Klein Syndrome (Mandibulofacial Dysostosis)

This syndrome includes palpebral antimongoloid fissures, hypoplasia of the facial bones, macrostomia, vaulted palate, malformations of both the external and internal ear, buccal-auricular fistula, abnormal development of the neck with stretching of the cheeks, accessory facial fissures, and skeletal deformities. Patients who have the complete syndrome usually die in infancy, but patients with the abortive type may live to an old age. Franceschetti-Klein syndrome is allelic to the Treacher Collins syndrome and caused by the Treacher Collins–Franceschetti *(TCOF1)* gene.

Treacher Collins Syndrome

Treacher Collins syndrome includes midface hypoplasia with micrognathia, microtia, conductive hearing loss, and cleft palate. It is inherited as an autosomal dominant trait and caused by mutations in the *TCOF1* gene, which encodes a protein called treacle.

Oculoauriculofrontonasal Syndrome

This syndrome is sporadic in nature, although autosomal recessive inheritance has been suggested by some authors. Features include hemifacial microsomia, microtia, ocular hypertelorism, upper palpebral colobomata, preauricular tags, lateral face clefting, and nasal clefting.

Popliteal Pterygium Syndrome

Pterygia or skinfolds may extend from the thigh down to the heel and thus prevent extension or rotation of the legs. Crural pterygia, cryptorchidism, bifid scrotum, agenesis of the labia majora, cleft

lip and palate, adhesions between the eyelids, syndactyly, and talipes equinovarus may be present. Autosomal dominant inheritance has been described, and popliteal pterygium syndrome is allelic to the van der Woude syndrome.

van der Woude Syndrome

The van der Woude syndrome is an autosomal dominant craniofacial disorder characterized by hypodontia, pits of the lower lip, and cleft palate due to mutations in the *IRF6* gene. Other reported associations include natal teeth, ankyloglossia, syndactyly, equinovarus foot deformity, and congenital heart disease. Lower lip pits may be found in other congenital disorders, such as popliteal pterygium syndrome, and occasionally in orofaciodigital syndrome type I (oral frenula and clefts, hypoplasia of alae nasi, and digital asymmetry). Surgical correction is the treatment of choice.

Apert Syndrome (Acrocephalosyndactyly)

Apert syndrome is autosomal dominant inherited and is characterized by craniosynostosis and fusion of the digits (syndactyly). Patients present with synostosis of the feet, hands, carpi, tarsi, cervical vertebrae, and skull. The facial features are distorted and the second, third, and fourth fingers are fused into a bony mass with a single nail. Occulocutaneous albinism and severe acne vulgaris have been reported with Apert syndrome, although some of the acneiform lesions actually represent follicular hamartomas. Neurologic defects may be caused in part by brain compression by the abnormal skull. Mutations in the fibroblast growth factor receptor *(FGFR2)* gene are responsible for Apert, Crouzon, and Pfeiffer syndromes. Nevus comedonicus has been shown to be due to a post zygotic mutation in *FGFR2*.

Pfeiffer Syndrome

Pfeiffer syndrome is autosomal dominant inherited and consists of osteochondrodysplasia and craniosynostosis.

Crouzon Syndrome

Crouzon syndrome includes craniosynostosis and acanthosis nigricans. It is associated with mutations in the *FGFR2* gene. The crouzonodermoskeletal syndrome with choanal atresia and hydrocephalus is caused by mutations in *FGFR3*, a gene associated with achondroplastic dwarfism. Affected patients can also present with acanthosis nigricans

Carpenter Syndrome

Carpenter syndrome is an acrocephalopolysyndactyly syndrome with craniosynostosis and acral deformities that include syndactyly.

Whistling Face Syndrome

In this rare disorder, also known as distal arthrogryposis type 2, the child appears to be whistling all the time. This configuration is the result of microstomia, deep-set eyes, flattened midface, coloboma, contracted joint muscles of the fingers and hands, and alterations of the nostrils. Ulnar deviation of the fingers, kyphoscoliosis, and talipes equinovarus may be present.

OTHER SYNDROMES THAT INCLUDE HAIR ABNORMALITIES

Hallerman-Streiff Syndrome

People with Hallerman-Streiff syndrome have characteristic "bird facies" (micrognathia with a small shin, a pointed nose, and microphthalmia along with a proportionately larger posterior part of their head). They can have congenital cataracts, hypotrichosis, and dental abnormalities, including absent teeth leading to malocclusion. The hair is diffusely sparse and brittle. Baldness may occur frontally or at the scalp margins, but sutural alopecia—hair loss following the lines of the cranial sutures—is characteristic of this syndrome. Nystagmus, strabismus, and other ocular abnormalities occur. Cleft palate and syndactyly may be present, representing overlap with oculodentodigital dysplasia associated with *GJA1* gene mutation.

Polyostotic Fibrous Dysplasia (Albright Disease)

Polyostotic fibrous dysplasia may present as slowly progressive, lifelong unilateral hair loss (scalp, pubic, axillary, and palpebral).

Cronkhite-Canada Syndrome

Cronkhite-Canada syndrome is characterized by alopecia, skin pigmentation, onychodystrophy, malabsorption, and generalized GI polyposis. Patients often present with diarrhea. The hyperpigmentation often involves the palms and soles. Recently the alopecia was proposed to be alopecia areata because it can affect body hair and may respond to systemic steroids.

Marinesco-Sjögren Syndrome

Marinesco-Sjögren syndrome consists of cerebellar ataxia, mental retardation, congenital cataracts, inability to chew food, thin brittle fingernails, and sparse hair. The dystrophic hairs do not have the normal layers (cortex, cuticle, medulla), and 30% of the hair shafts show narrow bands of abnormal, incomplete keratinization.

Multiple Familial Trichoepitheliomas

Generalized trichoepitheliomas, alopecia, and myasthenia gravis may be a variant of the generalized hair follicle hamartoma syndrome. There is a report of a localized variant of this syndrome. Histologically, there is replacement of the hair follicles by trichoepithelioma-like epithelial proliferations associated with hyperplastic sebaceous glands. It is caused by a mutation in the CYLD gene (similar to Brooks Spiegler and familial cylindromatosis).

Crow-Fukase (POEMS) Syndrome

This acquired syndrome is characterized by polyneuropathy, organomegaly, endocrinopathy, M-protein, and skin changes (POEMS) such as diffuse hyperpigmentation, dependent edema, skin thickening, hyperhidrosis, glomerluoid hemangiomas and hypertrichosis (see Chapter 28).

Fig. 27.50 Noninfectious granuloma in cartilage-hair hypoplasia.

Cartilage-Hair Hypoplasia (Mckusick-Type Metaphyseal Chondrodysplasia)

Cartilage-hair hypoplasia encompasses short-limbed dwarfism and abnormally fine and sparse hair in children. These children are especially susceptible to viral infections (varicella-zoster virus and herpes simplex virus) and recurrent respiratory infections. They can get sarcoidal-like granulomas (Fig. 27.50) likely due to inefficient handling of live rubella virus vaccine (similar to ataxia telangiectasia and other immunodeficiencies). A high incidence of non-Hodgkin lymphoma, leukemia, SCC, and basal cell carcinoma has been reported. A functional defect of small lymphocytes, with impaired cell-mediated immunity, may occur. Most patients are anergic to skin-test panels and have increased numbers of natural killer cells. The major mutation involves the *RMRP* gene, which encodes a component of mitochondrial RNA-processing endoribonuclease.

Cartilage-hair hypoplasia has been associated with Omenn syndrome *(RAG1/RAG2I* mutations), a variant of severe combined immunodeficiency disease, which includes erythroderma, eosinophilia, and susceptibility to various pathogens. Mutations in recombination-activating genes 1 and 2 or the protein Artemis have been associated with Omenn syndrome.

Trichorhinophalangeal Syndrome

This genetic disorder consists of fine and sparse scalp hair, thin nails, pear-shaped broad nose, and cone-shaped epiphyses of the middle phalanges of some fingers and toes. Supernumerary teeth have been reported. There is an autosomal dominant and also a recessive inheritance type. Trichorhinophalangeal syndrome can result from mutations in *TRPS1* gene. Type II (Langer-Giedion syndrome) includes mental retardation and multiple exostoses and is a contiguous gene syndrome caused by a one-copy deletion spanning the genes *TRPS1*, *RAD21*, and *EXT1*. Type III resembles a severe form of type I with short stature.

Papillon-Lefèvre Syndrome

Papillon-Lefèvre syndrome is characterized by hyperkeratosis palmaris et plantaris, periodontosis, and sparsity of the hair and is reviewed in Chapter 11.

Klippel-Feil Syndrome

Klippel-Feil syndrome consists of a low posterior scalp hairline extending onto the shoulders, with a short neck, limiting movement of the neck and suggestive of webbing. The cervical vertebrae are fused. This syndrome is caused by faulty segmentation of the mesodermal somites between the third and seventh weeks in utero. Strabismus, nystagmus, cleft palate, bifid uvula, and high palate are other features. Ear abnormalities include microtia, external ear canal stenosis, and chronic ear inflammation. Klippel-Feil syndrome occurs mostly in girls.

McKusick Syndrome

Features of McKusick syndrome include short-limbed dwarfism and fine, sparse, hypoplastic, and dysmorphic hair.

GAPO Syndrome

Growth retardation, alopecia, psuedoanondontia, and optic atrophy (GAPO) is a syndrome in which children have a very aged appearance along with alopecia caused by an ANTXR1 mutation.

Atrichia With Papules

This rare autosomal recessive disorder, often seen in patients of south Asian descent, is characterized by loss of hair beginning shortly after birth and the development of cutaneous cystic papules. The cyst epithelium demonstrates keratins 15 and 17, suggesting derivation from the follicular bulge and the presence of stem cells. Vitamin D receptor gene mutations can also present with congenital total alopecia, but the patients have severe vitamin D deficiency so this must be considered in the differential diagnosis. Both the hairless gene and the vitamin D receptor gene produce zinc-finger proteins and may have overlapping functions.

KERATOSIS PILARIS

Keratosis pilaris (KP) is a very common, chronic, autosomal dominantly inherited skin condition characterized by small, acuminate, follicular papules with a horny plug in each follicle. Mild KP may be limited to the posterior upper arms. The thighs are the next most common site, but lesions may occur on the cheeks, eyebrows, forearms, buttocks, trunk, and legs. Facial involvement may be mistaken for acne vulgaris and may leave small, pitted scars, even when the condition does not scar elsewhere. Because facial KP is common in prepubertal children it is important to distinguish from acne to avoid unnecessary concern for precocious puberty that would be warranted for true acne in a child under 8. KP may or may not be erythematous. Sometimes the keratotic plugs are the most prominent feature of the eruption, whereas at other times most of the lesions are punctate erythematous papules. Occasionally, inflammatory acneiform pustules and papules may appear. Variants of KP with more prominent scarring are included under the heading of keratosis pilaris atrophicans.

Forcible removal of one of the plugs leaves a minute, cup-shaped depression at the apex of the papule, which is soon filled by new keratotic material. The lesions tend to be arranged in poorly defined groups, dotting the otherwise normal skin in a fairly regular pattern. Fillagrin mutations lead to KP in association with hyperlinear palms and risk for atopic dermatitis.

Other conditions associated with KP are trisomy 21, ichthyosis follicularis, atrichia with papular lesions, mucoepidermal dysplasia, CFC syndrome (KP, curly hair, sparse hair with pulmonary valve stenosis, hypertrophic cardiomyopathy, or atrial septal defect), ectodermal dysplasia with corkscrew hairs, and KID syndrome. KP rubra has prominent erythema and widespread areas of skin involvement, but no atrophy or hyperpigmentation.

Treatment is difficult, but some patients respond to topical retinoids. Often the therapies that improve the keratotic component exacerbate the redness. Ammonium lactate 12% or urea-based moisturizers can produce some smoothing of the lesions but seldom result in improvement of the erythema. Topical calcipotriene is effective in some patients. Pulsed dye laser has been used for the erythema, especially if severe on the face.

ERYTHROMELANOSIS FOLLICULARIS FACIEI ET COLLI

This is characterized by follicular papules along with hyperpigmentation on the lateral cheeks extending to the neck seen mostly in males. The hyperpigmentation and extension to the neck help differentiate and it is most commonly described in patients with type III, IV, and V skin patients. A case has been described with reticulate pigmentation of the extremities.

FOLLICULAR ATROPHODERMA

Follicular atrophoderma consists of follicular indentations without hairs, notably occurring on extensor surfaces of the hands, legs, and arms. Scrotal (fissured) tongue may also be found. It has been described repeatedly in association with other genetically determined abnormalities, including X-linked dominant chondrodysplasia punctata, Bazex syndrome (follicular atrophoderma type), and keratosis palmoplantaris disseminata. Bazex (Bazex-Dupré-Christol) syndrome is characterized by congenital hypotrichosis, follicular atrophoderma, multiple milia, hypohidrosis, and basal cell carcinomas. Both trichorrhexis nodosa and pili bifurcati have been described in patients with the syndrome.

KERATOSIS PILARIS ATROPHICANS

Keratosis pilaris atrophicans presents with keratotic papules that result in atrophy and alopecia. It is seen in three syndromes: keratosis pilaris atrophicans faciei (ulerythema oophrogenes), atrophoderma vermiculata, and keratosis pilaris follicularis spinulosa decalvans. Keratosis pilaris atrophicans has been reported as being associated with woolly hair and Noonan syndrome. Overlap between the three entities may occur. Keratosis pilaris atrophicans faciei is characterized by persistent erythema and small, horny, follicular papules with onset during childhood on involution there are pitted, atrophic scars that lead to alopecia. The disorder involves the eyebrows, and in some the cheeks, forehead, and even the scalp. The term *ulerythema ophryogenes* is used to describe cases with involvement limited to the lateral third of the eyebrows. Lesions may also begin on the cheeks or temples, rather than the eyebrows. The follicles become reddened (Fig. 27.51), then develop papules, and finally follicular atrophy.

Fig. 27.51 Ulerythema ophryogenes.

Histologically, follicular hyperkeratosis of the upper third of the hair follicle is seen. A small, depressed scar forms when the lesion heals. It may occur with atopy or woolly hair and may be seen in Noonan syndrome and the CFC syndrome. Transmission is autosomal dominant. Response to therapy is often limited, but some success has been noted with keratolytics and retinoids. Pulsed dye laser therapy has led to improvement in erythema, but not skin roughness.

Ichthyosis Follicularis (Ichthyosis Follicularis, Alopecia, and Photophobia Syndrome)

Ichthyosis follicularis, alopecia, and photophobia (IFAP) is characterized by noncicatricial universal alopecia, severe photophobia, and generalized cutaneous follicular projections that are flesh colored and spiny. There is xerosis of nonspiny skin, and absence of sebaceous glands has been noted histologically. Hepatosplenomegaly, undescended testicles, nail dystrophy, inguinal hernia, short stature, seizures, psychomotor developmental delay, digital anomalies, and ptosis have been reported. Males outnumber females 5:1. The main considerations in the differential diagnosis are KID syndrome and keratosis follicularis spinulosa decalvans (KFSD). Ichthyosis follicularis results from mutations in the *MBTPS2* gene impairing cholesterol homeostasis. Patients can be treated with topical keratolytics and emollients. A partial response to acitretin therapy has been noted in some patients. Intensive lubrication of the ocular surface is essential. Cardiopulmonary complications remain the major cause of death.

Keratosis Follicularis Spinulosa Decalvans (Siemens-1 Syndrome)

In keratosis follicularis spinulosa decalvans (KFSD), keratosis pilaris begins on the face and progresses to involve the scalp, limbs, and

trunk. There is hyperkeratosis of the palms and soles. Cicatricial alopecia of the scalp and eyebrows is characteristic. Atopy, photophobia, and corneal abnormalities are frequently associated. Patients are often itchy and recently elevated substance P was found in a patient that may lead to a future therapeutic target. Deafness, physical and mental retardation, recurrent infections, nail abnormalities, acne keloidalis nuchae, tufted hair folliculitis, and aminoaciduria have also been purported associations. The disorder is genetically heterogeneous. The X-linked dominant form is caused by *MBTPS2* mutation that is allelic to IFAP, thus explaining the significant overlap. Autosomal dominant inheritance has also been described.

DISORDERS WITH ATROPHODERMA

Atrophodermia Vermiculata

Atrophodermia vermiculata is also known as atrophoderma vermiculata, atrophodermia ulerythematosa, folliculitis ulerythematosa reticulata, and honeycomb atrophy. It is characterized by symmetric involvement of the face by numerous small, closely crowded areas of atrophy separated by narrow ridges, producing a cribriform or honeycomb surface. This worm-eaten (vermiculate) appearance results from atrophy of the follicles and surrounding skin. Each atrophic area is an abrupt, pitlike depression 1–3 mm in diameter. Among the ridges, a few milia may be seen.

The skin covering the ridges is even with the normal skin but contrasts with it by being somewhat waxy, firmer, and apparently stretched. The cause of the disease is undetermined, but familial occurrence has been noted, and it may be associated with other diseases, such as congenital heart block, other cardiac anomalies, neurofibromatosis, oligophrenia, or Down syndrome.

Histologically, the epidermis is slightly atrophic, with diminution in size of the interpapillary projections. In the dermis, the capillaries are dilated, and the vessels have a moderate lymphocytic perivascular infiltration. Follicles may be enlarged, tortuous, dilated, and hyperkeratotic.

Rombo Syndrome

Rombo syndrome is a rare disorder characterized by atrophodermia vermiculata, cyanosis of the hands and feet, milia, telangiectases, hypotrichosis, multiple basal cell carcinomas, and trichoepitheliomas. The associated vermicular atrophoderma produces a coarse, grainy skin texture. Rombo syndrome is inherited in an autosomal dominant manner. It must be distinguished from Bazex syndrome, Rasmussen syndrome (milia, trichoepithelioma, cylindroma), and multiple trichoepitheliomas.

H SYNDROME

The "H syndrome" is an inherited syndrome characterized by hyperpigmentation, hypertrichosis, and indurated patches of skin involving the legs and most specifically inner thighs. Flexion contractures (hallux valgus) occur in over half. Genital masses, lymphadenopathy, and ichthyotic skin changes can also occur. Hearing loss, hypogonadism, hepatosplenomegaly, short height, and heart anomalies are some of the systemic findings. The patients exhibit growth hormone deficiency and hypergonadotropic hypogonadism with azoospermia. Biopsies of involved skin demonstrate acanthosis with dermal and subcutaneous infiltration by histiocytes, plasma cells, and mast cells.

Molho-Pessach V, et al: The H syndrome. J Am Acad Dermatol 2008l; 59: 79.

MELAS SYNDROME

MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis, strokelike episodes) is a rare neurodegenerative mitochondrial disorder inherited in the maternal line. Diffuse erythema with reticular pigmentation and vitiligo may occur. Caution is required during anesthesia for procedures, because severe acidosis, neurologic deterioration, and cardiorespiratory compromise may occur with a single dose of propofol.

28 Dermal and Subcutaneous Tumors

Bonus images for this chapter can be found online at expertconsult.inkling.com

In this chapter proliferations derived from vascular endothelial cells, fibroblasts, myofibroblasts, smooth muscle cells, Schwann cells, and lipocytes are reviewed. Also discussed are several neoplasms of cells invading or aberrantly present in the dermis, such as metastatic cancer, endometriosis, and meningioma.

CUTANEOUS VASCULAR ANOMALIES

Vascular anomalies are overgrowths of various types of blood or lymphatic vessels. They can either occur in isolation or as part of a syndrome caused by a localized or generalized genetic mutation.

The International Society for the Study of Vascular Anomalies (ISSVA) created a classification system that has become the standard way of categorizing vascular lesions (http://www.issva.org/UserFiles/file/Classifications-2014-Final.pdf). Vascular lesions can be divided into vascular tumors that are dynamic and can exhibit rapid growth and malformations that are more static but can still grow. Recently antiproliferative medical therapy such as sirolimus has been found to be effective for some vascular anomalies, indicating that many of the malformations are actually more dynamic than originally thought.

VASCULAR TUMORS

Benign Tumors

Infantile Hemangioma

Infantile hemangiomas (IHs) are the most common benign tumors of childhood, occurring in approximately 4%–5% of children. Importantly, IHs are either not detectable at birth or present with a patch of vasoconstriction called the "premonitory sign," or a slightly bruised or telangiectatic. Many other vascular tumors such as kaposiform hemangioendotheliomas, congenital hemangiomas, fibrosarcomas, and rhabdomyosarcomas can be fully formed tumors at birth, and this can help differentiate them from IH. As the vessels of the IH form, a rim of vasoconstriction can often be seen at the edge even if it was not present from the start.

Risk factors for IH include low birth weight, female gender, multiplets (twin, triplets), prematurity, and maternal age over 30, although low birth weight seems to be the strongest predictor and the other factors may be confounded by the low birth weight associated with them. IH happen in all ethnicities and in all cutaneous locations. The majority of IHs occur sporadically and there is no known genetic predisposition for hemangiomas.

The pathogenesis of IHs is complex and not fully elucidated. CD133+ stem cells within the hemangioma differentiate into mature blood vessels that express GLUT-1, a glucose transporter normally restricted to endothelial cells with blood-tissue barrier function, as in brain and placenta. The vessels proliferate, then involute. Some suggest the stem cells could originate from placental trophoblast. Histologically, IHs are composed of primitive endothelial cells that are similar to placenta. Ultrastructurally, they lack typical Weibel-Palade bodies but do have crystalloid inclusions typical of embryonic endothelium and stain for GLUT-1. They also stain for Fc-γ-RII, Lewis Y antigen (LeY), and merosin. Early hemangiomas show evidence of endothelial progenitor cells that stain with CD133 and CD34. In late stages, the endothelium flattens, and the lumina are more apparent because of increased blood flow. In time, fibrosis becomes pronounced as involution progresses.

IHs can present anywhere on the body and can be divided based on multiple features. Superficial IHs are easily seen on top of the skin and often have a bright red or maroon look when proliferating (Fig. 28.1). Deep hemangiomas are under the skin and often have a blue hue but are soft. Mixed hemangiomas have features of superficial and deep hemangiomas. Localized hemangiomas are round or oval and have well-defined margins. Segmental or patterned hemangiomas have less distinct borders and appear to grow in embryologic segments. Segmental hemangiomas can be associated with multiple syndromes as outlined later.

IHs go through a characteristic growth pattern with rapid growth occurring most commonly in the first 6 months, although they can grow up to 12 months. The most rapid growth of IH is between 5.5 and 7.5 weeks of life (no matter what the age of gestation) and 90% are finished significantly growing by 4 months, although larger lesions can continue to grow up to a year of life and very rarely longer. Therefore therapy, when needed, is ideally started early in life to prevent the rapid growth that can lead to tissue distortion. IHs then regress and although the majority of the regression happens by age 4 (Fig. 28.2), continued improvement can occur up to and past age 10.

Complications of hemangiomas are related mostly to their location and typically due to physical distortion of the tissue or ulceration. Lesions around the eye can lead to amblyopia or astigmatism and should be co-managed with an ophthalmologist. Nasal tip lesions can lead to permanent distortion of the nasal tissue, collapse of the columella, or obstruction of the nasal passages, impairing breathing and almost always require early therapy to prevent this. Hemangiomas (especially segmental) in the jawline or neck ("beard" distribution) can be associated with airway involvement with IH (Fig. 28.3). These patients present with inspiratory stridor in early infancy, often when there is severe airway occlusion or when there is a superimposed infection leading to airway inflammation. Airway IHs are often misdiagnosed as croup, especially because systemic steroids given for croup will shrink the hemangioma and thus ameliorate the symptoms. A lateral neck x-ray can show airway constriction, but direct visualization by an otorhinolaryngologist is necessary if an airway hemangioma is suspected. Perineal hemangiomas, lip hemangiomas, and those with a large or rapidly growing superficial component are at higher risk for ulceration (Fig. 28.4). Segmental hemangiomas can ulcerate even if there is very little cutaneous component.

The decision to treat a hemangioma is in part based on how completely a hemangioma will regress without therapy. A hemangioma with a very sharp angle at the skin (similar to a mushroom cap) will leave more redundant tissue than a hemangioma with a gentle slope. Central forehead, central cheek, nasal tip, and lip IHs are more likely to leave permanent distortion due to the need for these areas to have more taught skin, and treatment is often necessary to prevent this. The skin may appear normal after involution, but larger and more pedunculated lesions are more likely to leave atrophy, telangiectasia, or anetoderma-type redundancy. If a hemangioma ulcerates, there is invariably a scar.

There is a variant of IH that is present at birth as a flat patch of telangiectasia or vasoconstriction but proliferates very little or not at all. These IHs have been named infantile hemangiomas

Fig. 28.1 Infantile hemangioma. (Courtesy Steven Binnick, MD.)

Fig. 28.2 Involuting infantile hemangioma.

Fig. 28.3 Infantile hemangioma in beard distribution.

with minimal or arrested growth (IH-MAG) or "abortive" hemangiomas. IH-MAG are manifested by a congenital patch of telangiectatic blood vessels and often the premonitory sign around them. They are GLUT-1 positive and may have small areas of typical hemangioma that show up within the original telangiectatic patch, and they tend to regress in the same time frame as IH but can also ulcerate. IH-MAG are important to recognize and differentiate from capillary malformations because they also have associated risk of hemangioma syndromes such as PHACE and LUMBAR syndrome (see later in this chapter) depending on location. Therapy for IH-MAG is often not necessary, but the same therapies that work for regular IHs will work for IH-MAG.

Fig. 28.4 Infantile hemangioma with ulceration.

Simple observation may be appropriate for many hemangiomas, allowing the lesions to regress spontaneously. Parents should be informed of the appropriate time frame and the pros and cons should be explained. Indications for therapy include ulceration and threatened interference with vital functions (e.g., feeding, vision, respiration, passage of urine or stool). Specifically, there is a risk of occlusion amblyopia, astigmatism, and myopia from periorbital hemangiomas, as well as interference with limb function, tissue destruction, or cardiovascular compromise from high-output cardiac failure. Strong consideration should be given to treatment of hemangiomas that may lead to permanent disfigurement or long-term psychological consequences, such as large hemangiomas of the ear, nose, glabellar area, or lips.

For therapy, β-blockers are used most frequently, but systemic treatment can rarely be complicated by bradycardia or hypoglycemia, and regular feedings are critical before and during treatment. Propranolol is now approved by the U.S. Food and Drug Administration (FDA) for hemangiomas in children over 45 weeks of age (e.g., 40 weeks of normal gestation plus 5 weeks of infancy would equal 45 weeks). Atenolol and other more selective β-blockers have been used in patients who have concerns about propranolol in terms of its risk of bronchoconstriction and sleep disturbances. Propranolol crosses the blood-brain barrier, so some have argued that other β-blockers may have a lower risk of cognitive or behavioral impairment, although long-term studies do not seem to show any learning disabilities in children who have been given propranolol for hemangiomas. Side effects of propranolol include hypotension, bradycardia, and hypoglycemia. Symptoms of hypoglycemia may be masked by the propranolol because it blocks the tachycardia and sweating that often alerts someone to his or her hypoglycemia. It is extremely important that the child has been fed immediately before the propranolol administration to avoid hypoglycemia. If children are vomiting or having diarrhea or not feeding well, the medicine should be held. Protocols for starting propranolol typically involve checking a baseline heart rate and blood pressure and then starting oral propranolol at 1 mg/kg/day divided twice daily at least 10 hours apart (0.5 mg/kg/dose). If the vital signs are normal 1 and 2 hours after starting this dose, it is continued for a week and then the patient is uptitrated

to 2 mg/kg/day divided twice daily. In the same manner and if clinically indicated this can be repeated a week later up to 3 mg/kg/day divided twice daily. Regrowth of treated hemangiomas is frequently seen and seems to be more prominent the sooner the propranolol is stopped. Most authors will treat children until around 12–15 months of age and if there is rebound, the medication can be restarted. There are rarely children who need to stay on propranolol for multiple years and even more rarely children whose hemangiomas regrow somewhat a year or more after stopping the medicine.

Some hemangiomas respond to topical β-blockers. Topical timolol, although off label, is extremely effective for superficial hemangiomas and can help heal ulcerations. The timolol gel-forming solution 0.5% is typically used, but caution is advised in premature infants and ulcerations. Timolol is approximately 10 times more potent per drop than propranolol and some advocate that similar precautions should be taken as for propranolol. Timolol is absorbed especially through the scalp and likely through mucous membranes or ulcerations. One drop is applied to the hemangioma 2 or 3 times per day.

Oral prednisolone at a dose of 2–4 mg/kg/day has also been used for IH but has mostly been replaced by propranolol. In the patients who respond well to treatment, the enlarging hemangioma stops growing in 3–21 days. The prednisolone is continued for 30–90 days. Systemic steroids are still used if propranolol is contraindicated or in conjunction with propranolol in hemangiomas that need to be treated emergently. The use of both medications concomitantly is extremely effective but when tapering the prednisolone, hypoglycemia has been reported. Intralesional corticosteroid treatment has been used but carries some risk of embolization and occlusion of ocular vessels. Injection regularly produces pressures exceeding the systemic arterial pressure, leading to possible embolization. Selective arterial embolization may be necessary for extremely large lesions such as in life-threatening situations.

Treatment with recombinant interferon is not used because of the risk of spastic diplegia. Topical imiquimod, low-frequency ultrasound, and ultrapotent topical steroids have been used historically before the realization of the efficacy of β-blockers. Both neodymium-doped yttrium-aluminum-garnet (Nd:YAG) and potassium titanyl phosphate (KTP) lasers have been used to deliver intralesional therapy.

There are two hemangioma syndromes that are also associated with large segmental hemangiomas of specific locations. Segmental hemangiomas on the head, neck, and proximal upper shoulder/neck areas, especially if over 5 cm in length, can be associated with PHACE syndrome. Larger hemangiomas seem to have higher risk. PHACE denotes the association of posterior fossa brain malformations (primarily the Dandy-Walker malformation), large segmental hemangiomas, arterial anomalies, coarctation of the aorta and other cardiac defects, and eye abnormalities. Most patients do not exhibit all of the features of PHACE. Midline defects of the chest and abdomen such as sternal clefting or complete sternal absence, as well as supraumbilical raphe, can be seen, so an S is sometimes added to the acronym: PHACE(S). The face can be divided into four embryologic segments: S1 is the forehead lateral to the medial canthus including the upper eyelid, S2 is the midcheek, S3 is the jawline, and S4 is a stripe down the central face from forehead to chin. A fifth segment has been recently proposed that involves the ocular orbit because an isolated hemangioma of the orbit can be associated with PHACE. PHACE workup involves evaluating for all of the possible anomalies, therefore the following should be done:

1. An echocardiogram with special attention to the ascending aorta. Cardiac defects described include coarctation, aortic arch abnormalities, aberrant subclavian artery origin, vascular ring (less common), and interrupted or double aortic arch.
2. Magnetic resonance imaging (MRI) of the brain for evaluation of the posterior fossa and including fine cuts of the orbits if there is concern for an orbital hemangioma: posterior fossa abnormalities (Dandy-Walker), hypoplasia of medulla or pons, absent pituitary, or intracranial hemangioma.
3. Evaluation of the cervical and intracerebral blood vessels with MRI/magnetic resonance angiogram (MRA) of the head and neck: abnormal carotid, subclavian, or brachiocephalic arteries.
4. Ophthalmologic evaluation: "morning glory" disc, abnormal or persistent fetal vasculature.

Further imaging of the chest may be needed if the hemangioma extends down, as well as consultation with appropriate subspecialties depending on the findings of the imaging. Evaluate for any associated endocrinologic abnormalities, including hypopituitarism, hypogonadism, hypothyroidism, or growth hormone deficiency. Headaches have been reported at higher levels. Patients should also be followed for normal neurodevelopment.

Propranolol use is debated in PHACE. Some patients with PHACE have had stroke after starting propranolol. Ideally imaging is done before start to rule out significant enough vascular changes that there may be a higher risk of stroke. However, most agree that if the hemangioma is high risk (vision threatening, airway, ulcerating), lower-dose propranolol can be started while starting the process of imaging.

LUMBAR syndrome (also called SACRAL and PELVIS) is the constellation of a large segmental perineal hemangioma with associated spinal dysraphism, renal anomalies, bony anomalies, and gastrointestinal (GI) anomalies. The acronym LUMBAR syndrome has been used to describe the association of lower body hemangioma, urogenital anomalies, myelopathy, bony deformities, anorectal malformations, arterial anomalies, and renal anomalies. In patients with a segmental hemangioma in the perineum, imaging with ultrasound or MRI should be considered to rule out abnormalities of the urogenital or renal systems. Segmental hemangiomas, especially if larger than 5 cm involving the area above the intergluteal cleft (often seen as a part of LUMBAR), are an extremely high-risk marker of spinal cord tethering. Ultrasound may not be sensitive to diagnose some abnormalities, and MRI is recommended in those patients so that any necessary repair can happen before permanent damage.

Children with five or more hemangiomas may have hemangiomas involving internal organs, most commonly the liver. Liver ultrasound is recommended in these patients. The individual lesions are smaller in size ranging from 1–10 mm and there can rarely be hundreds of lesions. Visceral lesions may be present in the central nervous system (CNS), lungs, liver, or other organs, leading to obstructive jaundice, internal bleeding, or respiratory failure. Having a few small lesions in the liver may not have any sequelae and can often be monitored to ensure resolution. More extensive involvement of the liver can lead to shunting of cardiac output leading to high-output failure. Therapy can be rapidly beneficial to improve cardiac function. Hemangiomas secrete type III deiodinase, which is an enzyme that converts active T3 and T4 to reverse T3. If there is a large enough volume of hemangiomas, an infant can become floridly hypothyroid requiring intravenous repletion. Single large hemangiomas in the liver are typically congenital hemangiomas (see later section).

Rapidly Involuting Congenital Hemangioma and Noninvoluting Congenital Hemangioma

Rapidly involuting congenital hemangioma (RICH) and noninvoluting congenital hemangioma (NICH) are rare GLUT-1–negative vascular tumors that present fully grown at birth and either involute rapidly or fail to involute. Activating mutations in *GNA11* and *GNAQ* have been demonstrated in these congenital lesions. Because many lesions only partially involute, some are deemed partially involuting congenital hemangioma (PICH). Children with RICH or NICH and IH have been described, but because IH is so common this is likely coincidence. Clinically most NICH lesions are flatter plaques and most RICH lesions are more raised and nodular. Systemic steroids and propranolol have been tried without success. If therapy is necessary for an ulcerated or bleeding lesion surgery or embolization has been used successfully.

A new type of congenital hemangioma with fetal involution has been proposed. This may be a RICH that involutes partially or entirely before birth. These lesions leave behind atrophy once resolved.

Pyogenic Granuloma

A pyogenic granuloma is a small, eruptive, usually solitary, sessile or pedunculated, friable papule (Fig. 28.5). The lesion is common in children but may occur at any age, especially during pregnancy or with medication use as described later. Pyogenic granuloma occurs most often on an exposed surface: on the hands, forearms, or face, or at sites of trauma. The lesions can also occur in the mouth, especially on the gingiva, most often in pregnant women (granuloma gravidarum). On the sole of the foot or nail bed, it may be mistaken for a melanoma. Pyogenic granulomas bleed easily on the slightest trauma and, if cut off superficially, promptly recur. Recurring lesions may have one or many satellite lesions.

Pyogenic granulomas may be seen in patients treated with isotretinoin, capecitabine, vemurafenib, or indinavir. Isotretinoin treatment of acne vulgaris can be complicated by numerous exuberant pyogenic granuloma–like lesions of the trunk or periungual lesions. Some data suggest that patients with pyogenic granuloma have a statistically higher prevalence of *Bartonella* seropositivity compared with controls, but a definite etiologic role has not been established.

Fig. 28.5 Pyogenic granuloma. (Courtesy Steven Binnick, MD.)

Histologically, pyogenic granuloma is a lobular capillary hemangioma, with lobules separated by connective tissue septa. With time, the epidermis becomes thinned, then eroded. Heavy secondary staphylococcal colonization is common. Intravascular pyogenic granuloma appears as a lobular capillary proliferation within a vein.

Treatment is by curettage or shave excision, followed by destruction of the base by fulguration or aluminum chloride. Silver nitrate alone may be sufficient to treat smaller lesions but may leave a silver tattoo, and it does not allow histopathologic evaluation to rule out a bleeding amelanotic lesion such as a melanoma. Topical timolol, imiquimod under occlusion, and sclerotherapy with monoethanolamine oleate or sodium tetradecyl sulfate have been used successfully. At times, a recalcitrant lesion may require excision or laser ablation. The drug-induced variety will regress after lowering of the dose or discontinuation of the medication. Systemic corticosteroids have been used to treat recurrent giant pyogenic granulomas.

Locally Aggressive or Borderline Vascular Tumors

These tumors can proliferate more aggressively and show borderline malignant potential.

Hemangioendotheliomas

Hemangioendotheliomas (HEs) are a group of tumors that span the spectrum from benign to low-grade malignancy.

Kaposiform Hemangioendothelioma

Kaposiform hemangioendothelioma (KHE) is an uncommon vascular tumor that affects infants and young children. Rare cases have been reported in adults. It was first designated KHE in 1993. Although it frequently occurs in the retroperitoneum, KHE may

Fig. 28.6 Kaposiform hemangioendothelioma.

present as multinodular soft tissue masses, purpuric macules, plaques, and multiple telangiectatic papules (Fig. 28.6). The lesions extend locally and usually involve the skin, soft tissues, and even bone. The cutaneous variant may be associated with lymphangiomatosis. KHE is locally aggressive and may be complicated by platelet trapping and consumptive coagulopathy (Kasabach-Merritt syndrome), but distant metastases have not yet been reported. It has also been reported in association with Milroy-Nonne disease (primary hereditary lymphedema).

Histologically, there are combined features of cellular IH and Kaposi sarcoma. Additionally, in some tumors, lymphangiomatosis is seen sharply separated from the vascular lesion. There is a multilobular appearance that closely resembles that of tufted angioma, but in KHE, lesions are larger and less circumscribed and involve the deep soft tissue and even bone. Transition between these tumors has been described.

The prognosis depends on the depth and location of the lesion. Significant morbidity and mortality may result from compression and invasion of surrounding structures. If localized to the skin, lesions may be successfully excised. However, because of their tendency for deep and infiltrative growth, this is usually not possible. Combination of systemic corticosteroids and vincristine is often used but is being replaced by rapamycin (sirolimus).

Kasabach-Merritt Syndrome

In Kasabach-Merritt syndrome (KMS) there is platelet trapping within the vascular tumor and this leads to activation of the clotting cascade and disseminated intravascular coagulation (DIC). Low-grade KMS can be happening subtly but can worsen rapidly with acute, extreme swelling and purple discoloration to the lesion and this can be life threatening. The fibrinogen and platelet counts are low, the activated partial thromboplastin time and prothrombin time will be prolonged, and the D-dimer is elevated, indicating DIC. Before the onset of the acute event, the infant will often have a reddish or bluish plaque or tumor on the limb or trunk or, in rare instances, no visible lesion at all. The lesions usually have an associated lymphatic component, and most are KHEs. KMS also occurs in tufted angiomas and multifocal lymphangioendotheliomatosis, lesions that both demonstrate lymphatic differentiation.

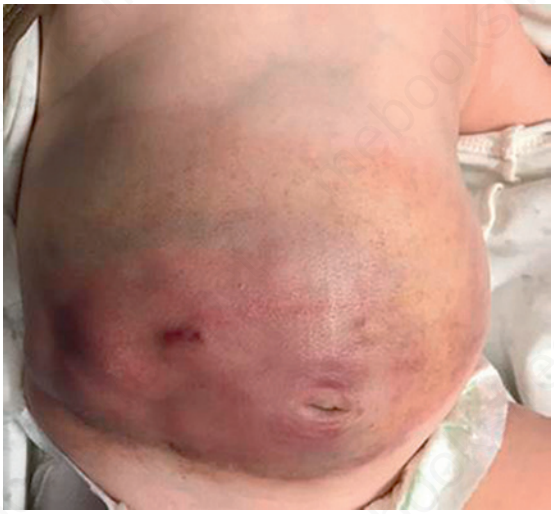

Fig. 28.7 Kasabach-Merritt syndrome.

Venolymphatic and lymphatic malformations can also cause platelet trapping with resultant DIC. KMS is rarely reported with angiosarcoma. Some patients with VMs will have a chronic low-grade consumptive coagulopathy that occurs throughout life, and RICH lesions can trap platelets but not induce KMS; these should not be confused with KMS. The original reports of KMS occurring in IHs are incorrect.

Infants with KMS suddenly develop a painful violaceous mass in association with purpura and thrombocytopenia (Fig. 28.7). The most striking sign is the bleeding tendency, especially in the hemangioma itself or into the chest or abdominal cavities. The spleen may be enlarged. Hemoglobin, platelets, fibrinogen, and factors II, V, and VIII are all reduced. Prothrombin time and partial thromboplastin time are prolonged, and fibrin split products may be elevated. Cases of microangiopathic hemolytic anemia have also been described. Repeated episodes of bleeding may occur, and although these may be spontaneous, bleeding can be precipitated by surgery, directed either at the hemangioma or elsewhere. The mortality rate may be as high as 30%, with most deaths secondary to bleeding complications.

KMS may be a self-limited disorder but often requires therapy. Systemic corticosteroids seem to work quickly, but often maintenance therapy is needed to prevent recurrence. Sirolimus has also become a favored therapy due to its efficacy and rapid benefit. Low-dose aspirin (5–10 mg/kg/day) can be used to decrease the platelet trapping and seems to help prevent KMS in some patients. This is a reasonable maintenance plan, but in children, care must be taken to avoid concomitant vaccination with live vaccines (especially influenza and varicella) and stopping aspirin if either primary infection is suspected to avoid Reye syndrome. Some have argued that the dose of aspirin is lower than the threshold to cause Reye syndrome. Adding ticlopidine may provide more benefit.

Historically, interferon (IFN) alfa-2a, vincristine, vinblastine, cyclophosphamide, actinomycin D, embolization, ε-aminocaproic acid, antiplatelet agents, irradiation, excision, and compression therapy have been used, alone or in combination.

Fig. 28.8 Spindle cell hemangioendotheliomas (spindle cell hemangiomas). (Courtesy Dr. Timothy Gardner.)

Spindle Cell Hemangioma (Spindle Cell Hemangioendothelioma)

Spindle cell hemangioma is a vascular tumor that typically presents in a child or young adult with blue nodules of firm consistency on a distal extremity (Fig. 28.8). Usually, multifocal lesions occur within an anatomic region. Histologically, a well-circumscribed dermal nodule will contain dilated vascular spaces with fascicles of spindle cells between them. Areas of the tumor will have an open alveolar pattern resembling hemorrhagic lung tissue. Phleboliths are common. A thrombosed, large, adjacent vessel with recanalization may be identified. The lesions appear to represent benign vascular proliferations in response to trauma to a larger vessel. They may recur after excision.

Epithelioid Hemangioendothelioma

Epithelioid hemangioendothelioma usually presents as a solitary, slow-growing papule or nodule on a distal area of an extremity and behaves as a low-grade malignancy (Fig. 28.9). There is a male preponderance, and onset is frequently before the individual is 25 years of age. Histologically, there are two components: dilated vascular channels and solid epithelioid and spindle-cell elements with intracytoplasmic lumina. It is caused by a fusion of *WWTR1-CAMTA1;* therefore *CAMTA1* nuclear expression can differentiate it from other tumors. Wide excision is recommended with evaluation of regional lymph nodes, which are the usual site of metastases.

Fig. 28.9 Large, ulcerated epithelioid hemangioendothelioma.

In the minority of cases in which distant metastatic lesions develop, chemotherapy, radiation, or both may be employed.

Retiform Hemangioendothelioma

Retiform hemangioendothelioma is another form of low-grade malignancy that presents as a slow-growing exophytic mass, dermal plaque, or subcutaneous nodule on the upper or lower extremities of young adults. Histologically, there are arborizing blood vessels reminiscent of normal rete testis architecture. Human herpesvirus 8 (HHV-8) deoxyribonucleic acid (DNA) sequences have been reported in this tumor. Wide excision is recommended, although local recurrences are common. To date, no widespread metastases have occurred, although regional lymph nodes may develop tumor infiltrates.

Epithelioid Sarcoma–Like (Pseudomyogenic) Hemangioendothelioma

The epithelioid sarcoma–like variant demonstrates sheets of spindle, epithelioid, and rhabdomyoblastic cells. They can occur on the palms or soles and mimic a recalcitrant wart. This variant also behaves as a low-grade malignancy.

Endovascular Papillary Angioendothelioma (Dabska Tumor)

Endovascular papillary angioendothelioma, a rare low-grade angiosarcoma, presents as a slow-growing tumor on the head, neck, or extremity of infants or young children. It shows multiple vascular channels with papillary plugs of endothelial cells surrounding central, hyalinized cores that project into the lumina, sometimes forming a glomeruloid pattern. The entity is controversial; similar histologic features have been observed in other vascular tumors, such as angiosarcoma, retiform hemangioendothelioma, and glomeruloid hemangioma. The tumor may be a distinct entity or may demonstrate a histologic pattern seen in other vascular tumors. Wide excision and excision of the regional lymph nodes, when involved, are usually curative.

Tufted Angioma (Angioblastoma)

The tufted angioma lesion usually develops in infancy or early childhood on the neck and upper trunk. Adult onset has also been described. The lesions present as poorly defined, dull-red plaques with a mottled appearance, varying from 2–5 cm in diameter. Some show clusters of smaller angiomatous papules superimposed on the main macular area (Fig. 28.10), and associated hypertrichosis has been noted. The lesions are usually sporadic, although familial cases have been reported. Histologic examination reveals small, circumscribed angiomatous tufts and lobules scattered in the dermis in a so-called cannonball pattern. Tumors with features of both tufted angioma and KHE have been described, and transformation between the tumors has also been noted. Immunostaining can be helpful in distinguishing these tumors. Tufted angioma is characterized by a proliferation of CD34+ endothelial cells with few actin-positive cells. KHE shows CD34 staining only in the luminal endothelial cells. In IH, GLUT-1 is positive.

Most lesions slowly extend with time, being progressive but benign in nature. Occasional spontaneous regression is documented. Therapy is dependent on the activity of the lesion. For small flat lesions aspirin may be enough but should be used with caution at low doses and stopped around the time of live vaccines such as varicella in young children to avoid Reye syndrome. For larger, growing lesions, especially with Kasabach-Merritt phenomenon, systemic steroids are rapidly effective. Vincristine is classically used, but sirolimus has proven to be very effective. Aspirin may then be used to maintain benefit more long-term. Treatment with pulsed dye laser, intense pulsed light, excision, and radiation has been successful. Lesions associated with KMS have also been treated with embolization, prednisone, and vincristine.

The term *angioblastoma* has also been used for a rare pediatric tumor often associated with destruction of regional structures, including bone. Basic fibroblast growth factor has been reported to be elevated, and some patients have responded to treatment with IFN alfa-2b.

Hemangiopericytoma

True hemangiopericytomas are rare. The term is now reserved for lesions that demonstrate differentiation toward pericytes and cannot be otherwise classified. Most lesions formerly classified as hemangiopericytomas are now classified as examples of solitary fibrous tumor or giant cell angiofibroma. Remaining lesions can often be classified as glomangiopericytoma/myopericytoma or infantile myofibromatosis.

Clinically, hemangiopericytomas are nontender, bluish red tumors that occur on the skin or in the subcutaneous tissues on any part of the body. The firm, usually solitary nodule may be up to 10 cm in diameter. Histologically, the tumor is composed of endothelium-lined vessels that are filled with blood and surrounded by cells with oval or spindle-shaped nuclei (pericytes). The pericytes often form a concentric perivascular pattern. Staghorn-like ectatic spaces are often encountered. Wide local excision is the treatment of choice, but radiation therapy may produce excellent palliation.

Lesions Formerly Classified as Hemangiopericytomas

Various soft tissue tumors can present with a hemangiopericytoma-like staghorn vascular pattern, the most common being solitary fibrous tumor. Solitary fibrous tumor is usually CD34+ and has a wide distribution in the skin, mucosa, and viscera. When excision cannot be accomplished, targeted therapy, including imatinib, may be helpful. Myofibromas demonstrate nodular, pale-blue, hypocellular zones with surrounding hypercellular zones that contain staghorn vessels. Some examples lack the hypocellular zones and present only with a hemangiopericytoma-like pattern. Myopericytoma is a rare mesenchymal neoplasm that typically involves the extremities. The tumor demonstrates concentric perivascular spindle cells with myoid differentiation. Glomangiopericytoma is a closely related tumor composed of perivascular spindle cells with myoid differentiation; it combines features of glomus tumors and a hemangiopericytoma-like vascular pattern.

Other Vascular Tumors

Cherry Angiomas (Senile Angiomas, de Morgan Spots)

These round, slightly elevated, ruby-red papules 0.5–6 mm in diameter are the most common vascular anomalies. It is a rare

30-year-old person who does not have a few, and the number increases with age. Probably every 70-year-old person has some senile angiomas. Most are on the trunk; they are rarely seen on the hands, feet, or face. Early lesions may mimic petechiae. When lesions are surrounded by a purpuric halo, amyloidosis should be suspected. Eruptive lesions have been described after nitrogen mustard therapy. Light electrodesiccation or laser ablation with intense pulsed light and long-pulse Nd:YAG laser systems can be effective. Shave excision can also be performed, but most patients accept reassurance and do not request removal.

Fodor L, et al: A side-by-side prospective study of intense pulsed light and Nd:YAG laser treatment for vascular lesions. Ann Plast Surg 2006; 56: 164.
Ma HJ, et al: Eruptive cherry angiomas associated with vitiligo. J Dermatol 2006; 33: 877.

Targetoid Hemosiderotic Hemangioma

In 1988 Santa Cruz and Aronberg described a lesion characterized by a central brown or violaceous papule surrounded by an ecchymotic halo (Fig. 28.11). The term *hobnail hemangioma* has been proposed because many lesions are not targetoid. These acquired hemangiomas occur in young to middle-aged individuals and are present on the trunk or extremities. Because of their dark purple/black color they clinically simulate melanoma. The color likely represents trauma to a preexisting vascular lesion, with thrombosis and subsequent recanalization. Histologically, a biphasic growth pattern is seen, with central, superficial, dilated vascular structures lined by prominent hobnail endothelial cells, and collagen-dissecting, narrow vessels in deeper parts of the lesion. The endothelial cells commonly stain for CD31, but not CD34. D2-40 staining suggests lymphangiomatous proliferation.

Gutte RM, Joshi A: Targetoid hemosiderotic hemangioma. Indian Dermatol Online J 2014; 5: 559.

Glomeruloid Hemangioma

Glomeruloid hemangioma is a distinctive benign vascular neoplasm first described in 1990 and reported in patients with POEMS (Crow-Fukase) syndrome and Castleman disease. Some have also been associated with idiopathic thrombocytopenic purpura and Sjögren syndrome. Similar lesions have been reported in patients who are otherwise healthy.

The POEMS syndrome consists of polyneuropathy (severe sensorimotor), organomegaly (heart, spleen, kidneys), endocrinopathy, M component (M protein, monoclonal gammopathy), and skin changes (hyperpigmentation, hypertrichosis, thickening, sweating, clubbed nails, leukonychia, angiomas). Small, firm, red to violaceous papules appear on the trunk and proximal extremities in approximately one third of patients. Histologically, the lesions may be microvenular hemangiomas, cherry angiomas, multinucleated cell angiohistiocytomas, or glomeruloid hemangiomas. The latter consist of ectatic vascular structures containing aggregates of capillary loops within a dilated lumen, simulating the appearance of a renal glomerulus. Sequestered degenerating red blood cells are a characteristic finding. Two types of endothelial cell have been noted within the lesions: a capillary-type endothelium with large vesicular nuclei, open chromatin pattern, and a large amount of cytoplasm; and sinusoidal endothelium with small basal nuclei, dense chromatin, and scant cytoplasm. Lesions associated with POEMS syndrome demonstrate increased expression of vascular endothelial growth factor (VEGF) and its receptor, Flt-1.

Fig. 28.11 Targetoid hemosiderotic hemangioma.

Jacobson-Dunlop E, et al: Glomeruloid hemangiomas in the absence of POEMS syndrome. J Cutan Pathol 2012; 39: 402.

Eccrine Angiomatous Hamartoma

Eccrine angiomatous hamartoma usually appears as a solitary nodular lesion on the acral areas of the extremities, particularly the palms and soles, but identical lesions also occur on areas of the body that normally have few eccrine glands. This lesion appears at birth or in early childhood and is often associated with pain and hyperhidrosis. The lesion is a dome-shaped, tender, bluish nodule. Hypertrichosis may be present. When it is stroked or pinched, drops or beaded rings of perspiration may be seen.

Histologically, there is a combination of lobules of mature eccrine glands and ducts with thin-walled blood vessels. Excessive mucin, fat, smooth muscle, nerve infiltration, and terminal hairs may be present. The lesion has been associated with spindle cell hemangioma, arteriovenous malformation (AVM), and verrucous hemangioma. Excision may be necessary because of pain.

Shin J, et al: Eccrine angiomatous hamartoma. Ann Dermatol 2013; 25: 208.

Vascular Malformations

Malformations are abnormal structures that result from an aberration in embryonic development or trauma. The abnormality may be caused by an anatomic malformation or a functional alteration (as in nevus anemicus). Anatomic malformations are subdivided according to the type of vessel involved: capillary, venous, arterial, lymphatic, or combined. The term *capillary malformation* is best used as a term encompassing a variety of entities, including salmon patch, certain telangiectasias, port wine stains (PWSs), and cutis marmorata telangiectatica congenita. The characteristics of capillary malformations help differentiate various syndromes.

Happle R: What is a capillary malformation? J Am Acad Dermatol 2008; 59: 1077.
Lee MS, et al: Diffuse capillary malformation with overgrowth. J Am Acad Dermatol 2013; 69: 589.

Capillary Malformations

There are multiple different forms of capillary malformations (CMs), and each type can be seen in isolation or in association with a syndrome. CMs notably develop eczematous changes more

easily over the top and will become darker red or purple with Valsalva maneuver or temperature changes. Differentiating the type of CM can help with diagnosis of the specific syndrome. Each of the different types of CM will be described and then the vascular syndromes that can present with CM will be discussed. Histologically, PWSs are made of dilated capillaries in the subpapillary network. Laser therapy has been used with satisfactory results, but a number of treatments are required, and recurrence years later usually requires some retreatment. The flashlamp pulsed dye 585- or 595-nm laser has the best record of safety and efficacy. Pulse durations are adjusted based on the size of the blood vessel and response to therapy. For darker-skinned patients, multiple pulse stacking with multiple cryogen spurts provides better epidermal protection. Long-pulse pulsed alexandrite lasers work best for hypertrophic, purple lesions, whereas pulsed dye lasers work best for flat, pink lesions. A frequency-doubled (532-nm) Nd:YAG laser that allows for shorter pulse widths, large spot sizes, and high fluences resulted in up to 75% improvement in color at 1 month after a single treatment. Topical sirolimus added to standard pulsed dye laser may augment therapy. The CMs associated with capillary malformation–arteriovenous malformation (CM-AVM) may have arterial flow and therefore laser may exacerbate them.

Nevus Simplex

Nevus simplex is a type of CM that is light pink, is easily blanchable, often has a splattered appearance, is located in characteristic locations along the neural axis, and tends to fade over time. There have been many names used historically, including nevus flammeus and PWSs, but the nomenclature has been clarified by Frieden et al. recently. Nevus simplex malformations are common birthmarks in children, occurring in approximately 80% of children. They may persist in at least 5% of the population. Colloquial terms are used for certain types: "stork bite" is a pink-red macule situated on the posterior midline between the occipital protuberance and the tip of the spine of the fifth cervical vertebra (Fig. 28.12); "angel's kiss" is located on the glabella. Other typical locations are upper eyelid (15% of babies), along the nasal philtrum and ala, the temples, vertex scalp, upper back, and along the lumbar spine. Lesions in the lumbar area in isolation are typically not associated with spinal dysraphism but in association with other features can be a marker and necessitate imaging. Frieden proposed the term *nevus simplex complex* when children have very widespread lesions. Nevus simplex malformations tend to fade over time and are only rarely associated with syndromes (reviewed later in chapter): Beckwith-Wiedemann, Roberts SC, Nova, odontodysplasia, or megalencephaly CM syndrome.

Fig. 28.12 Nevus simplex. (Courtesy Steven Binnick, MD.)

Port Wine Stains

Port wine stains (PWSs) occur in an estimated 3 per 1000 children. The stains are present at birth and vary in color from pink to dark or bluish red. The lesions are usually unilateral, and although the face and neck are common locations (Fig. 28.13), they can be located anywhere on the skin and may be widespread and involve as much as half the body. With facial lesions, the mucous membrane of the mouth may be involved. Although the surface of a PWS is usually smooth, small vascular nodular outgrowths or warty excrescences may develop over decades thus justifying early preventive intervention. These lesions often become more bluish or purple with age.

Rarely, PWS may appear as an acquired condition, usually with onset after trauma. The early inflammatory stage of morphea can also start with a purple patch that is mistaken for a PWS.

Reticulated Port Wine Stains

Reticulated PWSs are faint red-pink patches that have indistinct borders but often accentuate dramatically with Valsalva maneuver or temperature changes. They tend to be widespread and can be mistaken for cutis marmorata telangiectatica congenita (CMTC) (both lesions can occur in the same patient). Therefore some of the previous association between CMTC and systemic findings are likely mislabeled. Reticulated PWSs have been associated with various syndromes, including diffuse CM with overgrowth and some patients with PiK3Ca-related overgrowth syndromes (PROS), especially those with the megalencephaly capillary malformation (MCAP) phenotype.

Fig. 28.13 Port wine stain. (Courtesy Dr. Debarbrata Bandyopadhyay.)

Geometric Port Wine Stain

PWS can sometimes be dark purple and geometric with a sharp distinct cutoff. This CM phenotype is more associated with underlying venous or venolymphatic malformations such as can be seen in the following syndromes: Proteus syndrome; Klipell-Trenaunay syndrome; congenital lipomatous overgrowth with vascular anomalies, epidermal nevi, and skeletal, scoliosis, and spinal abnormalities (CLOVES) syndrome; and CLAPO syndrome. The geometric CM can have vascular and keratotic vascular papules within it.

Cutis Marmorata Telangiectatica Congenita

Cutis marmorata telangiectatica congenita (CMTC) has been recategorized as a type of capillary malformation. CMTC is characterized by the presence of a red-purple, livedo-appearing, reticulated, vascular network with a segmental distribution, usually involving the extremities (Fig. 28.14). The mottling is pronounced and is made more distinct by crying, vigorous activity, and cold. There is often associated atrophy giving a "pseudoathletic" look that outlines the muscles. CMTC can be difficult to differentiate from a reticulated PWS, but typically CMTC has more uniformity and is more netlike. Lesions tend toward improvement with time but may not fully resolve. If located around the eye, some have advocated for ophthalmologic evaluation. The condition occurs sporadically, and there is a female preponderance. CMTC can be associated with phakomatosis pigmentovascularis and the Adams-Oliver syndrome (limb abnormalities, scalp defects, skull ossification defects).

SYNDROMES ASSOCIATED WITH CAPILLARY MALFORMATIONS

Sturge-Weber Syndrome

PWS on the upper face may be a marker for Sturge-Weber syndrome (SWS; encephalotrigeminal angiomatosis) (Fig. 28.15). There is debate as to what pattern these PWSs are following and what locations portend the highest risk. Originally PWSs were described as following nerve distributions (V1, V2, etc.), but more recently it has been proposed that they actually follow similar embryologic segments to hemangiomas (S1, S2, etc.). With either delineation, it seems that the involvement of the forehead and the more of the face involved (as long as the PWS includes some part of the V1/S1 distribution) is the highest risk. Therefore a PWS that covers the forehead, upper cheek, and lower cheek has a higher risk than a PWS that covers only the forehead. The leptomeningeal component of SWS is present in only 10% of patients with all or most of one V1 branch of the trigeminal nerve involved. If bilateral V1 or V1/V2/V3 are involved the rate of SWS is significantly higher. Leptomeningeal angiomatosis may clinically manifest as epilepsy, mental retardation, hemiplegia, hemisensory defects, and homonymous hemianopsia. Characteristic calcifications are present in the outer layers of the cerebral cortex; these consist of double-contoured "tram tracks" that follow the brain convolutions. The most important initial evaluation of an infant with a PWS that involves the eyelid is by an ophthalmologist to rule out congenital glaucoma because this can be vision threatening. Ocular abnormalities, such as glaucoma, buphthalmos (infantile glaucoma, related to abnormal development of angle formed by cornea and iris), retinal detachment, and blindness can occur in SWS. These may be present without leptomeningeal involvement.

SWS results from the persistence of the primitive embryonal vascular plexus that develops during the sixth fetal week around the cephalic neural tube and in the region destined to become facial skin. Normally, the plexus regresses during the ninth week, but in SWS it persists. Mutations in *GNAQ* and *GNA11* have been implicated, although it is unclear if the mutation alone is sufficient to cause SWS.

Fig. 28.15 Capillary malformation (port wine stain) with Sturge-Weber syndrome.

Because the risk of SWS is fairly low even with a PWS on the forehead, historically not all infants underwent imaging because the management did not necessarily change. It has now been demonstrated that early institution of aspirin may help prevent seizures, cognitive delays, and hemiparesis. Therefore early imaging to rule out SWS is warranted in patients who have a significant risk to be able to know whom to offer aspirin. Although calcifications are the most notable CNS finding and can be seen on computed tomography (CT) scan, they can develop later, so an MRI is the most sensitive test in infancy.

PiK3CA-Related Overgrowth Syndromes (PROS)

Mutations in *PIK3CA* cause multiple different syndromes with varied findings of CM with overgrowth. Depending on which mutation occurs and how much tissue is involved (due to mosaicism) patients can have various phenotypes: MCAP or CLOVES syndrome. Collectively, because there is some overlap, these (along with fibroadipose hyperplasia and hemimegalencephaly) are collectively known as *PIK3CA*-related overgrowth syndromes (PROS). Klippel-Trenaunay syndrome and KTS–Parkes-Weber syndrome are also caused by postzygotic mutations in *PiK3CA*. *PIK3CA* mutations have also recently been found in patients with CLAPO syndrome characterized by a CM of the lower lip and asymmetric overgrowth and head/neck lymphatic malformation.

Megalencephaly Capillary Malformation

MCAP was originally called M-CMTC and therefore CMTC was historically incorrectly associated with multiple congenital anomalies. The cutaneous lesions in MCAP are actually reticulated PWS (as described earlier) and not CMTC. Other features are an upper lip/nasal philtrum PWS, megalencephaly, a sandal toe deformity with 2-3 syndactyly of the toes, polymicrogyrisa, and skin elasticity. Patients should be followed for signs of hydrocephalus, and brain MRI is recommended. Renal ultrasound every 3 months until age 8 to rule out Wilms tumor has also been recommended.

CLOVES

The lipomatous overgrowth in CLOVES is typically very prominent at birth. Affected patients also often have large venous or venolymphatic malformations, as well as AVMs that can involved the skin but also importantly the CNS. Epidermal nevi can be localized or widespread. There is usually significant overgrowth of hands and/or feet. Patients can have spinal cord tethering in addition to renal agenesis. Patients require multidisciplinary care, including neurosurgery and orthopedic surgery and other specialties depending on their symptoms. Imaging to establish the presence of CNS vascular lesions or other anomalies helps guide therapy. Recently systemic rapamycin has been shown to be helpful in shrinking complicated vascular anomalies, including lymphatic malformations.

Klippel-Trenaunay Syndrome (KTS) and KTS–Parkes-Weber

Klippel-Trenaunay syndrome (KTS) is characterized as a triad of nevus flammeus, venous and lymphatic malformations, and soft tissue hypertrophy of the affected extremity (Fig. 28.16). The lower limb is affected in approximately 95% of patients. When there is an associated arteriovenous (AV) fistula, Parkes-Weber is appended to the diagnosis.

The earliest and most common presenting sign is a geometric CM. The deeper venous malformation (VM) in this sporadic syndrome may be confined to the skin, but it often extends to muscle and bone. The involved limb is usually larger and longer than normal. Venous thromboembolism has been reported, with an incidence as high as 22%. In other patients, the deep venous system is hypoplastic. Other, less frequent features include intermittent claudication, venous ulcers, increased skin temperature, diffuse hair loss, hypertrichosis, lymphedema, altered sweating, lacrimation, or salivation. Gait abnormalities are common. Intradural spinal cord AVMs, epidural hemangioma, and epidural angiomyolipoma have been reported to occur at the same segmental level as cutaneous lesions of KTS. Clinical evaluation consists of color duplex ultrasonography to evaluate the patency of the deep venous system, MRI for visualization of hypertrophic muscle and bone, arteriography when an AV fistula is suspected, and conventional radiography of both extremities. Early venography may be performed, if the deep venous system is not hypoplastic, to determine whether there are defects that might be amenable to surgical correction. When AV shunting is found the term *KTS–Parkes-Weber* is used.

Fig. 28.16 Klippel-Trenaunay syndrome.

Flashlamp-pumped pulsed dye laser treatments may be used for the nevus flammeus component. The varicosities and malformations may respond to microfoam sclerosis, endovenous thermal ablation, or surgical stripping. Edema is managed through elevation, graded compression pumps, fitted garments, and diuretics. Surgery may be performed to correct the inequality in limb length, to relieve deep venous obstruction, or to correct an associated AV fistula. Skin ulcers have responded to sunitinib. The Klippel-Trenaunay Support Group website can be found at www.k-t.org.

Diffuse Capillary Malformation with Overgrowth

Diffuse capillary malformation with overgrowth is a clinical phenotype proposed to describe patients with widespread PWS (often reticulated) with some usually nondebilitating proportionate overgrowth. Patients had normal neurologic function but require orthopedic follow-up for limb discrepancies.

Capillary Malformation–Arteriovenous Malformation

CM-AVM syndrome is an autosomal dominant disorder caused by heterozygous *RASA1* mutations and resulting in multifocal

CMs and high risk for fast-flow lesions. The CMs in CM-AVM may have arterial flow. Affected individuals have widespread "thumbprint" or café au lait–like oval CMs but can also have AVMs in the brain and spine. Therefore imaging of the brain and complete spine to rule out AVMs is recommended. Cobb syndrome (cutaneous meningospinal angiomatosis) is characterized by a port wine hemangioma or other vascular malformation in a dermatome supplied by a segment of the spinal cord containing a VM or AVM and may also be from *RASA1* mutations.

Capillary Malformation–Arteriovenous Malformation 2

CM-AVM2 is a newly described similar phenotype caused by *EPHRIN B4* mutation but an apparently lower risk of CNS AVMs.

Microcephaly Capillary Malformation Syndrome

Microcephaly capillary malformation syndrome is characterized by microcephaly with seizures and severe developmental delay, along with similar small discrete CMs as are seen in CM-AVM.

Proteus Syndrome

Proteus syndrome is characterized by vascular malformations that include nevus flammeus, hemihypertrophy, macrodactyly, verrucous epidermal nevus, soft tissue subcutaneous masses, and cerebriform overgrowth of the plantar surface. It is caused by an *AKT-1* mutation and is reviewed in Chapter 27.

Beckwith-Wiedemann Syndrome

Patients with Beckwith-Wiedemann syndrome have prominent nevus simplex especially on the glabella in addition to a protruding large tongue, posterior ear pits on the helix, omphalocele or other anterior abdominal wall defects, and hypoglycemia. Other rare syndromes associated with nevus simplex include Nova syndrome (patients have hydrocephalus), odontodysplasia (patients have defects in dentin and failed rupture of teeth), and Roberts-SC syndrome (symmetric limb defects and developmental delay).

TAR Syndrome

TAR syndrome is defined by congenital thrombocytopenia and bilateral absence or hypoplasia of the radius, and some patients have been reported to have port wine stain.

VENOUS MALFORMATION

Venous malformations (VMs) present as rounded, blue or purple, spongy nodules. They often occur on the head and neck and may involve both the skin and the mucous membranes. There is usually a deep component with a connection to the venous circulation. Calcified phleboliths and localized hyperhidrosis may occasionally be present, and the lesions can sometimes be painful. In addition to typical VMs that are caused by a *TEK* mutation, there are other malformations categorized as VMs (glomuvenous malformations, cerebrocavernous malformations) Some lesions are amenable to sclerotherapy or surgical resection, but results are mixed. Compression may be helpful. Customized, snug-fitting garments are preferable to elastic bandages.

Several Syndromes Associated with Venous Malformations

Common and familial VMs in addition to blue rubber bleb nevus syndrome (BRBS) are caused by a *TEK* mutation (*TEK* encodes the protein TIE-2). It is proposed that VMCM is due to a germline mutation and BRBS is caused by a somatic mutation (see following subsections). Patients with VMCM seem to have a germline

mutation and then a second hit mutation in the *TEK* gene causes the VMs. In BRBS a progenitor cell may acquire a mutation in both *TEK* genes and then spread to other areas leading to multifocal lesions.

Multiple Cutaneous and Mucosal Venous Malformations (VMCM Syndrome)

VMCM patients have multiple small blue soft VMs. D-Dimer is sometimes elevated in VMCM but not in glomangiomas. The lesions of VMCM are small and unlike BRBS are not hyperkeratotic or firm.

Blue Rubber Bleb Nevus Syndrome

BRBS is characterized by cutaneous and GI venous malformations. There is often a dominant lesion that is much larger than the others. The skin lesions have a cyanotic, bluish appearance with a soft, elevated, nipple-like center, but deeper lesions may also occur. They can be emptied by firm pressure, leaving them flaccid. The lesions are located predominantly on the trunk and arms but also the palms and soles. Nocturnal pain may occur. Lesions can be found throughout the GI tract (Fig. 28.17) but are numerous in the small intestine, and rupture of a lesion may produce melena. Occasionally, other organs may express VMs, and symptomatic CNS lesions have been described. Localized coagulopathy (DIC) can occur. Treatment of bleeding or painful lesions is destruction or excision. Minimally invasive surgical techniques are well suited to the treatment of numerous lesions. For patients who continue to have bleeding episodes that require blood transfusions, octreotide, a somatostatin analog known to decrease splanchnic blood flow, may be effective. ε-Aminocaproic acid has also been used.

Bannayan-Riley-Ruvalcaba Syndrome

Bannayan-Riley-Ruvalcaba syndrome is described later in this chapter.

Maffucci Syndrome

Maffucci syndrome is characterized by multiple vascular malformations with dyschondroplasia caused in most patients by mutations in *IDH1* or *IDH2*. The dyschondroplasia is manifested by uneven bone growth as a result of the defects of ossification, with enchondromatosis that results in multiple and frequent fractures in the period of bone growth. During the prepubertal years, 1–2 cm nodules appear on the small bones of the hand or foot. Later, larger nodules, the enchondromas, appear on the long bones. Much later, similar lesions appear on the trunk. Sarcomatous degeneration occurs in 50% of patients. The distribution of the lesions is mostly unilateral. Multiple VMs of the skin and mucous membranes are present in this nonhereditary mesodermal dysplasia disorder. Lymphangiomas may also occur. Pigmentary changes, such as vitiligo and café au lait macules, have been noted. In Ollier disease, the enchondromatosis is present without the cutaneous abnormalities.

Fig. 28.17 Blue rubber bleb nevus syndrome.

Cerebral Cavernous Malformations

Cerebral cavernomas are vascular malformations in the brain that may be inherited in an autosomal dominant manner. The causative mutations are in *CCM1 (KRIT1)*, *CCM2*, or *PDCD10*. Cutaneous malformations are sometimes present, including hyperkeratotic cutaneous capillary VMs.

Glomuvenous Malformation

VM should be distinguished from glomuvenous malformation (GM, glomangioma). GM is made up of glomus cells and is caused by mutations in glomulin. GM can be pink at initial presentation but evolve to blue-black with a cobblestone appearance and minimal hyperkeratosis. Involvement of an extremity is typical, and the GMs are often painful if compressed because they are made of glomus cells. The lesion often shrinks with external pressure and is typically painful in the morning due to congestion. Increased pain may be noted at puberty, during menstruation, with pregnancy, or with oral contraceptives. Sclerotherapy is more effective in VM than in GM.

Glomus Tumor

The solitary glomus or neuromyoarterial tumor (also known as a solitary glomangioma) is most frequently a skin-colored or slightly dusky blue, firm nodule 1–20 mm in diameter. The characteristic location is subungual, but tumors may occur on the fingers and arms, or elsewhere. Subungual tumors show a bluish tinge through the translucent nail plate. The tumor is usually extremely tender, and paroxysmal pain occurs frequently. Sensitivity is likely to be present constantly, and when touched the tumor responds with severe radiating pain. However, nontender glomus tumors are encountered. Digital lesions are more common in women, and there is a male predominance of nondigital lesions. Hereditary multiple glomus tumors may represent an autosomal dominant mosaic trait and may be congenital. There appears to be an association between glomus tumor and neurofibromatosis. High-resolution MRI, high-resolution ultrasonography (5–9 MHz), and color duplex sonography may be used to define the limits of the tumor before surgery is undertaken. Progressive growth may lead to ulceration.

Histologically, glomus tumors contain numerous vascular lumina lined by a single layer of flattened endothelial cells. Peripheral to the endothelial cells are layers of glomus cells. Generally, these are round and arranged in distinct rows resembling strings of black pearls. Rarely, the cells have a somewhat spindled morphology. Multiple glomus tumors tend to have only one or two layers of glomus cells. Glomangiomyomas have a prominent muscularis media in addition to one or two layers of glomus cells. Both solitary and multiple glomus tumors are related to the arterial segment of the cutaneous glomus, the Sucquet-Hoyer canal. The glomus cells are modified vascular smooth muscle cells and stain with

vimentin rather than desmin. Smooth muscle actin is often positive.

Treatment of solitary glomus tumors is best carried out by complete excision, which immediately produces relief from pain. The subungual tumors are most difficult to locate and eradicate because they are usually small, seldom more than a few millimeters in diameter.

Rare reports of glomangiosarcomas describe large, deeply located extremity lesions that consist of sarcomatous areas intermingled with areas of benign glomus tumor.

ARTERIOVENOUS FISTULAS

An *arteriovenous fistula* (AV) is a route from artery to vein, bypassing the capillary bed. AV fistulas may be congenital or acquired. Congenital AV fistulas occur mostly on the extremities and may be recognized, or at least suspected, in the presence of varicose veins, ulcerations, and CMs. They may occur internally as a component of Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia). Acquired AV fistulas are usually the result of trauma (Fig. 28.18) but may be created intentionally for hemodialysis access.

The skin over AV fistulas is warmer, hair may grow faster, and the affected limb may be larger than the other; thrills and bruits may be discerned in some cases. Changes may result from stasis, a vascular steal syndrome, edema, a vascular mass, increased sweating, or paresthesias. At times, reddish purple nodules or a plaque may be present with a clinical resemblance to Kaposi sarcoma; this has been called pseudo–Kaposi sarcoma (Stewart-Bluefarb syndrome).

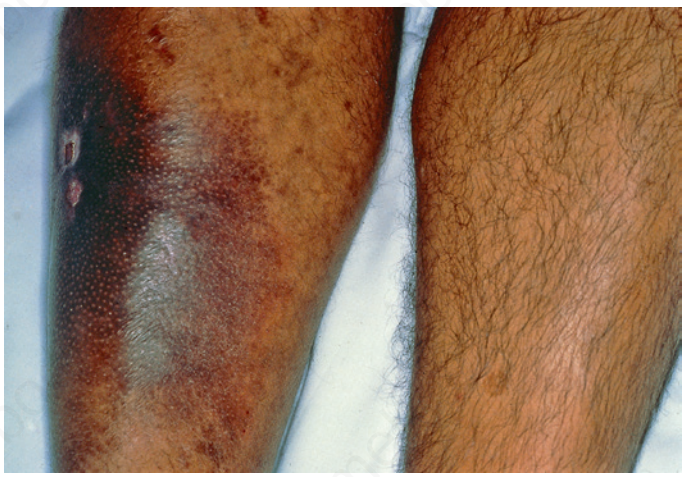

Fig. 28.18 Stasis-like changes below acquired arteriovenous fistula.

It may occur because of congenital malformations, in which case a unilateral purplish discoloration of the skin over or distal to the AV anomaly begins to appear in the second or third decade of life. This type accounts for 80% of cases; the remainder are secondary to fistulas caused by trauma. Iatrogenic AV fistulas, such as those produced to facilitate hemodialysis, may also bring about skin changes, including reactive angioendotheliomatosis. Histologically, there is an increase in thick-walled vessels lined by plump endothelial cells, extravasated erythrocytes, and deposits of hemosiderin. Proliferating endothelial cells may occlude the lumen.

Cirsoid aneurysms (angioma arteriale racemosum) are uncommon congenital AV fistulas of the scalp or face. They may appear on the skin as a pulsating mass that may extend over the neck and scalp and may penetrate into the cranium, or they may simply manifest as a solitary blue or red papule in the midadult period. Abdominal AV fistulas may be associated with lower extremity edema, cyanosis, pulsatile varicose veins, and scrotal edema.

Diagnosis of an AV fistula is established by plethysmography, thermography, determination of oxygen saturation of venous blood, or arteriography.

Treatment of traumatically induced AV fistulas by excision is curative. Because the congenital malformation variety consists of multiple small distal lesions, surgical intervention is not feasible in many patients. Color echo-Doppler ultrasonography–guided sclerotherapy with polidocanol microfoam has been used successfully in this setting. Sodium tetradecyl sulfate and ethanolamine oleate have both been used as sclerosants in various forms of AV malformation. Pressure and elevation as supportive measures may limit ulceration, infection, and other secondary complications.

OTHER LESIONS

Nevus anemicus is a congenital disorder characterized by macules of varying size and shape that are paler than the surrounding skin (Fig. 28.19) and cannot be made red by trauma, cold, or heat. The nevus resembles vitiligo, but there is a normal amount of melanin. Wood's light does not accentuate it, and diascopy causes it to merge into the surrounding blanched skin. The patches are usually well defined with irregular edges. Nevus anemicus can be an important early marker of neurofibromatosis in a young child, before other stigmata have appeared. Nevus anemicus can also be found in tuberous sclerosis or as one component of phakomatosis pigmentovascularis. In nevus anemicus, a flare does not develop after rubbing the skin but does develop after rubbing the adjacent normal skin. The underlying defect is an increased sensitivity of the blood vessels to catecholamines. On biopsy and with confocal microscopy, lesional skin resembles normal skin.

Nevus oligemicus presents as a patch of livid skin that is cooler than the normal skin as a result of decreased blood flow. Vasoconstriction of deep vessels is thought to be the underlying defect.

Sinusoidal hemangioma is a vascular malformation that usually presents in adults as a bluish purple nodule, less than 4 cm in diameter, on the trunk or breasts. Multiple lesions may occur, and a facial location has also been reported. Histologically, it appears as a lobular, circumscribed mass with dilated, interconnected vascular channels filled with blood.

Prominent Inferior Labial Artery

The arteries supplying the lips are normally tortuous to accommodate the movements of the mouth. Howell and Freeman reported a potentially troublesome arterial anomaly of the lower lip characterized by the appearance of a pulsating papule in the lower vermilion, 1 or 2 cm from the oral commissure, formed by an especially tortuous segment of the inferior labial artery. A similar anomaly may involve the upper lip. Caliber-persistent labial artery may be misdiagnosed as squamous cell carcinoma, and the biopsy may produce significant bleeding. On the lip, it is best to "palpate for pulsation prior to puncture."

Howell JB, Freeman RG: The potential peril from caliber-persistent arteries of the lips. J Am Acad Dermatol 2002; 46: 256.

LYMPHATIC MALFORMATIONS

Microcystic Lymphatic Malformation (Lymphangioma Circumscriptum)

The old term for microcystic lymphatic malformation (MLM) was lymphangioma circumscriptum; however, this is not a tumor but rather a congenital malformation of the superficial lymphatics. An MLM presents as groups of deep-seated, vesicle-like papules (Fig. 28.20), resembling frog spawn, at birth or shortly thereafter. The lesions are usually yellowish but may be pink, red, or dark when bled into. This creates the illusion that they are rapidly changing. When the papules are punctured, they exude clear, colorless lymph. The papules are arranged irregularly in groups that may be interconnected by sparsely scattered lymph cysts. The entire process, however, as a rule is localized to one region. The sites of predilection are the abdomen, axillae, genitalia, and mouth, particularly the tongue. The scrotum is subject to multifocal lymphatic malformations presenting as clear, thick-walled, vesicle lesions. At times, the surface is verrucous, in which case the color may be brownish, and the lesions may be mistaken for warts. Lesions resembling molluscum contagiosum have also been described.

Fig. 28.20 Microcystic lymphatic malformation adjacent to café au lait macule.

Frequently, the lesions consist of a combination of blood and lymph elements, so that purple areas are sometimes seen scattered within the vesicle-like papules. The lesions are also frequently associated with a deep component that occupies the subcutaneous tissues and muscles. Over time, these lymphatic malformations show only slight changes.

As with angiokeratomas, lymphangiomas may be seen adjacent to café au lait macules. This may represent a twin spotting phenomenon. Acquired lesions occur in the setting of chronic lymphedema. Lesions occurring after radiation therapy overlap with atypical vascular lesion (AVL). A peculiar penicillamine-induced dermopathy may result from damage to the underlying supporting structures of the dermis and allow dilation of lymph vessels within areas of trauma, such as the dorsal hands and knees. Central facial involvement may be seen in variegate porphyria, and sites of chronic high-potency steroid application may develop lymphangiectasia.

Excision and grafting, fulguration, or coagulation is frequently unsatisfactory because of recurrences resulting from vascular connections between the surface lesions and deep-seated lymphatic cisterns. The deeper component should be evaluated by MRI or other suitable radiologic imaging to delineate the extent of deep involvement before planned procedures. Vaporization with the carbon dioxide (CO_2) laser may be successful if deeper components are not present. Pulsed dye laser, intense pulse light systems, sclerosants, and electrosurgical techniques have also been reported as effective. Keloid formation has been described after laser vaporization of genital lymphangiomas. Sclerotherapy has been reported as successful, and radiotherapy has been used successfully in select refractory cases.

Macrocystic Lymphatic Malformation

Macrocystic lymphatic malformations are deep-seated, typically multilocular, poorly defined, soft tissue masses that are painless and covered by normal skin. They are most common in the oral cavity and on the extremities and have been described in Maffucci syndrome. Cystic hygromas are clinically better circumscribed, occurring usually in the neck (Fig. 28.21), axilla, or groin. The posterior neck lesions may be associated with Turner syndrome, other chromosomal aneuploidy conditions, hydrops fetalis, or other congenital abnormalities. Cytogenic analysis of children born with cystic hygromas is indicated, because aneuploidy may recur in subsequent pregnancies. Transabdominal or transvaginal sonography can visualize these lesions in utero. Usually, the lesions will recur after surgical treatment because of their depth, but injection sclerotherapy with agents such as OK-432 (picibanil) may result in regression. Sildenafil has been reported as an effective nonsurgical treatment in the setting of pediatric orbital lymphangioma.

Lymphangiomatosis

Diffuse or multifocal dilated lymphatic channels involving the skin, soft tissues, bone, and parenchymal organs are a rare congenital condition. If an extremity is affected, the prognosis is good; however, when vital internal organs are involved, the prognosis is poor. Skin lesions are presenting signs in 7% of patients with thoracic lymphangiomatosis. These patients have a high incidence of complications, including chylothorax (49%), pulmonary infiltrates (45%), bone lesions (39%), splenic lesions (19%), cervical involvement (15%), and DIC (9%). Splenic lymphangiomatosis has been associated with Proteus syndrome. Diffuse pulmonary lymphangiomatosis has been successfully treated with bevacizumab.

KAPOSIFORM LYMPHANGIOMATOSIS

Kaposiform lymphangiomatosis is a newly described entity made of spindled lymphatic endothelial cells that grow progressively and is in between a tumor and a malformation. The intrathoracic disease is prominent and it can present in the skin with subcutaneous masses or ecchymosis. Histopathology shows spindled cells that are arranged in parallel, strands and sheets that anastomose, and is less well defined than KHE. Kasabach-Merritt–like coagulopathy has been reported. There is significant mortality but sirolimus therapy shows promise.

Gorham-Stout Syndrome

Gorham-Stout syndrome is characterized by lymphangiomatosis and chylous effusions, with osteolytic changes resulting in "vanishing bones." The cutaneous lymphatic malformation may be the initial sign of the disease, which typically appears in young children, usually in areas adjacent to involved bones. If a patient has a lymphatic malformation that becomes painful, Gorham should be considered. Although multiple areas of the skeletal system may be involved, usually only a single bone is destroyed. The bone is completely or partially replaced with fibrous tissue. Sirolimus therapy has been helpful in some patients. Response to pegylated IFN alfa-2b was noted in a 9-year-old boy with systemic disease. Response to bisphosphonates has also been noted.

Multifocal Lymphangioendotheliomatosis

Patients with multifocal lymphangioendotheliomatosis present at birth with hundreds of red-brown plaques as large as several centimeters. Similar lesions occur in the GI tract and are associated with severe bleeding with a significant risk of mortality. Severe thrombocytopenia occurs in affected children with a coagulopathy (Kasabach-Merritt–like) that can be life threatening. There are reports of children with very few skin lesions and severe thrombocytopenia and reports of children with classic skin lesions but no thrombocytopenia. Treatment with corticosteroids and/or IFN alfa results in little to no improvement, but recently sirolimus has shown significant benefit. One patient was reported who did well with a liver transplant. The histology is distinctive, with delicate, thin-walled vessels lined by hobnailed endothelium with papillary tufting. The endothelial cells demonstrate a high proliferative fraction with Ki-67 staining and are reactive with LYVE-1, suggesting lymphatic differentiation.

Acquired Progressive Lymphangioma (Benign Lymphangioendothelioma)

This is a group of slow-growing lymphangiomas that present as bruiselike lesions or erythematous macules in children or middle-aged adults. Rarely, the lesion is yellow or alopecic. The histologic appearance is that of delicate, endothelium-lined spaces dissecting between collagen bundles. A similarity to the plaque stage of Kaposi sarcoma (KS) may be striking. Simple excision is curative. Topical and systemic steroids in addition to surgery have been effective.

Phakomatosis Pigmentovascularis

Patients with a combination of vascular malformations and melanocytic (Fig. 28.22) or epidermal nevi are grouped into this disorder. The revised classification includes only four types: phakomatosis cesioflammea (blue nevus/dermal melanosis and nevus flammeus), phakomatosis spilorosa (nevus spilus and a pale-pink vascular spot), phakomatosis cesiomarmorata (blue spots and cutis marmorata telangiectatica congenita), and unclassifiable cases not corresponding to the previous patterns. These may all be phenotypes of a common disorder, and a recent report shows *GNAQ* or *GNA11* mutations. Associated systemic findings may include intracranial and visceral vascular anomalies, ocular abnormalities, choroidal melanoma, and hemihypertrophy of the limbs. Phakomatosis cesioflammea is the most common type (85%), and half of patients with this type have serious manifestations. Bilateral deafness and malignant hypertension have also been described. Some authors have suggested that particularly extensive and aberrant mongolian spots may be a marker for more severe systemic involvement. Phakomatosis spilorosa has been associated with multiple granular cell tumors.

Phacomatosis pigmentokeratotica is now classified separately as a syndrome that includes speckled lentiginous nevi and nevus sebaceous and may be on the same spectrum as Schimmelpenning syndrome (nevus sebaceous syndrome). There can be associations of seizures, epibulbar dermoids, and potential malignancies. Phacomatosis pigmentokeratotica has been shown to be caused by an *HRAS* or *KRAS* mutation and can be considered a RASopathy (see Chapter 27).

Dilation of Preexisting Vessels

Spider Angioma (Vascular Spider, Spider Nevus, Nevus Araneus)

The lesion of spider angioma is suggestive of a red spider. The ascending central arteriole represents the "body" of the spider, and the radiating fine vessels suggest the multiple legs. These small telangiectases occur singly or severally, most frequently on the face, neck, and dorsal hands, indicating they may be induced by sun exposure.

Young children and pregnant women show these lesions most frequently. In pregnant women, palmar erythema is usually present with the vascular spiders. The presence of vascular spiders in otherwise healthy children is common.

Vascular spiders also occur in patients with cirrhosis, hepatitis C, malignant disease of the liver, and other hepatic dysfunctions. The common denominator has been shown to be an elevated blood estrogen level. Elevations in VEGF and basic fibroblastic growth factor are also significant predictors for spider angiomas in cirrhotic patients. When vascular spiders occur with palmar erythema and pallid nails with distal hyperemic bands, cirrhosis of the liver should be considered. AV hemangioma has also been reported to be associated with chronic liver disease.

The vascular spiders of childhood may involute without treatment, although several years may elapse before this occurs. In pregnant women, most lesions will involute soon after delivery. If active therapy will be performed pulse dye laser is effective without scarring, but electrodesiccation may produce good results in experienced hands.

Venous Lakes

Venous lakes (phlebectases) are small, dark-blue, slightly elevated blebs (Fig. 28.23). They are easily compressed and are located on the face, ears, lips, neck, forearms, and backs of the hands. These manifestations of chronic sun damage are extremely dilated, blood-filled spaces lined with thin, elongated endothelial cells and usually surrounded by prominent solar elastosis. Venous lakes may be treated by light electrocautery, laser ablation, fulguration, infrared coagulation, intralesional injection of 1% polidocanol, and cryotherapy.

Capillary Aneurysms

These flesh-colored solitary lesions, resembling an intradermal nevus, may suddenly grow larger and darker and become blue-black or black as a result of thrombosis. Capillary aneurysms are surrounded by a zone of erythema. The lesions may be clinically indistinguishable from malignant melanoma. Histologically, these are thrombotic, dilated capillaries lying just below the epidermis. Shave excision in stages will expose the clot and eliminate the uncertainty.

Fig. 28.23 Venous lake.

Telangiectasia

Telangiectases are fine, linear vessels coursing on the surface of the skin; collectively, they are named telangiectasia. Telangiectasia may occur in normal skin at any age, in both genders, and can occur anywhere on the skin and mucous membranes but if abundant or with other symptoms, they can be important markers of systemic disease. Fine telangiectases may be seen on the alae nasi of most adults. They are prominent in areas of chronic actinic damage seen in fair-skinned persons. Persons long exposed to wind, cold, or heat are also subject to telangiectasia.

Telangiectases can be found in such conditions as radiodermatitis, xeroderma pigmentosum, lupus erythematosus (LE), dermatomyositis, scleroderma and the CREST syndrome, rosacea, cirrhosis of the liver, acquired immunodeficiency syndrome (AIDS), poikiloderma, basal cell carcinoma, necrobiosis lipoidica diabeticorum, sarcoid, lupus vulgaris, adenoma sebaceum, keloid, angioma serpiginosum, angiokeratoma corporis diffusum, ataxia-telangiectasia, pregnancy, and Bloom syndrome. These entities are discussed in other sections with the disease states in which they occur.

Altered capillary patterns on the fingernail folds (cuticular telangiectases) are indicative of collagen vascular disease, such as LE, scleroderma, or dermatomyositis. Tortuous glomeruloid loops are characteristic of LE, whereas dilated loops and avascular areas are typical of scleroderma and dermatomyositis. Reticular telangiectatic erythema may occur overlying implantable cardioverter-defibrillators.

Electrodessication and laser ablation can be effective. Pulsed dye laser and other vascular lasers, such as the 532-nm Nd:YAG laser, are usually well tolerated and associated with a low risk of scarring. Larger vessels require a longer pulse duration. Contact or cryospray cooling can reduce the incidence of complications. Pulse stacking (multiple pulses of low fluences) has been used to reduce the incidence of side effects, such as purpura, hyperpigmentation, hypopigmentation, and scar formation.

Hereditary Hemorrhagic Telangiectasia

Hereditary hemorrhagic telangiectasia (HHT, Osler-Weber-Rendu disease) is a genetic syndrome caused by mutations in either *ENG*, *ACVRL1*, *GDF2*, or *SMAD4*. The telangiectasias are widespread and usually involve the mucosa. They can be very tiny or much larger patches that can bleed easily. Patients often present with severe nose bleeds in childhood or GI bleeding less commonly. Patients with mutations in *SMAD4* and have GI polyps. There are AVMs that can affect the skin, CNS, liver, GI tract, or lungs. Genetic testing can help prove the diagnosis and screening with pulmonary, CNS and liver imaging is recommended in affected patients to rule out AVMs in these locations. In addition to other causes of telangiectasias outlined earlier, CM-AVM and CM-AVM2 are in the differential.

Fig. 28.24 Unilateral nevoid telangiectasia.

Generalized Essential Telangiectasia

Generalized essential telangiectasia (GET) is characterized by the dilation of veins and capillaries over a large segment of the body without preceding or coexisting skin lesions. The telangiectases may be distributed over the entire body or localized to some large area, such as the legs, arms, and trunk. The lesions may be discrete or confluent. Distribution along the course of the cutaneous nerves may occur. This type of telangiectasia is rarely associated with systemic disease, although patients with a similar appearance may have autoimmune disease. One report documented GI bleeding from a "watermelon" stomach in a woman with GET.

Most frequently, GET develops in women in their forties and fifties. The initial onset is on the lower legs and then spreads to the upper legs, abdomen, and arms. The dilations persist indefinitely. Generally, this is a sporadic condition, although it has been described in families as an autosomal dominant trait, in which case it has been termed *hereditary benign telangiectasia*.

It has been reported that GET may be differentiated from telangiectasia associated with systemic disease by assessing alkaline phosphatase activity. Telangiectatic vessels in GET do not have alkaline phosphatase activity in the endothelium of the terminal arteriole and the arterial portion of the capillary loops.

Individual areas may be treated with laser ablation. High-energy, high-frequency, long-pulse Nd:YAG laser and the 585-nm flashlamp-pumped pulsed dye laser have been reported to produce good results. Tetracycline, ketoconazole, and treatment of a chronic sinus infection have led to involution in individual reports.

Unilateral Nevoid Telangiectasia

In unilateral nevoid telangiectasia, fine, threadlike telangiectases develop in a unilateral, sometimes dermatomal, distribution (Fig. 28.24). The areas most often involved are the trigeminal and C3 and C4 or adjacent areas, with the right side involved slightly

more often than the left. In some cases the condition is congenital, but more often it is acquired. Increased estrogen appears to play a role in the onset of acquired cases (e.g., pregnancy, puberty in women, adrenarche in men), and hepatitis/alcohol-related cases have been reported. Bilateral nevoid telangiectasia has been reported to be more common in older people, men and in the setting of some other illness such as liver disease or diabetes. Lesions have responded to pulsed dye laser treatment.

Angiokeratomas

Angiokeratomas are collections of blood vessels with an overlying hyperkeratotic surface. Angiokeratoma corporis diffusum (Fabry disease) is discussed in Chapter 26.

Angiokeratoma Circumscriptum

Angiokeratoma circumscriptum is a malformation of dermal and subcutaneous capillaries and veins that remains unclassified in the ISSVA classification. The lesions are purple or red and well defined, occurring mainly on the lower extremities, but can also occur on the chest or forearm. Lesions are often congenital and over time, a verrucous component appears. Linear segmental lesions have been described. Superficial ablative therapy is typically followed by recurrence, regardless of whether ablation is performed by excision, laser, cryotherapy, or electrocautery. In contrast, full-thickness excision is generally effective and may be used in combination with laser therapy if necessary.

Angiokeratoma of Mibelli

The lesions of angiokeratoma of Mibelli consist of 1–5 mm red vascular papules, the surfaces of which become hyperkeratotic over time. The papules are dull red or purplish black, verrucous, and rounded and are usually situated on the dorsum of the fingers and toes, the elbows, and the knees. Frequently, these are called telangiectatic warts. The patient often has cold, cyanotic hands and feet. Autosomal dominant inheritance has been described, and an association with chilblains is common. The condition is most frequently discovered in prepubertal children.

Histologically, hyperkeratosis, increased thickness of the granular layer, and dilation of the subpapillary vessels to form lacunae are the chief features.

The differential diagnosis of angiokeratomas of the dorsal hands in children includes acral pseudolymphomatous angiokeratoma in children (APACHE). However, APACHE is unilateral and sporadic in nature, without associated cold sensitivity; histologic examination reveals a dense, nodular, lymphohistiocytic infiltrate with occasional plasma cells, eosinophils, and multinucleated giant cells. It is a variant of pseudolymphoma and not primarily a vascular lesion. Similar lesions may occur in adolescents and adults, and the terms acral angiokeratoma-like pseudolymphoma and T-cell–rich angiomatoid polypoid pseudolymphoma of the skin have been used to describe these varied presentations.

Angiokeratoma may be treated with electrocautery, fulguration, CO_2 laser ablation, long-pulse vascular laser therapy, or cryotherapy, with fairly good results.

Angiokeratoma of the Scrotum (Fordyce)

Angiokeratomas have a predilection for the scrotum (Fig. 28.25) and sometimes the vulva in middle-aged and elderly individuals. There is often a diffuse redness of the involved area. Urethral or clitoral lesions may also be seen. Infrequently, the keratotic part may be accidentally scratched leading to considerable bleeding. Histologically, the many communicating lacunae in the subpapillary layer are lined with endothelium and connected underneath by dilated veins. The primary therapy is reassurance, but therapy with shave excision, cautery, laser ablation, or fulguration can be used.

HYPERPLASIAS

Angiolymphoid Hyperplasia with Eosinophilia

Angiolymphoid hyperplasia with eosinophilia (ALHE) is a benign vascular growth that usually presents with pink to red-brown, dome-shaped, dermal papules or nodules of the head or neck (Fig. 28.26). There is a predilection for the scalp, especially the retroauricular area. ALHE may also occur in the mouth and on the trunk, extremities, penis, and vulva. Grouped lesions merge to form plaques or grapelike clusters. There is a female preponderance, and the average age of onset is 32 years. Symptoms can include pain or pruritus, which may occur after trauma. An underlying AV shunt can be present. Histologically, central thick-walled vessels with hobnail endothelium are noted. Surrounding hyperplasia of smaller vessels and nodular lymphoid aggregates with eosinophils are present.

Lesions do not spontaneously regress. Treatment with surgical excision is successful in 65% of cases. The lesions may recur if the underlying AV shunt is not excised. Intralesional corticosteroids, pulsed dye laser therapy with conventional or ultralong pulsed systems, Nd:YAG laser, cryotherapy, pentoxifylline, indomethacin, imiquimod, and electrodesiccation have been successful in some patients. Difficult cases have been controlled with IFN alfa-2b,

Fig. 28.26 Angiolymphoid hyperplasia with eosinophilia. (Courtesy Dr. Debabrata Bandyopadhyay.)

Fig. 28.27 Kimura disease. (Courtesy Department of Dermatology, Keio University School of Medicine.)

isotretinoin, or vinblastine, and partial responses to intralesional bleomycin have been reported.

It is important to distinguish ALHE from Kimura disease (Fig. 28.27). Kimura disease is an inflammatory disorder that presents as massive subcutaneous swelling in the periauricular and submandibular region in young Asian men. Histologically, prominent germinal centers with eosinophils are present in the subcutaneous tissue. Although blood vessels are abundant, changes are less prominent than in ALHE. Additionally, Kimura disease is associated with allergic conditions such as asthma, rhinitis, and eczema, and it is frequently accompanied by lymphadenopathy, peripheral blood eosinophilia, and elevated IgE level. Although clonal T-cell gene rearrangement has been reported in both ALHE and Kimura disease, heteroduplex polymerase chain reaction (PCR) has disproved clonality in some cases positive on conventional PCR. Treatment of Kimura disease is either with watchful waiting for the expected regression or with surgery, radiation, or systemic steroids. Coexistence of ALHE and peripheral T-cell lymphoma has been reported.

Intravascular Papillary Endothelial Hyperplasia

Masson described this intravascular papillary proliferation that may mimic angiosarcoma. The lesions appear as red or purplish, 5-mm to 5-cm papules or deep nodules on the head, neck, or upper extremities. The condition represents recanalization of a thrombosed vessel. It can occur de novo or as part of a preexisting vascular lesion. Histologic examination reveals intravascular papillary projections lined by endothelial cells. Thrombi may still be present, and the papillary projections may have a fibrinous or hyaline core. High-resolution ultrasound imaging may be useful in establishing the diagnosis, although the diagnosis is usually made by biopsy. Excision is curative.

Angioma Serpiginosum

Angioma serpiginosum, first described by Hutchinson in 1889, is characterized by minute, copper-colored to bright-red angiomatous puncta that tend to become papular. These puncta occur in groups that enlarge through the constant formulation of new points at the periphery, whereas those at the center fade. In this manner, linear arrays, small rings, or serpiginous patterns are formed. No purpura is present, but a netlike or diffuse erythema forms the background. In the areas undergoing involution, a delicate tracery of rings and lines, a fine desquamation, and at times a semblance of atrophy are seen. Slight lichenification and scaling may be evident in the papular lesions. Dermoscopy shows small red dots and globules. The eruption predominates on the lower extremities. Although it affects both genders at all ages, 90% of cases occur in girls under 16. It is usually slowly progressive and chronic, and although involution may occur, it is probably never complete. Treatment with a pulsed dye laser will improve or eliminate such lesions. Angioma serpiginosum following Blaschko's lines, with associated esophageal papillomatosis, has been reported as an X-linked dominant condition with mild features of Goltz syndrome (see Chapter 27).

Angioma serpiginosum must be differentiated from the progressive pigmentary disease of Schamberg. In the latter, pinpoint areas of purpura, the so-called cayenne pepper spots, form macules that tend to coalesce and form diffusely pigmented patches. The pigment is hemosiderin. Purpura annularis telangiectodes (Majocchi) is

often bilateral and is characterized by acute outbreaks of telangiectatic points that spread peripherally and form small rings. In lichenoid purpuric and pigmentary dermatosis of Gougerot and Blum, the primary lesion is a minute, lichenoid, reddish brown papule that is sometimes hemorrhagic. It has a tendency toward central involution and residual pigmentation.

In angioma serpiginosum, the most important histologic finding is dilated and tortuous capillaries in the dermal papillae and the upper dermis. No inflammatory infiltrate or extravasation of red blood cells is observed. The dilated capillaries show no alkaline phosphatase activity, in contrast to normal capillaries.

Microvenular Hemangioma

The recently described microvenular hemangioma is an acquired, benign vascular neoplasm that presents as an asymptomatic, slowly growing, 0.5–2.0 cm, reddish lesion on the trunk or extremities of adults (average age 32). Multiple and eruptive variants have been described. Dermoscopic examination reveals multiple, well-demarcated, red globules. Monomorphous, elongated blood vessels with small lumina involve the entire reticular dermis. In many areas, the endothelial cells are surrounded by pericytes. The endothelial cells are podoplanin (D2-40) negative. GLUT-1 may be focally positive. The main differential diagnosis is Kaposi sarcoma. Along with glomeruloid hemangioma, microvenular hemangioma may sometimes be present in POEMS syndrome. Excision, if needed, is usually curative.

Napekoski KM, et al: Microvenular hemangioma. J Cutan Pathol 2014; 41: 816.

Proliferating Angioendotheliomatosis

Diseases designated angioendotheliomatosis have historically been divided into two groups: a reactive, involuting type and a malignant, rapidly fatal type. "Malignant angioendotheliomatosis" has been shown to be intravascular (angiotropic) lymphoma rather than a true vascular lesion.

The reactive type of angioendotheliomatosis is uncommon. It can be idiopathic or occur in patients who have subacute bacterial endocarditis, Chagas disease, pulmonary tuberculosis, cryoproteinemia, severe atherosclerotic disease, periodontal disease, antiphospholipid antibodies, and medications (trabectedin and pegfilgrastim). Patients present with red-purple patches, plaques, nodules, petechiae, and ecchymoses, usually of the lower extremities. Some may present with a livedoid pattern or lesions resembling atrophie blanche. Diffuse dermal angiomatosis is a variant associated with ischemia or atherosclerosis. The lesion occurs most often on the thigh, breast, or pannus in areas of vascular insufficiency (Fig. 28.28) and may clear with revascularization. It has also been described in association with an AV fistula and with anticardiolipin antibodies.

Histologically, the vessels in benign reactive angioendotheliomatosis are dilated and are filled with proliferating endothelial cells, usually without atypia. Some cases demonstrate a proliferation of capillaries in the dermis, with diffuse, lobular, or mixed patterns. Fibrin microthrombi are common, and some cases show amyloid deposits or positive immunohistochemical staining for HHV-8 in lesional endothelial cell nuclei. The course in this type is characterized by involution over 1–2 years. Therapy for the underlying condition has been considered as hastening involution.

Fig. 28.28 Diffuse dermal angiomatosis.

The malignant type of "angioendotheliomatosis" is actually a large-cell, intravascular lymphoma and is discussed in Chapter 32.

MALIGNANT NEOPLASMS

Kaposi Sarcoma

Moritz Kaposi described this vascular neoplasm in 1872 and called it "multiple benign pigmented idiopathic hemorrhagic sarcoma." Since his description, the disease has been reported in five separate clinical settings, with different presentations, epidemiology, and prognoses, as follows:

1. Classic KS, an indolent disease seen chiefly in middle-aged men of Southern and Eastern European origin
2. African cutaneous KS, a locally aggressive process affecting middle-aged Africans in tropical Africa
3. African lymphadenopathic KS, an aggressive disease of young patients, primarily children under age 10
4. KS in patients immunosuppressed by AIDS
5. Lymphoma or immunosuppressive therapy

Clinical Features

Classic Kaposi Sarcoma. The early lesions appear most often on the toes or soles as reddish, violaceous, or bluish black macules and patches that spread and coalesce to form nodules or plaques. These have a rubbery consistency. There may be brawny edema of the affected leg. Macules or nodules may appear, usually much later, on the arms and hands, and rarely may extend to the face, ears, trunk, genitalia, or buccal cavity, especially the soft palate. The course is slowly progressive and may lead to great enlargement of the lower extremities as a result of lymphedema. However,

Fig. 28.29 Kaposi sarcoma in an HIV-infected patient.

there may be periods of remission, particularly in the early stages of the disease, when nodules may undergo spontaneous involution. After involution, there may be an atrophic and hyperpigmented scar.

African Cutaneous Kaposi Sarcoma. Nodular, infiltrating, vascular masses occur on the extremities, mostly of men between ages 20 and 50. This form of KS is endemic in tropical Africa and has a locally aggressive but systemically indolent course.

African Lymphadenopathic Kaposi Sarcoma. Lymph node involvement, with or without skin lesions, may occur in children under age 10. The course is aggressive, often terminating fatally within 2 years of onset.

AIDS-Associated Kaposi Sarcoma. Cutaneous lesions begin as one or several red to purple-red macules, rapidly progressing to papules, nodules, and plaques. There is a predilection for the head (Fig. 28.29), neck, trunk, and mucous membranes. A fulminant, progressive course with nodal and systemic involvement is expected. KS may be the presenting manifestation of human immunodeficiency virus (HIV) infection.

Immunosuppression-Associated Kaposi Sarcoma. The lesion's morphology resembles that of classic KS; however, the site of presentation is more variable.

Internal Involvement. The GI tract is the most frequent site of internal involvement in classic KS. The small intestine is probably the viscus most often involved. In addition, the lungs, heart, liver, conjunctiva, adrenal glands, and lymph nodes of the abdomen may be affected. Skeletal changes are characteristic and diagnostic. Bone involvement is always an indication of widespread disease. Changes noted are rarefaction, cysts, and cortical erosion.

African cutaneous KS is frequently accompanied by massive edema of the legs and frequent bone involvement.

African lymphadenopathic KS has been reported among Bantu children, who develop massive involvement of the lymph nodes, especially the cervical nodes, preceding the appearance of skin lesions. The children also develop lesions on the eyelids and conjunctiva, from which masses of hemorrhagic tissue hang down. Eye involvement is often associated with swelling of the lacrimal, parotid, and submandibular glands, with a picture similar to Mikulicz syndrome.

In AIDS-associated KS, 25% of patients have cutaneous involvement alone, whereas 29% have visceral lesions only. The most frequent sites of visceral involvement are the lungs (37%), GI tract (50%), and lymph nodes (50%). Visceral involvement ultimately occurs in more than 70% of patients with AIDS-associated KS. Other immunosuppressed patients with KS may have visceral involvement in a variable percentage of cases.

Epidemiology. KS is worldwide in distribution. In Europe, there are foci of classic KS in Galicia, near the Polish-Russian border, and extending southward to Austria and Italy. In New York City, KS has occurred mostly in elderly Galician Jewish and southern Italian men. In Africa, KS occurs largely south of the Sahara Desert. Northeast Congo and Rwanda-Burundi areas have the highest prevalence, and to a lesser extent, West and South Africa.

The prevalence of AIDS-related KS has decreased since the 1980s. Most cases are in men who have sex with men (MSM). Very few reports have documented the exceptional occurrence of KS in patients with AIDS who acquired their infection from intravenous drug use, or in Haitians, children, or people with hemophilia. Patients at risk for developing KS associated with other causes of immunosuppression include those with iatrogenic suppression from oral prednisone or other chronic immunosuppressive therapies, as may be given to transplant patients. Endemic disease in southern Europe is strongly associated with oral corticosteroid use and diabetes and is inversely associated with cigarette smoking.

KS is associated with an increased risk of developing second malignancies, such as malignant lymphomas (Hodgkin disease, T-cell lymphoma, non-Hodgkin lymphoma), leukemia, and myeloma. The risk of lymphoreticular malignancy is about 20 times greater in KS patients than in the general population.

Etiopathogenesis. KS is formed by proliferation of abnormal vascular endothelial cells. HHV-8 is found in KS lesional tissue irrespective of clinical type. Primary effusion lymphoma, solid lymphoma, and Castleman disease are other confirmed associations with HHV-8 infection.

Histology. Histopathology of KS varies considerably according to the stage of the disease. Early lesions demonstrate irregularly shaped, ectatic vessels with scattered lymphocytes and plasma cells. The endothelial cells of the capillaries are large and protrude into the lumen, resembling buds. Later lesions show proliferation of vessels around preexisting vessels and adnexal structures. The preexisting structure may jut into the vascular space, forming a promontory sign. Dull-pink globules, extravasated erythrocytes, and hemosiderin are present. Nodular lesions are composed of spindle cells with erythrocytes that appear to line up between spindle cells with no apparent vascular space.

Treatment. All types of KS are radiosensitive. Radiation therapy has been used with considerable success, whether in small fractionated doses, in larger single doses to limited or extended fields, or by electron beam radiation. Local excision, cryotherapy, alitretinoin gel (Panretin), locally injected chemotherapy or IFN, and laser ablation have been used for troublesome, localized lesions.

Vincristine solution, 0.1 mg/mL injected intralesionally, not more than 3 mL at one time and at intervals of 2 weeks, produces involution of tumors, some for as long as 8 months. These studies indicate that adequate control of KS lesions may be achieved, at least for periods of 6–12 months. The development of resistance to medication seems to be inevitable.

Many other agents have been found to be effective; among the best are IFN, vinblastine, and actinomycin D. The response rate initially is high, but recurrent lesions, which are common, are generally less responsive. Systemic therapy is usually needed if more than 10 new KS lesions develop in 1 month, or if there is symptomatic lymphedema, symptomatic pulmonary disease, or symptomatic visceral involvement.

In the setting of HIV, protease inhibitors have been shown to have antiangiogenic effects; however, the results of nonnucleoside reverse transcriptase inhibitor–based regimens are not inferior to protease inhibitor–based therapy in the prevention of KS. This suggests that regression of KS is mediated by an overall improvement in immune function and not by the effects of specific antiretrovirals. Liposomal anthracyclines and paclitaxel have been approved by the FDA as first-line and second-line monotherapy, respectively, for advanced KS.

Rapamycin (sirolimus), an inhibitor of the mammalian target of rapamycin (mTOR), is an effective immunosuppressant for the prevention of transplant rejection, with benefits as a treatment for KS. Dual inhibition of PI3Kα and mTOR by PI-103 appears promising.

Course

Classic KS progresses slowly, with rare lymph node or visceral involvement. Death usually occurs years later from unrelated causes. African cutaneous KS is aggressive, with early nodal involvement, and death from KS is expected within 1–2 years. AIDS-related KS, although widespread, is almost never fatal; almost all patients die of intercurrent infection. The course of the disease is variable in patients who develop immunosuppression-related KS from causes other than AIDS. Removal of the immunosuppression may result in resolution of the KS without therapy. Among transplant patients, a change from a calcineurin inhibitor to sirolimus often results in regression of KS lesions. KS-associated immune reconstitution syndrome can run a severe course with lung involvement and thrombocytopenia associated with worse outcomes.

Atypical Vascular Lesion

Atypical vascular lesion (AVL) occurs after mastectomy and radiation. Staghorn-like, thin-walled vessels are present, but endothelial atypia is minimal. Lesions may represent a precursor to malignancy. *MYC* amplification is noted in postirradiation angiosarcomas but not in primary cutaneous angiosarcoma or in other radiation-associated vascular proliferations, such as AVL.

Udager AM, et al: MYC immunohistochemistry in angiosarcoma and atypical vascular lesions. Pathology 2016; 48: 697.

Angiosarcoma

Angiosarcomas of the skin occur in four clinical settings. First and most common are those that occur in the head and neck of elderly people. The male/female ratio is 2:1. The lesion often begins as a poorly defined bluish macule that may be mistaken for a bruise. Distinguishing features are the frequent occurrence of a peripheral erythematous ring, satellite nodules, presence of intratumoral hemorrhage, and the lesion's tendency to bleed spontaneously or after minimal trauma. The tumor progressively enlarges asymmetrically, often becomes multicentric, and develops indurated bluish nodules and plaques. The sudden development of thrombocytopenia may herald metastatic disease or an enlarging primary tumor.

Fig. 28.30 Stewart-Treves syndrome.

Solid sheets of atypical epithelioid cells may be present, but more often the pattern is that of subtle infiltration in the dermis, producing the appearance of cracks between collagen bundles. The spaces are lined by hyperchromatic nuclei. Immunoperoxidase staining for endothelial markers such as ERG (an endothelial transcription factor), CD31, CD34, and *Ulex europeus* lectin aids in the diagnosis, and most malignant vascular tumors are positive for podoplanin (D2-40).

The prognosis is worse in men and those older than 70. Surgical excision, and adjuvant radiotherapy radiotherapy are the best options for limited disease. Chemotherapy and radiation therapy for extensive disease are often only palliative, especially when dealing with scalp lesions and high-grade lesions. Doxorubicin-ifosfamide chemotherapy produces a modest response rate. Paclitaxel is now often used as a first-line palliative systemic therapy, achieving an objective response rate of 56%. Pazopanib has been used for taxane-resistant disease. Sirolimus and IFN both show promise for scalp and facial angiosarcomas. Because of the multicentricity of lesions, the frequent occurrence on the face or scalp, and the rapid growth with early metastasis, death occurs in most patients within 2 years.

The second classic clinical situation in which angiosarcoma develops is in chronic lymphedematous areas, as occurs in the upper arm after mastectomy, the so-called Stewart-Treves syndrome (Fig. 28.30). This tumor appears approximately 11–12 years after surgery in an estimated 0.45% of patients. The prognosis is poor for these patients, with a mean survival of 19–31 months and 5-year survival rate of 6%–14%. Metastases to the lungs are the most frequent cause of death. Early amputation offers the best hope.

A third setting includes tumors that develop in previously irradiated sites. If the condition for which radiation therapy was given was a benign one, the average interval between radiation and development of angiosarcoma is 23 years. If the preceding illness was a malignant condition, the interval is shortened to 12 years. Again, the prognosis is poor, with survival generally between

6 months and 2 years after diagnosis. Many patients with the Stewart-Treves syndrome received radiation, and radiation may play a pathogenic role.

Angiosarcomas develop in settings other than those previously described, and this small miscellaneous subset comprises the fourth category. An angiosarcoma producing granulocyte colony-stimulating factor was associated with prominent peripheral leukocytosis.

FIBROUS TISSUE ABNORMALITIES

Keloid

A keloid is a firm, irregularly shaped, fibrous, hyperpigmented, pink or red excrescence. The growth usually arises as the result of a cut, laceration, or burn—or less often an acne pustule on the chest or upper back—and spreads beyond the limits of the original injury, often sending out clawlike (cheloid) prolongations. The overlying epidermis is smooth, glossy, and thinned from pressure. The early, growing lesion is red and tender and has the consistency of rubber. It is often surrounded by an erythematous halo, and the keloid may be telangiectatic. Lesions may be tender, painful, and pruritic and may rarely ulcerate or develop draining sinus tracts.

Keloids are often multiple (Fig. 28.31). They may be as tiny as pinheads or as large as an orange. Those that follow burns and scalds are large. Lesions are often linear, frequently having bulbous expansions at each end. The surface may be larger than the base, so that the edges are overhanging. The most common location is the sternal region, but keloids also occur frequently on the neck, ears, extremities, or trunk and rarely on the face, palms, or soles. The earlobes are often involved as a result of ear piercing, but involvement of the central face is rare. Keloids are much more common and grow to larger dimensions in black persons than others.

Why certain individuals develop keloids remains unsolved. Trauma is usually the immediate causative factor, but this induces keloids only in those with a predisposition for their development. There is also a regional predisposition.

Fig. 28.31 Extensive keloids.

Histologically, a keloid is a dense and sharply defined nodular growth of myofibroblasts and collagen with a whorl-like arrangement resembling hypertrophic scar. Centrally, thick hyalinized bundles of collagen are present and distinguish keloids from hypertrophic scars. Elastic tissue is scanty, as in a scar. Through pressure, the tumor causes thinning of the normal papillary dermis and atrophy of adjacent appendages, which it pushes aside. Mucopolysaccharides are increased, and often there are numerous mast cells.

Keloids are usually distinctive. They may be distinguished from hypertrophic scars by their clawlike projections, which are absent in the hypertrophic scar; the extension of the keloid beyond the confines of the original injury; and the presence of thick, hyalinized collagen bundles histologically. Frequently, spontaneous improvement of the hypertrophic scar occurs over months, but not in the keloid. Atypical lesions should be biopsied because carcinoma en cuirasse may mimic keloid.

Initial treatment is usually by means of intralesional injection of triamcinolone suspension alone or in combination with 5-fluorouracil (5-FU), methotrexate, verapamil, and/or long-pulsed Nd:YAG laser or light-emitting diode. Using a 30-gauge needle on a 1-mL tuberculin Luer syringe, triamcinolone suspension is injected into various parts of the lesion; 40 mg/mL is generally used for initial treatment, although as the lesion softens, 10–20 mg/mL may be sufficient to produce involution with less risk of surrounding hypopigmentation and atrophy related to lymphatic spread of the corticosteroid. Injections are repeated at intervals of 6–8 weeks, as required. Flattening and cessation of itching are reliably achieved by this approach and in some cases may even be achieved with topical corticosteroids. The lesions are never made narrower, however, and hyperpigmentation generally persists. 5-FU can produce responses in refractory keloids but is associated with a somewhat higher risk of hyperpigmentation, pain, and ulceration after injection. Bleomycin is being investigated alone and in combination with triamcinolone. Transforming growth factor (TGF)–β is known to be involved in keloid formation, and triamcinolone acetonide–induced decreases in cellular proliferation and collagen production are associated with a statistically significant decrease in the level of TGF-β1 in both normal and keloid fibroblast cell lines. Anti–TGF-β1 therapy looks promising, as does nuclear factor (NF)–κB inhibition and green tea polyphenol epigallocatechin-3-gallate.

Other approaches to treatment include flashlamp pulsed dye laser treatment, which is also associated with reduced expression of TGF-β1. Cryosurgery (including contact, intralesional needle cryoprobe, and spray), intralesional etanercept, and calcium channel blockers have some demonstrated efficacy in the treatment of keloids. Fibroblasts derived from the central part of keloids grow faster than peripheral keloid and nonkeloid fibroblasts. Verapamil has been shown to decrease interleukin-6 (IL-6) and VEGF in these cultured cells and to inhibit cell growth.

If surgical removal by excision is feasible, and if narrowing of the keloid is a vitally important goal, the keloid may be excised. After the excision, intralesional injection of triamcinolone or IFN alfa-2b may be combined with postoperative irradiation or topical application of imiquimod. Silicone sheeting, gel, and pressure are other adjunctive methods used to limit recurrences. Results with these modalities have been mixed, and a Cochrane review concluded that the quality of evidence supporting silicone sheeting is generally poor. Keloids demonstrate an increased number of mast cells, and silicone gel–sheet treatment has been shown to reduce lesional mast cell numbers and decrease itching. Banding at the base of the keloid with a suture ligature for 5 weeks has been used successfully to treat pedunculated lesions.

Pierced-ear keloids occur with considerable frequency. When the keloid is young, intralesional injection of triamcinolone is frequently sufficient to control the problem. In old keloids, excision of the

lesion using lidocaine with triamcinolone, followed by injections at 2-week intervals, produces good results. CO_2 laser excision has also been successful in old, mature keloids in this site.

Dupuytren Contracture

Dupuytren contracture is a fibromatosis of the palmar aponeurosis. The lesion arises most frequently in men between ages 30 and 50 as multiple firm nodules in the palm. Usually, three to five nodules about 1 cm in diameter develop, proximal to the fourth finger. Later, the fibromatosis produces contractures, which may be disabling. The condition occurs at times with alcoholic cirrhosis, diabetes mellitus, muscular dystrophy, and chronic epilepsy. It is also associated with Peyronie disease, plantar fibromatosis, and knuckle pads. In some cases there is a familial predisposition. The fibrous nodules are composed of myofibroblasts that express androgen receptors. 5α-Dihydrotestosterone induces an increase in Dupuytren fibroblast proliferation. In contrast to deep fibromatoses, which behave more aggressively, superficial fibromatoses lack β-catenin and adenomatous polyposis coli (APC) gene mutations.

Early disease may respond well to intralesional triamcinolone, collagenase, or percutaneous needle fasciotomy, but surgical excision of the involved palmar fascia may be the only way to liberate severely contracted fingers. Androgen blockade represents a potential avenue of pharmacologic therapy. As with keloids, TGF-β2 inhibition appears promising.

Plantar Fibromatosis

The plantar analog of Dupuytren contracture, plantar fibromatosis (Ledderhose disease), occurs as slowly enlarging nodules on the soles that ultimately cause difficulty in walking or even weight bearing. The diagnosis is usually made clinically, but both biopsy and MRI can be used to confirm the diagnosis. The usual surgical treatment is wide excision of the plantar fascia. Subtotal excision is associated with a high rate of recurrence. Although adjuvant radiotherapy is effective in decreasing the recurrence rate, it has a significant complication rate, with functional impairment. As with other forms of fibromatosis, intralesional injection of triamcinolone acetonide or collagenase may represent nonsurgical alternatives.

Peyronie Disease

Plastic induration of the penis is a fibrous infiltration of the intercavernous septum of the penis. This fibrosis results in the formation of nodules or plaques. As a result of these plaques, a fibrous chordee is produced, and curvature of the penis occurs on erection, sometimes so severe as to make intromission difficult or impossible. In some patients, pain may be severe. The association of Peyronie disease with Dupuytren contracture has been recognized.

Injection of IFN alfa-2b, verapamil, or collagenase has been used. Intralesional triamcinolone suspension injected or iontophoresed into the plaques and nodules has shown mixed results. Oral therapies include tocopherol (vitamin E), para-aminobenzoate, colchicine, tamoxifen, and acetyl-L-carnitine, but data supporting oral therapy are weak. Surgical correction tailored to the degree of deformity is often successful. Extracorporeal shock wave therapy may reduce penile pain but may worsen curvature.

Lauritzson A, Atroshi I: Collagenase injections for Dupuytren's disease. BMJ Open 2017; 7: e012943.

Lipofibromatosis

Lipofibromatosis is a rare tumor of infancy that typically presents as a poorly demarcated, slow-growing soft tissue mass on an extremity. It is sometimes associated with other defects, such as syndactyly, cleft lip and palate, trigonocephaly, and atrial septal defect. Histologically, mature fat is separated by collagenous septa containing fibroblasts and myofibroblasts. A subtle honeycomb pattern of fibrosis may be noted at the edge of the fat lobule.

Boos MD, et al: Lipofibromatosis. Pediatr Dermatol 2014; 31: 298.

Knuckle Pads

Knuckle pads (heloderma) are well-defined, round, plaquelike, fibrous thickenings that develop on the extensor aspects of the proximal interphalangeal joints of the toes and fingers (Fig. 28.32), including the thumbs. They develop at any age and grow to about 10–15 mm in diameter over a few weeks or months, then persist permanently. They are flesh colored or somewhat brown, with normal or slightly hyperkeratotic epidermis overlying and adherent to them. They are a part of the skin and are freely movable over underlying structures.

Knuckle pads are sometimes associated with Dupuytren contracture, clubbing, or camptodactylia (irreducible flexion contracture of one or more fingers). Some cases are familial, and some are related to trauma or frequent knuckle cracking. Autosomal dominant associations of knuckle pads, mixed hearing loss, keratoderma, and leukonychia have been reported, including Bart-Pumphrey syndrome (*GJB2* mutations). Knuckle pads have also been associated with autosomal dominant epidermolytic palmoplantar keratoderma with a mutation in keratin 9.

Histologically, the lesions are fibromas. They are differentiated clinically from the nodular type of neurodermatitis and from the small, hemispheric pitted papules that may develop over the knuckles after frostbite or in acrocyanosis, and from rheumatic nodules. Treatment with intralesional injection of corticosteroids may be beneficial. As with keloids, intralesional 5-FU may be beneficial.

Fig. 28.32 Knuckle pads. (Courtesy Curt Samlaska, MD.)

Luber AJ, et al: Characterization of knuckle (Garrod) pads using optical coherence tomography in vivo. Cutis 2015; 96: E10.

Pachydermodactyly

Pachydermodactyly represents a benign fibromatosis of the fingers. There is a fullness of the medial and lateral digit just proximal to the proximal interphalangeal joint. This asymptomatic process most often is first noted in adolescence and usually involves multiple fingers. It can be misdiagnosed as juvenile idiopathic arthritis. Five types have been described: classic, localized, transgrediens (abnormality extends to metacarpophalangeal areas), familial, and pachydermodactyly associated with tuberous sclerosis. Some cases may result from repetitive ticlike obsessive-compulsive behaviors. Increased collagen or mucin accounts for the swelling. Patients with pachydermodactyly associated with repetitive tics respond to treatment for the obsessive-compulsive disorder.

El-Hallak M, et al: Pachydermodactyly mimicking juvenile idiopathic arthritis. Arthritis Rheum 2013; 65: 2736.

Desmoid Tumor

Desmoid tumors occur as large, deep-seated, well-circumscribed masses arising from the muscular aponeurosis. They most frequently occur on the abdominal wall, especially in women during or soon after pregnancy. Desmoid tumors have been divided into five types: abdominal wall, extraabdominal, intraabdominal, multiple, and those occurring in Gardner syndrome/familial adenomatous polyposis. They recur locally and can kill if they invade, surround, or compress vital structures. The most dangerous desmoid tumors are therefore those at the root of the neck and the intraabdominal type. MRI will aid in the evaluation of soft tissue extension and recurrence after treatment. Mutations in the β-catenin gene correlate with local recurrence. Treatment may be with wide local excision, radiotherapy, or hormonal manipulation. High-dose tamoxifen in combination with sulindac has been effective. Mesenteric desmoid tumors have been treated with antiangiogenic therapy with toremifene and IFN alfa-2b. Imatinib mesylate appears promising.

Skubitz KM: Biology and treatment of aggressive fibromatosis or desmoid tumor. Mayo Clin Proc 2017; 92: 947.

Collagenous Fibroma (Desmoplastic Fibroblastoma)

This slow-growing, deep-set, benign fibrous tumor is usually located in the deep subcutis, fascia, aponeurosis, or skeletal muscle of the extremities, limb girdles, or head and neck regions, including mucosa. It is characterized by hypocellularity and dense bands of hyalinized collagen that may infiltrate into skeletal muscle. Despite this, recurrence is unlikely after excision. Chromosomal translocation (2; 11)(q31; q12) and trisomy 8 have been reported. Tumor cells stain for vimentin and may stain for actin, but have been negative for CD34, S-100 protein, keratin, CD68, desmin, and β-catenin.

Pereira TD, et al: Desmoplastic fibroblastoma (collagenous fibroma) of the oral cavity. J Clin Exp Dent 2016 Feb 1; 8: e89.

Aponeurotic Fibroma

Aponeurotic fibroma has also been called juvenile aponeurotic fibroma (calcifying fibroma). It is a tumor-like proliferation characterized by the appearance of slow-growing, cystlike masses that occur on the limbs, especially the hands and feet. Histologically, the distinctive lesions are sharply demarcated and composed of collagenous stroma showing acid mucopolysaccharides infiltrated by plump mesenchymal cells with oval nuclei. Hyalinized areas are also present, suggesting chondroid or osteoid metaplasia. An aid to the diagnosis is stippled calcification, readily seen on radiographs. Surgical excision is the treatment of choice and can be guided by MRI.

Shim SW, et al: MRI features of calcifying aponeurotic fibroma in the upper arm. Skeletal Radiol 2016; 45: 1139.

Infantile Myofibromatosis

Infantile myofibromatosis is the most common fibrous tumor of infancy. Eighty percent of patients have solitary lesions, with half of these occurring on the head and neck. About 60% are present at or soon after birth.

Congenital generalized fibromatosis is an uncommon condition that presents at birth or soon after. It is characterized by multiple, firm, dermal and subcutaneous nodules. Skeletal lesions, primarily of the metaphyseal regions of the long bones, occur in 50% of patients. If only the skin and bones develop fibromas, the prognosis is excellent, with spontaneous resolution of the lesions and with no complications expected in the first 1–2 years of life. Some refer to this limited disease as "congenital multiple fibromatosis." Females more frequently contract the generalized disease.

The fibromas may involve the viscera, including the GI tract, breast, lungs, liver, pancreas, tongue, serosal surfaces, lymph nodes, or kidney. Autosomal dominant inheritance has been reported, and mutations in *PDGFRB* and *NOTCH3* have been described. Histologically, fascicles of spindle cells occur in a whorled pattern. These nodules are composed of myofibroblasts.

Mortality rate in the more widespread subset is high; 80% die of obstruction or compression of vital organs. Patients who survive past 4 months have spontaneous regression of their disease. Translocation-associated cases may respond to tyrosine kinase inhibitors imatinib and sunitinib with or without low-dose chemotherapy.

Diffuse Infantile Fibromatosis

This process occurs within the first 3 years of life and is usually confined to the muscles of the arms, neck, and shoulder area. There is multicentric infiltration of muscle fibers with fibroblasts resembling those in aponeurotic fibromas. Calcification does not occur. Recurrence after excision occurs in about one third of patients.

Aggressive Infantile Fibromatosis

The clinical presentation of this locally recurring, nonmetastasizing lesion involves single or multiple, fast-growing masses that are present at birth or that occur within the first year of life. Infantile fibromatosis may be seen in any location, although the arms, legs, and trunk are the usual sites. Histologically, it is hypercellular and mimics malignancy.

Mota F, et al: Infantile myofibromatosis—a clinical and pathological diagnostic challenge. Dermatol Online J 2017; 23.

Murray N, et al: The spectrum of infantile myofibromatosis includes both non-penetrance and adult recurrence. Eur J Med Genet 2017; 60: 353.

Hyaline Fibromatosis Syndrome (Juvenile Hyaline Fibromatosis and Infantile Systemic Hyalinosis)

Juvenile hyaline fibromatosis and infantile systemic hyalinosis are allelic autosomal recessive conditions characterized by multiple subcutaneous skin nodules, hyaline deposition, gingival hypertrophy, osteolytic bone lesions, and joint contractures. Nodular tumors of the scalp, face, and extremities usually appear in early childhood. Pink confluent papules may occur on the paranasal folds, periauricular area (Fig. 28.33), and perianal region. The gene has been mapped to chromosome 4q21 and the anthrax toxin receptor 2 gene *(ANTXR2)*. Histologically, fibroblasts with fine, intracytoplasmic eosinophilic granules are embedded in a homogeneous eosinophilic dermal ground substance. Ultrastructurally, the fibroblasts demonstrate defective synthesis of collagen, deposited as fibrillogranular material.

Fig. 28.33 Juvenile hyaline fibromatosis.

Baltacioglu E, et al: Juvenile hyaline fibromatosis. Indian J Dermatol 2017; 62: 210.

Infantile Digital Fibromatosis (Infantile Digital Myofibroblastoma, Inclusion Body Fibroma)

Infantile digital fibromatosis is a rare neoplasm of infancy and childhood that usually occurs on the dorsal or lateral aspects of the distal phalanges of the toes and fingers. The thumb and great toe are usually spared. These asymptomatic, firm, red, smooth nodules occur during the first year of life, 47% in the first month. Rare congenital lesions have been noted. The lesions do not metastasize but may infiltrate deeply. Histologically, the epidermis is normal, but the dermis is infiltrated with proliferating myofibroblasts and collagen bundles. Eosinophilic cytoplasmic inclusions in many of the fibroblasts are characteristic. Treatment by surgical excision has a high risk of recurrence, and conservative, nonsurgical management is often appropriate. Spontaneous regression is generally noted, but the lesion may cause functional impairment and may infiltrate deeply before regression occurs. Mohs micrographic surgery has been performed successfully using both trichrome staining and smooth muscle actin staining to demonstrate the inclusion bodies within tumor cells.

Marks E, et al: Infantile digital fibroma. Arch Pathol Lab Med 2016; 140: 1153.

Fibrous Hamartoma of Infancy

Fibrous hamartoma of infancy is a single dermal or subcutaneous firm nodule of the upper trunk that is present at birth or shortly thereafter. Overlying skin changes are uncommon but may include increased hair, alteration in pigmentation, and eccrine gland hyperplasia with hyperhidrosis. Most cases are solitary, but multiple tumors have been reported; 91% of lesions are noted within the first year of life, and 23% are congenital. The male/female ratio is 2.4:1. Most lesions occur in the axillary region, upper arm, upper trunk, inguinal region, and external genital area. An association with Williams syndrome has been reported. Biopsy shows an organoid pattern with different types of tissue organized in whorls or bands. In early lesions, lobules of mature fat are interspersed between myxoid and fibrous areas. Myxoid zones have primitive mesenchymal cells with stellate nuclei. Fibrosing areas demonstrate delicate collagen bundles and many elongated fibroblast nuclei. Very rarely, fibrosarcomatous features may be present. EGFR exon 20 insertion/duplication mutations have been described. The overlying skin may demonstrate abortive hair follicles, and many eccrine units may be present. Complex chromosomal translocations have been reported. Over time, both the myxoid and the fibrosing areas develop into cell-poor fibrous areas with thick collagen bundles. There is no recurrence after excision.

Al-Ibraheemi A, et al: Fibrous hamartoma of infancy. Mod Pathol 2017; 30: 474.

Park JY, et al: EGFR exon 20 insertion/duplication mutations characterize fibrous hamartoma of infancy. Am J Surg Pathol 2016; 40: 1713.

Fibromatosis Colli

In fibromatosis colli, there is a fibrous tissue proliferation infiltrating the lower third of the sternocleidomastoid muscle at birth. Fine-needle aspiration is useful to confirm the diagnosis. Spontaneous remission occurs within a few months. Occasionally, some patients are left with a wryneck deformity; however, this complication is amenable to surgery.

Fig. 28.34 Giant cell tumor of the tendon sheath.

Tenosynovial Giant Cell Tumor (Giant Cell Tumor of the Tendon Sheath and Pigmented Villonodular Tenosynovitis)

This giant cell tumor is most frequently attached to the tendons of the fingers (Fig. 28.34), hands, and wrists and has a predilection for the flexor surfaces. It is firm, 1–3 cm in diameter, and does not spontaneously involute. It recurs after excision in approximately 25% of cases. Fibroma of the tendon sheath represents a variant of the giant cell tumor that lacks giant cells. The fibroma tends to occur more in younger men (average age at onset 30) than the giant cell variety. When a proliferation similar to giant cell tumor of the tendon sheath occurs in deeper tissues, it is referred to as pigmented villonodular tenosynovitis. The pigment is hemosiderin.

Histologically, the giant cell tumor consists of lobules of densely hyalinized collagen. The characteristic osteoclast-like giant cells have deeply eosinophilic cytoplasm that molds to adjacent cells. Oval gray fibroblast nuclei are present throughout the lesion. Lipophages and siderophages may be numerous, and hemosiderin deposition may impart a brown color to the lesions on gross examination. The fibroma of the tendon sheath generally lacks lipophages and siderophages as well as giant cells, with the lobules composed of dense, fibrocollagenous tissue with oval gray fibroblast nuclei.

The rate of recurrence depends on the presence or absence of a pseudocapsule, lobulation of the tumor, extraarticular location, and presence of satellite lesions. Local recurrence has been treated with more extensive surgery, and imaging studies can define the extent of the tumor. Radiation therapy has been reported anecdotally.

Gouin F, et al: Localized and diffuse forms of tenosynovial giant cell tumor (formerly giant cell tumor of the tendon sheath and pigmented villonodular synovitis). Orthop Traumatol Surg Res 2017; 103: S91.

Ainhum

Ainhum is also known as dactylolysis spontanea, bankokerend, and sukhapakla. It is a disease affecting the toes, especially the fifth toe, characterized by a linear constriction around the affected digit that ultimately leads to the spontaneous amputation of the distal part. It occurs chiefly among black men in Africa. Usually, ainhum is unilateral but may be bilateral.

The disease begins with a transverse groove in the skin on the flexor surface of the toe, usually beneath the first interphalangeal articulation. The furrow is produced by a ringlike fibrosis and an induration of the dermis. It deepens and extends laterally around the toe until the two ends meet, so that the digit becomes constricted, as if in a ligature. The constricted part becomes swollen, soft, and after a time, greatly distended. Ulceration may result in a malodorous discharge, with pain and gangrene. The course of the disease is slow, but in 5–10 years, spontaneous amputation occurs, generally at a joint.

The cause is unknown. The condition may result from chronic trauma and exposure to the elements by walking barefoot in the tropics. Fissuring followed by chronic inflammation and fibrosis may then result.

Treatment in early cases by cutting the constricting band is unsuccessful. In advanced cases, amputation of the affected member is advisable. Surgical correction by Z-plasty has produced good results. Intralesional injection of betamethasone (15 injections total) has also been successful.

Pseudoainhum

Pseudoainhum has been a term used in connection with certain hereditary and nonhereditary diseases in which annular constriction of digits occurs. Hereditary disorders include hereditary palmoplantar keratodermas, especially Vohwinkel syndrome and mal de Meleda, pachyonychia congenita, Ehlers-Danlos syndrome, erythropoietic protoporphyria, and keratoderma with universal atrichia. Nonhereditary disorders associated with constriction of digits include ainhum, Hansen disease, cholera, ancylostomiasis, scleroderma, Raynaud syndrome, pityriasis rubra pilaris, psoriasis, Olmsted syndrome, Reynold syndrome (scleroderma and primary biliary cirrhosis with antimitochondrial antibodies), syringomyelia, ergot poisoning, gout, and spinal cord tumors. Factitial pseudoainhum may be produced by self-application of a rubber band, string, or other ligature. Congenital cases have been reported that may affect digits or limbs. Pseudoainhum may occur as a familial condition or may be secondary to amniotic bands. Treatment includes surgery or intralesional injection of corticosteroids, as in ainhum. Retinoids may be used in responsive diseases.

Connective Tissue Nevi

Connective tissue nevi are uncommon lesions that may present as acquired isolated plaques, as multiple lesions (acquired or congenital), or as one finding in a more generalized disease. Biopsy findings include abnormal collagen bundles and altered amounts elastin. These lesions characteristically occur on the trunk, most often in the lumbosacral area (Fig. 28.35). Although solitary lesions occur, they are often multiple and may show a linear or zosteriform arrangement. Individual lesions are slightly elevated plaques 1–15 cm in diameter, varying in color from light yellow to orange, with a surface texture resembling shagreen leather. In Proteus syndrome, the connective tissue nevi are present as plantar, or occasionally palmar, masses with a cerebriform surface. Connective tissue nevi of the acquired type have been classified as eruptive collagenomas, isolated collagenomas, or isolated elastomas, depending on the number of lesions and the predominant dermal fibers present. They cannot be differentiated clinically.

Hereditary types of connective tissue nevi include dermatofibrosis lenticularis disseminata in the Buschke-Ollendorff syndrome, familial cutaneous collagenoma, and the shagreen patches seen in tuberous sclerosis. Buschke-Ollendorff syndrome is an autosomal dominant inherited disorder in which widespread dermal papules and plaques develop asymmetrically over the trunk and limbs. Elastic fiber thickening, highly variable fiber diameter, and desmosine increases threefold to sevenfold above normal have been described in these patients. The associated feature of osteopoikilosis is asymptomatic but is diagnostic of the syndrome in x-ray evaluation. Focal sclerotic densities are seen, primarily in the long

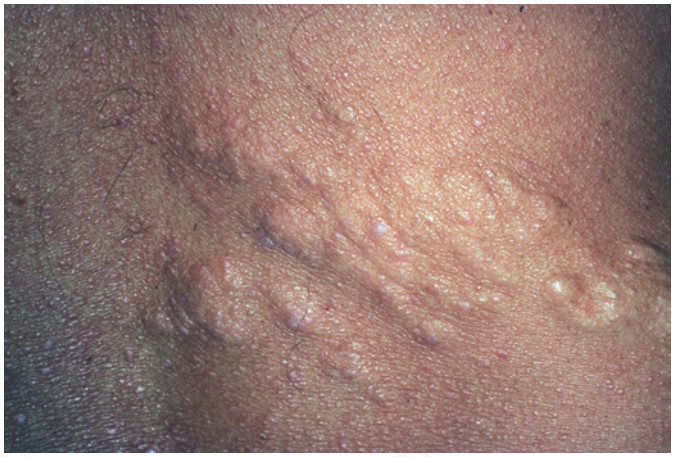

Fig. 28.35 Connective tissue nevus.

bones, pelvis, and hands. Buschke-Ollendorff syndrome is highly variable, and familial inheritance of elastic tissue nevi without evidence of osteopoikilosis has been reported.

Papular elastorrhexis is characterized by multiple white, evenly scattered papules, usually occurring on the trunk. Elastic fibers are decreased and may appear thin and fragmented. Most reported cases are sporadic, but familial occurrence has been described.

Patients with familial cutaneous collagenomas may present with numerous symmetric, asymptomatic dermal nodules on the back. The age of onset is usually in the middle to late teens. In patients with the inherited disease, multiple endocrine neoplasia type I (MEN-I) multiple collagenomas were reported in 23 of 32 patients. These were less than 3 mm in diameter and were on the upper torso, neck, and shoulders. They occurred in association with many other cutaneous findings, including angiofibromas, café au lait macules, and lipomas. Atrioseptal defect has also been reported in association with familial collagenomas.

The collagenomas of tuberous sclerosis are associated with adenoma sebaceum, periungual fibromas, and ash-leaf macules. Because at least half the cases of tuberous sclerosis result from new mutations, all patients with connective tissue nevi should be carefully studied for evidence of tuberous sclerosis, even in the absence of a family history of the disease. Isolated plantar collagenoma may exhibit a cerebriform appearance and resemble plantar fibromas of Proteus syndrome.

Eruptive collagenomas may be widespread or localized. Mucinous nevus is a form of connective tissue nevus characterized by increased ground substance without increases in collagen or elastin. Histologically, collagen bundles are widely separated by mucin and may be attenuated. Overlying follicular induction similar to that seen in dermatofibromas may be present. Both eruptive collagenoma and mucinous nevus have been described as a manifestation of syphilis.

Batra P, et al: Eruptive collagenomas. Dermatol Online J 2010; 16: 3.

McCuaig CC, et al: Connective tissue nevi in children. J Am Acad Dermatol 2012; 67: 890.

Elastofibroma Dorsi

Elastofibroma dorsi is a benign tumor usually located in the deep soft tissues in the subscapular region, but sometimes at other sites. The tumor is firm and unencapsulated and measures up to several centimeters in diameter. It is believed to represent an unusual response to repeated trauma. Histologically, the tumor consists of abundant compact sclerotic collagen mixed with large, swollen, irregular elastic fibers, often appearing as globules of elastic tissue. It usually appears on nuclear medicine scans, suggesting it is not as uncommon as once believed. CT and MRI can define the extent of the lesion, and excision is curative.

Fig. 28.36 Fibrous papule of the nose. (Courtesy Curt Samlaska, MD.)

Deveci MA, et al: Elastofibroma dorsi. Acta Orthop Traumatol Turc 2017; 51: 7.

Angiofibromas

These skin-colored to reddish papules show fibroplasia and varying degrees of vascular proliferation in the upper dermis. Angiofibromas may occur as a solitary nonhereditary form, the fibrous papule of the nose; as multiple nonhereditary lesions, the pearly penile papules; or as multiple hereditary forms, as in tuberous sclerosis, Birt-Hogg-Dube syndrome (in combination with the specific lesion, the fibrofolliculoma), and MEN-I. Reports of agminated or segmental angiofibromas may represent a segmental form of tuberous sclerosis. The multiple hereditary types may respond to rapamycin and are discussed in other chapters.

Cellular angiofibroma typically occurs in the genital region of older women. It consists of small spindle cells arranged in short fascicles and relatively abundant, small, rounded vessels. Cellular angiofibromas may express estrogen and progesterone receptors as well as CD34.

Fibrous Papule of Nose (Fibrous Papule of Face, Benign Solitary Fibrous Papule)

These lesions occur in adults as dome-shaped, sessile, skin-colored, white or reddish papules, 3–6 mm in diameter, on or near the nose (Fig. 28.36). Fibrous papule is usually solitary, but a few lesions can occur. It may be confused with a nevocytic nevus, neurofibroma, granuloma pyogenicum, or a basal cell carcinoma. As with other angiofibromas, fibrous papules demonstrate concentric fibrosis surrounding vessels and adnexal structures. Stellate dermal dendrocytes are often prominent. Clear cell, granular, and epithelioid variants have been described. They stain for factor XIIIa. Large, pyramidal, junctional melanocytes are often noted overlying

the lesion, and a superficial shave biopsy may be mistaken for a melanocytic lesion. Conservative excision is curative; recurrence is rare. Multiple lesions should prompt a search for other stigmata of tuberous sclerosis.

Pearly Penile Papules

This is the term given to pearly-white, dome-shaped angiofibromas occurring circumferentially on the coronal margin and sulcus of the glans penis. The lesions may be firm or soft and filiform. Occasionally, lesions are also present on the penile shaft. Pearly penile papules are not uncommon. Patients usually present at age 20–30, concerned that these are condylomata, or are referred as having treatment-resistant venereal warts. These lesions should be distinguished from papillomas, hypertrophic sebaceous glands, and condyloma acuminatum. No treatment is necessary, only reassurance. If treatment is desired, laser ablation or shave excision is effective.

Acral Fibrokeratoma

Acral fibrokeratoma, often called acquired digital fibrokeratoma, is characterized by a pinkish, hyperkeratotic, hornlike projection occurring on a finger, toe, palm, or sole. The projection usually emerges from a collarette of elevated skin. The average age of the patient is 40. The lesion resembles a rudimentary supernumerary digit, cutaneous horn, or neuroma. Onset during immunosuppressive therapy has been reported, and grouped lesions may occur. Multiple periungual lesions are associated with tuberous sclerosis.

Histologic sections show a central core of thick collagen bundles interwoven closely in a vertical position. This is surrounded by capillaries and a fine network of reticulum fibers. Stellate dermal dendrocytes may be present, as in fibrous papule. Simple surgical excision or laser ablation at the level of the skin surface is effective. The term *acquired reactive digital fibroma* has been proposed for a unique form of posttraumatic dermal nodular fibrous proliferation present on the digits. The lesions are composed of haphazard fascicles of spindle cells that express vimentin and occasionally CD34.

Marchini M, et al: Tuberous sclerosis complex. N Engl J Med 2017; 376: e42.

Wheless JW, et al: A novel topical rapamycin cream for the treatment of facial angiofibromas in tuberous sclerosis complex. J Child Neurol 2013; 28: 933.

Familial Myxovascular Fibromas

Multiple verrucous papules on the palms and fingers have been described that on biopsy show focal neovascularization and mucin-like changes in the papillary dermis. Clinically, these lesions closely resemble warts. They have been reported in several family members, with a probable autosomal dominant inheritance.

Superficial Acral Fibromyxoma (Digital Fibromyxoma)

Superficial acral fibromyxoma typically appears in the superficial soft tissues of the acral extremity of an adult. Most are painless. Histologically, they are characterized by a moderately cellular proliferation of bland, spindled and stellate fibroblasts with a loose storiform or fascicular growth pattern. Mucin and small blood vessels are prominent. Spindle cells typically express CD34, CD99, and epithelial membrane antigen. CD10 and nestin expression have also been reported. Conventional and Mohs excision have been used.

Hankinson A, et al: Superficial acral fibromyxoma (digital fibromyxoma). Dermatol Surg 2016; 42: 897.

Subungual Exostosis

Subungual exostosis is closely related to solitary osteochondroma, and both are found beneath the distal edge of the nail, most frequently of the great toe. Rarely, the terminal phalanges of other toes, particularly the little toe, or even the fingers, may be involved. The exostosis is seen mainly in women between ages 12 and 30. The first appearance is a small pinkish growth projecting slightly beyond the inner free edge of the nail. The overlying nail becomes brittle and either breaks or is removed, after which the tumor, being released, mushrooms upward and distally above the level of the nail. It grows slowly to a maximum diameter of about 8 mm. Pressure of the shoe on the lesion causes great pain.

Subungual exostosis must be differentiated from pyogenic granuloma, verruca vulgaris, pterygium inverum unguis, ingrowing nail, and glomus tumor. If subungual exostosis is suspected, the diagnosis can be confirmed by radiographic examination. Complete excision or curettage is the proper method of treatment. Secondary intention healing is generally good. Vacuum-assisted closure has been used for large wounds.

Russell JD, et al: Subungual exostosis. Cutis 2016; 98: 128.

Chondrodermatitis Nodularis Chronica Helicis

This small, nodular, tender, chronic inflammatory lesion occurs on the helix of the ear. Most patients are men. The lesions are not uncommon, and sometimes as many as 12 nodules may arrange themselves along the edge of the upper helix. The lesions are 2–4 mm in diameter, well defined, slightly reddish, and extremely tender. At times, the surface is covered by an adherent scale or a shallow ulcer. After the masses have reached a certain size, growth ceases, but the lesions persist unchanged for years. There is no tendency to malignant change. Similar lesions may occur on the anthelix, predominantly in women.

Chondrodermatitis nodularis chronica helicis is produced by ischemic necrosis of the dermis and generally occurs on the side the patient favors during sleep. The patient may have a history of frostbite, chronic trauma, or chronic actinic exposure with concomitant actinically induced lesions of the face and dorsal hands.

Histologically, a zone of eosinophilic necrosis of collagen is flanked by granulation tissue. Overlying acanthosis and hyperkeratosis and central ulceration may be present. The histologic changes resemble those of a decubitus ulcer, but on a smaller scale. Occasionally, bizarre reactive fibroblasts are noted, as in atypical decubital fibroplasia.

Topical nitroglycerin is effective in some patients with chondrodermatitis nodularis chronica helicis, and pressure-induced ischemia can be reduced with the use of a self-adhering foam before sleep. Refractory lesions may be removed by shave technique, or the underlying cartilage may be excised or fenestrated to reduce pressure on the overlying skin during sleep. Photodynamic therapy has also been used. The patient may be encouraged to change sleeping positions, but many find this difficult. Pillows with an ear slot are also available.

Shah S, Fiala KH: Chondrodermatitis nodularis helicis. Dermatol Ther 2017; 30.

Oral Submucous Fibrosis

A distinctive fibrosis of the oral mucosa has become common in the western Pacific basin and South Asia among persons whose diet is heavily seasoned with chili or who chew betel, a compound of the nut of the areca palm, the leaf of the betel pepper, and lime.

Fig. 28.37 Oral submucous fibrosis. (Courtesy Dr. Shyam Verma.)

Fig. 28.38 Dermatofibroma. (Courtesy Dr. Lawrence Lieblich.)

The irritation produced first causes a thickening of the palate, tonsillar pillars, and fauces secondary to dermal and muscular fibrosis (Fig. 28.37). As the disease progresses, opening of the mouth and protrusion of the tongue develop, such that eating, swallowing, and speech are impaired. Later, ulceration and leukoplakic areas occur, and finally, in approximately 7% of patients, malignant transformation to squamous cell carcinoma (SCC) develops. Treatment consists of the intralesional injection of triamcinolone or dexamethasone alone or with hyaluronidase or the antioxidant spirulina. In advanced cases, surgical excision and grafting or laser ablation has been used. Discontinuance of the offending substance and physical therapy are also needed.

Arakeri G, et al: Oral submucous fibrosis. J Oral Pathol Med 2017; 46: 413.

Fascial Hernia

Evanescent herniations in the form of nodules appear in the skin where the deep and superficial veins meet as they go through the fascia. These herniated nodules, seen most frequently on the lower extremities, become prominent when the underlying muscles contract, and pain may occur with prolonged exertion. Treatment is not indicated unless the area is chronically painful. Light compression may be effective.

Perineal Skin Tag (Infantile Perianal Pyramidal Protrusion)

Perineal skin tags may be congenital or acquired. They are generally asymptomatic but may require surgical intervention if inflamed or traumatized. A similar appearance may occur as a manifestation of lichen sclerosus.

Cutaneous Pseudosarcomatous Polyp and Umbilical Polyp

Cutaneous pseudosarcomatous polyps and umbilical pseudosarcomatous polyps are benign proliferations with a taglike configuration but also dramatic cytologic atypia and pleomorphism. The cells stain positive for vimentin and variably for CD34 and factor XIIIa. Their clinical behavior is benign.

Acrochordon (Fibroepithelial Papilloma, Skin Tag)

Small, flesh-colored to dark-brown, pinhead-sized and larger, sessile and pedunculated papillomas commonly occur on the neck, often in association with small seborrheic keratoses. These tags are also seen frequently in the axillae and on the eyelids and less often on the trunk and groins, where the soft, pedunculated growths often hang on thin stalks. These flesh-colored, teardrop-shaped tags feel like small bags. Occasionally, as a result of twisting of the pedicle, one will become inflamed, tender, and even gangrenous. Both genders have the same incidence, with almost 60% of individuals acquiring acrochordons by age 69. Skin tags often increase in number when the patient is gaining weight or during pregnancy and may be related to the growth hormone–like activity of insulin. They may be associated with diabetes mellitus. In patients preselected for GI complaints, skin tags appear to be more prevalent in those with colonic polyps. This association has not been proved for the general population.

Histologically, acrochordons are characterized by epidermis enclosing a dermal fibrovascular stalk. Smaller lesions often demonstrate seborrheic keratosis–like acanthosis and horn cysts.

Small lesions can be clipped off at the base with little or no anesthesia. Aluminum chloride may be applied for hemostasis if needed. Light electrodesiccation can also be effective. For larger lesions, anesthesia and snip excision are preferred.

An entity that is frequently reported as perianal acrochordons or skinfolds has now been named infantile perianal pyramidal protrusions. This occurs in young children, usually girls, in the midline anterior to the anus. It reduces with time, and no treatment is necessary. Child abuse, genital warts, hemorrhoids, granulomatous lesions of inflammatory bowel disease, or rectal prolapse must be considered in the differential diagnosis of these lesions.

Skin tag–like basal cell carcinomas in childhood should suggest a diagnosis of nevoid basal cell carcinoma syndrome (NBCCS). Biopsy should be performed on acrochordons in children because the lesions are uncommon in this age group and may be the presenting sign of NBCCS.

Dermatofibroma (Fibrous Histiocytoma)

This common skin lesion's appearance is usually sufficiently characteristic to permit clinical diagnosis. Dermatofibroma is generally a single, round or ovoid papule or nodule, about 0.5–1 cm in diameter, that is reddish brown, sometimes with a yellowish hue (Fig. 28.38). The sharply circumscribed nodule is more evident on palpation than expected from inspection. The larger lesions may present an abrupt elevation at the border to form an exteriorized tumor resting on a sessile base.

Dermatofibroma may be elevated or slightly depressed. The hard lesion is adherent to the overlying epidermis, which may be thinner from pressure or even indented, so that there is a dell-like

depression over the nodule. In such cases only the depression is seen, but on palpation the true nature of the lesion is found. Fitzpatrick proposed the term *dimple sign* for the depression created over a dermatofibroma when it is grasped gently between thumb and forefinger.

Dermatofibromas seldom occur in children and are encountered mostly in middle-aged adults. Their size generally varies from 4–20 mm, although giant lesions greater than 5 cm occur. After they reach this size, growth ceases, and the harmless lump remains stationary. The principal locations are on the lower extremities, above the elbows, or on the sides of the trunk. Systemic lupus erythematosus, treatment with prednisone or immunosuppressive drugs, chronic myelogenous leukemia, and HIV infection have been associated with the development of multiple dermatofibromas. It is suspected that many dermatofibromas are initiated by injuries to the skin, such as insect bites or blunt trauma.

Histologic examination reveals a dermal mass composed of close whorls of fibrous tissue in which there are numerous spindle or histiocytic cells. The cells have features of fibroblasts and myofibroblasts but are probably of primitive mesenchymal origin. Immunohistochemical studies show that most cells are positive for factor XIIIa and CD10, and negative for MAC387, S-100, and CD34. The tumor is not well circumscribed and may extend into adjacent structures and surround individual collagen bundles at the periphery (collagen trapping). Overlying acanthosis is typical, and induction of primitive epithelial germs or mature follicular structures may be noted. Basal cell carcinoma–like changes often overlie dermatofibromas, but true basal cell carcinoma is quite rare.

At times, large histiocytic cells within the lesion are strikingly atypical ("monster cells"). Occasionally, granular cytoplasm may predominate. Hemosiderin may be present, and foam cells and lipid deposits may be seen. The presence of Touton giant cells containing hemosiderin is pathognomonic of dermatofibroma. There is a great variation in the vascular components. Rarely, the vascularization is pronounced and suggests a form of hemangioma (sclerosing hemangioma). Deep, penetrating dermatofibromas may grow into the subcutaneous tissue through the fibrous septa or with a pushing front of tumor. They lack the extensive lacy and lamellar infiltrative growth pattern of dermatofibrosarcoma protuberans. Deep, fascial, fibrous histiocytomas may involve the fat or muscle at times. Signet ring and plaque-type variants have been described. A pigmented variant has shown histologic overlap with Bednar tumor (pigmented dermatofibrosarcoma protuberans). The lesion stained positive for CD34, a marker usually absent in dermatofibromas.

The clinical appearance of the lesion and its location, chiefly on the lower extremities, are distinctive. Clinically, granular cell tumor, dermatofibrosis lenticularis disseminata, clear cell acanthoma, and melanoma are some of the lesions to be considered. At times, only a biopsy can differentiate these. Progressive enlargement beyond 2 or 3 cm in diameter suggests a malignant fibrous histiocytoma or dermatofibrosarcoma protuberans, and excisional biopsy is indicated.

These lesions usually are asymptomatic and do not require treatment. Involution may occur after many years if the lesion is left alone. Simple reassurance is suggested.

Epithelioid Cell Histiocytoma

Usually solitary but occasionally multiple, these lesions appear as dome-shaped papules composed of bland epithelioid cells. These histiocytomas typically stain for factor XIIIa, and many consider them to be closely related to dermatofibromas.

Dermal Dendrocyte Hamartoma

Dendrocyte hamartoma presents as a rounded, medallion-like lesion on the upper trunk; it is composed of fusiform CD34-positive, factor XIIIa-negative cells in the middle and reticular dermis. The lesions are asymptomatic, brown or erythematous in color, and may have a slightly atrophic, wrinkled surface (Fig. 28.39). The major differential diagnosis is congenital atrophic dermatofibrosarcoma protuberans (DFSP), but to date there has been no evidence of chromosomal abnormalities, such as the t(17; 22)(q22; q13) translocation with the DFSP fusion gene *COL1A1-PDGFB*.

Fig. 28.39 Dermal dendrocyte hamartoma.

Nodular Fasciitis (Nodular Pseudosarcomatous Fasciitis)

Also known as subcutaneous pseudosarcomatous fibromatosis, this benign mesenchymal neoplasm occurs most often on the arms. Clinically, a firm, solitary, sometimes tender nodule develops in the deep fascia and often extends into the subcutaneous tissue. It usually measures 1–4 cm in diameter. The lesion appears suddenly over a few weeks, without apparent cause, in normal, healthy persons. Gender distribution is equal, and the average age at onset is 40.

Microscopic findings consist of well-defined, loose nodules of stellate and spindled cells that may have a myxoid "tissue culture" appearance. Capillary proliferation is typical, and erythrocyte extravasation between spindle cells is common. Nodular lymphoid infiltrates are often noted within the lesion. On electron microscopic examination, the component cells in the neoplasm have proved to be myofibroblasts. A characteristic t(17; 22)(p13; q13), balanced translocation has been described resulting in *MYH9-USP6* gene fusion.

Dermal, intravascular, and infiltrative variants with ganglionlike cells (proliferative fasciitis) have been described. These are designated when the nodular masses arise in the dermis, in intimate association with blood vessels, or show ganglionlike giant cells and infiltration of collagen. Some lesions respond to intralesional triamcinolone and do not require excision. Recurrence is rare, and the prognosis is excellent. Cranial fasciitis of childhood is an uncommon variant of nodular fasciitis, manifesting as a rapidly enlarging mass in the subcutaneous tissue of the scalp, which may invade the cranium. It occurs in infants and children, resembles nodular fasciitis histologically, and usually does not recur after surgical excision. Some lesions have demonstrated dysregulation of the Wnt/β-catenin pathway.

Proliferative fasciitis and proliferative myositis are closely related entities. Proliferative fasciitis demonstrates irregular extension

into the fibrous septa with collagen trapping and ganglionlike nuclei. Proliferative myositis has a similar appearance but extends into adjacent muscle.

Pseudosarcomatous ischemic fasciitis (atypical decubital fibroplasia) is a manifestation of pressure-induced necrosis. The histologic appearance is similar to that of chondrodermatitis nodularis of the ear, only on a much larger scale. A wide zone of fibrinoid necrosis is bordered by granulation tissue and large, atypical fibroblast nuclei that resemble radiation fibroblasts.

Oh BH, et al: Treatment of nodular fasciitis occurring on the face. Ann Dermatol 2015; 27: 694.

Solitary Fibrous Tumor

Solitary fibrous tumors occur in the mediastinum but may also be found in many other parts of the body. They have a diffuse, "patternless" growth pattern and stain strongly positive for CD34. Some express progesterone receptor. Their behavior is unpredictable, and complete excision is recommended. Spindle cell lipomas with few or no lipocytes ("low-fat" and "nonfat" spindle cell lipomas) may be misinterpreted as solitary fibrous tumors because they are also CD34 positive.

Kim JM, et al: Comparison and evaluation of risk factors for meningeal, pleural, and extrapleural solitary fibrous tumors. Pathol Res Pract 2017; 213: 619.

Plexiform Fibrohistiocytic Tumor

The rare plexiform fibrohistiocytic tumor arises primarily on the upper extremities of children and young adults. There is a strong female predisposition. It presents as a slowly growing, painless growth in the subcutaneous tissue. There is usually extension into the dermis or the underlying skeletal muscle. Histologically, it is a distinctly biphasic tumor, with a fibroblastic component mixed with aggregates of mononuclear histiocyte-like cells and multinucleated osteoclast-like cells. The multinucleated cells label for vimentin and CD68, whereas the spindle cells express smooth muscle actin but not factor XIIIa. There is considerable histologic overlap with cellular neurothekeoma. Both tumors are uniformly positive for NKIC3 and CD10. MiTF is strongly and diffusely positive in cellular neurothekeoma but negative in the plexiform fibrohistiocytic tumor, suggesting that the two are distinct. Although most patients are cured with excisional surgery, some tumors will recur locally, and infrequently, regional and systemic metastases can occur.

Lynnhtun K, et al: Plexiform fibrohistiocytic tumour. Histopathology 2012; 60: 1156.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is characterized by bulky, protuberant, neoplastic masses. Between 50% and 60% occur on the trunk, with less common involvement of the proximal extremities and the head and neck. The disease begins with one or multiple elevated, erythematous, firm nodules or plaques, often associated with a purulent exudate or with ulceration. Patients, usually middle-age, complain of a firm, painless lump in the skin that has been slowly increasing in size for several years. The course is slowly progressive, with pain becoming prominent as the lesion grows, and frequent recurrence after initial conservative surgical intervention (Fig. 28.40). In untreated patients, severe pain and contractures may result. There is minimal tendency to metastasize, although wide dissemination has been reported.

Histologically, DFSP shows a subepidermal fibrotic plaque with uniform spindle cells and variable vascular spaces. In many

Fig. 28.40 Recurrent dermatofibrosarcoma protuberans.

cases, there is a pronounced matlike woven pattern of spindle cells. Cytogenetic studies typically demonstrate a t(17; 22)(22; q13) fusion involving the *COL1A1* gene on chromosome 17 and the *PDGFB* gene on chromosome 22. Giant cells may be present in small numbers. Pigmented DFSPs, in which the cells contain melanin, predominantly affect persons of color and are called Bednar tumors. CD34 and nestin positivity are characteristic and serve as markers to distinguish DFSP from dermatofibroma. Nestin expression correlates with the degree of invasion. S-100 is negative and may be used to separate spindle cell melanoma from a Bednar tumor. Recurrent DFSP can be myxoid and resembles the diffuse type of neurofibroma histologically. A juvenile variant, called giant cell fibroblastoma, is characterized by a loose arrangement of spindle cells and by multinucleated giant cells adjacent to dilated spaces that resemble dilated lymphatic vessels.

The differential diagnosis, especially in the early stage, is that of keloid, large dermatofibroma, or medallion-like dermal dendrocytoma. CD34+ myxoid dermatofibrohistiocytoma of the skin occurs as an indolent posttraumatic tumor. It resembles myxoid DFSP.

Mohs surgical excision technique is the treatment of choice for DFSP. In a series of 50 patients, recurrence rate was 2%; with wide local excision, recurrence is 11%–50%. A preoperative MRI may assist in planning successful clearance. Radiation has been used as adjunctive therapy and imatinib mesylate has been effective in some unresectable tumors.

Li Y, et al: Clinical features, pathological findings and treatment of recurrent dermatofibrosarcoma protuberans. J Cancer 2017; 8: 1319.

Thway K, et al: Dermatofibrosarcoma protuberans. Ann Diagn Pathol 2016; 25: 64.

Atypical Fibroxanthoma

Atypical fibroxanthoma (AFX) of the skin is a low-grade malignancy that occurs chiefly on the sun-exposed parts of the head or neck in white persons over age 50. Most cases appear to be related to undifferentiated pleomorphic sarcoma (UPS) (malignant fibrous histiocytoma), which AFX resembles histologically. Its smaller size and more superficial location account largely for its more favorable prognosis. Some cases probably represent spindled or anaplastic SCC that has lost the ability to express keratin. Clinically, the tumor begins as a small, firm nodule, often with an eroded or crusted surface without characteristic morphologic features (Fig. 28.41). A distinct clinical variant has a different

Fig. 28.41 Atypical fibroxanthoma. (Courtesy Chris Miller, MD.)

presentation as a slowly enlarging tumor on a covered area, in patients with an average age of 39. This variant accounts for 25% of cases.

The lesion develops in the dermis and is separated from the epidermis by a thin band of collagen. The tumor consists of bizarre spindle cells mingled with atypical histiocytic cells. The cytoplasm may be vacuolated and resembles the xanthoma cell. Mitotic figures, prominent eosinophilic nucleoli, and the presence of a biphasic tumor cell population are characteristic findings, but purely spindle cell variants also occur. S-100 staining decorates colonizing dendritic cells, but not the tumor cells, and prekeratin staining is negative; this helps distinguish AFX from SCC. Variants with clear cells, granular cells, and osteoclast-type cells have been described. Tumor cells stain for CD10, S-100A6, and procollagen I, but none of these markers is specific for AFX.

The treatment of choice is complete surgical excision. Mohs microsurgery results in fewer recurrences and smaller defects than conventional excision. Although the prognosis is excellent, local recurrence after inadequate excision is common, and cases of metastasizing AFX have been reported.

Hanlon A, et al: LN2, CD10, and ezrin do not distinguish between atypical fibroxanthoma and undifferentiated pleomorphic sarcoma or predict clinical outcome. Dermatol Surg 2017; 43: 431.

Undifferentiated Pleomorphic Sarcoma (Malignant Fibrous Histiocytoma)

The undifferentiated pleomorphic type is the most common soft tissue sarcoma of middle and late adulthood. It arises deeply and is more likely to appear in deep fascial planes than in subcutaneous tissue. One third occur on the thigh or buttock. Peak incidence is in the seventh decade. These sarcomas sometimes arise in an area of radiodermatitis or in a chronic ulceration.

Several histologic variants have been described, including myxoid, inflammatory, and giant cell types. Gene expression profiling is now being used to define subtypes of pleomorphic sarcoma. Cell staining is positive for vimentin and factor XIIIa. Pleomorphic cellular elements and bizarre mitotic figures are characteristic. AFXs are smaller and more superficial tumors of the dermis, compared with the deeper location of UPS. Epithelioid sarcoma lacks the large, bizarre, multinucleated cells often seen in UPS.

Fig. 28.42 Epithelial sarcoma.

The prognosis in UPS is related to the site; deeper and more proximally located tumors have a poorer prognosis. The myxoid variant is less likely to metastasize. An especially poor prognosis attends tumors arising in sites of radiodermatitis. Local recurrence after excision occurs in 25%, 35% metastasize, and overall survival is 50%. Mohs surgical removal may result in fewer recurrences.

The angiomatoid type may have a different presentation on the extremities of children, as a slowly growing dermal or subcutaneous mass. It has been separated because it has a relatively good prognosis.

Cutaneous Myxofibrosarcoma

Myxofibrosarcoma is the term used for myxoid variants of UPS. The diagnosis of cutaneous myxofibrosarcoma is often delayed because the tumor may appear indolent clinically and may mimic an interstitial granuloma histologically. Areas of atypical spindle cells within a prominent myxoid stroma and pleomorphic multinucleated cells suggest the diagnosis. The main differential diagnosis is myxoid liposarcoma. The margins are often poorly defined, and preoperative MRI can be helpful in surgical planning.

Pasquali S, et al: Neoadjuvant chemotherapy in soft tissue sarcomas. Ther Adv Med Oncol 2017; 9: 415.

Epithelioid Sarcoma

Epithelioid sarcoma occurs chiefly in young adults, with onset usually from ages 20–40. Two thirds of cases are in men. Almost all lesions are on the extremities, with half on the hands or wrists (Fig. 28.42). They have been reported from a wide variety of locations, however, including the genital region ("proximal type").

The tumor grows slowly among fascial structures and tendons, often with central necrosis of the tumor nodules and ulceration of the overlying skin. Initial clinical diagnoses may include granuloma annulare, rheumatoid nodule, or ganglion cyst. Histologically, irregular nodular masses of large, deeply acidophilic, polygonal cells merge with spindle cells in a biphasic pattern. Central necrosis within masses of epithelioid cells may give the impression of a palisaded granuloma. Absence of staining for CD68 (KP-1) and coexpression of keratins and vimentin confirm the diagnosis. Loss of INI1 expression is also helpful diagnostically, but has no prognostic implications.

Wide local excision of small, early lesions may achieve a cure. Recurrence after attempted excision is seen in three of four patients, and late metastasis in 45%. There is a propensity for lymph node and lung metastases, and in one series of eight patients, 5-year and 10-year survival rates of 25% were reported. Women have a

Fig. 28.43 Carney syndrome.

more favorable prognosis; the proximal lesions have a worse prognosis.

Chbani L, et al: Epithelioid sarcoma. Am J Clin Pathol 2009; 131: 222.

Myxomas

Cutaneous myxomas may be solitary and may appear as flesh-colored nodules on the face, trunk, or extremities. They may also occur as part of Carney complex. This has also been reported under the acronyms NAME (nevi, atrial myxoma, myxoid neurofibromas, ephelides) and LAMB (lentigines, atrial myxoma, mucocutaneous myxomas, blue nevi) and simply as cutaneous lentiginosis with atrial myxoma.

The Carney complex consists of patients who have two or more of the following:

1. Cardiac myxomas (79%)
2. Cutaneous myxomas (not myxoid neurofibromas) (45%)
3. Mammary myxoid fibromas (30%)
4. Spotty mucocutaneous pigmentation, including lentiginoses (not ephelides) and blue nevi, often of a distinctive epithelioid variety (65%)
5. Adrenocortical adenoma/primary pigmented nodular adrenocortical disease (45%), which results in Cushing syndrome
6. Testicular tumors (56% of male patients)
7. Pituitary growth hormone–secreting tumors (10%).

A peculiar type of schwannoma featuring melanin and psammoma bodies may also be present.

The cutaneous myxomas occur as small (<1 cm), multiple, skin-colored papules with a predilection for development by a mean age of 18 years, and a tendency to occur on the ears, eyelids, and nipples. The lentigines are prominent on the face, lips, conjunctival mucosa, rectal mucosa, and genital mucosa (Fig. 28.43). Cardiac myxomas may occur in any of the four chambers of the heart and are recurrent in 20%. They may embolize to the skin, producing acral necrotic lesions.

Recognition of this syndrome, with diagnosis and removal of the atrial myxomas, can be lifesaving. The first-degree family members should be examined because this is an autosomal dominant inherited condition. The disease has been mapped to two loci, and a third is likely. Mutations in the gene coding for the protein kinase A type Ia regulatory subunit *(PPKAR1A)* on chromosome 17 have been documented in about half the families.

A malignant counterpart, the myxosarcoma, is a tumor that arises in the subcutaneous fat and underlying soft tissues. There is a tendency for local recurrence after wide and deep excision. Metastases are rare.

Aggressive Angiomyxoma

Aggressive angiomyxoma is an uncommon soft tissue neoplasm that usually involves the vulvoperineal and pelvic regions of young women. Any angiomyxoid tumor in this area is suspect for aggressive behavior. The tumor is mucinous and deeply infiltrative but does not demonstrate nuclear atypia or mitosis. The rate of local recurrence is high despite wide surgical resection, and MRI can be helpful in preoperative planning.

Mastocytosis

Mastocytosis is a general term applied to local and systemic accumulations of mast cells. Mast cells are bone marrow–derived CD34+ cells. These cells carry preformed mediators, such as histamine, heparin, and various cytokines, which, when released, may cause symptoms such as flushing, urticaria, diarrhea, abdominal pain, headache, dyspnea, syncope, and palpitations.

Mastocytosis is divided into childhood-onset and adult-onset disease. The condition varies in these two age-groups in terms of clinical presentation, prognosis, and pathogenic factors. Studies have revealed mutations in the *c-KIT* proto-oncogene in many adult-onset cases. Its protein product is the transmembrane tyrosine kinase KIT receptor (CD117), whose ligand is stem cell factor (also known as mast cell growth factor). Both clonality studies and mutational analysis indicate that many adult cases of mastocytosis result from a neoplastic proliferation of mast cells, with a mutation at codon 816 in the *c-KIT* gene. This mutation is activating, resulting in the proliferation of mast cells. A second mutation, a chromosomal deletion on 4q12, results in the juxtaposition of platelet-derived growth factor receptor-α and FIP1L1. This fusion gene activates hematopoietic cells and is pathogenic in a subset of patients with systemic mastocytosis (SM) and eosinophilia. This subset of patients has also been considered as having a type of "hypereosinophilic syndrome." Thus the vast majority of adults with mastocytosis have systemic disease that may be viewed as a fundamentally myelodysplastic disorder.

Children often do not express any *c-KIT* mutation; nor do the uncommon familial cases. The disease in the latter is usually transmitted by autosomal dominant inheritance with reduced expressivity, although other patterns may occur. The mutations leading to familial disease have not been defined. It appears that spontaneous childhood disease may occur from cytokine-derived hyperplasias, from mutations other than the activating 816 type, or from mutations yet to be described. Some pediatric cases, however, are known to have inactivating mutations of *c-KIT*, and a few have the adult-type activating mutations. Childhood disease is defined as occurring before age 15. The majority of children develop their disease before age 2, and in most of them, the condition spontaneously involutes.

Clinical Classification

Mast cell disease is divided into two broad categories—cutaneous and systemic. Cutaneous mastocytosis describes cases with involvement of only the skin and includes most cases of childhood mastocytosis and infrequent adult cases. Childhood cases usually fall into one of three categories of cutaneous mastocytosis. The most common (60%–80% of patients) is urticaria pigmentosa or so-called "maculopapular" cutaneous mastocytosis; fewer (10%–35%) patients present with solitary mastocytosis; the remainder have the rare forms of diffuse cutaneous mastocytosis or the telangiectatic type. A classification has been proposed by Akin and Metcalfe, which incorporates the World Health Organization (WHO) criteria (Box 28.1).

BOX 28.1 Classification of Mastocytosis

CUTANEOUS AND SYSTEMIC MASTOCYTOSIS

1. Indolent systemic mastocytosis (ISM)
   - Isolated bone marrow mastocytosis
   - Smoldering systemic mastocytosis (SSM)
2. Systemic mastocytosis with associated hematopoietic disease (SM-AHD, AHNMD [*associated* hematologic non–mast cell disorder]): systemic mastocytosis with leukemia, myelodysplastic syndrome/disease, or non-Hodgkin lymphoma
3. Aggressive systemic mastocytosis (ASM)
4. Mast cell leukemia
5. Mast cell sarcoma
6. Extracutaneous mastocytoma

Fig. 28.44 Bullous mastocytosis.

The vast majority of adult patients with mastocytosis are classified as having systemic mastocytosis, because they typically have clonal proliferation of the bone marrow–derived mast cells. Of adult patients with SM not associated with hematopoietic disease, 60% have indolent mastocytosis and 40% have aggressive mastocytosis. Patients with aggressive SM usually lack skin lesions. Mast cell leukemia and sarcoma are very rare. Many patients who present to the dermatologist with only skin lesions will have the indolent variety. Symptoms and signs of systemic disease are classified as those related to organ infiltration by mast cells and those caused by mediator release from mast cells. Direct organ involvement is most frequently bone pain from lytic bone lesions, hepatosplenomegaly, lymphadenopathy, or cytopenia from bone marrow involvement. For the dermatologist, the most important symptoms are those related to mediator release, usually acting on the GI tract, respiratory tree, or blood vessels. These include pruritus, flushing, urticaria, angioedema, headache, nausea, vomiting, abdominal cramps, diarrhea, gastric/duodenal ulcer, malabsorption, asthma-like symptoms, presyncope, syncope, and anaphylaxis. These may occur spontaneously or may result from massive histamine release after ingestion of known mast cell degranulators, such as alcohol, morphine, codeine, or extended rubbing of the skin. *Hymenoptera* stings may induce anaphylaxis. Mast cells also produce heparin, which may result in hematemesis, epistaxis, melena, and ecchymoses. Osteoporosis may also occur from chronic heparin release, resulting in fractures.

Cutaneous Mastocytosis

Cutaneous mastocytosis is relatively common, representing about 1 in 500 initial consultations to pediatric dermatologists.

Solitary Mastocytoma

About 10%–40% of childhood mastocytosis presents as the solitary lesion, which may be present at birth or may develop during the first weeks of life. It originates as a brown macule that urticates on stroking. It may develop into a papule, a raised round or oval plaque, or a tumor. The size is usually less than 1 cm, but occasionally it may reach two or three times this diameter. The surface is usually smooth but may have a peau d'orange appearance. Although the mastocytoma may occur anywhere on the body, it favors the dorsum of the hand near the wrist. Edema, urtication, vesiculation, and even bulla formation may be observed in the lesion. Even a solitary lesion may produce systemic symptoms, usually flushing.

Although the generalized form may begin with a single lesion, dissemination usually occurs within 3 months of its appearance. Most solitary mastocytomas involute spontaneously by age 10 or earlier. They also respond favorably to excision or to the application of a hydrocolloid dressing to prevent the rubbing that triggers mediator release and symptomatology. Progression to malignant disease does not occur.

Generalized Eruption, Childhood Type (Urticaria Pigmentosa)

The generalized form of cutaneous mastocytosis represents 60%–90% of childhood cases. In this type the eruption usually begins during the first weeks of life, presenting with rose-colored, pruritic, urticarial, slightly pigmented macules, papules, or nodules. The lesions are oval or round and vary in diameter between 5 and 15 mm and may coalesce. The color varies from yellowish brown to yellowish red. Occasionally, the lesions are a pale-yellow color, and this has been called xanthelasmoidea. Vesicle and bulla formation is a frequent prominent feature early in the disease (Fig. 28.44). Indeed, vesicles and bullae may be the initial presenting signs, but they usually persist no longer than 3 years. In the older age-groups, vesiculation rarely occurs.

At their onset, lesions are similar to urticaria, except that they are not evanescent. The lesions persist and gradually become chamois or slate colored (Fig. 28.45). When they are firmly stroked or vigorously rubbed, urticaria with a surrounding erythematous flare (Darier sign) usually develops. Dermatographism of clinically uninvolved skin is present in one third to one half of patients. For many years, the brown, waxy skin lesions may persist before they begin to involute. Pigmentation and all evidence of the disease usually disappear within a few years, generally before puberty. The eruption, however, may infrequently persist into adult life. Although systemic involvement is possible, malignant systemic disease is extremely rare.

Diffuse Cutaneous Mastocytosis

In this rare form with diffuse involvement, the entire integument may be thickened and infiltrated with mast cells to produce a peculiar orange color, giving rise to the term *homme orange*. There is an infiltrated doughy or boggy consistency to the skin, and lichenification may be present. In the neonatal period, diffuse cutaneous blistering may occur, leading to the diagnosis of epidermolysis bullosa or some other primary bullous disorder. This is termed *bullous mastocytosis*.

Systemic Mastocytosis

SM is diagnosed by fulfilling the one major criterion and one minor criterion, or three minor criteria. The major criterion is the finding of dense infiltrates of mast cells (aggregates of 15 or more) in bone marrow or other extracutaneous tissues. The four minor criteria are as follows:

Fig. 28.45 Urticaria pigmentosa.

Fig. 28.46 Mastocytosis.

1. Atypical mast cell morphology
2. Aberrant mast cell surface phenotype (CD25 or CD2)
3. Serum/plasma tryptase greater than 20 ng/mL
4. A codon 816 *c-KIT* mutation in peripheral blood, bone marrow, or lesional tissue

Patients with a history of *Hymenoptera*-induced anaphylaxis and an elevated tryptase level should be evaluated for systemic mastocytosis.

The most common type of SM in adults is indolent systemic mastocytosis. These patients lack evidence of an associated non–mast cell hematologic disorder; lack end-organ dysfunction such as ascites, malabsorption, cytopenias, and pathologic fractures; and lack mast cell leukemia. The disorder is then diagnosed through physical and histopathologic examination of skin lesions. Several different patterns of cutaneous involvement have been described.

Generalized Eruption, Adult Type

The generalized eruption is the most common pattern of mastocytosis presenting to the dermatologist. The most common lesions are macules, papules, or nodules disseminated over most of the body, but especially on the upper arms, legs, and trunk. The upper arms and upper inner thighs may be the only areas involved on presentation. These may be reddish purple (Fig. 28.46), rust colored, or brown. The brown lesions may closely resemble common nevi. They may urticate on rubbing, as seen in children with urticaria pigmentosa.

Erythrodermic Mastocytosis

There is generalized erythroderma, and the skin has a leather-grain appearance. Urtication can be produced over the entire surface.

Telangiectasia Macularis Eruptiva Perstans

This is a persistent, pigmented, asymptomatic eruption of macules usually less than 0.5 cm in diameter, with a slightly reddish brown tinge. Despite the name, little or no telangiectasia may evident. Darier sign may not be demonstrable, because the number of mast cells in the skin may not be greatly increased.

Classification and Prognosis in Adult Systemic Mastocytosis

The 2008 WHO classification includes indolent SM, aggressive SM, SM associated with a clonal non–mast cell lineage disease, and mast cell leukemia. Patients with SM with an associated hematologic non–mast cell lineage disorder (SM-AHNMD) are typically older adults with signs and symptoms of systemic disease. A variety of associated non–mast cell hematologic conditions, including polycythemia vera, hypereosinophilic syndrome, chronic myelogenous or monocytic leukemia, lymphocytic leukemia, primary myelofibrosis, and Hodgkin disease, may be seen. Typically, this type does not have skin lesions. The prognosis in these patients is that of their underlying hematologic condition. Smoldering SM is characterized by a slow progression and lack of end-organ dysfunction from mast cell infiltration. It describes patients with 30% or more infiltration of the bone marrow cavity by mast cells, a serum tryptase level greater than 200 ng/mL, and hepatosplenomegaly. Aggressive SM has a more fulminant course and describes the condition of patients with end-organ dysfunction caused by mast cell infiltration: bone marrow failure, liver dysfunction, splenomegaly with hypersplenism, pathologic fractures, and GI involvement with malabsorption and weight loss. This group of patients has a poor prognosis. Mast cell leukemia occurs when the atypical mast cells (multilobular or multiple nuclei) represent 10% of circulating cells or 20% of bone marrow cells. The prognosis is poor.

Mast Cell Sarcoma and Extracutaneous Mastocytoma

These are rare findings of isolated tumors of either atypical mast cells in mast cell sarcoma or benign-appearing mast cells in extracutaneous mastocytoma. They occur in sites other than the skin or bone marrow. Mast cell sarcomas are aggressive, locally destructive lesions, in contrast to the benign mastocytomas, which carry a good prognosis.

Biochemical Studies

Mast cells produce tryptase. Serum tryptase has become the preferred laboratory test to demonstrate evidence of increased mast cell burden, replacing urinary histamine and urinary histamine

metabolites. The test is of prognostic significance in some patients. Tryptase is measured as a total serum tryptase level. This should be obtained when the patient is in a normal state of health, because anaphylaxis will increase tryptase transiently. Mastocytosis patients may have a persistently and significantly elevated tryptase level. Results above 20 ng/mL are a minor criterion for the diagnosis of systemic mastocytosis.

Histopathology

The typical skin lesion shows a dense dermal aggregate of mononuclear cells with abundant amphophilic cytoplasm. When these large mononuclear cells are stained with Giemsa or toluidine blue, the metachromatic granules are observed. A Leder stain will stain the cells diffusely red. When blisters are present, the roof of the vesicle or bulla is subepidermal. The mast cells collect in a band below the vesicle. Infiltration of local anesthetic adjacent to the lesion rather than directly into it and the use of anesthetic without epinephrine may help to avoid mast cell degranulation. Monoclonal antibodies against tryptase and CD117 (KIT) are available and are very sensitive.

Diagnosis

The typical case of cutaneous mastocytosis is easily diagnosed by the presence of solitary or multiple pigmented macules, papules, or nodules that urticate when irritated by stroking or scratching. The diagnosis is confirmed by biopsy of the lesion with demonstration of increased numbers of mast cells. The bullous and vesicular lesions may be more difficult to diagnose clinically; however, scrapings from the base of the bulla when stained with Giemsa or Wright stain will show mast cells in profusion.

Once the diagnosis of skin lesions of mastocytosis is made, the decision to assess for bone marrow involvement is key. Although therapy to reduce the disease burden of proliferating clonal mast cells is not effective, bone marrow examination will provide information about the extent of the disease and the presence or absence of a non–mast cell hematologic disorder, and it will assist in the counseling on prognosis. All adult patients and children with the unexplained presence of an abnormal complete blood cell count (CBC), hepatomegaly, splenomegaly, lymphadenopathy, or serum baseline tryptase of greater than 20 ng/mL should be offered a bone marrow examination. Both serum tryptase levels and markers of bone turnover, including C-telopeptide and osteoprotegerin, are associated with extent of disease.

In asymptomatic adults whose only sign or symptom of mastocytosis is skin lesions, and who choose not to have a bone marrow examination, serum tryptase and CBC should be repeated at least yearly during a complete history and physical examination. Elevation of the tryptase level, a drop in the platelet count or hemoglobin, a rise in the monocytes, or the onset of organomegaly should trigger a bone marrow examination. In children with early-onset disease, the prognosis is good; usually, tryptase evaluation or mutational analysis is reserved for those with the findings just listed, or with persistent localized bone pain, severe GI symptoms, or biochemical evidence of hepatic insufficiency.

Differential Diagnosis. Clinically, a small solitary mastocytoma most frequently resembles a pigmented nevus or juvenile xanthogranuloma. Urtication establishes the diagnosis. The disseminated lesions are also distinctive enough to cause little or no difficulty in the diagnosis. The nodular form may resemble xanthomas; however, the presence of urtication is distinctive. The vesicular and bullous lesions are to be distinguished from various hereditary and nonhereditary bullous diseases. The main histologic similarity is to Langerhans cell histiocytosis.

Prognosis

Most cases of early-onset, skin-limited disease in children clear completely. The solitary mastocytoma involutes spontaneously, usually within 3 years of onset. In children and adults with indolent systemic mastocytosis, the prognosis is also good. This is the most common category of patients presenting for diagnosis in the dermatology clinic. Patients with AHNMD have the prognosis of the associated disease. In the newly described patients with smoldering systemic mastocytosis, the prognosis is intermediate and not yet well defined. Patients with aggressive systemic mastocytosis, mast cell leukemia, or mast cell sarcoma have a poor prognosis.

Treatment

Symptomatic relief of histamine-mediated symptoms may be achieved in many cases by the use of antihistamines. Both H1 and H2 blockers and antiserotonin drugs, such as cyproheptadine, may alleviate urtication, pruritus, and flushing. Nifedipine, 10 mg three times daily, may also be effective in isolated cases. Psoralen with ultraviolet A (PUVA) or medium-dose UVA1 therapy alone produces excellent clearing of the skin in most cases. Most patients will have sustained benefit for at least 6 months after treatment. Approximately 25% will have a remission lasting longer than 5 years, and in others the frequency of phototherapy may be tapered to once or twice a month, and patients still remain clear. Intralesional triamcinolone or potent topical corticosteroids under occlusion may also clear cutaneous lesions; however, the lesions do recur after discontinuance. Also, concern about local atrophy, striae, and systemic absorption limits the utility of this treatment.

The importance of avoiding physical stimuli such as extremes of temperature, pressure/friction, and chemical degranulators of mast cells cannot be overemphasized. The application of a hydrocolloid dressing over an isolated mastocytoma in an infant may reduce the flushing it produces. The chemicals that patients with mastocytosis must avoid include opiates, aspirin, alcohol, quinine, scopolamine, gallamine, decamethonium, reserpine, amphotericin B, polymyxin B, and D-tubocurarine. *Hymenoptera* stings may induce anaphylaxis; the patient (and parents of an affected child) should be taught to recognize the signs of anaphylactic shock, given a premeasured dose of epinephrine (EpiPen) for emergency use, and educated on its use. After such an event, it is prudent to treat for several days with 20–40 mg of prednisone to avoid recurrent attacks.

Control of diarrhea in SM may be achieved by orally administered disodium cromoglycate. GI ulcers may be treated with proton pump inhibitors and H2 antagonists. The treatment of systemic mast cell disease is of limited efficacy. For patients with indolent SM and severe osteoporosis, IFN alfa may be considered. In patients with smoldering systemic mastocytosis, watchful waiting is recommended, although IFN alfa, with or without glucocorticoids, may be considered for progressive "B" findings. In aggressive systemic mastocytosis, IFN alfa may also be used, with or without glucocorticoids. 2-Chlorodeoxyadenosine (as used in Langerhans cell histiocytosis) can also be effective in aggressive systemic mastocytosis. A gain-of-function D816V point mutation in the transmembrane receptor KIT kinase domain is found in the majority of patients with systemic mastocytosis. Patients with the mutation do not generally respond to imatinib mesylate. Patients with SM who have the *FIP1L1–PDGFRA* translocation, who lack the *c-KIT* mutation, or who have novel mutations may respond to imatinib, and it may even prove helpful in patients with associated leukemia. CD1a-positive familial cutaneous mastocytosis without germline or somatic mutations in *c-KIT* has been described. Cladribine (an adenosine deaminase inhibitor) has been used successfully for cytoreductive therapy in the setting of systemic mastocytosis. Bone

marrow transplantation for the most severely affected patients with SM is being investigated.

ABNORMALITIES OF NEURAL TISSUE

Solitary Neurofibroma

The typical solitary cutaneous neurofibroma is usually 3–6 mm in diameter. It is soft, flaccid, translucent, and pinkish white. Frequently, the soft small tumor can be invaginated, as if through a ring in the skin, by pressure with the finger (this is called "buttonholing").

When only one or two lesions are present, they are typically spontaneous tumors without internal manifestations. When three or more are present, a diagnosis of neurofibromatosis should be considered. Infrequently, large pendulous masses occur, in which numerous, tortuous, thickened nerves can be felt; this has been likened to a "bag of worms." These plexiform neurofibromas, which often have overlying pigmentation, usually occur in neurofibromatosis (see Chapter 27).

Histologically, the lesion demonstrates wavy spindled nuclei and fine collagen fibers. The stroma is often myxoid and contains many mast cells. Cholinesterase activity is markedly positive in the neurofibromas; the Schwann cells are S-100 positive; neurofilament protein staining demonstrates scattered axons; and CD34 demonstrates a characteristic fingerprint pattern. Shave removal is usually adequate therapy for symptomatic lesions.

Granular Cell Tumor

About one third of reported granular cell tumors occur on the tongue (Fig. 28.47), one third involve the skin, and one third occur in the internal organs. The tumor is usually a well-circumscribed, solitary, firm nodule ranging from 5–30 mm, with a brownish red or flesh tint, depending on nearness to the surface. Its surface is often rough or verrucous, corresponding to pseudoepitheliomatous hyperplasia overlying the tumor. Rarely, the lesions may ulcerate. They are multiple in 10%–15% of cases.

Fig. 28.47 Granular cell tumor.

The solitary lesion may be located anywhere on the body, but almost half of all tumors appear on the head or neck. Usually, patients are in their third to fifth decade. About two thirds of patients are black, and two thirds are women. In most cases, the tumor grows very slowly, and when completely removed, does not usually recur. However, local or multicentric recurrence may at times cause confusion in determining whether a granular cell tumor is malignant.

The histologic picture is distinctive. The cells are large, pale, and irregularly polygonal, with a poorly defined cellular membrane, and contain coarsely granular cytoplasm with scattered giant lysosomal granules. Some of the cells are multinucleated or contain vacuoles or small pyknotic or eosinophilic inclusions. At times, the arrangement is in cords or sheets, in irregular alveolar masses, or even organoid. Pseudoepitheliomatous hyperplasia is a regular feature. The cells stain positively with vimentin, neuron-specific enolase, S-100, myelin protein, p75 nerve growth factor, calretinin, NKI/C3, and PGP9.5. Hybrid forms that overlap with perineurioma have been described.

Malignant granular cell tumor is uncommon. Most are much larger than the benign granular cell tumors, with an average diameter of 9 cm; benign lesions average less than 2 cm. Most malignant granular cell tumors demonstrate cytologic atypia, but some are quite bland cytologically. Other factors that correlate with malignant behavior are an infiltrative growth pattern, history of local recurrence, older patient age, presence of necrosis, increased mitotic activity, spindling of tumor cells, and nuclear staining with the proliferation marker Ki67 (MIB 1) in more than 10% of tumor nuclei. Mutant p53 protein has been identified in more than half of malignant granular cell tumors studied. About one third are aneuploid, one third hyperdiploid, and one third diploid. In contrast, almost all benign tumors are diploid.

Because of the difficulties in distinguishing benign from some malignant granular cell tumors, complete excision is advisable whenever possible. Malignant granular cell tumors often have an infiltrative growth pattern and perineural extension. Mohs micrographic surgery may be helpful in ensuring complete excision.

Paul SP, et al: An unusual granular cell tumour of the buttock and a review of granular cell tumours. Case Rep Dermatol Med 2013; 2013: 109308.

Perineurioma

The normal perineurium is composed of flattened cells that surround the nerve. Perineuriomas are derived from these cells. Cutaneous lesions appear as nondescript papules clinically. Sclerosing perineuriomas demonstrate concentric lamellar fibrosis and are epithelial membrane antigen (EMA) positive. Reticular, granular, and lipomatous variants have been described.

Michal M, et al: Whorling cellular perineurioma. Ann Diagn Pathol 2017; 27: 74.

Neuroma Cutis

Cutaneous neuromas include traumatic neuromas, multiple mucosal neuromas, and solitary palisaded encapsulated neuromas. Segmental neuromas have also been described.

Traumatic neuromas result from the overgrowth of nerve fibers in the severed ends of peripheral nerves. The lesion may be tender

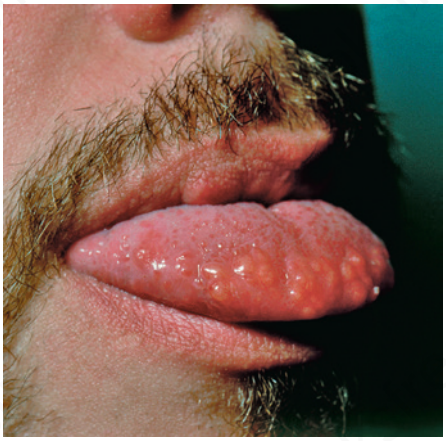

Fig. 28.48 Multiple mucosal neuromas.

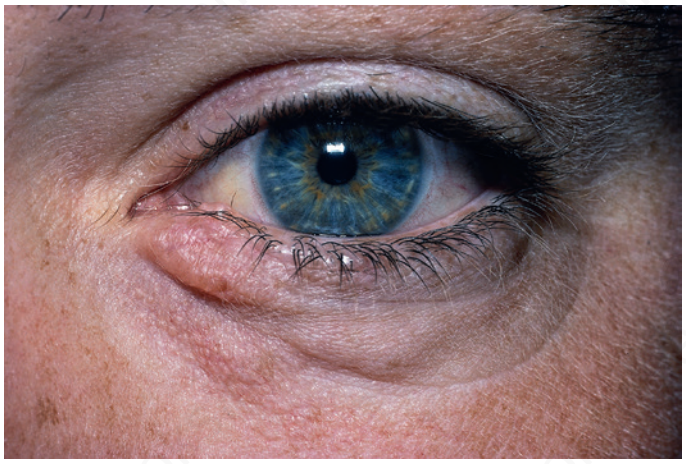

Fig. 28.49 Schwannoma. (Courtesy Dr. Curt Samlaska.)

or painful, and when scarring has occurred or the distal stump has been removed, a phantom limb syndrome may result. These often occur on the fingers, at sites of amputation of supernumerary digits, or on the sole, usually at the third metatarsal space.

Multiple mucosal neuromas occur as part of the autosomal dominant inherited, multiple mucosal neuroma syndrome (MEN-2b). These patients have a marfanoid habitus, thickened protruding lips, and multiple neuromas of the oral mucosa (lips, tongue, gingiva), conjunctiva, and sometimes sclera (Fig. 28.48). A few have multiple cutaneous neuromas, usually limited to the face. There is a strong association with medullary carcinoma of the thyroid, bilateral pheochromocytomas, and diffuse GI tract ganglioneuromatosis. Disease is caused by a mutation in the *RET* proto-oncogene. Infants at risk should be screened for this mutation and total thyroidectomy performed if positive.

The palisaded, encapsulated neuroma of the skin is a solitary, large, encapsulated tumor, usually of the face. It is a slow-growing, flesh-colored, dome-shaped, firm lesion, usually appearing around the mouth or nose. It closely resembles a basal cell carcinoma or an intradermal nevus.

Rodríguez-Peralto JL, et al: Benign cutaneous neural tumors. Semin Diagn Pathol 2013; 30: 45.

Neurothekeoma (Nerve Sheath Myxoma)

Neurothekeoma refers to a tumor of the nerve sheath and is composed of cords and nests of large cells packed among collagen bundles close to small nerves. Mitotic figures and nuclear atypia are sometimes seen, but the tumor is benign. These benign intradermal or subcutaneous tumors are divided histologically into two distinct subtypes: the classic or myxoid variant and the cellular type. An intermediate or mixed variety is also recognized. The myxoid variant (nerve sheath myxoma) is characterized by islands of stellate and spindled cells in a mucinous matrix. The cells stain strongly for S-100 protein. Myxoid neurothekeoma occurs in middle-age adults, primarily on the head, neck, and upper extremities. It is twice as common in women. The cellular type occurs in childhood, with a high female preponderance, and has a predilection for the head, neck, or shoulders. The cellular type does not stain for S-100 protein but does stain for S-100A6, PGP9.5, MiTF, and NK1C3. It is unclear if these tumors really demonstrate nerve sheath differentiation, but for now they are grouped with the myxoid neurothekeomas. Examples of cellular neurothekeoma with high mitotic rate and atypia mimic malignant spindle cell tumors. They have a significant rate of recurrence but at this point are not known to have a clear metastatic potential.

Schwannoma (Neurilemmoma)

Peripheral schwannomas are usually solitary nerve sheath tumors, most often seen in women. They occur almost exclusively in deep tissues, along the main nerve trunks of the extremities, especially the flexor surface of the arms, wrists, and knees. They are also seen on the scalp, sides of the neck, and tongue. The solitary tumor is a nodule of 3–30 mm in diameter (Fig. 28.49). It is soft or firm and pale pink or yellowish; it may or may not be painful. Schwannomas involve many other organs, and brain tumors such as meningiomas, gliomas, and astrocytomas may occur.

In some cases, the tumors are multiple, and these may be seen with neurofibromatosis type 1 (NF-1) or more often NF-2, or as an entity independent of neurofibromatosis. The independent type may be congenital or may have a delayed onset. It may be sporadic or familial. Three clinical patterns are described: elevated, dome-shaped nodules; pale-brown, indurated macules; and multiple papules coalescing into plaques 2–100 mm in diameter, with a predilection for the trunk. Cases have occurred that appeared to be unassociated with NF-2, but on further investigation of the individual or family, revealed other signs of NF-2 and the gene abnormality on chromosome 22.

Plexiform schwannomas may occur as single or multiple lesions, localized to a single anatomic site or more generalized, and arise in the dermis or subcutaneous tissue. They may occur as a solitary lesion or may be associated with NF-1, NF-2, or multiple schwannomas. Another subtype of schwannoma is the melanotic psammomatous type seen in association with Carney syndrome, featuring spotty pigmentation, myxomas, and endocrine overactivity. Plexiform melanocytic schwannoma may demonstrate mitotic figures and pleomorphic nuclei and must be differentiated from malignant melanoma. Important clues include the presence of focal Verocay bodies, as well as an EMA-positive capsule derived from perineurium.

Histologically, the classic forms are well encapsulated with characteristic subcapsular edema and two types of tissue, referred to as Antoni types A and B. Hard schwannomas are firm on gross examination and are composed of Antoni A tissue—palisades of basophilic Schwann cell nuclei separated by brightly eosinophilic zones (Verocay bodies). Soft schwannomas are diffusely edematous. They are composed mostly of Antoni B tissue, a degenerative change characterized by loose, edematous connective tissue and ectatic blood vessels. S-100, vimentin, and myelin basic protein stains are positive in hard schwannomas. Staining is variable in soft schwannomas. A Bodian or neurofilament protein stain reveals very few or no nerve fibers within the bulk of the tumor, although a compressed nerve may be present at one edge of the mass in a subcapsular location. "Ancient schwannomas" may demonstrate remarkable nuclear atypia, which represents a benign degenerative change. Mitoses are absent. Ancient schwannomas should not be confused with malignant peripheral nerve sheath tumor ("malignant schwannoma"), a tumor that arises in long-standing neurofibromas in the setting of NF-1. Excision is almost invariably curative, except in the malignant variety, for which combined wide resection and radiotherapy is needed.

Yeh I, et al: Plexiform melanocytic schwannoma. J Cutan Pathol 2012; 39: 521.

Infantile Neuroblastoma

Neuroblastoma is the most common malignant tumor of early childhood. Cutaneous nodules are most often seen in younger patients, being present in 32% of infants with the disease. These occur as multiple, 2–20 mm, firm, blue nodules that, when rubbed, blanch and form a halo of erythema. The blanching persists for 1–2 hours and is followed by a refractory period of several hours. Biopsy shows clusters of basophilic cells with a high nuclear/cytoplasmic ratio, surrounded by eosinophilic, fine fibrillar material. Elongated nuclei are often noted focally. Two other findings that may be present are periorbital ecchymoses (the so-called raccoon eyes) and heterochromia of the irises.

For infants with skin involvement, the prognosis is generally good, with either spontaneous remission or spontaneous transformation into benign ganglioneuromas expected. Prognostic factors other than age, based on molecular genetic characteristics such as the status of the oncogene *MYCN* and chromosome 1p deletion, are helping to stratify prognosis and therapeutic recommendations.

Monclair T, et al: The International Neuroblastoma Risk Group (INRG) staging system. J Clin Oncol 2009; 27: 298.

Ganglioneuroma

Ganglioneuroma has only rarely been described in the skin as an isolated entity. These tumors are composed of mature ganglion cells commingled with fascicles of spindle cells. They arise most often in von Recklinghausen neurofibromatosis or with neuroblastomas and usually occur in childhood. The tissue stains positively for both argyrophilic and argentaffin granules.

Furmanczyk PS, et al: Cutaneous ganglioneuroma associated with overlying hyperkeratotic epidermal changes. Am J Dermatopathol 2008; 30: 600.
Murphy M, et al: Cutaneous ganglioneuroma. Int J Dermatol 2007; 46: 861.

Nasal Glioma (Cephalic Brainlike Heterotopias)

Nasal gliomas are rare, benign, congenital tumors. When they occur extranasally, they are easily confused with hemangiomas. The tumor is usually a firm, incompressible (unlike hemangioma and encephalocele), reddish blue to purple lesion occurring on the nasal bridge or midline near the root (Fig. 28.50). It does not transilluminate or enlarge with crying, unlike some encephaloceles. It may also occur intranasally.

Fig. 28.50 Nasal glioma. (Courtesy Scott Bartlett, MD.)

Nasal gliomas differ from encephaloceles in that the latter are connected to the subarachnoid space by a sinus tract, whereas the former usually lose this connection before birth. Clinically, these cannot be absolutely differentiated, so a biopsy should not be performed. Skull radiographs, MRI, ultrasound, and Doppler flow studies may be performed, to help define the lesion and detect possible skull involvement. Neurosurgical consultation is advisable.

Histologically, the nodule consists of glial tissue associated with glial giant cells, fibrous tissue, and numerous blood vessels. It is unencapsulated. The lesion does not involute spontaneously.

Bellet JS: Developmental anomalies of the skin. Semin Perinatol 2013; 37: 20.
Gnagi SH, Schraff SA: Nasal obstruction in newborns. Pediatr Clin North Am 2013; 60: 903.

Cutaneous Meningioma

Primary cutaneous meningioma represents a continuum with rudimentary meningocele. It results from the presence of meningocytes outside the calvarium. If actual brain remnants are present, the lesion is called a rudimentary cephalocele. Small, hard, fibrous, calcified nodules occur along the spine, in the scalp, on the forehead, or rarely in the external ear canal. Most occur over the scalp, and some have an underlying connection to the CNS or an underlying bony abnormality. They usually come to medical attention in the first year of life. On the scalp, they may present with a dark tuft of hair or an alopecic area surrounded by a dark collar of hair (hair collar sign).

Type I lesions present at birth and develop from ectopic arachnoid cells. Type II lesions usually present in adults and demonstrate arachnoid cells surrounding nerve bundles. Type III lesions are caused by direct extension or metastasis from dural neoplasms. Cutaneous meningiomas may develop in the scalp secondary to an intracranial meningioma, either through erosion of the skull or by extension through an operative defect of the skull. Last, they may also arise from cranial or spinal nerves. Clinically, these lesions have no distinctive appearance. They are firm subcutaneous nodules adherent to the skin.

Diagnosis is made by histologic examination. The tumors consist of vascular-like anastomosing spaces with spindle cells forming whorls around collagen bundles. Lamellar, calcified psammoma bodies are often present. Psammoma bodies are not specific for

meningiomas and may also be found in intradermal nevi, juvenile xanthogranuloma, pituitary of the fetus and newborn, schwannomas associated with Carney syndrome, meninges, choroid plexus, pineal gland, papillary carcinoma of thyroid, ovarian neoplasms, and mammary intraductal papilloma. Meningiomas are usually EMA and p63 positive, creating the potential for confusion with epithelial lesions.

Fox MD, et al: Cutaneous meningioma. J Cutan Pathol 2013; 40: 891.

Encephalocele and Meningocele

Primary defects in the neural tube may lead to encephaloceles, meningoceles, or meningomyeloceles. They present in infancy along the midline of the face, scalp, neck, or back as soft, compressible masses that may transilluminate or enlarge with crying. Tufts of long, dark hair or alopecia with a surrounding collar of dark hair may overlie them.

Many cutaneous lesions of the midline of the back, most frequently at the base of the spine, suggest that malformations of the spinal cord and associated structures are present. Cutaneous manifestations of spinal dysraphism include depressed or polypoid lesions; dyschromic or hairy lesions; dermal or subcutaneous lesions; vascular malformations; or neoplasms of many types. Midline masses require intensive radiologic and neurosurgical evaluation before biopsy because of the possible connection to the CNS. MRI is the imaging modality of choice. Approximately 10% of patients will have evidence of occult spinal dysraphism if one abnormality is present, whereas the majority will have dysraphism if two or more abnormalities are present.

Chordomas, Parachordomas, and Myoepitheliomas

Parachordomas are closely related to myoepitheliomas and mixed tumor of skin and salivary gland. They generally occur as an isolated neoplasm. Both benign and malignant parachordomas occur in skin and can be differentiated by the degree of cellularity, atypia, and number of mitoses. Chordomas are soft tissue neoplasms that present as firm, smooth nodules in the sacrococcygeal region or at the base of the skull in middle-aged patients. They arise from notochord remnants. The pathologic appearance for each of these tumors is that of an incompletely encapsulated tumor with nests and cords of large epithelioid cells with multivacuolated physaliferous cells. Chordomas may metastasize late in their course to various sites, including the skin. Wide excision with postoperative radiation therapy is the treatment of choice.

Rekhi B, et al: Histopathological, immunohistochemical and molecular spectrum of myoepithelial tumours of soft tissues. Virchows Arch 2012; 461: 687.

ABNORMALITIES OF FAT TISSUE

Lipomas

Lipomas, subcutaneous tumors composed of fat tissue, may occur as a solitary sporadic lesion or as multiple lesions with or without a familial component. There are multiple histologic subtypes, and these frequently have an associated clinical correlation. Most have specific chromosomal alterations that help in their identification in difficult cases. Protease inhibitors given for HIV disease may induce lipomas, angiolipomas, or benign symmetric lipomatosis, as well as lipodystrophy.

Lipomas are most often found on the trunk. They also occur frequently on the neck, forearms, and axillae. They are soft, single or multiple, small or large, lobulated, compressible growths, over which the skin on traction often becomes dimpled, although otherwise unchanged. Lipomas usually stop growing after attaining a certain size, then remain stationary indefinitely. Frontalis-associated lipomas of the forehead are relatively large lesions arising either within or deep to the frontalis muscle.

A lipoma located in the midline of the sacral region may be a marker for spinal dysraphism or other embryologic malformation. Other midline lesions, such as tufts of hair ("fawn's tail"), hemangiomas (Cobb syndrome), skin tags, sinuses, or pigmented lesions, should also raise suspicion for occult embryologic malformations. MRI is the most sensitive imaging modality. If spinal dysraphism is diagnosed, early treatment may be possible before irreversible damage has occurred. Do not attempt to biopsy a sacrococcygeal lipoma; call a neurosurgeon into consultation. It may be a lipomeningocele with communicating sinuses to the dura.

Histologically, the lipoma is an encapsulated, lobulated tumor containing normal fat cells held together by strands of connective tissue. Occasionally, eccrine sweat glands may be associated, and then they are called adenolipomas. Alterations in chromosomes 12q13–15 and chromosomes 13q12–22 may be detected in benign lipomas.

Lipomas may be left untreated, unless they are large enough to be objectionable. They may be excised, removed with liposuction, extruded through a 3-mm incision after being freed with a cutting curette, or segmentally extracted through a stab incision. More advanced surgical technique is necessary to remove the deep lesions on the forehead, which may lie below the fascial plane. Injection with phosphatidylcholine has also been reported as successful.

Multiple lipomas may occur in groups of two to hundreds of confluent painless tumors of various sizes over any part of the body (Fig. 28.51). These lesions are sometimes painful when growing rapidly. When present in certain patterns, special designations are applied. Madelung disease (benign symmetric lipomatosis or multiple symmetric lipomatosis) occurs most often in middle-aged men, who may develop multiple, large, painless, coalescent lipomas around the neck, shoulders, and upper arms. Familial multiple lipomatosis is a dominantly inherited syndrome in which multiple asymptomatic lipomas of the forearms and thighs appear in the third decade of life. The shoulders and neck are spared, and the lipomas are encapsulated and movable. Diffuse lipomatosis is characterized by an early age of onset, usually before 2 years; diffuse infiltration of muscle by an unencapsulated mass of histologically mature lipocytes; and progressive enlargement and extension

Fig. 28.51 Multiple lipomas.

of the tumor mass. It usually involves a large portion of the trunk or an extremity. Some cases are associated with distant lipomas or hemangiomas or with hypertrophy of underlying bone.

Dercum disease (adiposis dolorosa) is seen most often in obese or corpulent menopausal women who develop symmetric, tender, circumscribed fatty lesions. These are often accompanied by weakness and psychiatric disturbances. Relief of pain lasting for weeks after intravenous infusions of lidocaine, 1.3 g/day for 4 days, has been reported.

Several other conditions are characterized by multiple abnormalities, including lipomas. Encephalocraniocutaneous lipomatosis is a rare neurocutaneous syndrome characterized by unilateral porencephalic cysts with cortical atrophy, ipsilateral facial and scalp lesions, ocular abnormalities, cranial asymmetry, and neurologic complications. The skin changes consist of unilateral lipomatous scalp tumors with overlying alopecia and connective tissue nevi. Ipsilateral lipodermoids, choristomas, and calcifications are the eye findings. CNS abnormalities include unilateral cerebral atrophy, dilated ventricles, porencephaly, cerebral calcifications, and lipomas of the leptomeninges. Seizures and mental retardation may occur. Some patients may have overlapping features of Proteus syndrome: multiple lipomas, epidermal nevi, cerebriform lesions of the plantar surfaces, vascular malformations, macrodactyly, hemihypertrophy, exostoses, and scoliosis.

Bannayan-Riley-Ruvalcaba syndrome is characterized by multiple subcutaneous lipomas and vascular malformations, lentigines of the penis and vulva, verrucae, and acanthosis nigricans. There is overlap in some of these cases with Cowden syndrome. Both syndromes have been associated with allelic mutations of the *PTEN* gene.

Multiple endocrine neoplasia type I has been associated with skin lesions consisting of multiple facial angiofibromas, collagenomas, café au lait spots, lipomas, confetti-like hypopigmented macules, and multiple gingival papules, in addition to the tumors of the parathyroid glands, endocrine pancreas, and anterior pituitary.

Fröhlich syndrome consists of multiple lipomas, obesity, and sexual infantilism.

Gardner syndrome consists of multiple osteomas, fibromas, desmoid tumors, lipomas, fibrosarcomas, epidermal inclusion cysts, and leiomyomas, associated with intestinal polyposis exclusively in the colon and rectum. The coexistence of cutaneous cysts, leiomyomas, and osteomas (mostly on the skull) with intestinal polyposis is frequently not recognized until malignant degeneration of one of the polyps occurs and surgical removal brings the syndrome to notice. Half of such patients develop carcinoma of the colon before age 30, and almost all these patients die before age 50, unless they have surgical treatment. In general, total colectomy is advised. Bony exostoses occur in 50% of patients and usually involve the membranous bones of the face and head. Cysts occur in 63% of patients and again, most frequently involve the face and scalp. These are epidermal inclusion cysts; two thirds have within them foci of pilomatrical differentiation. Pigmented lesions of the ocular fundus occurred in 90% of 41 patients with Gardner syndrome and 46% of 43 first-degree relatives. They are usually multiple and bilateral and, having been seen in a 3-month-old infant, are probably congenital. Gardner syndrome is transmitted as an autosomal dominant disease. The defect is a mutation in the *APC* gene located at chromosome 5q21. In some families, polyposis and carcinoma may occur without the skin and bone tumors. Lipomas have also been noted in the Carney complex, along with myxomas and pigmented lesions.

Subtypes

Angiolipomas present as painful subcutaneous nodules, having all the other features of a typical lipoma. Multiple subcutaneous angiolipomas are common and have no invasive or metastatic potential. They may be associated with CMs and may be induced by protease inhibitor therapy of HIV disease.

The angiolipoleiomyoma (angiomyolipoma of the skin) affects the acral skin of middle-aged men. No signs of tuberous sclerosis or renal angiomyolipoma are present. Mature adipocytes, thick-walled blood vessels, and smooth muscle cells in fascicles around blood vessels are present.

Neural fibrolipoma is an overgrowth of fibrofatty tissue along a nerve trunk that often leads to nerve compression. Patients are usually age 30 or younger and note a slowly enlarging subcutaneous mass with associated tenderness, decreased sensation, or paresthesia. The median nerve is most often involved. At times, macrodactyly appears, with elongation and splaying of the phalanges. MRI will provide the diagnosis, but unfortunately, there is no effective treatment.

Chondroid lipomas are deep-seated, firm, yellow tumors that characteristically occur on the legs of women. Histologically, there is a thin capsule around mature lipocytes that have a single large vacuole and multivacuolated, S-100/vimentin-positive cells within a chondromyxoid matrix.

The spindle cell lipoma is an asymptomatic, slow-growing subcutaneous tumor that has a predilection for the posterior back, neck, and shoulders of older patients. It is usually solitary, although multiple lesions may occur. Some patients have a familial background of similar lesions. The neoplasm consists of lobulated masses of mature adipose tissue with areas of spindle cell proliferation. The spindle cells stain positive for CD34. Abnormalities of chromosomes 16 and 13 have been reported. The spindled component of young spindle cell lipomas may be myxoid or cellular. The nuclei may be wavy and accompanied by mast cells, as in a neurofibroma. Examples with minimal fat may be misdiagnosed as solitary fibrous tumors. In old spindle cell lipomas (fibrolipomas), the spindle cell component has matured into dense collagen bundles.

Pleomorphic lipomas, as with spindle cell lipomas, occur mostly on the back or neck of older individuals. There are floret giant cells with overlapping nuclei. Occasional lipoblast-like cells and atypical nuclei may be present and require differentiation from a liposarcoma. There is loss of chromosome 16q material. Despite this alarming appearance, the lesions behave in a perfectly benign manner. Pleomorphic lipomas lack the size, depth, infiltrative growth, and arborizing vascular pattern of liposarcoma. The term *atypical lipomatous tumor* is used to describe well-differentiated, low-grade liposarcoma. Extensive or deeply infiltrating tumors should be reviewed by a clinician experienced in soft tissue pathology.

The intradermal spindle cell/pleomorphic lipoma is distinct in that it most often affects women and has a wide distribution, occurring with relatively equal frequency on the head and neck, trunk, and the upper and lower extremities. Histologically, these lesions are unencapsulated and have infiltrative margins. Again, the spindle cells stain positive for CD34.

Hibernoma (lipoma of brown fat) is a form of lipoma composed of finely vacuolated fat cells of embryonic type. Hibernomas have a distinctive brownish color and a firm consistency and usually occur singly. These tumors are benign. They occur chiefly in the mediastinum and the interscapular region of the back, but they also occur on the scalp, sternal region, and legs. They are usually about 3–12 cm in breadth, and the onset is most often in adult life. Abnormalities of chromosomes 10 and 11 have been reported in the lesions. Epidural lipomatosis, collections of fat in the epidural space, may cause acute chord compression in the course of systemic corticosteroid treatment. A case of this distinctive, uncommon side effect proved to be the result of deposits of brown fat.

Pinto CI, et al: Madelung's disease. AEsthetic Plast Surg 2017; 41: 359.

Nevus Lipomatosus Superficialis

Soft, yellowish papules or cerebriform plaques, usually of the buttock or thigh, less often of the ear or scalp, with a wrinkled rather than warty surface, characterize nevus lipomatosus superficialis. The distribution may be either zonal (as in the multiple lesions reported by Hoffmann and Zurhelle) or solitary. Solitary lesions appear as plaque, or linear array, but some resemble broad, fatty acrochordons. Onset before age 20 is the rule. Most do not require treatment, but diagnostic biopsy is sometimes performed, and intralesional phosphatidylcholine has been reported as successful.

Sendhil Kumaran M, et al: Nevus lipomatosus superficialis unseen or unrecognized. J Cutan Med Surg 2013; 17: 335.

Folded Skin With Scarring ("Michelin Tire Baby" Syndrome)

In this rare syndrome, the infant has numerous deep, conspicuous, symmetric, ringed creases around the extremities, resembling stacked tires (Fig. 28.52). The underlying skin may manifest a smooth muscle hamartoma, a nevus lipomatosis, or elastic tissue abnormalities. It may occur as an autosomal dominant or recessive trait, as a sporadic condition, as an isolated finding or in association with congenital facial and limb abnormalities, or with severe neurologic defects.

Ulucan H, et al: Circumferential skin folds and multiple anomalies. Clin Dysmorphol 2013; 22: 87.

Benign Lipoblastoma

Frequently confused with a liposarcoma, benign lipoblastoma affects infants and young children exclusively, with approximately 90% of cases occurring before 3 years of age. It most often involves the soft tissues of the upper and lower extremities. A circumscribed and a diffuse form can be distinguished. The circumscribed form is superficially located and clinically comparable to a lipoma. The diffuse form is more deeply situated and is analogous to diffuse lipomatosis. Microscopically, both forms consist of lobulated immature adipose tissue composed of lipoblasts, a plexiform capillary pattern, and a richly myxoid stroma. Cytogenetic studies for rearrangements of chromosome 8q11–q13 or fluorescence in situ hybridization (FISH) analysis for the *PLAG1–HAS2* fusion gene help to distinguish this tumor from liposarcoma, a distinction that can be difficult histologically. Complete local excision is the treatment of choice; however, recurrences may occur in as many as one quarter of patients.

Liposarcoma

Liposarcomas are the most common soft tissue sarcoma. They usually arise from the intermuscular fascia, and only rarely from the subcutaneous fat. They do not arise from preexisting lipomas. The usual course is an inconspicuous swelling of the soft tissue that undergoes an imperceptibly gradual enlargement. When a fatty tumor becomes larger than 10 cm in diameter, liposarcoma should be seriously considered. The upper thigh is the most common site. Other frequent sites are the buttocks, groin, and upper extremities. Adult males are mainly affected.

Liposarcomas may be well differentiated; subtypes include the adipocytic, sclerosing, inflammatory, spindle cell, and dedifferentiate variants. In this category, there are aberrations of chromosome 12. Myxoid and round cell–variant liposarcoma often shows poorly differentiated histology. In most cases, there is a reciprocal translocation t(12; 16)(q13; q11). The third major class is pleomorphic liposarcoma. Dermal lesions may resemble pleomorphic lipoma but are S100 positive and contain lipoblasts.

Treatment is adequate radical excision of the lesion. In patients with well-differentiated superficial lesions, the prognosis is good; for deeper, high-grade lesions, the extension between fascial planes and presence of small satellite nodules require carefully planned surgery, which may be assisted by MRI guidance. For metastatic liposarcomas, radiation therapy may be effective.

Al-Zaid T, et al: Dermal pleomorphic liposarcoma resembling pleomorphic fibroma. J Cutan Pathol 2013; 40: 734.

ABNORMALITIES OF SMOOTH MUSCLE

Leiomyoma

Cutaneous leiomyomas are smooth muscle tumors characterized by painful nodules that occur singly or multiply. They may be separated conveniently into solitary and multiple cutaneous leiomyomas arising from arrectores pilorum muscles (piloleiomyomas); solitary genital leiomyomas arising from the dartoic, vulvar, or mammillary muscle; and solitary angioleiomyomas arising from the muscles of veins.

Solitary Cutaneous Leiomyoma

The typical lesion is a deeply circumscribed, rounded nodule 2–15 mm in diameter. It is freely movable. The overlying skin may have a reddish or violaceous tint. Although the lesion is insensitive at first, painful paroxysms may occur. Once pain commences, it tends to intensify.

Multiple Cutaneous Leiomyomas

These brownish, grouped, papular lesions vary from 2–23 mm in diameter and are the most common variety of leiomyoma (Fig. 28.53). Two or more sites of the skin surface may be involved. The firm, smooth, superficial, sometimes translucent, and freely movable nodules are located most frequently on the trunk and extremities. They often form linear or dermatomal patterns, either alone or with scattered isolated nonsegmental lesions elsewhere. These leiomyomas may occur on the tongue or, less often, elsewhere in the mouth as well. The usual age at onset is the teens to the fourth decade. Eruptive lesions have been described in chronic lymphocytic leukemia.

Fig. 28.53 Multiple leiomyomas. (Courtesy Dr. Debabrata Bandyopadhyay.)

Multiple leiomyomas are inherited in an autosomal dominant manner as part of Reed syndrome. Women with this inherited type often have uterine leiomyomas as well. This is part of an inherited syndrome in which some patients also have a predisposition to type II papillary renal carcinomas or renal collecting duct cancer. Mutations in the fumarate hydratase gene are present in 75% of patients with Reed syndrome; these mutations may also be inherited in an autosomal recessive manner. Fully affected children have severe neurologic impairment. The adult carriers may develop leiomyomas. Sporadic leiomyoma, leiomyosarcomas, renal cancers, and uterine leiomyomas have a very low frequency of fumarate hydratase gene mutations.

Genital Leiomyomas

These lesions are located on the scrotum, on the labia majora, or rarely on the nipples. They may be intracutaneous or subcutaneous in location. Most genital leiomyomas are painless and solitary. Alport syndrome is an X-linked dominant syndrome consisting of hematuric nephropathy, deafness, and maculopathy caused by mutations in type IV collagen. Some of these patients will have diffuse leiomyomatosis, which may affect the esophagus, tracheobronchial tree, perirectal area, and genital tract and vulva. Bilateral nipple leiomyomas have been associated with *BRAF* inhibition therapy.

Angioleiomyoma (Vascular Leiomyoma)

Angioleiomyoma arises from the muscle of veins. Pain, either spontaneous or provoked by pressure or cold, occurs in about half the cases. Vascular leiomyoma is found mostly on the lower leg in middle-aged women. Solid tumors occur three times more frequently in women, and cavernous tumors occur four times more often in men. Solid lesions on the extremities are usually painful; tumors of the head are rarely painful. In AIDS patients, multiple skin and visceral angioleiomyomas may occur. These tumors' cells possess the Epstein-Barr virus genome.

Histologically, the leiomyoma is made up of bundles and masses of smooth muscle fibers. Varying amounts of collagen are intermingled. The smooth muscle cells are finely fibrillated and contain a glycogen vacuole adjacent to the nucleus. The nuclei are typically long, thin, and cigar shaped.

Angiolipoleiomyoma

Fitzpatrick et al. reported eight patients with acquired, solitary, asymptomatic acral nodules. Seven were men, and all were adults. Histologically, they had well-circumscribed subcutaneous tumors composed of smooth muscle cells, blood vessels, connective tissue, and fat.

Treatment

Leiomyomas are benign. Solitary painful lesions may be excised. When they are multiple and familial, monitoring for renal cell or collecting duct carcinoma is important. When multiple lesions are present and painful, as may occur especially in the winter, relief of pain may be achieved by giving doxazosin, an oral α_1-adrenoceptor antagonist. This is better tolerated than phenoxybenzamine, an α-adrenergic blocker, which also has been reported to provide pain relief. Nifedipine (10 mg three times daily or long acting forms 30–90 mg daily), amlodipine, gabapentin, oral nitroglycerin, and α-blockers have also had variable success. An ice cube applied over the lesions often induces pain, and the effectiveness of therapy may be assessed by the length of time it takes for the ice cube to cause pain. Botulinum toxin type A (Botox) injection has also been reported as effective.

Congenital Smooth Muscle Hamartoma

Congenital smooth muscle hamartoma is typically a skin-colored or lightly pigmented patch or plaque with hypertrichosis. It is often present at birth, usually on the trunk, with the lumbosacral area involved in two thirds of patients. Older patients may have perifollicular papules. They vary in size from 2×3 to 10×10 cm. The "Michelin tire baby" syndrome may result from a diffuse smooth muscle hamartoma. One patient presented with a linear reddish purple plaque. The incidence is approximately 1 in 2600 newborns. Transient elevation on rubbing may be seen (pseudo-Darier sign) in 80% of patients. An association with multiple adult myofibromas has been reported, as has association with congenital melanocytic nevus.

Histologically, numerous thick, long, well-defined bundles of smooth muscle are seen in the dermis at various angles of orientation. There may be an increase in hair follicles, and some cases have been associated with congenital or blue nevi.

In some patients, there is clinical and histologic overlap with Becker nevus. Classically, Becker nevus is a unilateral (rarely bilateral) acquired hyperpigmentation, usually beginning as a tan macule on the shoulder or pectoral area of a teenage male. Over time, hypertrichosis develops within it. Biopsy of such lesions shows acanthosis, papillomatosis, and increased basal cell pigmentation. Occasional congenital lesions manifesting hyperpigmentation and hypertrichosis have shown biopsy findings consistent with those of a Becker nevus (no smooth muscle proliferation), and lesions with a typical late-onset history compatible with Becker nevus have occasionally shown smooth muscle hamartoma–like changes in the dermis. Other cases of late-onset smooth muscle hamartomas are occasionally reported that are not hyperpigmented or hypertrichotic. No treatment is necessary.

Tzu J, et al: Combined blue nevus–smooth muscle hamartoma. J Cutan Pathol 2013; 40: 879.

Leiomyosarcoma

Superficial leiomyosarcomas, originating in the dermis or subcutaneous tissue, account for approximately 2% of all soft tissue sarcomas. An association with Reed syndrome has been reported. Occasionally, a lesion may present in the skin that is a metastasis from an internal source. The cutaneous leiomyosarcoma appears in the dermis as a solitary nodule. It may originate from the arrector pili or genital dartoic muscle. This has a good prognosis. Recurrence rates with Mohs surgery are approximately 15%, with metastases a rare event. Subcutaneous leiomyosarcomas, on the contrary, have a guarded prognosis, because hematogenous metastases occur in approximately 35% of patients. These prove fatal in about one third of patients. Lung metastases are common, so chest imaging is an important part of monitoring these patients.

The clinical appearance of leiomyosarcomas is not distinctive, and thus the diagnosis is established by the histopathologic findings. These differ from the leiomyoma by dense cellularity, nuclear pleomorphism, numerous mitotic figures, and disarray of the smooth muscle bundles. Collagen is found only in the septa. Desmin, smooth muscle actin, and h-caldesmon are helpful in differentiating leiomyosarcoma from other spindle cell or pleomorphic tumors.

The preferred method of treatment is wide local excision with a 1-cm margin. The Mohs surgical approach is useful in limiting recurrences and sparing tissue. Radiation therapy and chemotherapy are generally not effective.

MISCELLANEOUS TUMORS AND TUMOR-ASSOCIATED CONDITIONS

Cutaneous Endometriosis

Endometriosis of the skin is characterized by the appearance of brownish papules at the umbilicus or in lower abdominal scars after gynecologic surgery in middle-aged women. The usually solitary tumor ranges from a few to 60 mm (average 5 mm) in diameter. The tender or painful lesion is bluish black from the bleeding that occurs cyclically in many patients. Histopathologic findings are glandular structures with a columnar epithelium and a surrounding fibromyxoid stroma typically containing extravasated red blood cells and hemosiderin. Decidualized endometriosis demonstrates glassy-pink epithelioid cells surrounding contracted lumina. Treatment of choice is surgical excision. Preoperative treatment with danazol or leuprolide may reduce its size.

DeClerck BK, et al: Cutaneous decidualized endometriosis in a nonpregnant female. Am J Dermatopathol 2012; 34: 541.

Teratoma

Teratomas may develop in the skin but are most common in the ovaries or testes. Occurrence with a myelomeningocele has been reported. They have no characteristic clinical features, but on microscopic examination many types of tissue, representative of all three germ layers, are present. Hair, teeth, and functioning thyroid tissue are examples of fully differentiated tissues that may develop. Occasionally, malignancy may occur.

Bellet JS: Developmental anomalies of the skin. Semin Perinatol 2013; 37: 20.

Metastatic Carcinoma

Malignant tumors are able to grow at sites distant from the primary site of origin; thus dissemination to the skin may occur with any malignant neoplasm. These infiltrates may result from direct invasion of the skin from underlying tumors, may extend by lymphatic or hematogenous spread, or may be introduced by therapeutic procedures.

From 5%–10% of patients with cancer develop skin metastases. The reported incidence figures vary widely according to the type of study undertaken and the site of primary tumor studied. The frequency of involvement of the skin is low when other sites are considered, such as the lung, liver, lymph nodes, and brain.

Usually, metastases occur as numerous firm, hard, or rubbery masses, with a predilection for the chest, abdomen, or scalp, in an adult over age 40 who has had a previously diagnosed carcinoma. However, many variations exist in morphology, number of lesions, site of growth, age at onset, and timing of metastases. They are most often intradermal papules, nodules, or tumors that are firm, skin colored to reddish, purplish, black, or brown; may be fixed to underlying tissues; and rarely ulcerate.

Several unusual morphologic patterns occur. Carcinoma en cuirasse is a diffuse infiltration of the skin that imparts an indurated and hidebound leathery quality to skin. This sclerodermoid change, also referred to as scirrhous carcinoma, is produced by fibrosis and single rows of tumor cells. This type primarily occurs with breast carcinoma. Carcinoma telangiectaticum is another unusual type of cutaneous metastasis from breast carcinoma that presents as small, pink to purplish papules, pseudovesicles, and telangiectases.

Inflammatory carcinoma (carcinoma erysipelatoides) is characterized by erythema, edema, warmth, and a well-defined leading edge, similar to erysipelas in appearance (Fig. 28.54). This is usually caused by breast carcinoma but has been reported with many other primary tumors. Histologically, there is minimal to no inflammation, but rather neoplastic cells within dilated superficial dermal vessels.

Fig. 28.54 Carcinoma erysipeloides.

Fig. 28.55 Alopecia neoplastica secondary to breast carcinoma.

Fig. 28.56 Sister Mary Joseph nodule.

Alopecia neoplastica may present as a cicatricial localized area of hair loss (Fig. 28.55). On biopsy it is usually seen to be caused by breast metastases in women and by lung or kidney carcinoma in men. Metastatic breast cancer may be darkly pigmented, as may Paget disease of the breast.

The so-called Sister Mary Joseph nodule is formed by localization of metastatic tumors to the umbilicus (Fig. 28.56). The most common primary sites are the stomach, large bowel, ovary, and pancreas. Zosteriform, linear, or chancroidal ulcerations of the genitalia and verrucous nodules of the legs are other, rarely reported clinical presentations.

The primary tumor is usually diagnosed before the appearance of metastases, and dissemination to the skin is often a late finding. Metastases to other, more frequently involved organs, such as the lung and liver, have usually occurred. A poor prognosis is thus the rule. Skin infiltrates may, however, be the first harbinger of a malignant visceral neoplasm and are often the first clinically apparent metastatic site.

The principal anatomic sites to which metastases localize are the chest, abdomen, and scalp, with the back and extremities being relatively uncommon areas. Involvement of the skin is likely to be near the area of the primary tumor. Thus chest lesions are usually caused by breast carcinoma in women and lung carcinoma in men, abdominal or perineal lesions by colonic carcinoma, and the face by SCC of the oral cavity. Extremity lesions, when they occur, are most often caused by melanoma.

Because of its overall high prevalence, breast cancer is the type most frequently metastatic to the skin in women, and melanoma, followed by lung cancer, is the type seen most often in men. Colon carcinoma is also common because of its high incidence in both genders. Renal cell carcinoma, although less common, has a predilection for scalp metastases. Metastatic lesions are uncommon in children, but when they do occur, neuroblastoma and leukemia are the most frequent causes.

Lymphangiosarcoma (Stewart-Treves syndrome) develops in a site of chronic lymphedema, such as in breast cancer patients who have had lymph node resection. Antikeratin antibodies are useful in identifying metastatic breast carcinoma, whereas CD34, CD31, and *Ulex europeus* lectin are positive in Stewart-Treves angiosarcoma. Differential staining with keratins 7 and 20 can help suggest the site of origin in cases of cutaneous metastatic adenocarcinoma.

Sittart JA, et al: Cutaneous metastasis from internal carcinomas. An Bras Dermatol 2013; 88: 541

Paraneoplastic Syndromes

Some cancers produce findings in the skin indicating that an underlying internal malignancy may be present. These may range from a specific eruption characteristic of a particular type of cancer, such as necrolytic migratory erythema, to a nonspecific cutaneous reaction pattern, such as that caused by an internal malignancy. Although many of these syndromes are discussed in other chapters, a few are mentioned here as illustrative examples of this phenomenon.

Bazex syndrome, or acrokeratosis paraneoplastica, is characterized by violaceous erythema and scaling of the fingers, toes, nose, and aural helices. Nail dystrophy and palmoplantar keratoderma may be seen. These cases are secondary to primary malignant neoplasms of the upper aerodigestive tract or metastatic cancer to lymph nodes, often in the cervical region.

The glucagonoma syndrome is characterized by weight loss, glucose intolerance, anemia, glossitis, and necrolytic migratory erythema. Erythematous patches with bullae and light-brown papules with scales involving the face, groin, and abdomen characterize the skin eruption. This is seen with glucagon-secreting tumors of the pancreas.

Erythema gyratum repens is a gyrate serpiginous erythema with characteristic wood grain–pattern scales; it is almost always associated with an underlying malignancy. Hypertrichosis lanuginosa acquisita, or malignant down, is the sudden growth of profuse, soft, nonmedullated, nonpigmented, downy hair in an adult. The most common sites of associated carcinoma reported were the lung and colon.

The sign of Leser-Trélat is the sudden appearance of multiple pruritic seborrheic keratoses, associated with an internal malignancy. Trousseau sign, or migratory thrombophlebitis, is usually associated with pancreatic carcinoma (Fig. 28.57). A form of pemphigus, paraneoplastic pemphigus, is most frequently associated with lymphoma, chronic lymphocytic leukemia, and Castleman disease.

Several cutaneous diseases that are not associated with internal malignancy with the frequency of the previous conditions, but that may be a sign of internal malignancy in some cases, are exfoliative erythroderma (lymphoproliferative disease), acanthosis nigricans (adenocarcinoma), multicentric reticulohistiocytosis, Sweet syndrome (acute myelogenous leukemia), nodular fat necrosis (pancreatic carcinoma), Paget disease (underlying adnexal or breast carcinoma, or adenocarcinoma of genitourinary tract or colon), dermatomyositis in patients over age 40, palmar fasciitis and polyarthritis syndrome, and acquired ichthyosis (lymphoproliferative).

A variant of acquired ichthyosis, pityriasis rotunda, manifests circular, brown, scaly patches from 1–28 cm in diameter and varying in number from 1 to 20. They may occur on the trunk or extremities. These symptomless patches may be a clue to the diagnosis of hepatocellular carcinoma in South African black patients. Tripe

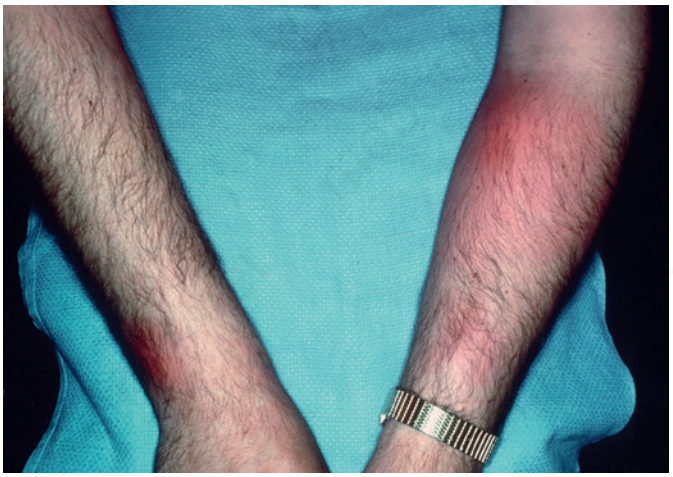

Fig. 28.57 Superficial migratory thrombophlebitis

palms, considered by some to be acanthosis nigricans of the palms, are associated with carcinoma in more than 90% of cases. Filiform hyperkeratosis of the palms may present in patients who develop cancer.

Carcinoid

Carcinoid involves the lungs, heart, and GI tract, as well as the skin. The outstanding feature of the skin is flushing, usually lasting 5–10 minutes. It most prominently involves the head and neck, but also produces a diffuse, scarlet color, with mottled red patches on the thorax and abdomen. Striking color changes may occur, with salmon red, bluish white, and other colors appearing simultaneously on various portions of the skin. Cyanosis may also be present. As the episodic flushing continues over months to years, telangiectases and plethora appear, as though the patient has polycythemia vera. Gyrate and serpiginous patches of erythema and cyanosis flare up and subside, not only on the face, but also on all parts of the body and extremities.

Pellagroid changes may appear as a result of shunting of dietary tryptophan away from the kynurenine-niacin pathway and into the 5-hydroxyindole pathway. Periorbital swelling, edema of the face, neck, and feet, and sclerodermatous changes may occur. Disseminated deep dermal and subcutaneous metastatic nodules from a primary bronchial carcinoid tumor have been documented. The clinical features of the carcinoid syndrome become evident only after hepatic metastases have occurred, or when the primary tumor is a bronchial carcinoid, or if the carcinoid arises in an ovarian teratoma, where the venous drainage bypasses the hepatic circulation.

The release of excessive amounts of serotonin and bradykinin into the circulation produces attacks of flushing of the skin, weakness, abdominal pain, nausea, vomiting, sweating, bronchoconstriction, palpitation, diarrhea, and collapse. These attacks may last a few hours. Right-sided cardiac valvular fibrosis occurs in 60% of chronically affected patients. Symptoms may be induced in these patients by the injection of epinephrine, at which time kinin peptide is released. Alcohol, hot beverages, exercise, and certain foods, among other factors, may induce flushing. The patient will provide the relevant triggers by history.

Etiologic Factors

Carcinoid, also called argentaffinoma, is a tumor that arises from the argentaffin Kulchitsky chromaffin cells in the appendix or terminal ileum, as well as in other parts of the GI tract, from the lungs as bronchial adenomas, and rarely from ovarian or testicular teratomas. Some of these produce large amounts of serotonin (5-hydroxytryptamine), a derivative of tryptophan, and others do not. The primary lesion is more active in the production of serotonin than are the metastases. The tumor frequently metastasizes to the draining lymph glands or to neighboring organs, especially the liver, and rarely to more distal sites.

Laboratory Findings

The diagnosis may be established by finding a high level of 5-hydroxyindolacetic acid (5-HIAA) in the urine. The normal urinary excretion of 5-HIAA is 3–8 mg/day, but in the presence of carcinoid it may reach 300 mg. Urinary values greater than 25 mg/day are diagnostic of carcinoid. Any value above the normal output is considered suspicious. The ingestion of bananas may cause significant elevations of 5-HIAA in the urine within a few hours, because banana pulp contains serotonin (4 mg/banana) and catecholamines. Tomatoes, red plums, pineapples, avocados, and eggplants also contain serotonin, but in much smaller amounts.

A screening test for 5-HIAA is the addition of nitrosonaphthol to the urine. A purple color is produced when 40 mg/day of 5-HIAA is excreted. Other serotonin metabolites besides 5-HIAA are found in the urine. The blood also contains serotonin in amounts of 0.2–0.4 mg%. In the presence of carcinoid, the amount may be 10 times normal.

Metastatic carcinoid may appear in the skin. A high index of suspicion is needed, because metastatic carcinoid has been reported to mimic apocrine poroma on shave biopsy.

Treatment

In the rare cases where there is only a primary tumor without metastases, this should be removed. Excision of metastatic lesions in the liver may also be considered. If this is impossible, long-acting somatostatin analogs provide good long-term symptomatic control of the flushing and diarrhea. Injections are given monthly. Vitamin supplementation with niacin and avoidance of known trigger factors to flushing are recommended. Restriction of tryptophan-containing foods for short periods may limit serotonin production.

29 Epidermal Nevi, Neoplasms, and Cysts

Bonus images for this chapter can be found online at expertconsult.inkling.com

EPIDERMAL NEVI

Epidermal nevi are hamartomatous growths of the epidermis that are present at birth in about half of patients or develop early in childhood. The term *epidermal nevus* includes several entities, including keratinocytic epidermal nevi, nevus sebaceus, and nevus comedonicus, depending on which epidermal cell or structure comprises the lesion. Epidermal nevi of all types are considered an expression of cutaneous mosaicism with genetic mutation in the affected skin. Lesions follow the lines of Blaschko, suggesting that they represent postzygotic mutations. Some syndromes have also been included in this classification, such as Proteus, CHILD, and phakomatosis pigmentokeratotica (a RASopathy with reported HRAS and KRAS mutations), and both localized lesions and systematized presentations may be caused by the same genetic mutations. In general, larger lesions, more widespread lesions, and lesions of the head and neck are more likely to have associated internal complications. The combination of an epidermal nevus and an associated internal problem is termed *epidermal nevus syndrome*. For each histologic type, the frequency and nature of associated systemic problems may be characteristic. Overall, about 1 in 1000 children have an epidermal nevus of some type.

Keratinocytic Epidermal Nevi

Keratinizing epidermal nevi are the most common type of epidermal nevus and are described by a great variety of terms, such as *linear epidermal nevus*, *hard nevus of Unna*, *soft epidermal nevus*, and *nevus verrucosus (verrucous nevus)*. If the lesion is widespread on half the body, the term *nevus unius lateris* has been used. The term *ichthyosis hystrix* is used if the lesions are bilateral and widespread.

The most common pattern of keratinocytic epidermal nevus is linear epidermal nevus. The individual lesions are verrucous, skin-colored, dirty-gray, or brown papules, which coalesce to form a serpiginous plaque (Fig. 29.1). Interspersed in the localized patch may be horny excrescences and rarely comedones. The age of onset of epidermal nevi is generally at birth, but they may also develop within the first 10 years of life. They follow the lines of Blaschko.

The histologic changes in the epidermis are hyperplastic and affect chiefly the stratum corneum and stratum malpighii. There is variable hyperkeratosis, acanthosis, and papillomatosis. Up to 62% of biopsies of epidermal nevi have this pattern, so-called nonepidermolytic epidermal nevi. About 16% show epidermolytic hyperkeratosis. At times, other histologic patterns may be found, including a psoriatic type, an acrokeratosis verruciformis–like type, and a Darier disease–like type. It is assumed that each of these types would be associated with a specific mutation in the affected skin that, if widespread, would give rise to the cutaneous disorder with the same histology. For example, epidermal nevi that show epidermolytic hyperkeratosis would have the same gene mutation as the disorder of cornification, bullous congenital ichthyosiform erythroderma (i.e., keratins K1 and K10). In fact, patients with this type of epidermal nevus may have gonadal mosaicism that can result in offspring with the full-blown disorder. In a significant portion of the classic and common keratinocytic epidermal nevi that simply shows hyperkeratosis, papillomatosis, and acanthosis histologically, there is an activating gene mutation in fibroblast growth factor receptor 3 *(FGFR3)*, *HRAS*, or *PIK3CA*, a downstream effector of FGFR signaling. FOXN1 is highly expressed in these lesions. These same gene mutations are found in sporadic seborrheic keratoses, which, not surprisingly, have the same histology.

Keratinocytic epidermal nevi may be associated with skeletal abnormalities and central nervous system (CNS) manifestations. CNS manifestations appear to be more common when the lesions are large and located on the head and neck. Large keratinocytic epidermal nevi of the trunk and extremities are more frequently associated with skeletal abnormalities. Because both nevus sebaceus and keratinocytic epidermal nevi were included in the original and large reports of epidermal nevus syndrome, the precise characterization of the "keratinocytic epidermal nevus syndrome" remains to be defined.

Both Proteus syndrome and CLOVE syndrome (congenital lipomatous overgrowth, vascular malformations, and epidermal nevi) can have skin lesions of epidermal nevus. CLOVE is distinguished from Proteus syndrome by congenital overgrowth of a ballooning nature, which grows proportionately with the patient and typically affects the feet.

The CHILD syndrome and verruciform xanthoma are both characterized by the presence histologically of elongated and widened dermal papillae filled with xanthoma-like cells. Epidermal hyperplasia, with acanthosis, papillomatosis, parakeratosis, and hyperkeratosis, is also present (the features of a keratinocytic epidermal nevus). In rare cases, instead of half the body being affected, large quadrants of the body, favoring folds, are the sites of the epidermal growths (ptychotropism). CHILD and verruciform xanthoma (in some cases) contain mutations in the *NSDHL* gene, located on the X chromosome and required for cholesterol biosynthesis.

Epidermal nevus syndrome associated with *FGFR3* mutation is characterized by widespread epidermal nevus and developmental brain defects. Epidermal nevus syndrome may also be associated with vitamin D–resistant hypophosphatemic rickets, perhaps from circulating fibroblast growth factor 23 (FGF-23) acting as a phosphaturic.

Rarely, malignancies occur in keratinocytic epidermal nevi or in other organs. Any newly appearing lesion within a stable epidermal nevus should be biopsied to exclude this possibility. Management of keratinocytic epidermal nevi is difficult because, unless the treatment extends into the dermis (and thus may cause scarring), the lesion recurs. The use of a combination of 5% 5-fluorouracil (5-FU) plus 0.1% tretinoin creams once daily may be beneficial, and the response may be enhanced by occlusion. Cryotherapy can be quite effective, with good cosmetic results. Corticosteroids or a combination of a topical corticosteroid and calcipotriene may be beneficial. Carbon dioxide (CO_2) and erbium:yttrium-aluminum-garnet (Er:YAG) laser treatment may also be effective. If the lesion is small, simple excision can be considered.

Nevus Comedonicus

Nevus comedonicus is characterized by closely arranged, grouped, often linear papules that have at their center dilated follicular openings with keratinous plugs resembling comedones. Cysts, abscesses, fistulas, and scars develop in about half the cases, which have been described as "inflammatory" nevus comedonicus. As with other epidermal nevi, lesions may be localized to a small area or may have an extensive distribution. They are most frequently unilateral, although bilateral cases are also seen. Lesions occur mostly on the trunk and follow the lines of Blaschko. The lesions may develop any time from birth to age 15 but are usually present by age 10. Follicular tumors, including trichofolliculoma and pilar sheath acanthoma, can appear within the lesion. An "epidermal nevus syndrome" or "nevus comedonicus syndrome" has been reported with electroencephalogram (EEG) abnormalities, ipsilateral cataract, corneal changes, and skeletal anomalies (hemivertebrae, scoliosis, and absence of fifth ray of hand).

The pilosebaceous follicles are dilated and filled with keratinous plugs (Fig. 29.2). On the palms, pseudocomedones are present. Histologic examination reveals large dilated follicles filled with orthokeratotic horny material and lined by atrophic squamous epithelium. The interfollicular epidermis is papillomatous, as seen in typical epidermal nevi. Hair follicle differentiation, well-formed follicular structures, and normal sebaceous glands are not common in well-formed lesions.

Somatic mutations in *NEK9* are frequently associated. Apert syndrome is characterized by skeletal anomalies and acne. It is caused by a mutation in *FGFR2.* A mutation has also been found in *FGFR2* in at least one case of nevus comedonicus, suggesting that nevus comedonicus may be a mosaic form of Apert syndrome.

Treatment of lesions not complicated by inflammatory cysts and nodules is primarily cosmetic. Pore-removing cosmetic strips and comedone expression may improve the cosmetic appearance. Topical tretinoin may be beneficial, as may Er:YAG or CO_2 laser. Patients with inflammatory lesions are much more difficult to manage. If the area affected is limited, surgical excision may be considered. Oral isotretinoin, chronically at the minimum effective dose (0.5 mg/kg/day, or less if possible), may partially suppress the formation of cysts and inflammatory nodules; however, many

Fig. 29.2 Nevus comedonicus.

cases of nevus comedonicus fail to respond. The comedonal lesions do not improve with oral isotretinoin.

Epidermal Nevus Syndrome

Epidermal nevus syndrome does not represent a single entity, but rather multiple syndromes characterized by keratinocytic or organoid nevi, at times associated with internal organ involvement. Each variant has characteristic cutaneous findings and at times relatively specific internal findings. There are at least five variants of organoid epidermal nevus syndrome:

1. Schimmelpenning syndrome (Fig. 29.3). Nevus sebaceus coexists with cerebral, ocular, and skeletal defects. Lesions of the head and neck may lack prominent sebaceous hyperplasia. Coloboma and lipodermoid of the conjunctiva can occur. Vitamin D–resistant hypophosphatemic rickets may be present.
2. Phacomatosis pigmentokeratotica. Nevus sebaceus and papular nevus spilus coexist. The nevus sebaceus may have a flat, erythematous central area with an elevated margin showing features of a nonorganoid epidermal nevus. Multiple angiomas may be found in the nevus spilus component. True basal cell carcinomas develop in the nevus sebaceus of this syndrome. CNS complications can occur, along with hyperhidrosis, weakness, and sensory or motor neuropathy. Vitamin D–resistant rickets may also be present.

Fig. 29.3 Schimmelpenning syndrome.

Fig. 29.4 Inflammatory linear verrucous epidermal nevus.

3. Nevus comedonicus syndrome. Nevus comedonicus with ipsilateral ocular, skeletal, or neurologic defects defines this syndrome.
4. Angora hair nevus syndrome. A linear epidermal nevus is covered with long, white hair growing from dilated follicular pores. CNS, eye, and skeletal abnormalities may be found.
5. Becker nevus syndrome. Becker nevus is associated with ipsilateral hypoplasia of the breast.

Keratinocytic nevi are seen in at least four epidermal nevus syndromes:

1. Proteus syndrome.
2. Type 2 segmental Cowden disease. A linear soft, thick, papillomatous keratinocytic nevus in the absence of cerebriform hyperplasia of the palms and soles, but with segmental glomerulosclerosis. It is caused by loss of heterozygosity in an embryo carrying a *PTEN* germline mutation. Associated anomalies include lipomas, connective tissue nevi, vascular nevi, hemihypertrophy, seizures, hydrocephalus, and gastrointestinal (GI) polyps.
3. CHILD syndrome. X-linked dominant, male lethal trait. It is caused by a mutation in *NSDHL*. Chondrodysplasia punctata is characteristic. There is a marked affinity of the nevus for the body folds (ptychotropism). There is a tendency to spontaneous involution.
4. Fibroblast growth factor receptor 3 epidermal nevus syndrome (Garcia-Hafner-Happle syndrome). A velvety-type nonepidermolytic epidermal nevus and cerebral defects identify this syndrome.

Less well-defined syndromes include the following:

1. Nevus trichilemmocysticus. Multiple trichilemmal cysts along Blaschko's lines are associated with osteomalacia and fractures.
2. Didymosis aplasticosebacea. Sebaceous nevus coexists with aplasia cutis, usually in close proximity to each other.
3. SCALP syndrome: sebaceous nevus, CNS malformations, aplasia cutis congenital, limbal dermoid, and pigmented nevus. It is a combination of didymosis aplasticosebacea and a large melanocytic nevus.
4. Gobellos syndrome: systematized, linear, velvety, orthokeratotic nevus with hypertrichosis and follicular hyperkeratosis. Multiple bony defects are present.
5. Bafverstedt syndrome: horny excrescences in a linear pattern with mental retardation and seizures. Diffuse ichthyosis-like hyperkeratosis covers the entire body, including the palms and soles.
6. NEVADA syndrome: keratinocytic, verrucous nevus with angiodysplasia.
7. CLOVE syndrome: congenital lipomatous overgrowth, vascular malformation, and epidermal nevus. Extensive truncal vascular malformations and overgrown feet are characteristic.

Asch S, Sugarman JL: Epidermal nevus syndromes. Handb Clin Neurol 2015; 132: 291.
Happle R: The group of epidermal nevus syndromes. J Am Acad Dermatol 2010; 63: 25.

Inflammatory Linear Verrucous Epidermal Nevus

The term inflammatory linear verrucous epidermal nevus (ILVEN) may encompass as many as four separate conditions, with some representing mosaicism for erythrokeratodermia variabilis et progressiva. The most common form is the classic ILVEN, or "dermatitic" epidermal nevus. At least three quarters of these cases appear before age 5 years, most before age 6 months. Later onset in adulthood has been reported. ILVEN is characteristically pruritic and pursues a chronic course. Lesions follow the lines of Blaschko. The individual lesions comprising the affected region are erythematous papules and plaques with fine scale (Fig. 29.4). The lesions are morphologically nondescript and, if the distribution is not recognized, could be easily overlooked as an area of dermatitis or psoriasis. Multiple, widely separated areas may be affected, usually on only one side of the body; this may also be bilateral, analogous to other epidermal nevi. Familial cases have been reported. Rarely, systemic involvement, with musculoskeletal and

neurologic sequelae (developmental delay, epilepsy), has been reported.

Histologically, classic ILVEN demonstrates abruptly alternating areas of hypergranulosis with orthokeratosis, and parakeratosis with agranulosis. An inflammatory infiltrate of lymphocytes is present in the upper dermis. At times, the histology may simply be that of a subacute dermatitis. Although the histologic diagnosis of psoriasis can be considered, the correct diagnosis can be established if the dermatopathologist is made aware of ILVEN as a consideration. If there is a question, the presence of involucrin expression in the parakeratotic areas can distinguish ILVEN from psoriasis.

Three other types of inflammatory nevus have been included in this group. Some cases of "linear" lichen planus have been considered as "epidermal nevi," because they typically follow lines of Blaschko. CHILD syndrome, also considered a type of "inflammatory" epidermal nevus, is usually clinically distinct, demonstrating its characteristic hemidysplasia. The most confusing entity has been the "nevoid" or "linear" psoriasis. These cases are of two types. The first type is a child with a family history of psoriasis who has a nevoid lesion at or near birth. The child later develops psoriasis that "koebnerizes" into the ILVEN lesion, suggesting it is a "locus minoris resistensiae" for psoriasis. Treatment of the psoriasis clears the psoriasis overlying the ILVEN, but not the ILVEN. Arthritis developed in one such patient. In the second type, psoriasis initially presents in one band or area. Histologically, it resembles psoriasis. Most of these patients develop typical psoriasis later in life, suggesting a mosaicism that allowed expression of the psoriasis earlier in the initially affected area.

Inflammatory LVEN is differentiated from other epidermal nevi by the presence of erythema and pruritus clinically and by histologic features. Lichen striatus can be distinguished by its histology and natural history. Topical corticosteroids and topical retinoids appear to have limited benefit in ILVEN. However, topical vitamin D (calcipotriol and calcitriol) and topical anthralin have been beneficial. Surgical modalities include excision, cryotherapy, and laser. In cases of "nevoid," "linear," or "blaschkolinear" psoriasis, acitretin, narrow-band (NB) ultraviolet (UV) B therapy, and calcipotriene have been beneficial, but etanercept has failed.

HYPERKERATOSIS OF THE NIPPLE AND AREOLA

Hyperkeratosis of the nipple and areola (HNA) is an uncommon, benign, asymptomatic, acquired condition of unknown pathogenesis. Women represent 80% of cases, and HNA presents in their second or third decade. In men, the time of presentation is variable. Most cases are bilateral, although unilateral cases can occur. In about half the cases, both the areola and the nipple are involved. Breastfeeding is usually not affected. Clinically, there is verrucous thickening and brownish discoloration of the nipple and/or areola. Histologically, orthokeratotic hyperkeratosis occurs, with occasional keratinous cysts in the filiform acanthotic epidermis. The course is chronic. Treatment with cryotherapy, electrosurgical superficial removal of hyperkeratosis, excision and reconstruction, low-dose acitretin, topical steroids, radiofrequency ablation and calcipotriol have benefitted some patients. A similar clinical manifestation has been seen in graft-versus-host disease (GVHD), malignant acanthosis nigricans, and candidiasis of the nipple associated with mucocutaneous candidiasis. Painful areolar hyperkeratosis may be seen as a complication of sorafenib therapy. HNA must be distinguished from acanthosis nigricans, pregnancy-associated hyperkeratosis of the nipple, nipple eczema with lichenification, and Darier disease. Isolated papules or small plaques in this location probably represent seborrheic keratoses affecting the nipple or areola. The relationship of HNA and areolar melanosis is unclear; these conditions have significant clinical similarity, except for the absence of hyperkeratosis in those lesions described as areolar melanosis.

CLEAR CELL ACANTHOMA (PALE CELL ACANTHOMA)

Clear cell acanthoma is also known as Degos acanthoma. The typical lesion is a circumscribed, red, moist, shiny nodule with some crusting and peripheral scale (Fig. 29.5); it is usually about 1–2 cm in diameter. A collarette of scale is usually observed, and there may be pigmented variants. Exophytic nodules have been reported. The favorite site is on the shin, calf, or occasionally the thigh, although other sites (e.g., abdomen, scrotum) have been reported. The lesion is asymptomatic and slow growing and can occur in either gender, usually after age 40. Solitary lesions are most common, but multiple nodules have been described, including the setting of Cowden syndrome. Rarely, an eruptive form of the disease occurs, producing up to 400 lesions. Squamous cell carcinoma (SCC) arising from clear cell acanthoma has also been reported. Lesions occurring in plaques of psoriasis on the buttocks have been described, and clear cell acanthoma on the nipple has been associated with chronic eczema, suggesting a possible inflammatory etiology.

Fig. 29.5 Clear cell acanthoma.

The acanthotic epidermis consists of pale, edematous cells and is sharply demarcated. The basal cell layer is normal. Neutrophils are scattered within the acanthoma and in groups below and within the stratum corneum, a finding similar to the micropustules of psoriasis. The dermal blood vessels are dilated and tortuous, as seen in psoriasis. The clear keratinocytes abound in glycogen, staining positive with periodic acid–Schiff (PAS). Several centers have reported identification of human papillomavirus (HPV) in clear cell acanthomas, making distinction of these lesions from warts difficult. Clear cell acanthoma must be differentiated from eccrine poroma, which appears most frequently on the hair-free part of the foot, and from clear cell hidradenoma, which occurs most often on the head, especially the face and eyelids. Treatment is surgical, with cryotherapy, CO_2 laser, or excision.

WAXY KERATOSES OF CHILDHOOD (KERINOKERATOSIS PAPULOSA)

Waxy keratoses of childhood is a genodermatosis that is either sporadic or familial. It may be generalized or segmental. Clinically, the lesions are keratotic, flesh-colored papules that affect the trunk and extremities. They appear before age 3 years. Histologically, there is papillomatosis with focal "church-spire" tenting of the epidermis and marked hyperkeratosis. The natural history of this rare disorder is unknown. Clinically and histologically, the lesions must be distinguished from warts.

Gönül M, et al: A case of waxy keratoses of childhood. Dermatology 2008; 217: 143.

Mehrabi D, et al: Waxy keratoses of childhood in a segmental distribution. Pediatr Dermatol 2001; 18: 415.

MULTIPLE MINUTE DIGITATE HYPERKERATOSIS

Multiple minute digitate hyperkeratosis (MMDH) is a rare disorder. About half of cases are familial, inherited in an autosomal dominant manner, and the other half are sporadic. This condition has also been called digitate keratoses, disseminated spiked hyperkeratosis, minute aggregate keratosis, and familial disseminated piliform hyperkeratosis. Clinically, hundreds of tiny, asymptomatic digitate keratotic papules appear on the trunk and proximal extremities. They are not associated with follicular structures. Histologically, each lesion represents a spiked, digitate, or tented area of acanthotic epidermis with overlying orthohyperkeratosis. Similar lesions can be seen after inflammation and radiation therapy. The relationship of the familial/sporadic cases and the postinflammatory condition is unclear. In some adult patients, an underlying malignancy is found.

Caccetta TP, et al: Multiple minute digitate hyperkeratosis. J Am Acad Dermatol 2012; 67: e49.
Pimentel CL, et al: Multiple minute digitate hyperkeratosis. J Eur Acad Dermatol Venereol 2002; 16: 422.

ACANTHOLYTIC ACANTHOMA, EPIDERMOLYTIC ACANTHOMA, ACANTHOLYTIC DYSKERATOTIC ACANTHOMA

These three acanthomas represent benign, usually solitary, but at times multiple papules that are nondescript and may be mistaken for basal cell carcinoma (BCC), SCC, or HPV infection. Histologic examination shows epidermal hyperplasia with acantholysis resembling pemphigus vulgaris, pemphigus foliaceus, or Hailey-Hailey disease. The condition multiple epidermolytic acanthoma usually occurs in the genital area and histologically resembles Hailey-Hailey disease. This probably represents a localized variant of that condition.

WARTY DYSKERATOMA

Warty dyskeratomas are usually solitary and are found on the head and neck (70%), trunk (20%), or extremities. Rare oral lesions occur. The lesion is a brown-red papule or nodule with a soft, yellow, central keratotic plug. Histologically, a cuplike depression filled with a keratotic plug is most common. The epithelium lining the invagination shows the features of Darier disease, with intraepidermal clefts, acantholytic cells, and pseudovilli. Keratin pearls, corps ronds, and grains may be seen. Cystic lesions with prominent keratinous cysts can occur, especially in the vulva. Cutaneous lesions appear to originate from a hair follicle. Warty dyskeratoma must be distinguished histologically from keratoacanthoma and acantholytic SCC. Acantholytic acanthoma has a similar histology, but dyskeratosis is absent, distinguishing it from warty dyskeratoma. Treatment is surgical.

SEBORRHEIC KERATOSIS

Seborrheic keratoses are incredibly common and usually multiple. They present as oval, slightly raised, tan or light-brown to black, sharply demarcated papules or plaques, rarely more than 3 cm in diameter (Fig. 29.6). They appear "stuck on" the skin, as if they could be removed with the flick of a fingernail. They are located mostly on the chest and back but also frequently involve the scalp, face, neck, and extremities. An inframammary accumulation is common. Occasionally, genital lesions are seen. The palms and soles are spared; "seborrheic keratoses" in these areas are usually eccrine poromas. The surface of the warty lesions often becomes crumbly, resembling a loosely attached crust. When this is removed, a raw, moist base is revealed. Seborrheic keratoses may be associated with itching. Some patients have hundreds of these lesions on the trunk. Although it had been thought that the age of onset is generally in the fourth to fifth decade, in Australia the prevalence of seborrheic keratoses was 20% in males and 25% in females age 15–25. Typical lesions of the trunk are much more common in white persons; however, the "dermatosis papulosa nigra" variant of the central face is common in African Americans and Asians.

Fig. 29.6 Seborrheic keratosis. (Courtesy Steven Binnick, MD.)

The pathogenesis of seborrheic keratoses is unknown. Clinically, they usually originate de novo or appear initially as a lentigo. A sudden eruption of many seborrheic keratoses may follow an exfoliative erythroderma, erythrodermic psoriasis, or an erythrodermic drug eruption. These lesions may be transient. Seborrheic keratoses are more common in areas of sun exposure, including favoring the driver's side in truck drivers. In about one third or more of cases, solar lentigines and seborrheic keratoses both have gain-of-function mutations in *FGFR3* and *PIK3CA*, the genes mutated in keratinocytic epidermal nevi. This supports the concept that some seborrheic keratoses begin as flat lesions that cannot be distinguished from solar lentigines.

Histologically, most seborrheic keratoses demonstrate acanthosis, varying degrees of papillomatosis, hyperkeratosis, and at times, keratin accumulations within the acanthotic epidermis (pseudo–horn cysts). The epidermal cells lack cytologic atypia, except at times in the irritated variant, where typical mitoses may occur. Six histologic types are distinguished: hyperkeratotic, acanthotic, adenoid or reticulated, clonal, irritated, and melanoacanthoma. Poor correlation exists between the clinical appearance and the observed histology, unlike for inverted follicular keratosis, dermatosis papulosa nigra, and stucco keratosis, where the histologic features are characteristic and match the clinical lesion. Melanoacanthoma differs from regular seborrheic keratosis by the presence of numerous dendritic melanocytes within the acanthotic epidermis. Oral melanoacanthoma, which has also been called melanoacanthosis, is clinically a reactive pigmented lesion seen primarily in young black patients (see Chapter 34). Many cases of inverted follicular keratosis represent irritated seborrheic keratoses. Some view granular parakeratotic acanthomas a variant of irritated seborrheic keratosis, and others see it as a separate entity.

The differential diagnosis usually poses no problems in most cases, but clinically atypical lesions can be a challenge. The most difficult, especially for the nondermatologist, is to differentiate the solitary black seborrheic keratosis from melanoma. The regularly shaped verrucous lesion is often different from the smooth-surfaced and slightly infiltrating pattern of melanoma. Dermoscopy can sometimes be of great value; at other times, however, seborrheic keratoses may demonstrate dermatoscopic features typical of melanocytic lesions, and the presence of horn cysts does not exclude a melanocytic lesion. Actinic keratoses are usually erythematous, more sharply rough, and slightly scaly. The edges are not sharply demarcated, and they occur most often on the face, bald scalp, and backs of the hands. Nevi may be closely simulated. Clonal seborrheic keratoses demonstrate intraepidermal nests suggestive of intraepidermal epithelioma of Jadassohn. Rarely, Bowen disease, SCC, BCC, trichilemmal carcinoma, or melanoma arises within typical-appearing seborrheic keratosis. Some of these may represent collision lesions, not cancers arising from seborrheic keratoses. It is prudent to biopsy any lesion that appears atypical, because even the most seasoned dermatologist has been humbled by the occasional diagnosis of melanoma in low-suspect lesions.

Seborrheic keratoses are easily removed with liquid nitrogen, curettage, or both, to avoid the need for local anesthesia to perform the curettage. The spray freezes the lesion to make it brittle enough for easy removal with the curette. Scarring is not produced by this method. Light freezing with liquid nitrogen alone is also effective, and most patients prefer it to simple curettage with local anesthesia mainly because of decreased wound care. Light fulguration and shave removal are other acceptable methods. A novel topical agent is in clinical trials.

SIGN OF LESER-TRÉLAT

The sudden appearance of numerous seborrheic keratoses in an adult may be a cutaneous sign of internal malignancy. Sixty percent of the neoplasms have been adenocarcinomas, primarily of the GI tract. Other common malignancies are lymphoma, breast cancer, and SCC of the lung, but many other types have been reported. To be considered a case of Leser-Trélat, the keratoses should begin at approximately the same time as the development of the cancer, have a rapid onset, and run a parallel course in regard to growth and remission. The lesions are often pruritic, and acanthosis nigricans and tripe palms may accompany the appearance of the seborrheic keratoses of Leser-Trélat.

DERMATOSIS PAPULOSA NIGRA

Dermatosis papulosa nigra occurs in about 35% of black persons and is also relatively common in Asians. It usually begins in adolescence, appearing first as minute, round, skin-colored or hyperpigmented macules or papules that develop singly or in sparse numbers on the malar regions or on the cheeks below the eyes. It has been described in patients as young as age 3. The lesions increase in number and size over time, so that over the course of years, the patient may have hundreds of lesions (Fig. 29.7). These are distributed over the periorbital regions initially but may occur on the rest of the face as well as the neck and upper chest. Lesions do not spontaneously resolve. They closely simulate seborrheic keratoses. The lesions are asymptomatic and do not develop scaling, crusting, or ulceration.

Microscopically, the chief alterations are in the epidermis. Irregular acanthosis, papillomatosis, and deposits of uncommonly large amounts of pigment throughout the rete, particularly in the basal layer, are characteristic. Many believe this to be a form of seborrheic keratosis. This concept is supported by the finding of *FGFR3* mutations in the lesions of dermatosis papulosis nigra, similar to those found in seborrheic keratoses.

Fig. 29.7 Dermatosis papulosa nigra.

Treatment is made difficult by the tendency for the development of dyspigmentation. Light curettage with or without anesthesia; light, superficial liquid nitrogen application; and light electrodesiccation are effective but may result in hyperpigmentation or hypopigmentation. KTP, CO_2, and Nd:YAG lasers have been reported effective but not superior to simple electrodesiccation. Aggressive treatment should be avoided to minimize dyspigmentation and scarring.

STUCCO KERATOSIS

Stucco keratoses have been described as "stuck on" lesions occurring on the lower legs, especially in the vicinity of the Achilles tendon. They are also seen on the dorsa of the feet, forearms, and dorsal hands. The palms, soles, trunk, and head are never affected. Varying in diameter from 1–5 mm, the lesions are loosely attached and thus can easily be scratched off. They vary in number from a few to more than 50. Stucco keratoses are common in the United States and Australia. They occur mostly in men over 40 years old. Histologically, the picture is that of a hyperkeratotic type of seborrheic keratosis, with no hypergranulosis and no wart particles seen on electron microscopy. The presence of *PIK3CA* mutations in stucco keratoses suggests they are a variant of seborrheic keratosis. The treatment, if required, consists of emollients, which soften the skin and cause the scaly lesions to fall off. Ammonium lactate 12% lotion may be effective in improving the appearance of the lesions. Stucco keratoses must be distinguished from Flegel disease.

Fig. 29.8 Benign lichenoid keratoses.

HYPERKERATOSIS LENTICULARIS PERSTANS (FLEGEL DISEASE)

Rough, yellow-brown, keratotic, flat-topped papules 2–5 mm in diameter and found primarily on the dorsal feet and lower legs are characteristic. The palms, soles, and oral mucosa may rarely be involved. Familial cases have been reported.

The histologic findings are distinctive, with hyperkeratosis and parakeratosis overlying a thinned epidermis and irregular acanthosis at the periphery. A bandlike inflammatory infiltrate occurs in the papillary dermis. Topical emollients, topical keratolytics, topical corticosteroids, zinc bandages, topical 5-FU, and psoralen plus ultraviolet A (PUVA) therapy have been reported useful. Oral retinoids may result in improvement but are difficult to justify in this chronic, asymptomatic condition except in rare severe cases. Both benefit and failure with topical vitamin D analogs have been reported. The lesions do not recur after shallow shave excision.

BENIGN LICHENOID KERATOSES (LICHEN PLANUS–LIKE KERATOSIS)

Benign lichenoid keratoses are usually solitary, dusky-red to violaceous, papular lesions up to 1 cm in diameter and at times larger (Fig. 29.8). They occur most often on the distal forearms, hands, or chest of middle-aged white women. The lesions are typically biopsied because the clinical features are identical to those of a superficial BCC. A slight violaceous hue or the presence of an adjacent solar lentigo can raise the suspicion of lichen planus–like keratosis. Multiple lesions may simulate a photodermatitis, such as lupus erythematosus (LE). Evolution from preexisting solar lentigines is often noted histologically or by history, and the presence of the same underlying genetic mutations (*FGFR3*, *PIK3CA*, and *RAS*) supports this concept.

Histologically, the lesion may be indistinguishable from idiopathic lichen planus. Whereas idiopathic lichen planus rarely demonstrates parakeratosis, plasma cells, or eosinophils, these may be present in lichen planus–like keratosis. The remnants of a solar lentigo may be seen at the periphery. These features, plus the clinical information that this represents a solitary lesion, suggest the correct diagnosis. Clinical correlation is essential because similar histologic findings may be seen in lichenoid drug eruptions, acral LE, and lichenoid regression of melanoma. Direct immunofluorescence is

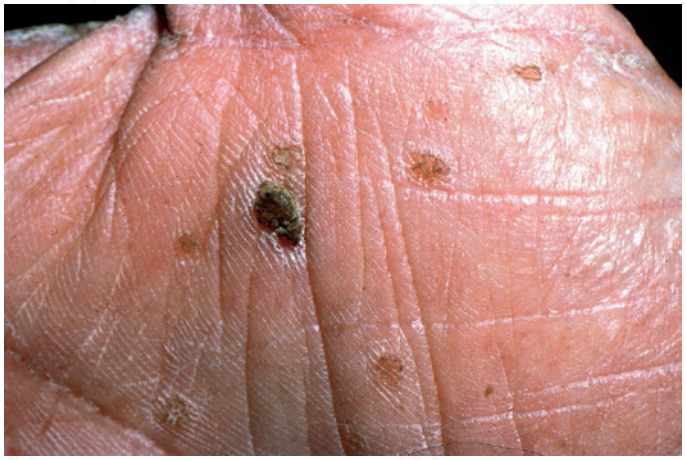

Fig. 29.9 Arsenical keratosis of the palm.

positive, with clumped deposits of immunoglobulin M in a lichen planus–like pattern at the dermoepidermal junction (DEJ). This differs from the continuous granular immunoglobulin deposition of acral LE. Cryotherapy with liquid nitrogen is effective.

ARSENICAL KERATOSES

Arsenical keratoses are keratotic, pointed, 2–4 mm, wartlike lesions on the palms, soles, and sometimes ears of persons who have a history of drinking contaminated well water or taking medications containing arsenic trioxide, usually for asthma (e.g., Fowler's solution, Bell's Asthma Mixture), atopic dermatitis, or psoriasis, often years previously (Fig. 29.9). These lesions resemble palmar pits but may have a central hyperkeratosis. When the keratosis is picked off with the fingernails, a small, dell-like depression is seen.

Bowen disease (BD) and invasive arsenical SCC may be present, with the latent period being 10 and 20 years, respectively. The profound increase in BD and SCC appears to be characteristic of patients with arsenic exposure from well water. In patients exposed to arsenic through elixirs, BCCs are more characteristically seen. The latency period for development of BCC is also 20 years. Lesions are most common on the scalp and trunk. Arsenical keratoses may be a marker for increased lung and urothelial carcinoma.

NONMELANOMA SKIN CANCERS AND THEIR PRECURSORS

More nonmelanoma skin cancers (NMSCs) are diagnosed annually in the United States than all other cancers combined. In 2006 more than 3.5 million new NMSC cases were estimated to occur, and the incidence is rising. One in two men and one in three women

Fig. 29.10 Actinic keratosis/Bowen disease in transplant recipient.

in the United States will develop NMSC in their lifetime, usually after age 55. Although these result in only about 2000–2500 deaths annually, because of their sheer numbers, NMSCs represent about 5% of all Medicare cancer expenditures. Those at risk for skin cancer are fair-skinned individuals who tan poorly and who have had significant chronic or intermittent sun exposure. Red hair phenotype with loss-of-function mutations in the melanocortin-1 receptor may be a risk factor as well. Additional risk factors include a history of skin cancer, prior radiation therapy, PUVA treatment, arsenic exposure, and systemic immunosuppression (Fig. 29.10). Once an individual has developed an NMSC, the risk for a second is increased 10-fold. Over the 3-year period after the initial NMSC diagnosis, more than 40% of BCC and SCC patients develop a BCC, and 18% of SCC patients develop another SCC. By 5 years, as many as 50% of women and 70% of men will develop a second NMSC. The rate of developing NMSCs is no different 3 years or 10 years after the initial NMSC diagnosis. Patients with a history of NMSC should be examined regularly for NMSCs.

Ultraviolet radiation (UVR) is the major cause of nongenital NMSCs and actinic keratoses. The effect of UVR appears to be mediated through mutation of the *p53* gene, which is found mutated in a substantial percentage of NMSCs and actinic keratoses. Most skin cancers are highly immunogenic, but the immune response is suppressed by continued actinic exposure. Both chronic sun exposure and intermittent intense exposure are risk factors for

the development of NMSCs. It is believed that avoiding sun exposure reduces the risk for NMSC. The use of sunscreens in the prevention of NMSCs has been controversial; they may inadvertently lead to prolonged intentional sun exposure, negating their possible beneficial effect. Nonetheless, dermatologists and their societies recommend a program of sunscreen use together with sun avoidance to patients at risk for skin cancer. This includes avoiding midday sun, seeking shade, wearing protective clothing, and regularly applying a sunblock of sun protection factor (SPF) 15–30 with both UVB and UVA coverage. This program was pioneered in Australia and has led to improvements in some skin cancer rates there.

ACTINIC KERATOSIS (SOLAR KERATOSIS)

Actinic keratoses represent in situ dysplasias resulting from sun exposure. They are found chiefly on the chronically sun-exposed surfaces of the face (Fig. 29.11), ears, balding scalp, dorsal hands, and forearms. They are usually multiple, discrete, flat or elevated, verrucous or keratotic, red, pigmented, or skin colored. Usually, the surface is covered by an adherent scale, but sometimes it is smooth and shiny. On palpation, the surface is rough, like sandpaper, and at times lesions are more easily felt than seen. The patient may complain of tenderness when the lesion is rubbed or shaved over with a razor. The lesions are usually relatively small, measuring 3 mm to 1 cm in diameter, most being less than 6 mm. Rarely, lesions may reach 2 cm in size, but a lesion larger than 6 mm should be considered an actinic keratosis only if confirmed by biopsy or if it completely resolves with therapy. The hypertrophic type, which may lead to cutaneous horn formation, is most frequently present on the dorsal forearms and hands.

Actinic keratoses are the most common epithelial precancerous lesions. Although lesions typically appear in persons over age 50, actinic keratoses may occur in the twenties or thirties in patients who live in areas of high solar irradiation and have fair skin. Patients with actinic keratoses have a propensity for the development of nonmelanoma cutaneous malignancies. Actinic keratoses can be prevented by the regular application of sunscreen and by a low-fat diet. Beta carotene is of no benefit in preventing actinic keratoses.

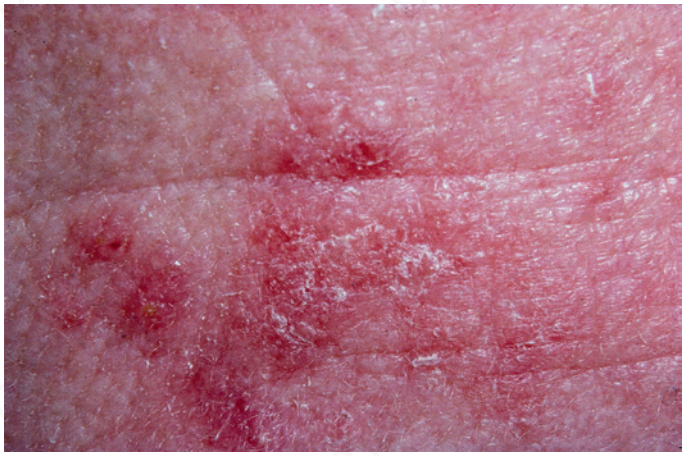

Fig. 29.11 Actinic keratosis.

Six types of actinic keratosis can be recognized histologically: hypertrophic, atrophic, bowenoid, acantholytic, pigmented, and lichenoid. The epidermis may be acanthotic or atrophic. Keratinocyte maturation may be disordered, with overlying parakeratosis sometimes present. The basal cells are most frequently dysplastic, although in more advanced lesions, dysplasia may be seen throughout the epidermis, simulating BD (bowenoid actinic keratosis).

The clinical diagnosis of actinic keratosis is usually straightforward. Early lesions of chronic cutaneous LE, erosive and pustular dermatosis of the scalp, and pemphigus foliaceus are sometimes confused with actinic keratoses. Seborrheic keratoses, even when lacking pigmentation, are usually more "stuck on" in appearance and more sharply marginated than actinic keratoses. Dermoscopy may aid in this distinction. It is difficult to distinguish hypertrophic actinic keratoses from early SCC, and a low threshold for biopsy is recommended. Similarly, actinic keratoses, which present as red patches, cannot easily be distinguished from BD or superficial BCC. If there is a palpable dermal component, or if on stretching the lesion there is a pearly quality, a biopsy should be considered. Any lesion larger than 6 mm, and any lesion that has failed to resolve with appropriate therapy for actinic keratosis, should also be carefully evaluated for biopsy.

Because some percentage of actinic keratoses will progress to NMSC, their treatment is indicated. There are many effective therapeutic modalities. Cryotherapy with liquid nitrogen is most effective and practical when there are a limited number of lesions. A bulky cotton applicator dipped into liquid nitrogen or a handheld nitrogen spray device can be used. If the cotton-tipped applicator method is used, the liquid nitrogen into which the applicator is dipped should be used for only one patient, because there is a theoretic risk of cross-contamination from one patient to another. Infectious agents are not killed by freezing, so many dermatologists now use the spray devices. We recommend using a small-opening tip with continuous bursts of nitrogen spray in a circular motion, depending on the size of the lesion, attempting an even frosting. Only the lesion should be frosted, and the duration of cryotherapy must be carefully controlled. A long freeze that results in significant epidermal-dermal injury produces white scars, which are easily seen on the fair skin of those at risk for actinic keratoses. When correctly performed, healing usually occurs within 1 week on the face, but may require up to 4 weeks on the arms and legs. Caution should be exercised when treating below the knee, because wound healing in these regions is particularly poor, and a chronic ulcer can result. Also, caution is required in persons at risk for having a cryoprotein, such as hepatitis C virus–infected patients and those with connective tissue disease or lymphoid neoplasia, who may have an excessive reaction to cryotherapy. It is better on the first visit to "undertreat" until the tolerance of a patient's skin to cryotherapy is known. Application of 0.5% 5-FU for 1 week before cryotherapy improves the response.

For extensive, broad, or numerous lesions, topical chemotherapy is recommended. Any lesion that could represent an NMSC should be biopsied before beginning topical chemotherapy or photodynamic therapy (PDT) for actinic keratoses. The two agents most frequently used are 5-FU cream, 0.5%–5%, or imiquimod 5% cream. Topical tretinoin and adapalene do not have the efficacy of these two agents but can be used for prolonged periods and represent an option for patients with a few early lesions. They are also useful for pretreatment of hyperkeratotic lesions before a course of 5-FU. Also, 3% diclofenac in 2.5% hyaluronan gel can be effective when used for 60 days for actinic keratoses. Topical

resiquimod and ingenol mebutate are newer topical therapeutic options and trichloracetic acid peels may still be useful in some patients. The inflammatory reaction with these agents parallels efficacy, but some data suggest a trend toward less irritation without diminished efficacy if dimethicone lotion is applied before ingenol mebutate.

The frequency and duration of treatment are determined by the individual's reaction and the anatomic site of application. 5-FU is applied once daily in most cases. For the face, 0.5% 5-FU tends to give a predictable response, which is slightly less severe than that produced by the 1%–5% concentrations. Some patients prefer the stronger concentration for a briefer period, while others favor a slower onset of the reaction and a more prolonged course. For the 5% cream, treatment duration rarely needs to exceed 2–3 weeks. For the 0.5% cream, the treatment course is typically 3–6 weeks. Usually, the central face will respond more briskly than the temples and forehead, which may require a longer duration of treatment. If the reaction is brisk, a midstrength corticosteroid ointment can be helpful or the treatment can be stopped and restarted at a lower concentration. Depending on the individual's sensitivity, an erythematous burning reaction will occur within several days. Treatment is stopped when a peak response occurs, characterized by a change in color from bright to dusky red, reepithelialization, and crust formation. Healing usually occurs within another 2 weeks of stopping treatment, depending on the treatment site. Certain areas of the face are prone to intense irritant dermatitis when exposed to 5-FU, and tolerance can be improved if the patient avoids application to the glabella, melolabial folds, and chin. For the scalp, the 0.5% concentration may be adequate, but prolonged or multiple treatment courses often are required if this low concentration is used. The 5% cream produces a more predictable, although brisk, reaction. A thick cutaneous horn can prevent penetration of 5-FU, and hypertrophic actinic keratoses on the scalp, dorsal hand, and forearm may respond poorly unless the area is pretreated with an agent to remove excessive keratin overlying the lesions. Pretreatment with tretinoin for 2–3 weeks can improve efficacy and shorten the duration of subsequent 5-FU treatment. It has been observed that 5-FU "seeks out" lesions that may not be clinically apparent. The use of topical 5-FU to the face can also reverse photoaging. Clinically inapparent BCCs may be detected during or on completion of the treatment. Rarely, patients who have had multiple courses of 5-FU topical chemotherapy will develop a true allergic contact dermatitis to the 5-FU. This is manifested by the redness, edema, or vesiculation extending beyond the area of application and by the patient developing pruritus rather than tenderness of the treated areas. Patch testing can be confirmatory.

Imiquimod is an interferon (IFN) inducer and eradicates actinic keratoses by producing a local immunologic reaction against the lesions. The ideal protocol for application of imiquimod may not yet be determined. About 80% of patients respond to imiquimod, and 20% may not respond at all, perhaps because that they lack some genetic component required to induce an inflammatory cascade when imiquimod is applied. If it is applied three times a week, patients develop an inflammatory reaction similar to that seen with daily application of 5-FU. The severity of the reaction is somewhat unpredictable, with a small subset of patients, especially fair-skinned women, developing a severe burning and crusting reaction after only one or a few applications. In others, no reaction at all occurs. With twice-weekly application, the treatment course is prolonged, up to 16 weeks. Severe erythema occurs in 17.7% and scabbing/crusting in 8.4% of patients so treated. The median percentage reduction in actinic keratoses is 83.3% with this treatment protocol. However, only 7% of patients treating actinic keratoses on the arms and hands with imiquimod three times per week achieved complete clearance. Applying it more frequently leads to increased toxicity. Overall, although the reaction is less predictable with imiquimod, it is also typically less severe than with high-concentration 5-FU. The adverse event rates are similar to those with low-concentration (0.5%) 5-FU. Another regimen is to apply imiquimod for long periods at a reduced frequency, once or twice weekly. Applications can be in alternating 1-month cycles or continuous for many months. This may allow management of some patients who require treatment but cannot tolerate any significant changes in appearance. Ultimately, the choice between topical 5-FU and imiquimod will be based on patient preference, prior physician and patient experience with the modalities, and the cost. Imiquimod is significantly more expensive per gram than any form of 5-FU. A meta-analysis comparing efficacy studies of the two agents dosed in various concentrations and regimens suggested imiquimod may have higher efficacy for actinic keratosis on the face and scalp. A recent Cochrane review concluded that 5-FU, imiquimod, ingenol mebutate, and diclofenac are similarly efficacious but have different adverse events and cosmetic outcomes. Direct comparative trials between these agents would be of great value in determining the optimal and most cost-effective strategy for the treatment of extensive actinic keratosis, and the cost of treatment can vary widely depending on the modality chosen.

Surgical management of actinic keratoses with chemical peels, laser resurfacing, and PDT are discussed in Chapters 37 and 38.

CUTANEOUS HORN (CORNU CUTANEUM)

Cutaneous horns are encountered most frequently on the dorsal hands and scalp. Lesions may also occur on the hands, penis, ears (Fig. 29.12), and eyelids. They are skin-colored, horny excrescences 2–60 mm long, sometimes divided into several antler-like projections.

These lesions are most often benign, with the hyperkeratosis being superimposed on an underlying seborrheic keratosis, verruca vulgaris, angiokeratoma, molluscum contagiosum, or trichilemmoma in about 60% of cases. However, 20%–30% may overlie premalignant keratosis, and 20% may overlie SCCs or BCCs. The risk for a cutaneous horn overlying a malignancy is much higher in fair-complexioned elderly persons. Hyperkeratotic actinic plaques less than 1 cm in diameter on the dorsum of the hand, wrist, or

forearms in white patients have been shown to have a malignancy rate of 50%. One third of penile horns are associated with underlying malignancies. Excisional biopsy with histologic examination of the base is necessary to determine the best therapy, which would be dictated by the diagnosis of the underlying lesion and by the apparent adequacy of removal.

KERATOACANTHOMA

Clinical Features

There are four types of keratoacanthoma: solitary, multiple, eruptive, and keratoacanthoma centrifugum marginatum. The exact biologic behavior of keratoacanthoma remains controversial. In the past, it had been considered a reactive condition or pseudomalignancy that could be treated expectantly. Now, the favored view is that keratoacanthomas are low-grade SCCs, which in many cases will regress. The regression may be partially mediated by immunity but takes the form of terminal differentiation. The course of these tumors is unpredictable. Even those that ultimately involute can cause considerable destruction before they regress. Any lesions that have the histologic features of keratoacanthoma and appear in an immunosuppressed host should be managed as an SCC, with complete eradication.

Sunlight appears to play an important role in the etiology, especially in the solitary types, with light-skinned persons being predominantly affected. Cases of keratoacanthoma after trauma, hypertrophic lichen planus, discoid LE, tattoos, fractional thermolysis, and imiquimod erosions, and along the distal ends of surgical excisions, suggest that an isomorphic phenomenon is common. The keratoacanthomas appear about 1 month after the traumatic injury. All these associated conditions result in damage to the dermis, especially along the DEJ, and necessitate wound healing. The biologic behavior of these lesions is unknown, but they have added to the controversy of keratoacanthoma as a reactive versus a malignant process. Eruptive keratoacanthomas and SCCs have appeared during treatment for metastatic melanoma with the *BRAF* inhibitor vemurafenib as well as with anti-PD1 agents such as pembrolizumab. In Muir-Torre syndrome, sebaceous tumors and keratoacanthomas occur in association with multiple internal malignancies. A second, less common cancer scenario is the keratoacanthoma–visceral carcinoma syndrome (KAVCS); only a handful of cases have been reported. Patients have multiple or large keratoacanthomas that appear at the same time as an internal malignancy, always of the genitourinary tract. The relationship of Muir-Torre syndrome (MTS) to KAVCS awaits identification of the genetic basis of both syndromes.

Solitary Keratoacanthoma

The solitary keratoacanthoma is a rapidly growing papule that enlarges from a 1-mm macule or papule to as large as 25 mm in 3–8 weeks. When fully developed, it is a hemispheric, dome-shaped, skin-colored nodule that has a smooth crater filled with a central keratin plug (Fig. 29.13). The smooth shiny lesion is sharply demarcated from its surroundings. Telangiectases may run through the lesion. Subungual keratoacanthomas are tender subungual tumors that usually cause significant nail dystrophy. Subungual lesions often do not regress spontaneously and induce early underlying bony destruction, characterized on radiograph as a crescent-shaped lytic defect without accompanying sclerosis or periosteal reaction.

The solitary keratoacanthoma occurs mostly on sun-exposed skin, with the central portion of the face, backs of the hands, and arms most often involved. Less frequently, other sites are involved, such as the buttocks, thighs, penis, ears, and scalp. Elderly fair-skinned individuals most frequently develop keratoacanthomas. Lesions of the dorsal hands are more common in men, and keratoacanthomas of the lower legs are more common in women. The most interesting feature of this disease is the rapid growth for 2–6 weeks, followed by a stationary period for another 2–6 weeks, and finally a spontaneous involution over another 2–6 weeks, leaving a slightly depressed scar. The stationary period and involuting phase are variable; some lesions may take 6 months to 1 year to resolve completely. An estimated 5% of treated lesions recur. Invasion along nerve trunks has been documented and may result in recurrence after a seemingly adequate excision.

Histopathology

The histologic findings of keratoacanthoma and a low-grade SCC are so similar that it is frequently difficult to make a definite diagnosis on the histologic findings alone. When a properly sectioned specimen is examined under low magnification, the center of the lesion shows a crater filled with eosinophilic keratin. Over the sides of the crater, which seems to have been formed by invagination of the epidermis, a "lip" or "marginal buttress" of epithelium extends over the keratin-filled crater. At the base and sides of the crater, the epithelium is acanthotic and composed of

keratinocytes, which are highly keratinized and have an eosinophilic, glassy cytoplasm. Surrounding the keratinocyte proliferation, a dense inflammatory infiltrate is frequently seen. Neutrophilic microabscesses are common within the tumor, and trapping of elastic fibers is often identified at the periphery of the tumor. These features favor a diagnosis of keratoacanthoma. The most definitive histologic feature is evidence of terminal differentiation, where the scalloped outer border of the tumor has lost its infiltrative character and is reduced to a thin rim of keratinizing cells lining a large, keratin-filled crater. The presence of acantholysis within the tumor is incompatible with a diagnosis of keratoacanthoma. It is also important to distinguish keratoacanthoma from marked pseudoepitheliomatous hyperplasia, as seen in prurigo nodularis. Unfortunately, histology does not completely correlate with biologic behavior. The diagnosis of benign-behaving keratoacanthoma versus a potentially aggressive SCC may not always be possible. Even if the classic histologic features of keratoacanthoma are seen, the diagnosis of SCC should be considered if the lesion does not behave as expected.

Treatment

Although keratoacanthomas spontaneously involute, it is impossible to predict how long this will take. The patient may be faced with destructive growth of a tumor for as long as 1 year. More importantly, SCC cannot always be excluded clinically. Therefore excisional biopsy of the typical keratoacanthoma of less than 2 cm in diameter should be considered in most cases. If the history is characteristic, or multiple lesions have appeared simultaneously, less aggressive interventions may be considered. Nonsurgical therapy may also be considered in certain sites to preserve function or improve cosmetic outcome.

Intralesional injections of 5-FU solution, 50 mg/mL (undiluted from ampule) at weekly intervals; bleomycin, 0.5 mg/mL; or methotrexate, 25 mg/mL, can be effective. For a typical lesion, four injections along the base at each pole are recommended. Low-dose systemic methotrexate can be considered if multiple lesions are present and there is no contraindication. For clinically typical lesions, these modalities may be tried before resorting to surgical removal, especially if the latter presents any problem. Excision is recommended if there is not at least 50% involution of the lesion after 3 weeks. Radiation therapy may also be used on giant keratoacanthomas when surgical excision or electrosurgical methods are not feasible.

Eruptive Keratoacanthomas of the Lower Leg

In older patients, especially older women, keratoacanthomas on the lower legs are often multiple and erupt in great numbers when one is treated surgically. The old quip is that "you kill one and five come to the funeral." An effective approach is to treat the lesions with 5-FU cream under Unna boot occlusion. Topical imiquimod, intralesional 5-FU, intralesional methotrexate, psoriatic doses of oral methotrexate, and oral acitretin can also be useful.

Multiple Keratoacanthomas (Ferguson Smith Type)

This type of keratoacanthoma is frequently referred to as the Ferguson Smith type of multiple self-healing keratoacanthoma. These lesions are identical clinically and histologically to the solitary type. There is frequently a family history of similar lesions. The condition has been traced to two large Scottish kindreds. Affected families from other countries have also been reported. Beginning on average at about age 25, but possibly as early as the second decade, patients develop crops of keratoacanthomas that begin as small red macules and rapidly become papules that evolve to typical keratoacanthomas. Lesions may number from a few to hundreds, but generally only 3–10 lesions are noted at any one time. Sun-exposed sites are favored, especially the ears and nose, and in most cases scalp lesions occur. In addition, these patients typically develop keratoacanthomas at sites of trauma, often at the ends of surgical excisions. Lesions grow over 2–4 weeks, reaching a size of 2–3 cm, then remain stable for 1–2 months before slowly involuting. They leave a prominent crateriform scar. If the early lesions are aggressively treated with cryotherapy, shave removal, or curettage, the scar may be less marked than that induced by spontaneous involution. Treatment with an oral retinoid can be effective in stopping the appearance of new lesions and causing involution of existing ones.

Generalized Eruptive Keratoacanthomas (Grzybowski Variant)

The generalized eruptive keratoacanthoma is very rare and sporadic, with most patients having no affected family members. The usual age of onset is between 40 and 60. The patients are usually in good health and are not immunosuppressed. The cause of this condition is unknown. HPV has not been detected in most patients in whom it was sought. The clinical features are characteristic and unique. The Grzybowski type of multiple keratoacanthoma is characterized by a generalized eruption of numerous dome-shaped, skin-colored papules 2–7 mm in diameter. Multiple larger typical keratoacanthomas may also appear. Thousands of lesions may develop. The eruption is usually generalized, but spares the palms and soles. The oral mucous membranes and larynx can be involved. Severe pruritus may be a feature. Clinically, pityriasis rubra pilaris or widespread lichen planopilaris are often considered. Bilateral ectropion, narrowing of the oral aperture, and severe facial disfigurement can result. Linear arrangement of some lesions, especially over the shoulders and arms, has also been noted. Despite the multiplicity of lesions, no case of "metastasis" from a skin lesion or increased risk of internal malignancy has been reported in the Grzybowski variant of keratoacanthoma. Dr. Grzybowski's original patient died of a myocardial infarction 16 years after diagnosis. Oral treatment with retinoids, methotrexate, and cyclophosphamide can prove effective.

Keratoacanthoma Centrifugum Marginatum

This uncommon variant of keratoacanthoma is usually solitary, although multiple lesions can occur. Keratoacanthoma centrifugum marginatum is characterized by progressive peripheral expansion and concomitant central healing, leaving atrophy. Spontaneous involution, as may be seen in other variants of keratoacanthoma, does not occur. Lesions range from 5–30 cm in diameter (Fig. 29.14). The dorsum of the hands and pretibial regions are favored sites. Oral treatment with etretinate and methotrexate with prednisone has been effective in isolated cases.

BASAL CELL CARCINOMA

Basal cell carcinoma (BCC) is the most common cancer in the United States, Australia, New Zealand, and many other countries with a largely white, fair-skinned population with moderate sun exposure. In Hawaii, the incidence of BCC is 14-fold higher in persons of European ancestry (especially Celtic) than in Japanese, and 34-fold higher than in Filipinos. Still, persons of color can develop BCCs, especially fair-skinned Asians and Hispanics who have accumulated significant lifetime sun exposure from occupational sources, usually farm work. White Hispanics have less skin cancer awareness, use sun protection less frequently, and are more likely to use tanning beds than darker-skinned Hispanics. They represent a prevalent at-risk population for skin cancer over the next decades.

Intermittent intense sun exposure, as identified by prior sunburns; radiation therapy; a positive family history of BCC; immunosuppression; a fair complexion, especially red hair; easy sunburning (skin types I or II); and blistering sunburns in childhood are risk factors for the development of BCC. Indoor tanning is a strong risk factor for early-onset BCC, particularly among women.

Fig. 29.15 Basal cell carcinoma.

Of interest, actinic elastosis and wrinkling are not risk factors for the development of BCC. In fact, BCCs are relatively rare on the dorsal hand, where sun exposure is high, whereas actinic keratoses and SCCs abound. SCC is three times more common than BCC on the dorsum of the hand. These findings suggest that the mechanism by which UVR induces BCC is not related solely to the total amount of UVR received. In contrast to actinic keratoses and SCCs, prevention with regular use of sunscreens is more difficult to demonstrate. The ratio of BCC to SCC decreases as one moves from northern (≈10) to southern (≈2) United States. Once a person has had a BCC, his or her risk for a subsequent BCC is high: 44% in the next 3 years.

Many clinical morphologies of BCC exist. Clinical diagnosis depends on the clinician being aware of the many forms BCC may take. Because these clinical types may also have different biologic behavior, histologic classification of the type of BCC may also influence the therapy chosen.

Nodular Basal Cell Carcinoma (Classic Basal Cell Carcinoma)

The classic or nodular BCC constitutes 50%–80% of all BCCs. Nodular BCC is composed of one or a few small, waxy, semitranslucent nodules forming around a central depression that may or may not be ulcerated, crusted, and bleeding. The edge of larger lesions has a characteristic rolled border. Telangiectases course through the lesion. Bleeding on slight injury is a common sign. As growth progresses, crusting appears over a central erosion or ulcer, and when the crust is knocked or picked off, bleeding occurs, and the ulcer becomes apparent. This ulcer is characterized by chronicity and gradual enlargement over time. The lesions are asymptomatic, and bleeding is the only difficulty encountered. The lesions are most frequently found on the face (Fig. 29.15) (85%–90% on head and neck) and especially on the nose (25%–30%). The forehead, ears, periocular areas, and cheeks are also favored sites. However, any part of the body may be involved.

Cystic Basal Cell Carcinoma

These dome-shaped, blue-gray cystic nodules are clinically similar to eccrine and apocrine hidrocystomas.

Morpheaform, or Cicatricial Basal Cell Carcinoma

This type of BCC presents as a white sclerotic plaque, and 95% of these occur on the head and neck. Ulceration, a pearly rolled border, and crusting are usually absent. Telangiectasia is variably present. Therefore the lesion is often missed or misdiagnosed

for some time. The differential diagnosis includes desmoplastic trichoepithelioma, a scar, microcystic adnexal carcinoma, and desmoplastic melanoma. The unique histologic feature is the strands of basal cells interspersed amid densely packed, hypocellular connective tissue. Morpheic BCCs constitute 2%–6% of all BCCs. Data suggest use of fluorouracil may be a risk factor for morpheaform versus nonmorpheaform BCC.

Infiltrative Basal Cell Carcinoma

Infiltrative BCC is an aggressive subtype characterized by deep infiltration of spiky islands of basaloid epithelium in a fibroblast-rich stroma. Clinically, it lacks the scarlike appearance of morpheiform BCC. Histologically, the stroma is hypercellular, the islands are jagged in outline, and squamous differentiation is common.

Micronodular Basal Cell Carcinoma

These tumors are not clinically distinctive, but the micronodular growth pattern makes them less amenable to curettage.

Superficial Basal Cell Carcinoma

Superficial BCC is also termed superficial multicentric BCC. This is a common form of BCC, comprising at least 15% of the total. It favors the trunk (45%) or distal extremities (14%). Only 40% occur on the head and neck. The multicentricity is merely a histologic illusion created by the passing of the plane of section through the branches of a single, multiply branching lesion.

This type of BCC most frequently presents as a dry, psoriasiform, scaly lesion. It is usually a superficial flat growth, which in many cases exhibits little tendency to invade or ulcerate. The lesions enlarge very slowly and may be misdiagnosed as patches of eczema or psoriasis. They may grow to be 10–15 cm in diameter. Close examination of the edges of the lesion will show a threadlike raised border (Fig. 29.16). These erythematous plaques with telangiectasia may occasionally show atrophy or scarring. Some lesions may develop an infiltrative component in their deeper aspect and grow into the deeper dermis. When this occurs, they may induce dermal fibrosis and multifocal ulceration, forming a "field of fire" type of large BCC. Sometimes the lesion will heal at one place with a white atrophic scar and then spread actively to the neighboring skin. A patient can have several of these lesions simultaneously or over time. This form of BCC is the most common pattern seen in patients with human immunodeficiency virus (HIV) infection and BCC.

Fig. 29.16 Superficial basal cell carcinoma.

Pigmented Basal Cell Carcinoma

This variety has all the features of nodular BCC, but in addition, brown or black pigmentation is present (Fig. 29.17). When dark-complexioned persons, such as Latin Americans, Hispanics, or Asians, develop BCC, this is the type they tend to develop. Pigmented BCCs make up 6% of all BCCs. In the management of these lesions, it should be known that, if ionizing radiation therapy is chosen, the pigmentation remains at the site of the lesion.

Rodent Ulcer

Also known as Jacobi ulcer, rodent ulcer is a neglected BCC that has formed an ulceration. The pearly border of the lesion may not be recognized. If it occurs on the lower extremity, it may be misdiagnosed as a vascular ulceration.

Fibroepithelioma of Pinkus

First described by Pinkus as premalignant fibroepithelial tumor, this is usually an elevated, skin-colored, sessile lesion on the lower trunk, lumbosacral area, groin, or thigh and may be as large as 7 cm. The lesion is superficial and resembles a fibroma or papilloma. Histologically, interlacing basocellular sheets extend downward from the surface to form an epithelial meshwork enclosing a hyperplastic mesodermal stroma. As with infundibulocystic BCC, fibroepithelioma is composed of pink epithelial strands with blue basaloid buds. Fibroepithelioma has a more prominent fibromucinous stroma and lacks the horn cysts characteristic of infundibulocystic BCC. Fibroepithelioma often demonstrates sweat ducts within the pink epithelial strands. A slight inflammatory infiltrate may also be present. Simple removal by excision or electrosurgery is the treatment of choice.

Polypoid Basal Cell Carcinoma

The polypoid BCCs present as exophytic nodules of the head and neck.

Porelike Basal Cell Carcinoma

Patients with thick sebaceous skin of the central face may develop a BCC that resembles an enlarged pore or stellate pit. The lesions virtually always occur on the nose, melolabial fold, or lower forehead. Affected patients are generally men, and the majority are smokers. Many years pass from the appearance of the lesion until a diagnostic biopsy is taken, because the lesion is considered inconsequential.

Fig. 29.17 Pigmented basal cell carcinoma. (Courtesy Debabrata Bandyopadhyay, MD.)

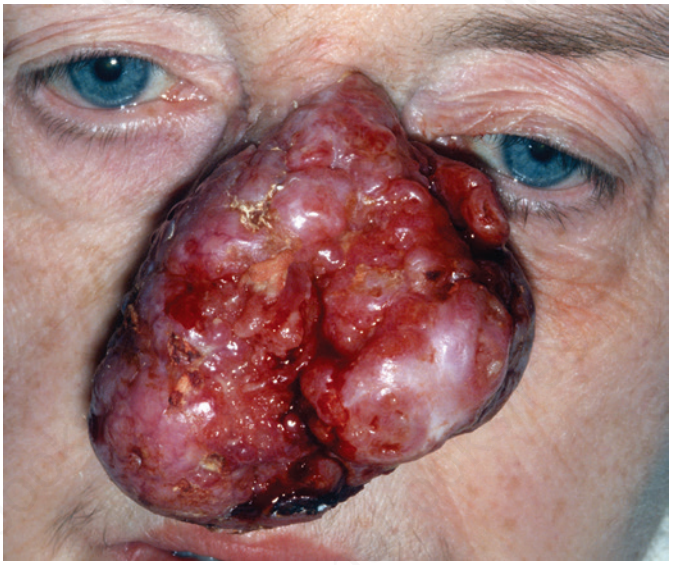

Fig. 29.18 Large basal cell carcinoma.

Aberrant Basal Cell Carcinoma

Even in the absence of any apparent carcinogenic factor, such as arsenic, radiation, or chronic ulceration, BCC may occur in odd sites, such as the scrotum, vulva, perineum, nipple, and axilla.

Solitary Basal Cell Carcinoma in Young Persons

These curious lesions are typically located in the region of embryonal clefts in the face and are often deeply invasive. Complete surgical excision is much safer than curettage for their removal. Cases in children and teenagers, unassociated with the basal cell nevus syndrome or nevus sebaceus, are well documented.

Natural History

Basal cell carcinomas run a chronic course as the lesion slowly enlarges and tends to become more ulcerative (Fig. 29.18). As a rule, the lesions tend to bleed without pain or other symptoms. Some tend to heal spontaneously and form scar tissue as they extend. Peripheral spreading may produce configurate, somewhat serpiginous patches. The ulceration may burrow deep into the subcutaneous tissues or even into cartilage and bone, causing extensive destruction and mutilation. At least half the deaths that occur from BCC result from direct extension into a vital structure rather than metastases.

Metastasis

Metastasis is extremely rare, occurring in 0.0028%–0.55% of BCCs. This low rate is believed to occur because the tumor cells require supporting stroma to survive. The following criteria are now widely accepted for the diagnosis of metastatic BCC:

1. The primary tumor must arise in the skin.
2. Metastases must be demonstrated at a site distant from the primary tumor and must not be related to simple extension.
3. Histologic similarity must exist between the primary tumor and the metastases.
4. The metastases must not be mixed with SCC.

Metastatic BCC is twice as common in men as in women. Immunosuppression does not appear to increase the risk of metastasis of BCC. Most BCCs that metastasize arise on the head and neck and tend to be large tumors that have recurred despite multiple surgical procedures or radiation therapy. The histologic finding of perineural or intravascular BCC increases the risk for metastasis. The regional lymph nodes are the most common site of metastasis, followed by the lung, bone, skin, liver, and pleura. Spread is equally distributed between hematogenous and lymphatic. An average of 9 years elapses between the diagnosis of the primary tumor and metastatic disease, but the interval for metastasis ranges from less than 1 year to 45 years. Although the primary tumor may be present for many years before it metastasizes, once metastases occur, the course is rapidly downhill. After metastasis, fewer than 20% of patients survive 1 year, and fewer than 10% will live for more than 5 years.

Association with Internal Malignancies

Frisch et al. reported a series of 37,674 patients with BCCs followed over 14 years. Comparison of cancer rates for the general population was remarkable, with 3663 new cancers versus 3245 in the control population. Malignant melanoma and lip cancers were most frequently found; however, internal malignancies were also noted to be excessive, involving the salivary glands, larynx, lung, breast, kidney, and lymphatics (non-Hodgkin lymphoma). The rate of non-Hodgkin lymphoma was particularly high. Patients receiving the diagnosis of BCC before age 60 had a higher rate of breast cancer, testicular cancer, and non-Hodgkin lymphoma.

Immunosuppression

Immunosuppression for organ transplantation increases the risk for the development of BCC by about 10-fold. Some increased risk for BCC is also thought to occur in HIV-infected patients and in those receiving immunosuppressive medications for other reasons. Patients with chronic lymphocytic leukemia are also at increased risk for BCC. In the immunosuppressed population, a history of blistering sunburns in childhood is a strong risk factor for the development of BCC after immunosuppression.

Etiology and Pathogenesis

It appears that BCCs arise from immature pluripotential cells associated with the hair follicle. Mutations that activate the hedgehog signaling pathway, which controls cell growth, are found in most BCCs. The affected genes are those for sonic hedgehog, patched 1, and smoothened *(SMO)*. Inactivation of patched 1 is most common, and *SMO* mutations are associated with 10%–20% of sporadic BCCs.

Histopathology

The general belief is that a correlation exists between histologic subtype of BCC and biologic behavior. BCCs are considered as being of low risk or high risk, depending on their probability of causing problems in the future: subclinical extension, incomplete removal, aggressive local invasive behavior, and local recurrence. Therefore the dermatopathology report of a BCC should include a subtype descriptor when possible. Unfortunately, many shave biopsy specimens do not allow for accurate typing, and the presence of an indolent growth pattern superficially does not exclude the possibility of a deeper, more aggressive growth pattern. The common histologic patterns are nodular, superficial, infiltrative, morpheic, micronodular, and mixed. The nodular type is a low-risk type. High-risk types include the infiltrative, morpheic, and micronodular patterns, because of aggressive local invasive behavior and a tendency to recur. Superficial BCC is prone to increased recurrence due to inadequate removal. When evaluating the

histologic margin of superficial BCC, tumor stroma involving the margin should be considered a positive margin.

The early lesion shows small, dark-staining, polyhedral cells resembling those of the basal cell layer of the epidermis, with large nuclei and small nucleoli. These occur within the epidermis as thickenings or immediately beneath the epidermis as downgrowths connected with it. After the growth has progressed, regular compact columns of these cells fill the tissue spaces of the dermis, and a connection with the epidermis may be difficult to demonstrate. At the periphery of the masses of cells, the columnar cells may be characteristically arranged like fence posts (palisading). This may be absent when the tumor cells are in cord arrangement or in small nests. Cysts may form. The interlacing strands of tumor cells may present a lattice-like pattern. The dermal stroma is an integral and important part of the BCC. The stroma is loose and fibromyxoid, with a sparse lymphoid infiltrate often present. The stroma can be highlighted by metachromatic toluidine blue staining, which can be useful during Mohs surgery.

Differential Diagnosis

Distinguishing between small BCCs and small SCCs is largely an intellectual exercise. Both are caused chiefly by sunlight, neither is likely to metastasize, and both will require removal, usually by simple surgical excision or curettage. A biopsy is always indicated but may be performed at the definitive procedure, when the likelihood of the diagnosis of NMSC is high and the patient is fully informed and gives consent.

A waxy, nodular, rolled edge is fairly characteristic of BCC (Fig. 29.19). The SCC is a dome-shaped, elevated, hard, and infiltrated lesion. The early BCC may easily be confused with sebaceous hyperplasia, which has a depressed center with yellowish small nodules surrounding the lesion. However, these lesions never bleed and do not become crusted.

Bowen disease, Paget disease, amelanotic melanoma, and actinic and seborrheic keratoses may also simulate BCC. Ulcerated BCC on the shins is frequently misdiagnosed as a stasis ulcer, and a biopsy may be the only way to differentiate the two. Pigmented BBC is frequently misdiagnosed as melanoma or as a pigmented nevus. The superficial BCC is easily mistaken for psoriasis or eczema. The careful search for the rolled edge of the peripheral nodules is important in differentiating BCC from all other lesions.

Treatment

Each lesion of BCC must be thoroughly evaluated individually. Age and gender of the patient as well as the size, site, and type of lesion are important factors to be considered when choosing the proper method of treatment. No single treatment method is ideal for all lesions or all patients. The choice of treatment will also be influenced by the experience and ability of the treating physician in the various treatment modalities. A biopsy should be performed in all patients with suspected BCC to determine the histologic subtype and confirm the diagnosis.

Fig. 29.19 Basal cell carcinoma, accentuation of pearly border when skin is stretched.

The aim of treatment is for a permanent cure with the best cosmetic results. This is important because the most common location of BCC is the face. Recurrences result from inadequate treatment and are usually seen during the first 4–12 months after treatment. A minimum 5-year follow-up is indicated, however, to continue a search for new lesions, because the development of a second BCC is common.

Treatment of BCC is usually surgical (see Chapter 37), but some forms of BCC are amenable to medical treatment, PDT or radiation therapy. Vismodegiband related inhibitors of smoothened that targets the hedgehog pathway, has antitumor activity and clinically meaningful response in locally advanced or metastatic BCC. Electrochemotherapy, combining bleomycin with short electric pulses, has been used as palliative skin-directed therapy for patients with multiple or large BCC for whom conventional treatments are not viable options.

Topical Therapy

Topical therapy appears to be most effective in the treatment of superficial BCC. For nodular BCCs, the cure rates are only 65%, which is unacceptable given the other options available. On the other hand, superficial BCCs may be cured 80% of the time with topical treatment. Topical 5-FU applied twice daily for at least 6 weeks can yield acceptable results in properly selected (i.e., thin) tumors but is not otherwise very effective, with high recurrence rates. Imiquimod applied three times a week with occlusion, or five times a week without occlusion, is the favored form of topical, patient-applied treatment for superficial BCC. Duration of treatment is 6 weeks but may be extended if the lesion does not appear to have been eradicated. Cosmetic results are excellent, especially for lesions of the anterior chest and upper back, where significant scarring usually results from surgical procedures. PDT has also emerged as a treatment option for BCC. A randomized controlled trial (RCT) found imiquimod to be superior, and 5-FU not to be inferior, to PDT for superficial BCC. Cure rates are higher with surgical excision than with topical therapy.

Fig. 29.20 Multiple basal cell carcinomas in nevoid basal cell carcinoma syndrome.

NEVOID BASAL CELL CARCINOMA SYNDROME (GORLIN SYNDROME)

Clinical Features

The nevoid BCC syndrome (NBCCS) or basal cell nevus syndrome is an autosomal dominant inherited disorder. The major diagnostic criteria for NBCCS include the following:

1. Development of multiple BCCs (>5) or a BCC before age 30 (Fig. 29.20)
2. Odontogenic keratocysts of the jaws
3. Pitted depressions on the hands and feet (palmar plantar pits) (two or more)
4. Lamellar calcification of the falx under age 20
5. First-degree relative with NBCCS

Minor criteria are as follows:

1. Childhood medulloblastoma
2. Lympho-mesenteric or pleural cysts
3. Macrocephaly (97th percentile)
4. Cleft lip/palate
5. Vertebral/rib abnormalities
6. Preaxial or postaxial polydactyly
7. Ovarian/cardiac fibromas
8. Ocular abnormalities

The diagnosis of NBBCS is made if the affected individual has two major criteria and one minor criterion, or one major criterion and three minor criteria. Genetic testing has revealed that some persons carrying the genetic mutation do not meet the diagnostic criteria.

Essentially, all cases of NBCCS are caused by mutations in the *PTCH* (or *PTCH1*) gene. One family with a mutation in the *SUFU* gene has been reported. *SUFU* mutations have been reported with meduloblastoma susceptibility. Mutations occur throughout the *PTCH* gene, and no correlation appears to exist between the site of the mutation and the clinical phenotype. Most mutations result in premature termination and production of shortened gene product. Loss of the *PTCH* gene can also occur by deletions of part of the long arm of chromosome 9, where the *PTCH* gene is located (region q22). This represents about 6% of NBCCS patients.

The clinical findings seen with NBCCS depend on two characteristics: the race of the patient and the form of mutation (nucleotide point mutation or chromosome deletion). Of 105 patients reported in one series, 80% were white. The first tumor developed by the mean age of 23 years for white patients. Palmar pits were seen in 87%. Jaw cysts were found in 74%, with 80% manifested by age 20. The total number of cysts ranged from 1 to 28. Medulloblastomas developed in four patients, and three had cleft lip or palate. Physical findings in this series included "coarse face" (54%), macrocephaly (50%), hypertelorism (42%), frontal bossing (27%), pectus deformity (13%), and Sprengel deformity (11%). In Japanese and African American patients with NBCCS, palmar and plantar pits, odontogenic keratocysts, and skeletal abnormalities are most common, with BCCs not appearing until much later in life. Those patients with NBCCS caused by deletions of chromosome 9q22 have all the stigmata of typical NBCCS patients, and in addition often have severe mental retardation, hyperactivity, overfriendliness with strangers, short stature, and less often, neonatal hypotonia, epicanthic folds, short neck, pectus, scoliosis, and epilepsy.

Skin Tumors

The BCCs occur at an early age or any time thereafter as multiple lesions, usually numerous. The usual age of appearance is 17–35 years. Although any area of the body may be affected, there is a marked tendency toward involvement of the central facial area, especially the eyelids, periorbital area, nose, upper lip, and cheeks. Persons with fair skin (type 1) and prior excessive UV exposure are particularly prone to develop many BCCs. Lesions typically appear as 1–10 mm, hyperpigmented or skin-colored, dome-shaped papules. They have a striking resemblance to typical compound or intradermal nevi. Polypoid BCC or acrochordon-like BCC is a more unusual variant that tends to occur in NBCCS patients in childhood. Among the many BCCs that an NBCCS patient may have, some sit indolently and others may grow more aggressively.

Jaw Cysts

Jaw cysts occur in approximately 90% of patients. They occur as early as age 5 years and rarely after age 30. Both the mandible and the maxilla may show cystic defects on x-ray, with mandibular involvement occurring twice as often. Jaw cysts most commonly present as painless swelling. They usually have a keratinized lining (keratocysts) but uncommonly a cyst may be an ameloblastoma.

Pits of Palms and Soles

An unusual pitting of palms and soles is a distinguishing feature of the disease. This usually becomes apparent in the second decade of life. Up to 87% of patients with NBCCS will have pits. Histologically, they show basaloid proliferation, but the lesions do not progress or behave as a BCC.

Skeletal Defects/Birth Defects

Most NBCCS patients have skeletal anomalies that are easily detected on radiographs. Macrocephaly is the first feature observed and explains the high rate of cesarean delivery of NBCCS-affected neonates. Other skeletal defects include bifid, fused, missing, or splayed ribs; scoliosis; and kyphosis. Radiographic evidence of multiple lesions is highly suggestive of this syndrome; and because most are present congenitally, radiology may be useful in diagnosing this syndrome in patients too young to manifest other

abnormalities. Cleft lip/palate is seen in 5% of patients; lamellar calcification of the falx will be evident in 90% of patients by age 20; and polydactyly also occurs. Numerous ocular findings have been reported, and if NBCCS is suspected or confirmed, an ophthalmologic evaluation should be performed. Spina bifida is, fortunately, uncommon.

Histopathology

The histology of BCCs arising in syndromic patients is identical to that arising in nonsyndromic patients, with the solid and superficial types being most common.

Differential Diagnosis

Several other unique types of BCC presentation should not be confused with NBCCS. One type is the linear unilateral BCC syndrome, in which a linear arrangement of close-set papules, sometimes interspersed with comedones, is present at birth. Biopsy reveals BBCs, but they do not increase in size with the age of the patient. A second type, referred to as Bazex syndrome, is an X-linked dominant inherited disease comprising follicular atrophoderma of the extremities, localized or generalized hypohidrosis, hypotrichosis, and multiple BCCs of the face, which often arise at an early age. A third type consists of multiple hereditary infundibulocystic BCCs and is an autosomal dominant syndrome. It is distinguished from NBCCS by the absence of palmar pits and jaw cysts in most cases. Clinically, patients appear to have multiple trichoepitheliomas. Numerous skin-colored pearly papules affect the central face, accentuated in the nasolabial folds. The generalized basaloid follicular hamartoma (BFH) syndrome differs from NBCCS by having basaloid follicular hamartomas instead of BCCs. It is reported from a large kindred in the southeastern United States (see later). Tiny palmar pits are present. Histologically, infundibulocystic BCC and BFH may be indistinguishable, so the two familial syndromes may be difficult to separate. Rombo syndrome, reported in one large Swedish family, has multiple BCCs, vermiculate atrophoderma, and hypotrichosis. A patient with multiple BCCs and myotonic dystrophy has been reported, suggesting yet another genodermatosis associated with multiple BCCs.

Treatment

Genetic counseling is essential. Strict sun avoidance and maximum sun protection, as recommended for xeroderma pigmentosum patients, is advised. Avoidance of ionizing radiation is also paramount, because NBCCS patients are particularly sensitive to radiation; multiple BCCs may appear in the distribution of radiation therapy used to treat medulloblastoma or BCC or other cancers. Treatment involves very regular monitoring and biopsy of suspicious lesions. Topical therapy with tazarotene and imiquimod may be of some use in preventing and treating the superficial tumors. Oral retinoid therapy may reduce the frequency of new BCCs appearing and may slow the growth of existing small BCCs. However, once the oral retinoids are stopped, the lesions again begin to grow. Vismodegib, the hedgehog pathway inhibitor, reduces BCC tumor burden and prevents growth of new BCCs in those with NBCCS; however, poor tolerability of the medication leads to a high rate of discontinuation (≈50%). A topical formulation of a smoothened inhibitor appears to be effective and better tolerated, leading to BCC regression. Surgical treatments are used for most lesions, either curettage and desiccation or excision. At times, megasessions, with removal of multiple tumors under general anesthesia in the operating room, are needed to keep up with the large number of BCCs these patients develop. PDT appears to be particularly beneficial when used to treat areas that have had multiple BCCs in the past.

SQUAMOUS CELL CARCINOMA

Squamous cell carcinoma (SCC) is the second most common form of skin cancer. Most cases of SCC of the skin are induced by UVR. Chronic, long-term sun exposure is the major risk factor, and areas that have had such exposure (face, scalp, neck, dorsal hands) are favored locations. SCC becomes relatively more common as the annual amount of UVR increases, so SCC is more common in Texas than in Minnesota, for example. Immunosuppression greatly enhances the risk for the development of SCC, approximately 65-fold to 250-fold among organ transplant recipients, with azathioprine exposure especially associated with greater risk for development of cutaneous SCC. Sorafenib and possibly the tumor necrosis factor (TNF) inhibitors may be associated with increased risk of cutaneous SCC. High-risk genital HPVs, primarily 16, 18, 31, and 35, play a role in SCCs that develop on the genitalia and periungually. Chronic ulcers, hidradenitis suppurativa, recessive dystrophic epidermolysis bullosa, lesions of discoid LE, erosive lichen planus, prior radiation exposure, and PUVA therapy also appear to enhance the risk for SCC development. Metastasis, with mortality of 18%, is very uncommon for SCCs arising at sites of chronic sun damage, whereas it is relatively high (20%–30%) in SCCs occurring in the various scarring processes. In recessive dystrophic epidermolysis bullosa, metastatic SCC is the most common cause of death in adulthood. Patients with epidermodysplasia verruciformis (EDV) also develop SCCs on sun-exposed sites, associated with unique HPV types. These unique EDV HPV types (e.g., HPV-5, HPV-8) may also play a role in SCCs that develop in immunosuppressed persons. SCC of the oral mucosa is discussed in Chapter 34. Because the vast majority of cutaneous SCCs are induced by UVR, sun protection, with avoidance of the midday sun, protective clothing, and the regular application of a sunblock of SPF 30 or higher, is recommended. Some researchers have suggested that smoking is also a risk factor for cutaneous SCC, but this is controversial.

Clinical Features

Frequently, SCC begins at the site of actinic keratosis on sun-exposed areas such as the face and backs of the hands. BCCs far outnumber SCCs on facial skin, but SCCs on the hand occur three times more frequently than BCCs (Fig. 29.21). The lesion may be superficial, discrete, and hard and arises from an indurated, rounded, elevated base. It is dull red and contains telangiectases. In the course of a few months, the lesion becomes larger, deeply nodular, and ulcerated. The ulcer is at first superficial and hidden by a crust. When the crust is removed, a well-defined papillary base is seen, and on palpation, a discrete hard disk is felt. In the early phases, this tumor is localized, elevated, and freely mobile over underlying structures; later it gradually becomes diffuse, more or less depressed, and fixed. The growth eventually invades the

Fig. 29.21 Squamous cell carcinoma.

Fig. 29.22 Squamous cell carcinoma via burn scar. (Courtesy Dr. Debabrata Bandyopadhyay.)

underlying tissues. The tumor above the level of the skin may be dome shaped, with a corelike center that later ulcerates. The surface in advanced lesions may be cauliflower-like, composed of densely packed, filamentous projections, between which are clefts filled with a viscous, purulent, malodorous exudate.

In black patients, SCCs are 20% more common than BCCs. The most favored sites are the face and lower extremities, with involvement of non–sun-exposed areas more common. Elderly women (mean age 77) are primarily affected in cases involving the lower legs. Prior direct heat exposure from open fireplaces may be the predisposing factor. In contrast, the most frequently found predisposing conditions in white patients are scarring processes, such as burns (Fig. 29.22), leg ulcers, and hidradenitis suppurativa.

On the lower lip, SCC often develops on actinic cheilitis. From repeated sunburn, the vermilion surface becomes dry, scaly, and fissured. At the beginning, only a local thickening is noticeable. This then becomes a firm nodule. It may grow outward as a sizable tumor or inward with destructive ulceration. A history of smoking is also a frequent and significant predisposing factor. Lower lip lesions far outnumber upper lip lesions; men greatly outnumber women (12 : 1); and the median age is the late sixties. SCCs occurring on the lower lip metastasize in 10%–15% of cases. SCC of the lip may also occur in areas of discoid LE in black patients. Neoplastic transformation into SCC may develop in 0.3%–3% of patients with discoid LE of the lip.

Periungual SCC frequently presents with signs of erythema and scaling, which can superficially resemble a wart. The patient may even have periungual warts on other digits. Early on, pain and ulceration are uncommon. Radiographs show that 50% have changes in the terminal phalanx. There is a low rate of metastases (3%), but local excision with Mohs microsurgery is recommended, as it reduces the risk of recurrence. Periungual SCC is strongly associated with genital HPV types, primarily 16, 18, 31, and 35.

Given the numerous presentations of SCC on the skin, there should be a low threshold for biopsy of any suspicious keratotic, ulcerated, or nodular lesion, especially on the background of chronic sun exposure.

Histopathology

SCC is characterized by irregular nests, cords, or sheets of neoplastic keratinocytes invading the dermis to various depths. Thickness is an important risk factor for metastasis, with thickness >2 mm associated with a metastatic rate of 4% and >6 mm with a rate of 16%. Less than 5% of patients with metastatic SCC had a primary cutaneous SCC <2 mm in thickness. Immunosuppression, location on the ear, and increased horizontal size all increase the risk of metastasis by twofold to fourfold. Desmoplasia and tumor thickness also increase local recurrence risk, by 16 and 6 times, respectively. Although histologic differentiation should be reported, it seems less important than these other tumor features in predicting prognosis. In tumors that are poorly differentiated or of primary clear cell morphology, other types of neoplasm must be excluded, such as melanoma. Immunoperoxidase staining for keratins is very useful in this setting. Desmoplastic SCCs by light microscopy have prominent trabecular growth patterns, narrow columns of atypical epithelial cells, and marked desmoplastic stromal reaction. These tumors tend to recur. Acantholytic SCC is a recognized histologic subtype but is of no prognostic importance. The finding of perineural or vascular invasion and recurrence are poor prognostic features.

Differential Diagnosis

The differentiation of SCC from keratoacanthoma is of academic interest in most cases, because simple surgical excision is performed on most of these lesions. However, if nonsurgical modalities are contemplated, a biopsy confirming the diagnosis of keratoacanthoma is recommended. In the setting of immunosuppression, keratoacanthoma-like lesions should be managed as SCCs. The rapid growth and presence of a rolled border with a keratotic central plug suggest the diagnosis of keratoacanthoma, as does explosive growth. An early SCC may be confused with a hypertrophic actinic keratosis, and indeed, the two may be indistinguishable clinically. Biopsy to include the base of the lesion is necessary to make the diagnosis.

Pseudoepitheliomatous hyperplasia (PEH) must be distinguished histologically from true SCC. Marked PEH may be seen in granular cell tumor, bromoderma, blastomycosis, granuloma inguinale, and chronic pyodermas. It is frequently mistaken for SCC in chronic stasis ulcers, ulcerations occurring in thermal burns, lupus vulgaris, leishmaniasis, and even sporotrichosis. PEH arises from adnexal structures, as well as the surface epidermis. Hyperkeratosis and hypergranulosis of adjacent hair follicles are often present. Strands of epidermal cells may extend into the reticular dermis and usually

trap elastic fibers, a finding also seen in keratoacanthoma but rarely in conventional SCCs. A potential diagnostic pitfall is the presence of benign PEH adjacent to and overlying invasive SCC. This is particularly common in lesions that have been picked or scratched.

Metastases

The rate of SCC metastasis from all skin sites ranges from 0.5%–5.2%. Lesions at elevated risk of metastasis (and recurrence) are those on the lip, ear, or anogenital skin; those occurring at the site of chronic scar or irradiation; those 2 cm or more in diameter; those more than 4 mm thick; those that are recurrent, have poor histologic differentiation, or perineural invasion; and those occurring in patients with organ transplantation or hematologic malignancy. Such patients may be considered for more aggressive surgical management and adjuvant radiotherapy. Careful attention should be paid to regional lymph nodes draining the site of the SCC. These should be examined at the initial evaluation when the suspicious lesion is identified and at the regular visits that follow the treatment of the SCC.

Patients with SCC are at increased risk of developing other malignancies, such as cancers of the respiratory organs, buccal cavity, pharynx, and small intestine (in men), as well as non-Hodgkin lymphoma and leukemia.

Prevention/Treatment

The primary treatment of SCC of the skin is surgical (see Chapter 37). Oral retinoids may be useful as a preventive strategy in patients with immunosuppression who develop frequent cancers. PDT might be beneficial to reduce the number of SCCs occurring in areas of prior UV damage where SCCs have already occurred, and pembrolizumab may have a role in treating advanced disease. As with BCC, electrochemotherapy has been used as palliative skin-directed therapy for patients a for whom conventional treatments are not viable options. Organ transplant recipients should be educated about sun protection and skin cancer risk, ideally *before* their transplantation, and should have regular skin examinations by a trained dermatologist. The use of sirolimus instead of other immunosuppressives appears to reduce the prevalence of SCCs in organ transplant recipients. Immunosuppressed patients receiving voriconazole for treatment or prophylaxis of invasive fungal infections should be made aware of its role in photocarcinogenesis and its link to increased SCC incidence and should be similarly educated about sun protection measures.

VERRUCOUS CARCINOMA (CARCINOMA CUNICULATUM)

Verrucous carcinoma is a distinct, well-differentiated, low-grade SCC. It affects mostly elderly men. The primary characteristic of these lesions is their close resemblance, clinically and histologically, to a wart. The lesions present as a bulbous mass with a soft consistency and often multiple sinuses opening to the surface, resembling "rabbit burrows." Lesions of this type are most common on the sole (Fig. 29.23) but also occur in the genital area and on the oral mucosa. In some cases, as in the Buschke-Lowenstein tumor, verrucous carcinomas are induced by HPV. These HPVs may be of the "low-risk" types, such as HPV-6 or HPV-11, or the high-risk types, such as HPV-16 or HPV-18. In other cases, no HPV can be found, and pressure or other factors (but not UV light) are thought to play a role. The natural history is of a

Fig. 29.23 Verrucous carcinoma. (Courtesy Dr. Tatiana Andrade.)

slow-growing mass that over years may invade the bones beneath the tumor.

Histologically, the lesion shows a characteristic picture of bulbous rete ridges topped by an undulating keratinized mass. The squamous epithelium is well differentiated, and cytologic atypia is minimal. The cytoplasm is often apple-pink and may have a glassy appearance. The tumor border is smooth and pushing, rather than spiky and infiltrative.

Excision is the best treatment, and Mohs microsurgery may be a helpful technique. Radiotherapy has been reported to induce anaplastic transformation, and although the risk appears to be low, it is best avoided if other treatment options exist. Lymph node metastasis is rare, and the prognosis is favorable when complete excision is accomplished. Other treatments used for cutaneous verrucous carcinomas with variable success include topical or systemic chemotherapy (bleomycin, 5-FU, cisplatin, methotrexate), CO_2 laser, intralesional IFN alfa, imiquimod, and PDT.

BOWEN DISEASE (SQUAMOUS CELL CARCINOMA IN SITU)

Bowen disease (BD) is intraepidermal SCC. Multiple possible agents can induce BD, including HPV of certain types, arsenic exposure, and sun exposure. An association with the Merkel cell polyomavirus has been reported in immunosuppressed patients. The origin of the cells developing into BD is unknown but might be a pluripotential epidermal cell. BD may ultimately become invasive. When it does, it may have an aggressive biologic behavior.

Clinical Features

BD may be found on any part of the body as an erythematous, slightly scaly and crusted, noninfiltrated patch from a few millimeters to many centimeters in diameter (Fig. 29.24). The lesion is sharply defined. The scale may be pronounced enough for the lesion to be mistaken for psoriasis, or the plaque may have a stuck-on appearance and be mistaken for a broad, sessile seborrheic keratosis. Papillated keratotic lesions can occur. When BD occurs on the vulvar skin, vaginal mucosa, or perianal areas, it may be deeply pigmented (Fig. 29.25). Infrequently, BD may be pigmented elsewhere. Invasion is often indicated by the development of an exophytic, endophytic, or ulcerative component. A rare but particularly difficult clinical scenario is the elderly female patient with multicentric BD of the shins.

As the lesion slowly enlarges, spontaneous cicatrization may develop in portions of the lesion. When the intraepithelial growth becomes invasive, the lesion may appear ulcerated and fungating. The squamous carcinoma that evolves from BD tends to be more aggressive than SCC arising in actinic keratosis. When SCC in situ occurs as a velvety plaque on the glans penis, it is referred to as erythroplasia of Queyrat (see later discussion).

Fig. 29.24 Bowen disease. (Courtesy Steven Binnick, MD.)

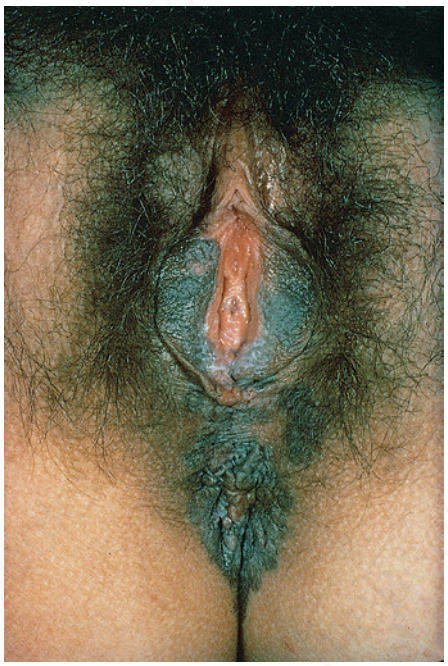

Fig. 29.25 Bowen disease.

Around or beneath the nail, BD can be difficult to diagnose. It can present as a red (erythronychia) or black/brown (melanonychia) longitudinal band of several millimeters in width. HPV may be associated with these lesions, which should be biopsied.

Histopathology

The atypical keratinocytes may invade the adjacent epidermis in a buckshot or clonal nested pattern. With time, they may replace the entire epidermis, often with deep, full-thickness involvement

of adnexal structures, especially the hair follicles. The epidermis shows hyperkeratosis, parakeratosis, and broad acanthosis or anastomosis of adjacent rete ridges. Epidermal maturation is absent, so the epidermis appears disorganized, and individually keratinizing cells and atypical cells are seen at all levels of the epidermis. There is, however, a sharp delineation between dermis and epidermis, and the basement membrane is intact. The upper dermis usually shows a chronic inflammatory infiltrate. Although the cells tend to be anaplastic with a high nuclear/cytoplasmic ratio, variants with smaller nuclei and abundant cytoplasm exist, and transitional areas between the patterns may be seen. Invasive lesions of BD tend to have a squamoid to basaloid appearance, with central necrosis. Adnexal differentiation may be present.

Differential Diagnosis

Frequently, BD is misdiagnosed as psoriasis, superficial multicentric BCC, tinea corporis, nummular eczema, seborrheic keratosis, or actinic keratosis. Paget disease, especially the extramammary type, may mimic BD not only clinically but also histologically. There is no dyskeratosis in Paget disease, and the intervening nonvacuolated epidermal cells are not atypical. Stains for mucin and carcinoembryonic antigen (CEA) are positive in Paget disease and negative in pagetoid BD. BD may be heavily pigmented, especially when occurring in the anogenital region. Lesions of bowenoid papulosis show a histologic spectrum from genital warts with buckshot atypia to full-thickness atypia indistinguishable from BD. If the lesions are multicentric and behave as genital warts, the term bowenoid papulosis may be applied. Treatment is guided completely by the clinical pattern. Genital SCC is induced by high-risk HPV, so bowenoid papulosis represents the initial clinical lesion in the progression from HPV infection to carcinoma. There is no clear boundary where bowenoid papulosis stops and SCC in situ begins.

Treatment

Topical treatment of SCC in situ with cryotherapy and topical 5-FU has been disappointing because of a high recurrence rate. Imiquimod 5% cream, applied once daily for up to 16 weeks, seems to be effective enough to be recommended as a therapeutic option. Response rates have been as high as 90%. It may allow treatment of large lesions that might be difficult to approach surgically. Combination treatment with imiquimod 5% cream, three times a week, and 5% 5-FU, twice daily (except at the times of the imiquimod application), has also been reported effective. Tazarotene could be added to this treatment for hyperkeratotic lesions or to enhance penetration. PDT can be considered. Ingenol mebutate has also been used.

Simple excision of small lesions is a reasonable treatment option. Large, poorly defined lesions, or lesions in which preservation of normal tissue is critical, are indications for Mohs microsurgery. Other surgical techniques to treat SCC in situ are described in Chapter 37. Curettage and desiccation may also be performed, but recurrence may occur if extension down the follicles is not eradicated. Lesions of the lower legs are particularly problematic, because they are often multiple and in elderly persons are often found in conjunction with significant venous insufficiency. Any form of therapy may result in chronic leg ulceration in this setting. Using a compression bandage should be considered after surgery, similar to that applied to a chronic leg ulcer, to help prevent ulceration.

ERYTHROPLASIA OF QUEYRAT

Erythroplasia of Queyrat is SCC in situ of the glans penis or prepuce. SCC in situ on the penile shaft also occurs. Both conditions are caused by high-risk HPV types (16, 18, 31, 35). Clinically, erythroplasia of Queyrat is characterized by single or multiple, fixed, well-circumscribed, erythematous, moist, velvety or smooth, red-surfaced plaques on the glans penis (Fig. 29.26). Uncircumcised men, usually over age 40, are most often affected, and when SCC in situ affects the penile shaft, it is usually distally under the

Fig. 29.26 Erythroplasia of Queyrat.

foreskin. The differential diagnosis includes Zoon balanitis, candidiasis, penile psoriasis, irritant balanitis, and extramammary Paget disease. A biopsy is usually indicated to confirm the diagnosis. The intensity of the inflammatory infiltrate under lesions of erythroplasia of Queyrat can be great, and plasma cells can be numerous. This may lead to the histologic misdiagnosis of both erythroplasia and Zoon balanitis occurring simultaneously or sequentially.

Because red lesions on the glans of elderly uncircumcised men are common, the following factors suggest that a biopsy is indicated:

1. The lesion is fixed (does not move or resolve).
2. The patient lacks other stigmata of psoriasis or another skin disease that could affect the glans penis.
3. The patient's sexual partner has cervical dysplasia.
4. The lesion does not resolve with effective topical therapy for irritant balanitis, candidiasis, or psoriasis.

Once the diagnosis of SCC in situ of the penis is made, the patient's sex partner(s) should be referred for evaluation. Sexual partners of men with SCC of the penis are more likely to develop preinvasive and invasive cancer of the cervix or anus.

Progression to invasive SCC is more common in erythroplasia of Queyrat than in BD of the nongenital skin, and the resulting SCCs are more aggressive and tend to metastasize earlier than those that develop in BD of the nongenital skin. There is no evidence of an increase in internal malignancy in patients with erythroplasia.

Topical therapy can be effective in the treatment of erythroplasia of Queyrat and has the advantage that it can identify and treat areas not visible clinically. Topical 5% 5-FU cream applied once daily under occlusion (with the foreskin or a condom) can be effective. It will induce a brisk reaction and superficial erosion, which can be uncomfortable. Treatment is continued for 3–12 weeks, depending on the response. Imiquimod cream 5%, applied between once daily and three times weekly, will similarly induce a significant reaction and may clear the lesion after 3–12 weeks. Careful follow-up is required, especially for the first few years. Surgical modalities such as excision, laser therapy, and PDT are reserved for patients failing topical treatments. Radiation therapy can also be effective.

BALANITIS PLASMACELLULARIS (ZOON BALANITIS)

Balanitis plasmacellularis is also known as balanoposthitis chronica circumscripta plasmacellularis or Zoon balanitis. Zoon balanitis represents about 7% of persistent genital lesions biopsied for diagnosis. It is a benign inflammatory lesion of the glans penis, which histologically demonstrates a plasma cell–rich infiltrate. The plasma cell infiltrate, although characteristic, may not be present in all lesions of this type, and in fact, some researchers believe there is a spectrum of histology in idiopathic, benign, nonscarring balanitis, from lesions containing few plasma cells to lesions containing many plasma cells. Clinically, Zoon balanitis is characterized by a red patch, which is usually sharply demarcated and usually on the inner surface of the prepuce or the glans penis (Fig. 29.27). The lesion is erythematous, moist, and shiny. It occurs as a single lesion but may consist of several confluent macules. It is asymptomatic and does not produce inguinal adenopathy. Uncircumcised men from ages 24–85 are most often affected. As with erythroplasia of Queyrat, presence of the foreskin constitutes a significant risk factor, and the disease is rarely seen in circumcised men.

Fig. 29.27 Zoon balanitis.

Vulvitis chronica plasmacellularis is the counterpart of balanitis in women. The vulva shows a striking, lacquer-like luster. Erosions, punctate hemorrhage, synechiae, and a slate to ochre pigmentation may supervene.

Plasmacytosis circumorificialis is the same disease on the oral mucosa, lips, cheeks, and tongue. The differential diagnosis of Zoon balanitis is penile psoriasis, lichen planus, lichen sclerosus, and SCC in situ. Histologically, the epidermis is atrophic, with flattened diamond-shaped keratinocytes and mild spongiosis. In the papillary dermis, a band of infiltrate consisting almost exclusively of plasma cells is present. Dilated vessels are also seen. This picture is strikingly different from that of the main clinical differential diagnosis, erythroplasia of Queyrat, in which the epidermis is principally involved, with atypia of keratinocytes throughout the entire epithelium. HPV has not been detected.

Topical corticosteroids, alone or in combination with anticandidal treatment, are helpful in patients with Zoon balanitis. Potent topical steroids, pimecrolimus cream 1%, tacrolimus ointment 0.1%, mupirocin and imiquimod cream 5% have all been reported effective in select cases. Circumcision may be curative. Laser ablation and PDT can also be effective.

PSEUDOEPITHELIOMATOUS KERATOTIC AND MICACEOUS BALANITIS

Pseudoepitheliomatous keratotic and micaceous balanitis was described by Lortat-Jacob and Civatte in 1966. The lesions occurring on the glans penis are verrucous excrescences with scaling. Ulcerations, cracking, and fissuring on the surface of the glans are frequently present. The keratotic scale is usually micaceous and resembles psoriasis. Most patients are over age 50 and frequently have been circumcised for phimosis in adult life. Histologically, there is marked hyperkeratosis and parakeratosis, as well as pseudoepitheliomatous hyperplasia. Acanthotic masses give rise to a crater-like configuration. HPV has not been detected. This lesion is probably best considered as a form of verrucous carcinoma. The treatment is usually surgical or cryosurgical and Mohs micrographic surgery may play a role. PDT has also been used. Topical 5-FU has been effective, but the hyperkeratotic scale may make penetration suboptimal. If topical chemotherapy is used, posttreatment biopsies are recommended.

PAGET DISEASE OF THE BREAST

Clinical Features

Paget disease (PD) of the nipple affects women primarily (there are very rare male cases). Between 1% and 4% of breast carcinomas present with PD. It is characterized by a unilateral, sharply marginated, erythematous, and at times crusted patch or plaque affecting the nipple and occasionally the areola (Fig. 29.28). At times, it may be hyperpigmented and may mimic melanoma. As the lesion grows, it may spread to the areola, and even beyond, making the areolae appear asymmetric. Over months or years, it may become eroded. The nipple may or may not be retracted. In advanced cases, a subjacent mass and ipsilateral axillary adenopathy may be palpable. About 5% of patients have PD without confirmed evidence of underlying carcinoma, and the remaining 95% have either an invasive or an intraductal carcinoma in proportions of 35%–65%, depending on the reporting center. In rare cases, even when no underlying carcinoma is found on surgical removal, the sentinel node may be positive.

Fig. 29.28 Paget disease of the breast. (Courtesy Steven Binnick, MD.)

Histopathology

PD is characterized by the presence of Paget cells: large, round, pale-staining cells with large nuclei. Intercellular bridges are absent. The cells appear singly or in small nests between the squamous cells. Usually, acanthosis is present, the granular layer is preserved, and there is no parakeratosis, but atypical cells may be "spat out" into the stratum corneum. Frequently, a layer of basal cells separates the Paget cells from the basement membrane and is seen crushed beneath the nests of Paget cells. This histologic feature helps distinguish PD from pagetoid melanoma and Bowen disease. In the dermis, an inflammatory reaction is often present. Unusual variants include PD with marked intraepidermal melanin and an acantholytic anaplastic form.

The Paget cell is PAS positive, diastase resistant, almost always HER-2/neu positive, and EMA positive; it stains with CAM 5.2 and CK 7. This staining profile and negativity for S-100 and cytokeratins 5/6 allow clear distinction from pagetoid melanoma and pagetoid Bowen disease. CEA positivity is variable in PD of the breast, being positive in 0%–50% of PD cases compared with virtually 100% of extramammary PD cases. The Toker cell, a normal clear cell of the breast, stains similarly but is HER-2/neu negative. It has been proposed as the precursor cell of PD and may be so for some cases of PD with no underlying breast cancer.

Diagnosis

The presence of unilateral eczema of the nipple recalcitrant to simple treatment should lead to suspicion of PD, and the lesion should be biopsied. The presence of bilateral lesions suggests a benign process, usually atopic dermatitis. Papillary adenoma of the nipple clinically resembles PD, but on biopsy it shows a papillary and adenomatous growth in the dermis with connection to the surface. There is a lining of apocrine-type secretory epithelium. HNA may occasionally be unilateral but histologically reveals only hyperkeratosis, acanthosis, and papillomatosis.

Treatment

Patients with PD of the breast should be referred to a center with expertise in the management of breast cancer. Prognosis depends on the presence of an underlying invasive ductal carcinoma or nodal metastases. Patients presenting with a palpable breast mass typically have more advanced disease and lower 5-year survival. Some data suggest PD itself may be an independent marker of worse prognosis of invasive breast carcinoma (IBC) compared with IBC of similar stage and characteristics without PD.

EXTRAMAMMARY PAGET DISEASE

Extramammary Paget disease (EMPD) is much less common than PD. It affects adults, usually between 65 and 70 years of age. The vulva is the most common location, except perhaps in China, where penoscrotal EMPD is reported in large numbers. Penoscrotal EMPD is uncommon in black persons. EMPD presents most often as a unifocal process, but multifocal lesions may occur, including cases involving as many as four anatomic locations simultaneously. Lesions typically affect apocrine sites, including the vulva, scrotum, perianal area, penis, inguinal folds and axilla, but rare cases can affect other anatomic locations. Axillary lesions

Fig. 29.29 Extramammary Paget disease.

typically appear with or after genital lesions and are more frequent in men. The growths are typically erythematous, well-demarcated plaques measuring several centimeters in diameter (Fig. 29.29). The condition often goes undiagnosed for months to years, as the misdiagnoses of pruritus ani, a fungal infection, contact dermatitis, lichen sclerosus, or intertrigo are made. A nonhealing banal eczematous patch persisting in the anogenital or axillary region should raise concern about EMPD and trigger a biopsy. Intense pruritus is common. Bleeding, nodularity, and induration are late signs. Underpants erythema, or redness in the whole genital area, may be indicative of widespread lymphatic involvement in the pelvic basin and is a poor prognostic sign. Lesions may be hyperpigmented or hypopigmented.

Extramammary PD can be divided into the following four forms:

1. Primary EMPD (arising intraepidermally), with or without invasion
2. EMPD associated with an underlying apocrine carcinoma
3. EMPD associated with an underlying adjacent malignancy
4. EMPD associated with an underlying distant carcinoma

The majority of patients with EMPD do not have underlying carcinoma, and the process apparently begins as an intraepidermal neoplasm, which can then invade (invasive EMPD). The clinical appearance of all types of EMPD is identical. The location of the EMPD determines the percentage of patients who have other associated malignancies. In vulvar EMPD, 4%–17% have an associated adnexal neoplasm, and 11%–20% have a distant carcinoma of the breast, cervix, vagina, bladder, colon, rectum, ovary, liver, gallbladder, or skin. In perianal EMPD, an underlying adnexal carcinoma occurs in 7%–10% of cases, and a distant carcinoma of the rectum, stomach, breast, or ureter is present in 15%–45%. Penoscrotal EMPD has an associated carcinoma of the prostate, bladder, testicles, ureter, or kidney in 11% of cases. In a large series from The Netherlands, underlying malignancy was found in 35% of patients with EMPD. In all patients with EMPD, an extensive and targeted cancer workup should be undertaken, depending on the histologic staining pattern (see next) and the location. Prolonged follow-up and malignancy screening should be considered, because EMPD patients have an increased risk of secondary malignancy at these sites even years after the initial EMPD diagnosis.

Histologically, the findings are similar to those found in mammary PD: acanthosis, hyperkeratosis, parakeratosis, and pale, vacuolated Paget cells in suprabasilar levels of the epithelium. Signet ring Paget cells are present in a small minority of cases. Paget cells can form nests that compress basal keratinocytes. Conventional histopathologic findings are similar in both primary cutaneous EMPD and most cases in which EMPD is caused by an underlying malignancy. Mucin, stainable by alcian blue or colloidal iron, is present in the majority of cases. The finding of cytoplasmic mucin makes a urothelial origin unlikely.

Significant effort has been put into developing a series of stains that would clearly distinguish PD from EMPD and identify patients who have underlying carcinomas, either local apocrine cancers or distant neoplasms. This involves examining the expression of various cytokeratins, mucins, and other products specific to certain organ systems. RCAS1 may be very sensitive for EMPD cells, and measurement of serum levels of this marker can be used to monitor patients with invasive disease, analogous to following prostate-specific antigen (PSA) in patients with treated prostate cancer. In vulvar and perianal EMPD, two distinct staining patterns have been defined. CK7+/CK20+/GCDFP15 negative is called the type I or endodermal pattern and is associated with EMPD and distant cancers. Ectodermal or cutaneous pattern (type II) stains the atypical cells CD7+/CK20-/GCDFP15 positive. This is associated with a cutaneous origin for the EMPD. In addition, tissue-specific markers may at times identify the distant tumor responsible for the EMPD. Immunohistochemical studies can provide some guidance in distinguishing between these possibilities, largely through identifying antigens that are not found on the cells of primary cutaneous EMPD. The specificity of these studies is limited, but a positive finding of an immunoprofile that differs from that of typical primary EMPD should lead to a thorough investigation. Primary cutaneous EMPD has an immunophenotype similar to that of apocrine epithelium: cytokeratin 7 positive, cytokeratin 20 negative, and CEA positive. Cases caused by spread from an underlying bladder carcinoma are typically uroplakin and p63 positive. Those caused by rectal carcinoma are usually CK7 negative, CDX2 positive, and CK20 positive. Prostatic adenocarcinoma can also result in EMPD and can be identified by staining for PSA or the marker P504S. Unfortunately, PSA positivity can be seen in female patients with EMPD, and not all males with PSA positivity of the EMPD cells have underlying prostate cancer. The p63 staining in vulvar EMPD suggests an underlying urothelial carcinoma. Staining with AKT, CDK2, mTOR, and other proteins in the mTOR pathway suggests that this pathway may be important in the pathogenesis of EMPD.

Extramammary PD can remain within the epithelium or "invade" the dermis. "Invasive" EMPD has a high rate of metastasis and a very poor prognosis. Sentinel node examination of patients with "invasive" EMPD should be considered because it predicts the risk for metastasis.

Surgical removal is the treatment of choice, with Mohs microsurgery having a better outcome than fixed surgical margins. Despite what appears to be adequate clinical margins, recurrence rates are high because of the discontinuous and microscopic wide extension of EMPD. The recurrence rate after micrographic surgery is about 12% and more than 30% for standard 2-cm margins. Positive KI67 and PAS staining of surgical margins may suggest the need for wider excision. Imiquimod has been used with success in multiple reports, but follow-up is limited. Topical 5-FU, radiation therapy, PDT, and laser therapy have also been used. Intralesional IFN alfa-2b was beneficial in one case. Some cases of genital EMPD are HER-2/neu positive and have responded to trastuzumab, a monoclonal antibody directed against HER-2.

CLEAR CELL PAPULOSIS

Clear cell papulosis is an uncommon disorder that presents with multiple, minimally elevated, hypopigmented papules. Most cases have been reported in Asian or Hispanic children. Onset is usually before age 6 and may be as soon as 4 months of age. The eruption favors the pubic region, lower abdomen, and along the milk lines. Histology demonstrates mild acanthosis, decreased epidermal pigmentation, and the presence of single or small clusters of large clear cells in the basal and occasionally suprabasal layers of the epidermis. The cells are positive for EMA, CEA, and CD7, identical to Toker cells.

MERKEL CELL CARCINOMA (TRABECULAR CARCINOMA)

Merkel cell carcinoma (MCC) was first described by Toker in 1972. The cell of origin is the Merkel cell, a slow-acting mechanoreceptor in the basal layer of the epidermis. Although still a rare tumor occurring at an incidence of about 0.44 per 100,000 population, MCC recently increased threefold over 15 years, an increased incidence of 8% per year. Melanoma, by comparison, increased at a rate of only 3% per year over the same period. More than 1500 MCCs occur yearly in the United States. This is a tumor of the elderly population, with 90% of cases found in persons older than 50, 76% in those over 65, and 72% in those over 70. The mean age is 76 in women and 74 in men. About 60% of MCC patients are men, and 95% occur in white people. There is strong evidence that MCC is induced by sun exposure. About 90% of cases occur on sun-exposed sites, with 27% of cases on the face, 9% on the scalp and neck (or 36% on the head and neck), 22% on the upper extremity, 15% on the lower extremity (37% on the extremities), and only 11% on the trunk. About 3% occur on the ear, eyelid, or lip. PUVA therapy is associated with an increased risk for MCC. Immunosuppression by organ transplantation, chronic lymphocytic leukemia, and HIV infection all substantially increase the risk for developing MCC, so that in some series, 8%–15% of patients with MCC have some form of immune impairment.

Clinically, this tumor presents as a rapidly growing, nontender, red to violaceous nodule with a shiny surface (Fig. 29.30) and overlying telangiectasia. Most cases are *not* considered malignant by the dermatologist at biopsy. The acronym AEIOU has been suggested: asymptomatic/lack of tenderness, expanding rapidly, immune suppression, older than 50 years, and ultraviolet-exposed site on a person with fair skin. MCC is an aggressive tumor with a propensity for local recurrence and nodal and distant metastases. At presentation, about one third of cases have regional node involvement, and hematogenous spread will eventuate in at least one third of patients. Spontaneous remissions have been reported, primarily in women with head and neck tumors; this is most often associated with reduction of iatrogenic immunosuppression. The regression is rapid, but the MCC can recur after "spontaneous resolution." MCC can present as a metastatic disease without an evident primary tumor; such patients have a significantly better prognosis than those of the same stage with a known primary.

Fig. 29.30 Merkel cell carcinoma.

Approximately 80% of MCCs in North America and 25% of MCCs in Australia are associated with a virus, the Merkel cell polyomavirus (MCPyV). The virus is found integrated into the genome of the MCC when present, and all progenitor cells have the same viral genome, suggesting that the viral infection began at the time the neoplasia was developing, or before. MCC patients are more likely to be seropositive for MCPyV. Infection with this virus is widespread, with seroprevalence increasing from 30% in children younger than 5 to almost 80% in persons older than 50. Lymphoid tissue, especially the tonsils, seems to be the reservoir. The virus may behave similar to HPV, with increasing seroprevalence with exposure over time and spontaneous clearance in most adults. MCPyV can be recovered from about 4% of immunocompetent persons and 36% of immunosuppressed patients. This may explain the high risk for MCC with immunosuppression, analogous to the high risk of HPV-related neoplasia in immunosuppressed patients. MCPyV has also been reported in NMSCs in both immunocompetent and immunosuppressed patients. Bowen disease, BCC, and SCC have been associated with viral infection in up to 40% of cases in some laboratories, but these results have not been reproduced and may represent laboratory overidentification. At the University of California, San Francisco, the rate is less than 1%. Normal skin infection has also been reported, and the viral copies in these NMSCs are much fewer than in MCC. The pathogenic role of MCPyV in NMSCs other than MCC is speculative. Visceral tumors and other small cell neuroendocrine tumors of other organ systems do *not* contain MCPyV, substantiating its role in the development of MCC.

Staging predicts prognosis and guides therapy. Sentinel lymph node biopsy (SLNB) should be performed at definitive excision of the primary tumor. One third of patients with no palpable adenopathy have a positive SLNB. The SLNB sample must be stained with CK20 (if the primary tumor is positive) to detect micrometastases. Computed tomography (CT) will detect metastatic disease in only 20% of MCC patients. Whether tumors less than 1 cm in diameter require SLNB is controversial, but even in small

tumors, lymph node metastases can be found; in one study, 14% of those with 0.5-cm tumors had regional nodal involvement. Imaging with CT, magnetic resonance imaging (MRI), or positron emission tomography (PET) may be used to search for metastatic disease. Palpable lymph nodes must be sampled to exclude the presence of metastatic disease. MCC patients who harbor MCPyV have a better prognosis (45% vs. 15% 5-year survival), and the MCC is more likely to present on an extremity. Natural killer cell response also correlates with prognosis. MCC should be treated expeditiously; patients have developed metastatic disease in the weeks awaiting definitive surgery.

The treatment of MCC should be directed by persons with expertise in managing this rare tumor. Therapy may need to be individualized, depending on various risk factors present. Many of these patients are elderly and may not be able to tolerate some of the recommended treatments. The goal of therapy for patients with only local disease or regional nodal metastases is cure and local control. This involves the combined use of surgery and radiation therapy in most cases. Radiation therapy alone can be efficacious and is recommended for patients unable to tolerate surgery. Radiation therapy is directed at both the primary site and the draining and/or regional lymph node basins in most cases and should be considered even if the sentinel lymph nodes are negative. Recurrence is seen in 46%–76% of untreated lymph nodes. Even after Mohs surgery, radiation therapy reduces the local recurrence rate from 16% to near 0%. Prophylactic lymph node dissection enhances local control but does not improve survival. It is gradually being replaced with radiation therapy of the affected nodal basin. Locoregional recurrence remains a substantial problem in patients with MCC and is a poor prognostic sign. Therefore the emerging consensus is that addressing the regional lymph nodes is crucial in therapy. Traditional adjuvant chemotherapy has been disappointing because it does not prevent later development of metastatic, regional, or local disease, but avelumab appears very promising. MCC may be initially responsive to chemotherapy, but disease progression occurs. In the setting of metastatic MCC, chemotherapy would be considered palliative. Partial response was seen with use of a multikinase inhibitor, pazopanib.

Histologically, MCC is a dermal tumor that may extend into the subcutaneous tissue. The cells are about 15 μm in diameter and have very scant cytoplasm and hyperchromatic nuclei with a distinctive smudged chromatin pattern. Mitoses and apoptotic cells are numerous. The cells are arranged in sheets and cords. Depth of invasion, lymphovascular involvement, and mitotic index may be poor prognostic histologic features. MCC must be distinguished from small cell lung cancer, lymphoma, neuroblastoma, small cell endocrine carcinoma, Ewing sarcoma, melanoma, and even BCC. Immunoperoxidase confirmation of the diagnosis and exclusion of other small cell tumors is required to establish the diagnosis. The tumor should be CK20 positive and thyroid transcription factor 1 (TTF-1) negative. CK20 staining is of the "perinuclear dot pattern." CK7 tends to stain small cell lung cancer and not MCC. MCC is negative for S-100 and leukocyte common antigen (LCA).

SEBACEOUS NEVI AND TUMORS

Nevus Sebaceus (Organoid Nevus)

Nevus sebaceus of Jadassohn presents as a sharply circumscribed, yellow-orange hamartoma, varying from a few millimeters to several centimeters in size. These lesions are usually solitary, congenital, and linear in configuration. The scalp is the most common location (50%), but other areas of the head and neck (45%) are also common. The trunk is involved in 5% or less of cases. The lesions persist throughout life and are usually alopecic. In childhood, they are only slightly papillated or velvety, but in adulthood, with hyperplasia of the sebaceous elements, the lesions become more elevated and cerebriform (Fig. 29.31). Large, pedunculated lesions presenting as exophytic tumors at birth are an unusual phenotype. Recent work has shown that somatic *HRAS* and *KRAS* mutations give rise to nevus sebaceus.

Numerous neoplasms, most of them adnexal, have been described arising in nevus sebaceus. The most common tumors are trichoblastoma and syringocystadenoma papilliferum, each occurring in about 5% of nevus sebaceus. HRAS mutation has been implicated in the pathogenesis of trichoblastomas in this setting. Both these tumors present as new, often pigmented papules or nodules arising in the nevus sebaceus. BCC is uncommon, occurring in less than 1% of lesions. Many cases previously diagnosed as BCC are actually trichoblastomas. Many of the tumors are difficult to classify precisely. Development of benign tumors occurs in less than 5% of nevus sebaceus before age 16, and malignant tumors are rare in childhood or adolescence. The risk for tumor development increases with age. Rarely, aggressive malignant adnexal neoplasms may arise, usually in older adults. Familial cases have been described.

Nevus sebaceus may be associated with multiple internal abnormalities, making it one of the cutaneous abnormalities to be included within the epidermal nevus syndrome (see earlier).

Fig. 29.31 Nevus sebaceus.

Schimmelpenning syndrome is a synonym for sebaceous nevus syndrome (SNS). In cases of SNS, the nevus sebaceus is usually on the scalp and is linear and large (≥10 cm). The sebaceous nevi usually occupy more than one dermatome. Ocular colobomas and choristomas are characteristic. Neurologic findings are present in 7% of all patients with nevus sebaceus and up to two thirds of patients with SNS. Epilepsy is seen in about two thirds of cases, usually beginning in the first year of life. Mental retardation can occur. Although numerous anatomic abnormalities of the brain have been described in SNS, CT and MRI are frequently normal in children with seizures and mental retardation. Urologic and cardiovascular defects have also been reported. A rare variant of SNS is the SCALP syndrome: sebaceous nevus syndrome, CNS malformations, aplasia cutis congenita, limbal dermoid, and pigmented nevus (giant congenital melanocytic nevus). The aplasia cutis and sebaceous nevus are adjacent and on the scalp. SCALP syndrome is also called didymosis aplasticosebacea.

A rare but frequently reported association is that of nevus sebaceus and hypophosphatemic rickets. Most patients have large sebaceous nevi and evidence of "SNS." If the rickets goes unrecognized, permanent bone loss and orthopedic injury result. Serum phosphate is low, and there is excess phosphate in the urine. Serum calcium is normal. It is now clear that the nevus sebaceus itself secretes a factor responsible for phosphorus wasting. FGF-23 and matrix extracellular phosphoglycoprotein (MEPE) are both elevated in the blood of patients with this syndrome, and the levels of these substances parallel the hypophosphatemia. Surgical removal of the nevus sebaceus is the treatment of choice. When the nevus sebaceus is removed, the metabolic abnormalities normalize, and FGF-23 and MEPE levels return to normal. Partial removal can ameliorate the condition. Octreotide can also be used if surgical removal is not possible.

Histologically, in prepubertal lesions, the epithelium is acanthotic and papillomatous. Pilosebaceous structures are immature and resemble the fetal pilar germ. After puberty, the epidermis is more hyperplastic and at times papillomatous. It may resemble a seborrheic keratosis or acanthosis nigricans or may have features of an epidermal nevus. Sebaceous glands are usually abundant, placed high in the dermis, and connect directly to the epidermal surface. Follicular structures, if present, are usually vellous or partially formed. Apocrine glands are present in about half the lesions. The dermis is thickened, with increased vascularity and fibrous connective tissue. Mature lesions have been described as broad, bald, bumpy (papillomatous), and bubbly (sebaceous). The finding of EDV–associated and genital-mucosal HPV DNA in nevus sebaceus is of unclear significance.

Although the risk of development of malignancy exists, it is small, and virtually always occurs after adolescence. For this reason, surgical removal can be delayed until adulthood, when the patient can make an informed decision regarding removal. If the lesion leads to disfigurement, stigmatization, or symptomatology, it may be removed at any age.

Sebaceous Hyperplasia

Onset of sebaceous hyperplasia is usually after age 40, and the prevalence increases with age. The areas of predilection are the forehead, infraorbital regions, and temples. The lesions are small, cream-colored or yellowish, umbilicated papules 2–6 mm in diameter. Dermoscopy can be helpful in confirming the diagnosis and identifies the central crater, the yellow lobules, and the associated telangiectasia. Unusual sites may be affected, such as the areolae, nipples, penis, neck, and chest, where disease occurs as solitary lesions, clustered papules, or beaded lines. Prominent sebaceous hyperplasia occurs in 15% of patients taking cyclosporine and may involve ectopic sites such as the oral mucosa. It often appears many years after the cyclosporine is begun. Histologically, sebaceous hyperplasia demonstrates hyperplasia of one sebaceous gland, with normal-sized surrounding glands. The glands are multilobulated, each dividing into smaller lobules to produce a cluster resembling a bunch of grapes. Clinically, they may mimic an early BCC.

Premature sebaceous hyperplasia, also known as familial presenile sebaceous hyperplasia, presents with extensive sebaceous hyperplasia with onset at puberty and worsening with age. Familial patterns have been reported, inherited in an autosomal dominant manner. It involves the face, neck, and upper thorax but spares the periorificial regions.

Treatment is solely for cosmetic purposes and employs electrosurgery, laser therapy, PDT, or even shallow shave biopsy. Isotretinoin will reduce lesions, but they immediately recur when the drug is stopped, so isotretinoin is probably not indicated for this condition. Long-term successful therapy with isotretinoin requires low-dose maintenance therapy.

Fig. 29.32 Sebaceous adenomas of Muir Torre syndrome. (Courtesy Steven Binnick, MD.)

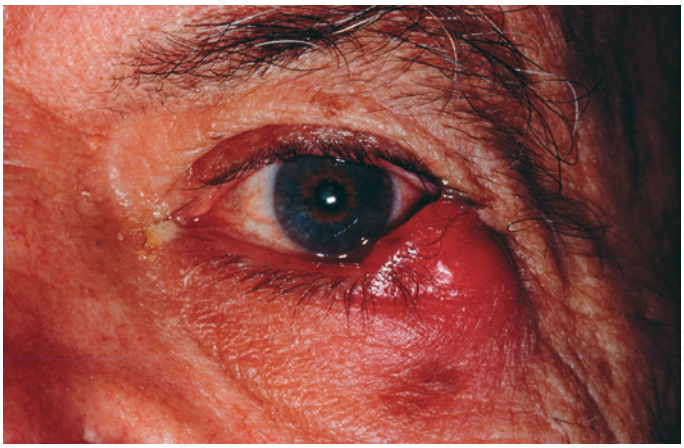

Fig. 29.33 Sebaceous carcinoma in patient with Muir-Torre syndrome.

Sebaceous Adenoma

This slow-growing tumor usually presents as a pink, flesh-colored, or yellow papule or nodule (Fig. 29.32). Sebaceous adenoma occurs primarily on the head and neck (70%) in elderly persons (mean age 60). Histologically, the tumor is composed of multiple, sharply marginated, sebaceous lobules. Each lobule has a basal layer of darker germinative cells, but the maturation is not as well developed as in a normal sebaceous gland. The basaloid cells occupy more than the typical one to two cell layers seen in the normal sebaceous gland or in sebaceous hyperplasia. Multiple openings directly to the overlying epidermis may be found. Sebaceous adenoma may be a cutaneous marker of the Muir-Torre syndrome.

Sebaceoma (Sebaceous Epithelioma)

Clinically, they appear as yellow or orange papules, nodules, or plaques, usually on the scalp, face, and neck. Sebaceous epitheliomas also may be associated with Muir-Torre syndrome. Histologically, the tumor consists of oval nests of irregularly shaped basaloid cells with differentiation toward sebaceous cells. The basaloid cells should outnumber the differentiated sebocytes in a sebaceoma. Also, there may be cystic spaces containing vacuolated, amorphous material.

Reticulated Acanthoma With Sebaceous Differentiation

This rare tumor presents as an enlarging, erythematous to brown plaque, often on the back. Histologically, the tumor has a reticulated seborrheic keratosis–like pattern, being broad and well circumscribed. There are clusters of sebocytes at the bases of the rete ridges. Sebaceous ducts may also be seen. These ductal elements are EMA positive and CEA negative. This tumor can also be associated with Muir-Torre syndrome.

Sebaceous Carcinoma

Sebaceous carcinoma is a rare neoplasm, and 75% of cases occur on the eyelid or around the eye. It most frequently arises on the eyelids from the meibomian or Zeis glands. It usually appears in the tarsal region of the upper eyelids (75%) and represents 1% or more of eyelid malignancies. It is frequently misdiagnosed as a chalazion, delaying appropriate treatment. The scalp, other areas of the face, and the trunk are the next most common areas involved. Lesions present as a painless subcutaneous nodule or less often a pedunculated growth. Rarely, sebaceous carcinoma has been reported to involve the feet, external genitalia, and oral mucosa. Fatal metastatic disease occurs in 9%–50% of cases (30% of eyelid cases), and 5-year survival for this tumor is 80%. Sebaceous carcinomas arising in nonocular locations can also metastasize, usually to regional lymph nodes. Sebaceous carcinoma may be seen in MTS (Fig. 29.33).

Histologically, the tumor is composed of lobules or sheets of cells that extend deeply into the dermis, subcutaneous fat, or muscle. The tumor cells are pleomorphic and show various degrees of sebaceous differentiation, manifested by a vacuolated rather than clear cytoplasm. Undifferentiated cells with mitotic figures can be found. The cells vary greatly in size and shape. A characteristic feature in ocular tumors is pagetoid or bowenoid spread of the tumor onto the overlying conjunctiva or skin. Sebaceous differentiation may be minimal in this in situ component, leading to the misdiagnosis of SCC in situ.

Treatment is surgical, with Mohs micrographic surgery having the best results; there is an 11% recurrence rate after Mohs and 30% after standard excision. Given the extent of sebaceous carcinomas, oculoplastic reconstruction is usually required. In extraocular cases, complete excision, as for an adnexal carcinoma, and careful follow-up are recommended.

Muir-Torre Syndrome

Sebaceous tumors of the skin were first reported by Muir in 1967 and Torre in 1968 as being associated with the development of internal malignancy, a combination that has been called the Muir-Torre syndrome (MTS). The cutaneous lesions may be sebaceous adenomas, sebaceomas, or sebaceous carcinomas. In MTS, these tumors occur more often on the trunk than they do in the general population, in whom sebaceous tumors favor the head and neck. Keratoacanthomas (KAs) are also common and multiple. The KAs may show sebaceous differentiation. The combination of a sebaceous tumor and a KA should be highly suggestive of MTS. The recognition of the association of sebaceous neoplasms and MTS is highlighted by one report, in which 42% of persons with a sebaceous neoplasm had MTS. Between 22% and 32% of patients with MTS present with the sebaceous neoplasm before development of the internal malignancy. About 60% have already had an internal malignancy by the time the sebaceous neoplasm occurs. Because the mean age of presentation of the sebaceous neoplasm is 63 years, the confirmation of MTS becomes important for genetic counseling of the patient's children. MTS is inherited in an

autosomal dominant manner in about 60% of cases; penetrance is high, but expression is variable.

MTS is now recognized to be a subset of the Lynch syndrome, or hereditary nonpolyposis colorectal cancer syndrome (HNCCS). HNCCS and MTS are caused by mutations in mismatch repair (MMR) genes (*MLH1*, *MSH2*, and *MSH6* for MTS and Lynch syndrome, and *PMS2* only in Lynch syndrome). *MSH2* mutations are responsible for 90% of MTS families. The most common malignancy is colonic adenocarcinoma (47%), usually proximal to the splenic flexor. Multiple polyps are not present. Genitourinary tumors (21%), breast cancer (12%), and hematologic disorders (9%) are also common.

The absence of an MMR enzyme results in microsatellite instability (MSI). Although staining for markers such as *MSH-2* and *MSH-6* can prove the presence of MSI within the tumor, this is a common finding in sebaceous neoplasms and most patients will not have germline mutation or clinical evidence of MTS. Clinical history and physical examination are key to the diagnosis. If the Mayo MTS risk score is 2 or greater, genetic testing and counseling may be appropriate:

Mayo Muir-Torre Syndrome (MTS) Risk Score Algorithm

Variable	Score
Age at sebaceous neoplasm diagnosis (years)	
≥60	0
<60	1
Total number of sebaceous neoplasms	
1	0
≥2	2
Personal history of Lynch syndrome–related cancer	
No	0
Yes	1
Family history of Lynch-related cancer	
No	0
Yes	1
Sum of scores creates a total score, referred to as the "Mayo MTS Risk Score." A Mayo MTR Risk Score of ≥2 has a sensitivity of 100% and specificity or 81% for predicting a germline mutation in a Lynch Syndrome mismatch repair gene.	
Information for patients regarding the syndrome and genetic testing can be found at the following sources: https://rarediseases.info.nih.gov/diseases/6821/muir-torre-syndrome/cases/30944; http://www.cancer.net/cancer-types/muir-torre-syndrome; and https://www.myriad.com/patients-families/disease-info/colon-cancer/.	

Once the diagnosis is confirmed, the patient and genetically related family members should be appropriately screened for underlying malignancies of the GI and genitourinary systems. This screening should begin at a much younger age than is standard: 20–25 years for colonoscopy and 30–35 years for transvaginal ultrasound. Other organs are screened if the affected family has such cancers; screening might include upper endoscopy, urine cytology, or abdominal ultrasound. The value of screening for noncolonic carcinomas has not been demonstrated. Genetic counseling should be provided.

SWEAT GLAND TUMORS

Syringoma

Syringomas are common neoplasms demonstrating sweat duct differentiation. They present as small papules 1–3 mm in diameter and may be yellow, brown, or pink. They are virtually always multiple and most frequently occur on the eyelids and upper cheeks (Fig. 29.34). Syringomas are disproportionately common in these sites in Japanese women. Other sites of involvement include the axillae, abdomen, forehead, penis, and vulva. Genital syringomas may cause genital pruritus and may be mistaken for genital warts. Rarely, they may be unilateral or linear. Symmetric distal extremity involvement has also been reported. Eruptive syringomas are histologically identical to syringomas of the eyelid but appear suddenly as numerous lesions on the neck, chest, axillae, upper arms, in the pubic area (Fig. 29.35), and periumbilically, usually in young persons. Some have suggested that eruptive syringomas represent a proliferative process of inflamed normal eccrine glands, analogous to traumatic neuroma being a proliferation of normal peripheral nerve. The fact that numerous lesions appear after "waxing" in the pubic areas supports this hypothesis. Many individual case reports document unusual clinical variants of

Fig. 29.34 Syringomas. (Courtesy Steven Binnick, MD.)

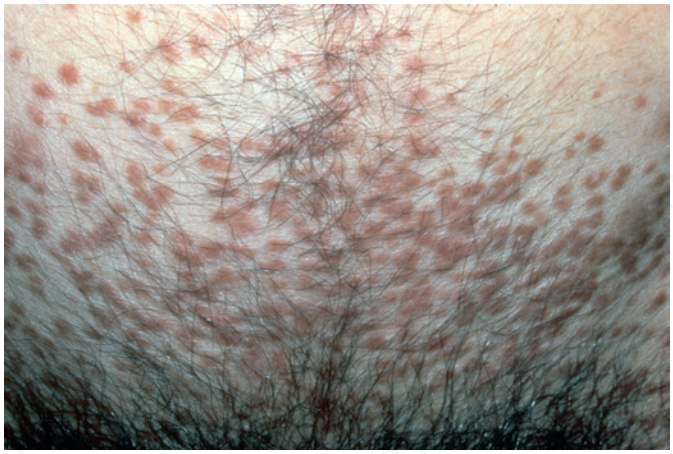

Fig. 29.35 Syringomas.

syringomas. These include types limited to the scalp, associated with alopecia; a unilateral linear or nevoid distribution; those limited to the vulva or penis; those limited to the distal extremities; and the lichen planus–like and milia-like types. Syringomas may calcify and may be mistaken for subepidermal calcified nodules. The rare "plaque-type" syringoma may be mistaken for a microcystic adnexal carcinoma.

Familial cases of syringomas occur. In general, except in eruptive cases, syringomas develop slowly and persist indefinitely without symptoms. Acral lesions are often present. Syringomas occur in 18% of adults with Down syndrome, particularly females. This is approximately 30 times the frequency seen in patients with other syndromes.

Histologically, syringomas are characterized by dilated cystic spaces lined by two layers of cuboidal cells and epithelial strands of similar cells. Some of the cysts have small, comma-like tails, which produce a distinctive picture, resembling tadpoles or the pattern of a paisley tie. There is a dense fibrous stroma. At times, the cells of the syringoma have abundant clear cytoplasm, which represents accumulated glycogen. This has been called "clear cell syringoma." Syringomas stain positive for keratins 5, 6, 14, 6, 16, 19, and 77 on the inner cell layer, and K5 and K14 on the outer cell layer, in a pattern identical to the intraglandular eccrine duct. The microscopic differential diagnosis of "paisley tie" epithelial islands embedded in a sclerotic stroma includes microcystic adnexal carcinoma (sclerosing sweat duct carcinoma), desmoplastic trichoepithelioma, and morpheaform BCC.

Treatment is difficult, but many lesions respond to very light electrodessication or shave removal. For larger lesions, surgical removal may be considered. CO_2 laser treatment by the pinhole method or by fractional thermolysis has been reported as effective.

Hidrocystomas

Hidrocystomas, which may be of eccrine or apocrine differentiation, are 1–3 mm translucent cystic papules that occasionally have a bluish tint. They usually are solitary, occur on the face (Fig. 29.36) or scalp, and are more common in women. In some patients, multiple lesions may be present, and they may be pigmented. They may become more prominent during hot weather. They most often occur periocularly. Multiple hidrocystomas with apocrine secretion on the eyelids are the hallmark of Schopf-Schulz-Passarge syndrome (SSPS), an adult-onset autosomal recessive form of ectodermal dysplasia associated with *WNT10A* mutations. Other features include hypodontia, hypotrichosis, nail dystrophy, and palmoplantar keratoderma. Multiple palmoplantar syringofibroadenomas are present in most cases of SSPS and can present as a palmoplantar keratoderma. Up to 44% of patients have other adnexal tumors. Skin and visceral malignancies are not increased in SSPS.

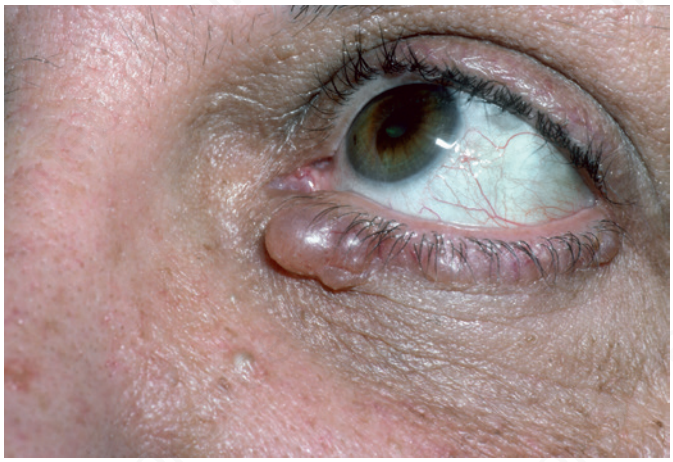

Fig. 29.36 Hidrocystoma. (Courtesy Steven Binnick, MD.)

Microscopically, a single cystic cavity is lined by two layers of small, cuboidal epithelial cells. Apocrine differentiation in the form of decapitation secretion is common. Lesions with papillary proliferations of the lining are classified as cystadenomas. Treatment, if desired, is by excision for solitary lesions. Laser treatment may be effective, both with CO_2 and pulsed dye laser. Topical atropine ointment 1% or scopolamine cream 0.01% (1.2 mL of 0.25% scopolamine eyedrops in 30 g of Eucerin), once daily, has been used with variable success in patients with multiple lesions. Pupil size may increase with these agents. Oral glycopyrrolate, 1 mg twice daily, may be useful in suppressing exercise-induced and hot weather–induced enlargement. Botulinum toxin may also be effective, either injected or applied topically.

Acrospiromas (Poroma, Hidroacanthoma Simplex, Dermal Duct Tumor, Nodular Hidradenoma, Clear Cell Hidradenoma)

Acrospiromas are benign tumors with acrosyringial differentiation. A poroma presents as a slow-growing, 2–12 mm, slightly protruding, sessile, soft, reddish tumor that occurs most often on the sole (Fig. 29.37) or side of the foot. Palmar lesions may also occur, and, more

Fig. 29.37 Poroma.

rarely, lesions appear wherever sweat glands are found. The lesion will bleed on slight trauma. A distinctive finding is the cup-shaped shallow depression from which the tumor grows and protrudes. Poromas tend to occur singly, but multiple lesions may also occur. A rare variant is called eccrine poromatosis, in which more than 100 lesions may involve the palms and soles and may be associated with hidrotic ectodermal dysplasia, immunosuppression, or chemotherapy. These may represent acrosyringeal nevi. Dermal duct tumors present deep nodules that may involve any part of the body. Nodular and clear cell hidradenomas are larger nodules that often involve the head or neck but may occur anywhere. Hybrid combinations of different patterns of acrospiroma are very common.

Histologically, poromas demonstrate solid masses of uniform, cuboidal epithelial cells with ample cytoplasm and focal duct differentiation. The cells are smaller than those in the contiguous epidermis and tend to arrange themselves in cords and broad columns extending downward from the normal epidermis. Areas of clear cell and cystic degeneration may be present, and an underlying dermal duct tumor or hidradenoma may be present. Melanocytes may be dispersed throughout the tumor and may be clinically hyperpigmented. The surrounding stroma is highly vascular, with telangiectatic vessels. Hidroacanthoma simplex represents an intraepidermal eccrine poroma. These lesions resemble clonal seborrheic keratoses, except for the presence of focal duct differentiation. Dermal duct tumors are composed of the same small acrosyringeal cells as other acrospiromas. The cells form small dermal islands with ductal differentiation. When the cells form a large nodule, the tumor is referred to as a nodular hidradenoma. When clear cells and cystic degeneration are prominent, the tumor is referred to as a clear cell hidradenoma. A distinctive feature of the latter two tumors is the presence of areas of eosinophilic hyalized stroma. All the cells in a poroma, except entrapped ducts, stain with K5/14. Focally, they are K1/10 positive and uniformly K77 negative. This is the staining pattern of the sweat duct ridge and acrosyringium (intraepidermal portions of sweat duct). The clinical differential diagnosis includes porocarcinoma, pyogenic granuloma, melanoma (amelanotic and melanotic), Kaposi sarcoma, BCC, and seborrheic keratosis. The lesions are benign but often recur after inadequate excision. Malignant degeneration may occur, and atypia is sometimes minimal within tumors that have metastasized. For these reasons, simple complete excision is recommended when feasible.

Malignant Acrospiroma (Malignant Poroma, Porocarcinoma)

This represents the most common form of sweat duct carcinoma. Most malignant acrospiromas appear clinically similar to poromas but may also manifest as a blue or black nodule, plaque, or ulcerated tumor. Porocarcinoma affects men and women equally at an average age of 70 years. The most frequent sites of involvement are the legs (30%), feet (20%), face (12%), thighs (8%), and arms (7%). Of interest is the rare involvement of the palms and soles, despite these having the greatest concentration of sweat glands. The average age from onset to treatment is 4–8 years. These tumors are of intermediate aggressiveness, with metastases usually occurring to regional lymph nodes and, less often, hematogenously.

Histologically, the tumor may be seen adjoining benign acrospiroma. Atypia may be marked or minimal, with pleomorphic or monomorphous nuclei and abundant or scant eosinophilic cytoplasm. Most frequently, the cells are smaller and more basophilic than those in benign acrospiromas with a high mitotic rate. Focal squamous or sarcomatous differentiation may be present. Pagetoid spread within the adjacent epidermis may be seen. As in benign acrospiromas, clear cell and cystic degeneration may be present. The degree of ductal differentiation is variable. The tumors can be deeply infiltrative. Perineural and lymphovascular involvement by the tumor can be present and should be noted on the dermatopathology report. The epidermis may be invaded by metastatic porocarcinoma. Mohs surgery can be a valuable technique, particularly on the face. As with other cutaneous neoplasms, margins should be free of tumor islands and tumor stroma to be considered negative. Local recurrence approaches 20%, and lymph node metastases occur in about 20% of patients. SNLB could be considered. Distant metastases occur in 10% of cases, often at a distant skin site.

Spiradenoma

Spiradenoma presents clinically as a solitary, 1-cm, deep-seated nodule, occurring most frequently on the ventral surface of the body, especially over the upper half. Normal-appearing skin covers the nodule, which may be skin colored, blue, or pink (Fig. 29.38). Occasionally, multiple lesions may be present and may occur in a linear or segmental pattern. Giant lesions that are very vascular are rarely seen. Lesions may be painful, but not universally. Spiradenoma has a generally benign clinical course and occurs most frequently between ages 15 and 35, although it has also been reported in infancy and childhood. Familial cases have been

Fig. 29.38 Spiradenoma.

described. Rarely, malignant transformation occurs, and the subsequent tumor may also have features of a cylindroma (spiradenocylindrocarcinoma).

Microscopically, spiradenoma demonstrates either a single nodule or multiple basophilic nodules within the dermis. Tumor cells have minimal to no visible cytoplasm. They are often arranged in characteristic small rosettes. Three cell types are present: cells with large, pale-gray nuclei; those with smaller, darker-gray nuclei; and jet-black lymphocytes peppered throughout the nodule. Ductlike structures are often present, as are large, pink hyaline globules that resemble the bright-red hyaline basement membrane material that outlines the islands of cylindromas. In fact, spiradenomas and cylindromas often occur together in the same patient, and hybrid collision tumors are quite common. These have historically been thought to be of eccrine lineage, but both tumors may instead originate from the hair follicle bulge.

When painful, eccrine spiradenoma may be mistaken for leiomyoma, glomus tumor, neuroma, and angiolipoma. Treatment is simple excision. Spiradenocylindrocarcinoma presents as a solitary nodule that may have experienced an abrupt change in size. Histologically, these lesions have focal areas of atypia, mitoses, and invasion. They may metastasize to regional lymph nodes or hematogenously, and PET/CT scans may be helpful for staging.

Cylindroma

Cutaneous cylindroma occurs predominantly on the scalp and face as a solitary lesion (Fig. 29.39). The tumor is firm but rubber-like and pink-blue; it ranges in size from a few millimeters to several centimeters. The solitary cylindroma is considered to be nonhereditary and at times may be found in areas other than the head and neck. Women are affected more than men.

The dominantly inherited form, Brooke-Spiegler syndrome (BSS), appears soon after puberty as numerous rounded masses of various sizes on the scalp. The lesions resemble bunches of grapes or small tomatoes. Lesions appear in the second or third decade of life. Sometimes they cover the entire scalp like a turban. BSS is characterized by the presence of multiple adnexal neoplasms, including cylindroma, trichoepitheliomas, spiradenomas, trichoblastomas, follicular cysts, and milia. Familial cylindroma is now considered a variant of BSS because it harbors the same mutation. There is no genotypic/phenotypic correlation in these two syndromes. BSS is caused by a mutation in the *CYLD* tumor suppressor gene.

Histologically, these are cylindrical masses of epithelial cells surrounded and segmented by thick bands of a hyaline material. Cylindroma may be mistaken for pilar cyst, but the distinctive appearance and consistency make diagnosis easy, especially in the multiple type. Treatment is surgical; success using ablative laser therapy has also been reported.

Mixed Tumor (Chondroid Syringoma)

Cutaneous mixed tumor is an uncommon skin tumor, representing about 1 in 1000 skin lesions removed electively. It favors men between ages 25 and 65. Mixed tumor presents clinically as a firm, intradermal or subcutaneous nodule, virtually always located on the head or neck. These tumors are usually asymptomatic and measure 5–30 mm in diameter, but may be much larger.

Histologically, nests of cuboidal or polygonal epithelial cells in the dermis give rise to tubuloalveolar and ductal structures and occasionally, keratinous cysts. These structures are embedded in a matrix varying from a faint-blue chondroid substance to an acidophilic hyaline material. Myoepithelial and lipomatous elements may also be found in the tumor in addition to the chondroid stroma. Ossification may occur. The treatment is surgical. Mixed tumors may also occur in other organs, especially salivary glands, where they are also known as pleomorphic adenomas. In salivary and rarely in cutaneous chondroid syringoma, tyrosine crystals may be seen in the tumor. Tumors with only focal glandular elements, or with no epithelial elements, have been called "cutaneous myoepitheliomas." They are tumors of the myoepithelial cells; these cells surround the sweat glands and, by their contraction, help deliver the product of the glands to the surface. Both cutaneous mixed tumors and cutaneous myoepitheliomas stain positively with SOX-10, supporting the notion that these tumors exist on a spectrum.

Malignant Mixed Tumor (Malignant Chondroid Syringoma)

The rare malignant mixed tumor favors the trunk and extremities, whereas the benign mixed tumor of the skin favors the head and neck. At presentation, the masses range from 1–10 cm, with a median size of 4 cm. They often grow rapidly. The chance of metastasis is greater than 50%, with a predilection for visceral spread. Metastases usually take the form of an adenocarcinoma, and the chondroid stroma found in primary lesions is often not found. Histologic features that distinguish malignant mixed tumor from chondroid syringoma include cytologic atypia, pleomorphism, increased mitotic activity, and focal necrosis. Treatment is surgical.

Ceruminoma

Ceruminous glands, modified apocrine glands of the external ear, may give rise to both benign and malignant tumors. Distinguishing these may be difficult; thus both the malignant and the benign tumors have been termed *ceruminomas*. The tumors present as a firm papule or nodule in the external auditory canal. Ulceration and crusting may occur, and continued growth may obstruct the meatus, resulting in hearing loss. Histologically, glands and cysts are present, lined by a tuboglandular proliferation with two layers: an inner layer of ceruminous cells (containing cerumen and with decapitation secretion) and a basal spindled or cuboidal myoepithelial layer. Treatment is excision, which is curative if margins are clear.

Hidradenoma Papilliferum

Hidradenoma papilliferum is a benign adenoma that arises from anogenital mammary-like glands and is located almost exclusively in the vulvar and perianal areas. The tumor is covered by normal skin. On palpation, it is a firm papule less than 1 cm in diameter. Malignant transformation is rare and can resemble a focus of ductal carcinoma in situ. Microscopically, hidradenoma papilliferum is encapsulated and lies in the dermis, having no connection with the epidermis. There is a cystlike cavity lined with villi. The walls of the cavity and the villi are lined, occasionally with a single layer but usually with a double layer of cells: luminal secretory cells and myoepithelial cells. PIK3CA and AKT1 mutations have been identified. This is a benign lesion, and the diagnosis and treatment are accomplished by excisional biopsy.

Syringadenoma Papilliferum (Syringocystadenoma Papilliferum)

This lesion develops in a nevus sebaceus of Jadassohn on the scalp or face in about one third of patients. Around half are present at birth, whereas approximately 25% arise on the trunk and genital and inguinal regions during adolescence. The lesions are rose-red papules of firm consistency (Fig. 29.40); they vary from 1–3 mm and may occur in groups. Vesicle-like inclusions are seen, pinpoint to pinhead in size, filled with clear fluid. Some of the papules may be umbilicated and simulate molluscum contagiosum. Extensive verrucous or papillary plaques may also be present.

Histologically, the tumor shows ductlike structures that extend from the surface epithelium. Numerous papillary projections may extend into the lumina, which may be cystic. The papillary projections are lined by glandular epithelium, often consisting of two rows of cells. The tumor cells stain positive for CEA. The dermal

Fig. 29.40 Syringocystadenoma papilliferum.

stroma contains numerous plasma cells. Rarely, malignant transformation may occur. Excision is recommended.

Papillary Eccrine Adenoma/Tubular Apocrine Adenoma

Papillary eccrine adenoma/tubular apocrine adenoma (PEA/TAA—sounds like "pita") is an uncommon benign sweat gland neoplasm that presents clinically as dermal nodules located primarily on the extremities of black patients, especially on the dorsal hand or foot. Histologic findings consist of a well-circumscribed, dermal, unencapsulated growth composed of dilated ductlike structures lined by two or more layers of cells. Intraluminal papillations may project into the cystic spaces. Because this lesion tends to recur locally, complete surgical excision with clear margins is recommended. Hybrid or overlapping lesions with a superficial component resembling syringocystadenoma papilliferum and a deep component resembling tubular adenoma can occur.

Syringofibroadenoma (Acrosyringeal Nevus of Weedon and Lewis)

First described by Mascaro in 1963, five variants of eccrine syringofibroadenoma are now recognized:

1. Solitary
2. Multiple, in Schopf syndrome
3. Multiple, without other skin manifestations
4. Nonfamilial unilateral linear
5. Reactive

The solitary type presents frequently as a hyperkeratotic nodule or plaque involving the extremities. The linear type may be linear, blaschkoid, or zosteriform in appearance, and some cases may represent an acrosyringeal nevus. Multiple lesions have been termed *eccrine syringofibroadenomatosis* (ESFA) and occur in both variants of hidrotic ectodermal dysplasia, Schopf syndrome, and Clouston syndrome. The multiple ESFAs may appear in a mosaic pattern. In Clouston syndrome (due to mutation in the *GJB6* gene), HPV-10 has been detected in the tumors. Multiple lesions have also been reported without other associated cutaneous findings. Many cases represent a reactive epithelial proliferation, whereas others represent a true neoplasm of acrosyringeal cells. Histologically, the strands resemble those of the fibroepithelial tumor of Pinkus, but with broader anastomosing cords without the basaloid buds. "Reactive eccrine syringofibroadenoma" most often occurs on the lower leg and may show adjacent changes of an associated dermatosis. Carcinomatous transformation of ESFA has been reported.

Microcystic Adnexal Carcinoma (Sclerosing Sweat Duct Carcinoma)

This tumor generally presents as a very slow-growing plaque or nodule. It occurs most frequently on the head and neck (87%), face (73%), and scalp (10%). Lesions favor the midface and periorbital area, with a predilection for the left side. The upper lip (Fig. 29.41) is involved nine times more often than the lower lip. Given their propensity for sun-exposed sites, long-term sun exposure may play a role in the pathogenesis of microcystic adnexal carcinomas; they have also occurred at sites of prior therapeutic radiation. The lesions are locally aggressive, with local recurrences in 50% of cases. Metastasis rarely occurs. Microcystic adnexal

Fig. 29.41 Microcystic adnexal carcinoma.

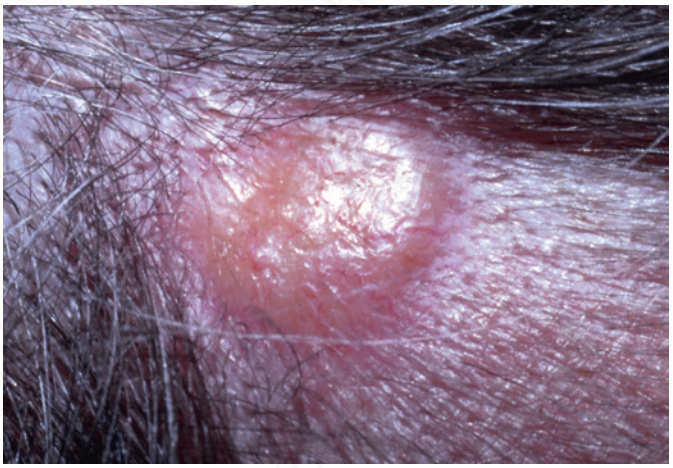

Fig. 29.42 Eccrine carcinoma.

carcinoma occurs most often in Caucasians (90%) but also is reported in Japanese Americans and in African Americans, in whom it may be found in atypical locations. Histologically, the superficial part of the tumor is composed of ducts, keratinous cysts, and small cords of cells, superficially resembling a syringoma. The deeper component consists of nests and strands in a dense stroma. Perineural invasion is common and may be extensive. This explains the frequent recurrence after initial excision. Specific immunohistochemical markers have been proposed to distinguish microcystic adnexal carcinoma from infiltrative BCC, desmoplastic trichoepithelioma, and SCC. Mohs microsurgery is the treatment of choice. Radiation treatment of the tumor is controversial; it may be useful as adjuvant therapy but appears to be inadequate as monotherapy, with potential for recurrence and more aggressive behavior of the tumor.

Eccrine Carcinoma (Syringoid Carcinoma)

Eccrine carcinoma is rare and presents as a plaque or nodule on the scalp (Fig. 29.42), trunk, or extremities. Local recurrence is common, but metastases are rare. It is composed of ducts and tubules with atypical basaloid cells. A more cellular tumor with numerous tubules and ducts has been termed *polymorphous sweat gland carcinoma.* Overlap features with microcystic adnexal carcinoma occur, but in general, eccrine carcinoma has a less desmoplastic stroma.

Mucinous Carcinoma

Mucinous carcinoma is typically a round, elevated, reddish, and sometimes ulcerated mass, usually located on the head and neck (75%). Forty percent occur on the eyelid. It grows slowly and is usually asymptomatic. Local recurrence is seen in 36%, but the rate of metastasis and widespread dissemination is low (15%). Rare tumors on the eyelid (derived from glands of Moll) may express estrogen and progesterone receptors, analogous to mucinous carcinoma of the breast. Mucinous gut carcinomas may also metastasize to skin and must be excluded before diagnosing a primary cutaneous mucinous carcinoma.

Histologically, tumors are characterized by the presence of large areas of mucin, in which small islands of basophilic epithelial cells are embedded (blue islands floating in a sea of mucus). Basaloid cells in a cribriform pattern, with ductlike structures, are typical. The recommended treatment is surgical excision; Mohs surgery leads to lower rates of recurrence compared with those treated with traditional surgical excision (13% vs. 34%).

Aggressive Digital Papillary Adenocarcinoma (Digital Papillary Adenocarcinoma)

This aggressive malignancy involves the digit between the nail bed and the distal interphalangeal joint spaces in most cases, or occurs just proximal to this region. It presents as a solitary cystic nodule. Ulceration and bleeding can occur, and rarely the malignancy may be fixed to underlying tissues. Most patients are men in their fifties. The tumor is locally aggressive, with a 50% local recurrence rate. Metastases, particularly pulmonary, occur in about 15% of cases. The tumor is poorly circumscribed and is composed of tubuloalveolar and ductal structures with areas of papillary projections. The tumor is positive for S-100, and the cystic contents are positive for CEA and EMA. Complete excision is the treatment of choice. Cases previously called aggressive digital papillary "adenoma" are best regarded as adenocarcinoma.

Hsu HC, et al: Aggressive digital papillary adenocarcinoma. Clin Exp Dermatol 2010; 35: 113.
Suchak R, et al: Cutaneous digital papillary adenocarcinoma. Am J Surg Pathol 2012; 36: 1883.

Primary Cutaneous Adenoid Cystic Carcinoma

This rare cutaneous tumor usually presents on the chest, scalp, or vulva of middle-aged to older persons. It is similar histologically to adenoid cystic carcinoma of the salivary gland, with a proliferation of small, ductlike islands and larger islands with a "Swiss cheese" or cribriform pattern. Detection of HPV and overexpression of p16 (a tumor suppressor protein also called CDKN2A) has been demonstrated in many of these lesions. Adenoid cystic carcinoma may recur locally or rarely metastasizes. Surgical excision, perhaps with Mohs micrographic surgery, is the treatment of choice.

Apocrine Gland Carcinoma

Apocrine gland carcinoma unrelated to PD is rare. The axilla or anogenital region is the most common site, but occasionally other areas with apocrine glands may be involved. Lesions present as a mass. Widespread metastases occur in at least 40% of cases.

HAIR FOLLICLE NEVI AND TUMORS

Pilomatricoma (Calcifying Epithelioma of Malherbe)

Also known as Malherbe calcifying epithelioma and pilomatrixoma, this benign tumor is derived from hair matrix cells. It usually occurs as a single lesion, which is most often found on the face, neck, or proximal upper extremity. Lesions may also be located on the scalp, trunk, and lower extremities. Pilomatricoma is an asymptomatic, deeply seated, 0.5–7 cm, firm nodule covered by normal or pink skin (Fig. 29.43). On stretching, it may show the "tent sign," with multiple facets and angles; on gentle pinching, it may show the "skin crease sign," with a central longitudinal crease. Overlying epidermal atrophy is common, leading to an appearance that may resemble anetoderma or striae. "Giant" and "bullous" presentations have been described. In a review of 239 patients, the youngest was 1 year and the oldest 83 years. There is a bimodal age distribution, in the first and sixth decades. Females are more often affected than males.

Fig. 29.43 Pilomatricoma, larger lesion with yellow tint.

Multiple pilomatricomas are uncommon. They are usually seen in association with myotonic dystrophy–Steinert syndrome. They may also occur in Rubinstein-Taybi syndrome, trisomy 9, and Turner syndrome. Patients with Gardner syndrome have epidermoid cysts with focal areas of pilomatricoma-like changes. Rarely, multiple pilomatricomas will be inherited in an autosomal dominant pattern with no other association.

The histopathology shows an encapsulated mass. Basophilic cells with minimal cytoplasm resemble those of the hair matrix. They evolve into eosinophilic "shadow" cells. Calcification occurs frequently. Ossification, melanin deposits, and foreign body reaction with giant cells may all be present. Activating mutations in β-catenin are present in the majority of pilomatricomas. It is expressed in the basophilic but not the shadow cells. "Melanocytic matricoma" is a rare lesion presenting as a small papule, which histologically is composed of metrical cells, some shadow cells, and numerous dendritic melanocytes containing melanin. It appears to be a fairly common variant in the Japanese population.

Clinical differential diagnosis is usually impossible in the adult, but in children, because epidermoid cysts are rare, this diagnosis should be considered for any firm cystic mass of the face and upper body. When palpated, pilomatricomas are firmer and more faceted than epidermoid and pilar cysts. Fine-needle aspiration has led to misdiagnosis, with the basophilic cells being interpreted as carcinoma. Treatment is surgical excision.

Malignant Pilomatricoma (Pilomatrix Carcinoma, Pilomatrical Carcinoma)

Malignant pilomatricomas are rare tumors. Described as being locally aggressive, but with limited metastatic potential, many cases labeled "malignant" may actually have been "proliferating" pilomatricomas. Metastases to regional lymph nodes are most common. Mohs micrographic surgery may be considered to obtain clear margins.

Trichofolliculoma

Trichofolliculoma is a benign, highly structured tumor of the pilosebaceous unit, characterized by a small, dome-shaped nodule about 5 mm in diameter on the face or scalp. From the center of the flesh-colored nodule, a small wisp of fine, vellus hairs protrudes through a central pore (Fig. 29.44). It may occur at any age but mostly affects adults. Mouse studies suggest that dysregulation of bone morphogenic protein signaling in hair follicle progenitors may contribute to trichofolliculoma formation.

Histologically, the tumor consists of one or more large follicles with smaller, radiating, secondary follicular structures, sometimes referred to as "the mother follicle with her babies." The secondary follicles range from an immature rudimentary matrix to well-formed follicles with papillae, matrix, trichohyaline, and fine hairs ("fingers of fully formed follicles forming fiber"). The tumor may have little stroma or may be embedded in a fibrous orb. Sebaceous glands may be prominent, a variant termed *sebaceous trichofolliculoma*. The follicular structures in trichofolliculomas transition through phases of the hair cycle. In telogen, they may resemble fibrofolliculomas. The presence of hair shafts helps distinguish the two. Folliculosebaceous cystic hamartoma may closely resemble a sebaceous trichofolliculoma. Treatment is surgical removal.

Brooke-Spiegler Syndrome (Multiple Familial Trichoepithelioma, Epithelioma Adenoides Cysticum)

This autosomal dominant condition usually presents in childhood or around puberty. Familial cylindroma, multiple familial trichoepithelioma, and Brooke-Spiegler syndrome are all variants of the same condition. The favored term is *Brooke-Spiegler syndrome* (BSS). There is a variable phenotypic expression among and within families and patients. The multiple trichoepitheliomas present as multiple cystic and solid papules on the face, favoring the upper lip, nasolabial folds, and eyelids (Fig. 29.45). The individual lesions are small, round, smooth, shiny, slightly translucent, firm, circumscribed papules or nodules. The individual lesions average 2–4 mm in diameter. The center may be slightly depressed. Most frequently, the lesions are grouped but discrete. On the face, they are often symmetric. Other sites may be the scalp, neck, and trunk. Multiple linear and dermatomal trichoepitheliomas may rarely be seen. Multiple cylindromas and spiradenomas, epidermoid cysts, and milia may occur in association with multiple trichoepitheliomas. BSS is caused by mutations in *CYLD*, which functions as a tumor suppressor gene. It has a critical role in deubiquinating proteins,

Fig. 29.44 Trichofolliculoma.

Fig. 29.45 Brooke-Spiegler syndrome.

which is important in controlling their biologic function. Some individuals in these families have primarily trichoepitheliomas, others have primarily cylindromas, and others have a panoply of adnexal tumors, including cylindromas, trichoepitheliomas, and spiradenomas. BSS patients seem to be at particular risk for degeneration of their cylindromas and spiradenomas to carcinomas. Topical sirolimus has been reported as helpful for patients with multiple tumors.

Solitary Trichoepithelioma

The singly occurring trichoepithelioma is nonhereditary and mostly favors the face. However, it may also be found on the scalp, neck, trunk, and proximal extremities. It presents as a firm dermal papule or nodule and must be distinguished from BCC.

Giant Solitary Trichoepithelioma

The lesions may be several centimeters in diameter, occurring most frequently on the thigh or perianal regions. They are found in older adults.

Desmoplastic Trichoepithelioma

This lesion, which is difficult to differentiate from morpheiform BCC histologically, occurs as solitary or multiple lesions on the face. Desmoplastic trichoepitheliomas are firm and slightly indented (central dell sign), with a raised, annular border (Fig. 29.46). Young women are most often affected, and familial solitary and multiple desmoplastic trichoepitheliomas have been described.

Trichoepitheliomas are dermal tumors with multiple nests of basaloid cells, some of which show abortive follicular differentiation. Keratinous cysts, calcification, and amyloid may all be seen. The stroma in most trichoepitheliomas resembles the fibrous sheath of a normal hair follicle. It contains many fine collagen fibers and fibroblasts that surround the tumor islands in a concentric array. Clusters of plump nuclei resembling the cells of the follicular papilla (papillary mesenchymal bodies) are common. In the desmoplastic variety, the tumor is composed of small cords of epithelium embedded in a dense eosinophilic stroma with fewer fibroblasts. The islands often present a "paisley tie" appearance, and the microscopic differential diagnosis includes morpheaform BCC, syringoma, and microcystic adnexal carcinoma. The clinical features may distinguish these entities. Focal calcification, horn cysts, and a central dell favor trichoepithelioma. In desmoplastic trichoepithelioma, clefts form between collagen fibers in the stroma, whereas in BCC, clefts form between the tumor islands and stroma. Trichoepitheliomas are best classified as benign tumors of the hair germ. As such, they may be considered variants of trichoblastoma. Histologically, trichoepithelioma must be differentiated from keratotic BCC, with which it is frequently confused.

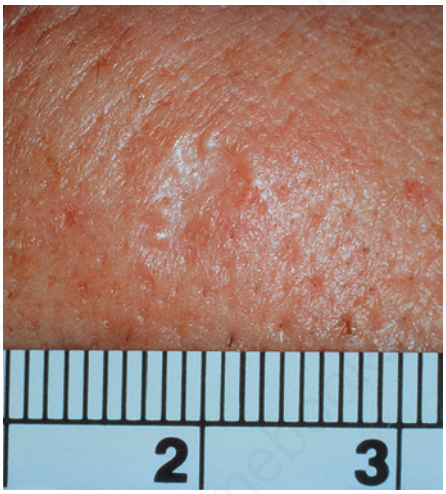

Fig. 29.46 Trichoepithelioma, desmoplastic type.

Solitary lesions can be treated by surgical excision. Multiple lesions can be smoothed down by resurfacing the skin with laser surgery, dermabrasion, or electrosurgery. This procedure must be repeated at regular intervals, as the lesions gradually recur.

Trichoblastoma

These benign neoplasms of follicular germinative cells usually present as asymptomatic nodules 0.5–1 cm in size in the deep dermis or subcutaneous tissue. The scalp is the most common location, especially if associated with nevus sebaceus of Jadassohn. Trichoblastomas usually occur in adult men and women, but children can also develop them. The lesions may be pigmented. Trichoblastomas arise in organoid nevi and represent the majority of basaloid neoplasms described as "basal cell carcinomas" in nevus sebaceus. The rare Curry-Jones syndrome, with cutaneous streaky hypopigmentation, hyperpigmented linear atrophic lines on the soles, and many other musculoskeletal, ocular, and GI defects, can feature multiple trichoblastomas. Histologically, trichoblastoma is a dermal or subcutaneous tumor composed of basaloid cells with areas of follicular differentiation. The islands may connect with the overlying epidermis, especially in the setting of an organoid nevus. The stroma is identical to that seen in trichoepithelioma and typically contains papillary mesenchymal bodies. Merkel cells may be prominent within the tumor, and amyloid can be found. Cutaneous lymphadenoma is a variant of trichoblastoma with extensive infiltration of the tumor islands by lymphocytes and histiocytes. The stroma resembles that of other trichoblastomas. A single or double row of basaloid tumor cells is seen at the periphery of each island, whereas the center is composed of histiocytes and lymphocytes. Surgical excision is curative.

Trichilemmoma and Cowden Syndrome (Cowden Disease, Multiple Hamartoma Syndrome)

Trichilemmoma is a benign neoplasm that differentiates toward cells of the outer root sheath. It usually occurs as a small, solitary papule on the face, particularly the nose and cheeks. Sporadic tumors are often caused by activating HRAS mutations. Most lesions are clinically misdiagnosed as BCC or benign keratosis.

Trichilemmomas may also occur as multiple facial lesions. When they do, this is a specific cutaneous marker for Cowden syndrome (CS), an autosomal dominant inherited condition. The prevalence

Fig. 29.47 Cowden syndrome.

Fig. 29.48 Oral papillomas in Cowden syndrome.

of CS is 1 in /200,000–250,000. The penetrance is almost complete, with 90% of affected patients having stigmata by age 20. Diagnostic criteria for CS have been established, and certain mucocutaneous manifestations are considered pathognomonic, including trichilemmomas of the face, acral keratoses, papillomatous papules (Fig. 29.47), and mucosal lesions (Fig. 29.48). The trichilemmomas, or "facial papules," are present in 86% of CS patients and appear on average at age 22 but can appear at any age from childhood to advanced age (75 years). Trichilemmomas are generally limited to the head and neck, especially the central face, around the orifices; however, other sites may be involved (e.g., ears). Because not all facial papules have characteristic histology, the presence of "papillomatous" lesions is a diagnostic criterion. The other pathognomonic mucocutaneous benign features are acral keratoses, which present as either verrucous hyperkeratosis on the extensor extremities, or palmoplantar translucent keratoses, in 28% and 20% of CS patients, respectively. Acral neuromatosis may present as translucent papules on the backs and sides of the fingers. The mucous membranes are involved in more than 80% of patients and usually in multiple anatomic locations, favoring the buccal and gingival mucosa. They can coalesce and form the characteristic cobblestone pattern seen in 40% of CS patients. Involvement of the respiratory mucosa can occur, with an acanthosis nigricans–like appearance. The mucosal lesions develop after the cutaneous lesions and have a persistent but benign course. Other cutaneous lesions include lipomas, hemangiomas, xanthomas, acanthosis nigricans, and various hyperpigmented macules. Macrocephaly with head circumference of greater than 97% is a major criterion for the diagnosis.

Malignancies develop in up to 40% of patients with CS. They are major criteria for the diagnosis and include breast, endometrial, and thyroid carcinoma. Breast cancer occurs in 25%–50% of female patients and has been reported in male patients with CS. For breast cancer, the average age at diagnosis is 36 years. About 75% of affected females have fibrocystic disease of the breast. Endometrial cancer occurs in 6% of women with CS and has appeared as early as adolescence. Although not criteria for the diagnosis, multiple GI polyps (in 70%–85%) and GI malignancies also occur. Minor criteria include thyroid lesions (including adenomas or goiter, and thyroiditis, in two thirds of patients), mental retardation, lipomas, fibromas (multiple sclerotic fibromas or storiform collagenomas), and genitourinary tumors. Multiple lipomatosis of the testicles is a common manifestation. The adult form of Lhermitte-Duclos disease, or dysplastic gangliocytoma of the cerebellum, represents the neurologic manifestation of CS. Lhermitte-Duclos disease is another pathognomonic criterion for the diagnosis of CS. A number of mucocutaneous malignancies have been found in patients with CS, including melanoma, BCC, SCC, MCC, and trichilemmal carcinoma.

Mutations in the tumor suppressor gene *PTEN* are responsible for the majority of CS. Patients who do not have a mutation in *PTEN* have mutations in the promoter region for *PTEN* or have methylation and downregulation of *KILLIN*, another tumor suppressor, with resultant rates of breast and renal cancer higher than those seen with *PTEN* mutation. In 10% of cases, the mutation is not in *PTEN* or the promoter and may be in the succinate dehydrogenase genes. Another disorder caused in 65% of cases by mutations in *PTEN* is Bannayan-Riley-Ruvalcaba syndrome (BRRS): autosomal dominant inherited macrocephaly, genital lentigines, motor and speech delay, mental retardation, hamartomatous polyps, myopathies, lipomas, and hemangiomas. BRRS is now considered a variant of CS that presents earlier in life, and patients having overlap syndromes with features of both CS and BRRS have been described. Some patients with a Proteus-like syndrome also have mutations in *PTEN*. These diseases have been called the "*PTEN* hamartoma tumor syndrome."

Microscopically, trichilemmomas show variable hyperkeratosis and parakeratosis. Tumor lobules extend downward from the epidermis and demonstrate glycogen-rich clear cells, peripheral palisading, and a thick, hyalinized basement membrane.

Facial papillomas can be removed with surgical procedures, but new lesions continue to appear throughout life. Some patients achieve satisfactory cosmetic results from dermabrasion or CO_2 laser. Regular cancer screening and genetic counseling are paramount in CS. Rapamycin prevents the development of mucocutaneous lesions and premature death in the animal model for CS, suggesting that the mTOR pathway is involved in the development of the cutaneous lesions and the later complications of CS.

Trichilemmal Carcinoma

Trichilemmal carcinomas are reported to arise on sun-exposed areas, most often the face and ears. They present as a slow-growing papule, indurated plaque, or nodule with a tendency to ulcerate. They may arise in the association of immunosuppression. It may be difficult to distinguish trichilemmal carcinoma from invasive BD (which often shows adnexal differentiation) or a clear cell SCC. Surgical removal is recommended; Mohs micrographic surgery has been used successfully. Local recurrence and metastasis have occurred.

Trichodiscoma, Fibrofolliculoma, Perifollicular Fibromas, Mantleomas, and Birt-Hogg-Dubé Syndrome

These benign tumors form a spectrum of neoplasms combining a follicular element and the specialized periadventitial dermis of the upper portion of the hair follicle. They may represent variations of the same tumor cut in different planes of section. All these lesions clinically appear as 2–4 mm, asymptomatic, skin-colored, dermal papules affecting the face and upper trunk. They may be single but are frequently multiple. When multiple, they are often numerous and are a marker for Birt-Hogg-Dubé syndrome (BHD) (Fig. 29.49). The histomorphology of these hair follicle tumors is identical in patients with BHD and in cases unassociated with BHD. Fibrofolliculoma demonstrates cords and strands of two-cell to four-cell epithelium emanating from a follicular structure. The epithelial elements may anastomose, and sebaceous elements may be present. This follicular structure is surrounded by a collagenous or fibromucinous orb. Trichodiscomas represent a sectioning artifact that demonstrates only the tumor stroma.

The BHD syndrome is inherited in an autosomal dominant manner. It is caused by a mutation in the gene folliculin *(FLCN)*, which is located on chromosome 17p. Many of the mutations occur in a hypermutable region of the gene. This gene is conserved in many species and expressed in many tissues, but its exact function is unknown. Recently it has been linked to numerous cell pathways important in cancer biology, including cell growth, metabolism, adhesion, motility, kinesis, and survival. Homozygous loss of function of the folliculin gene is embryonically lethal, suggesting that *FLCN* may indeed play a broad and important role in the cell. Cutaneous lesions are common in patients with BHD, affecting more than 80% of persons 30 years or older. The fibrofolliculomas appear in adulthood and usually precede other stigmata but can be quite subtle. In the vast majority of cases, they are multiple and often very numerous. They can be widespread but always affect the nose, paranasal area, back of the pinna, and behind the ear. Comedo-like papules with keratinous plugs may be seen. Lesions can coalesce into plaques and be grouped. Multiple epidermoid cysts can occur. Hyperseborrhea may be seen, with numerous facial fibrofolliculomas. Skin tags are present in 100%

Fig. 29.49 Birt-Hogg-Dubé syndrome.

of patients, most often in the axillae. Small, discrete, soft, mucosa-colored or white papules of the lips, gingiva, tongue, and buccal mucosa are present in about 40% of patients and families with BHD. Biopsies of the oral lesions reveal an acanthotic epithelium overlying a fibrotic process.

In addition to the cutaneous lesions previously noted, patients are at risk for the development of renal tumors and spontaneous pneumothorax. The renal tumor risk is seven times that of the general population and especially affects men (at twice the risk) and those over 40. At least 30% of patients with BHD develop renal tumors, and these can appear after age 20. Renal tumors may be multiple and bilateral, a clinical scenario that should suggest the diagnosis of BHD. Patients with BHD develop renal oncocytomas and chromophobe renal carcinomas, or a mixed type that is characteristic of BHD. These are otherwise rare histologic variants of renal cell carcinoma. Multiple renal cysts may also occur.

Patients with BHD have greater than 30 times the risk of developing a spontaneous pneumothorax than unaffected persons—a lifetime risk of 24%. Pneumothorax can occur at a young age in BHD; 17% of BHD patients under 40 will have a spontaneous pneumothorax. Median age of pneumothorax occurrence is 38 years. Spontaneous pneumothorax results from multiple pulmonary cysts, which affect 83% of BHD patients. The cysts are at the lung base and subpleural. Recurrent pneumothorax is common and should suggest BHD. Patients do not seem to have progressive pulmonary failure, and severe chronic obstructive pulmonary disease is not associated with *FLCN* mutations. Colonic polyps and neoplasms, which were initially reported to be associated with BHD syndrome, do *not* appear to be increased in BHD syndrome. Thyroid nodules are seen in 90% of affected families and 65% of BHD patients. BHD must be differentiated from familial multiple discoid fibroma, which presents similarly with facial papules but is histologically distinct, lacks systemic complications, and does not involve the *FLCN* gene.

The treatment of the fibrofolliculomas is surgical debulking. In most patients, the lesions are small and can be cosmetically removed by shave removal, curettage, or resurfacing if the lesions are numerous. Smoking is proscribed because it may worsen lung complications. Renal imaging should be periodically performed, but the best method is unclear. CT is more accurate than ultrasound, especially for smaller lesions, but repeat scans lead to unacceptable radiation exposure. MRI is expensive but diagnostically most accurate. Although there is no genotype/phenotype correlation known at this time for *FLCN* mutations, certain families seem to be predisposed to certain complications of BHD. In those families, more aggressive screening for the particularly prevalent complication seems warranted. Because the *FLCN* gene seems to interact with the mTOR pathway, it has been suggested that the use of rapamycin has potential benefit in BHD; however, an RCT showed no benefit.

Other Hair Follicle Tumors

Dilated Pore (of Winer)

This lesion typically presents as a solitary, prominent, open comedo on the face or upper trunk of an elderly individual. Histologically, it is composed of a greatly dilated follicular pore lined by outer root sheath epithelium. Multiple short, bulbous, acanthotic projections extend from the central infundibulum-like pore.

Pilar Sheath Acanthoma

Pilar sheath acanthoma is most often found on the face, particularly above the upper lip in adults. Patients present with a solitary, 5–10 mm, skin-colored nodule with a central keratinous plug. Histologically, pilar sheath acanthoma differs from a dilated pore by having larger tumor lobules radiating from the central infundibulum-like pore.

Trichoadenoma

Presenting as a solitary growth ranging from 3–15 mm in diameter, this lesion may be clinically mistaken for a seborrheic keratosis, having a vegetative or verrucous appearance. Although most frequently found on the face, it may occur at other sites, especially the buttock, which is the second most common location. Trichoadenomas also differentiate toward the follicular infundibulum. Histologically, they are quite distinctive, being composed of a collection of ringlike eosinophilic structures that often occur in pairs (resembling eyeglasses). No hair shafts are present.

Basaloid Follicular Hamartoma

Basaloid follicular hamartoma (BFH) is a distinctive benign adnexal tumor that has four described variants: solitary papule, localized plaque of alopecia, linear or blaschkoid unilateral plaque, and

Fig. 29.50 Basaloid follicular hamartoma. (Courtesy Dr. J. English.)

generalized papules. Generalized BFH form has also been termed *generalized hair follicle hamartoma*. Most often affecting the skin of the face and scalp, BFHs are solitary or multiple, skin-colored, 2–3 mm papules (Fig. 29.50) or infiltrating plaques associated with progressive hair loss in the affected areas. Congenital and adult appearances have been described. In some generalized cases, there is an association with alopecia, myasthenia gravis, or circulating autoantibodies (antinuclear and antiacetylcholine receptor antibodies). Cystic fibrosis and generalized follicular hamartomas have been reported in three siblings, suggesting a possible genetic linkage. A familial, autosomal dominant form has been described, with numerous milia; comedo-like lesions; hyperpigmented papules of the face, scalp, ears, neck, and trunk; hypotrichosis; hypohidrosis; and pinpoint palmar pits. It presents in early childhood. Happle-Tinschert syndrome is segmentally arranged BFH, linear atrophoderma with hypopigmentation or hyperpigmentation, enamel defects, ipsilateral hypertrichosis, and skeletal and cerebral anomalies.

Histologically, BFH may be indistinguishable from infundibulocystic BCC. Lesions are characterized by thin, branching eosinophilic strands and thick cords with associated basaloid buds and keratin cysts. Unlike most other pilar tumors, the stroma is loose, fibrillar, or mucinous. In nevoid and generalized forms, apparently normal skin may also demonstrate small islands of basaloid cells. Trichoblastomas may occur within nevoid lesions. *PTCH* gene signaling is upregulated in the cells contacting the dermis in BFH. Generalized BFH syndrome must be distinguished from Bazex-Dupré-Christol syndrome, Brown-Crounse syndrome, Rombo syndrome, basal cell nevus syndrome, and Brooke-Spiegler syndrome. Its differentiation from multiple hereditary infundibulocystic BCC syndrome may be difficult. Treatment essentially consists of recognition of the correct diagnosis, avoidance of unnecessary surgery, and periodic monitoring (malignant growths may arise within BFH, if not transform from it). Oral and topical retinoids and PDT have been reported effective for widespread BFH.

Folliculosebaceous Cystic Hamartoma

Folliculosebaceous cystic hamartoma is a benign hamartoma of epithelial and mesenchymal elements. It presents as a solitary, 0.5–1.5 cm papule or nodule virtually always on the head, with two thirds occurring on or adjacent to the nose. Rare giant lesions up to 15 cm in diameter have been reported. Age of onset ranges from infancy to the sixth decade. Histologically, the lesion is composed of three elements: an intradermal cystic structure lined by squamous epithelium identical to that of the infundibulum; numerous sebaceous lobules radiating from the cystic structure; and a surrounding stroma with fibrous, adipose, vascular, and neural tissues. Stromal spindle cells are positive for CD34. The tumor may represent a sebaceous trichofolliculoma biopsied during telogen phase.

Tumors of the Follicular Infundibulum

These flat, keratotic papules, and sometimes hypopigmented macules, of the head and neck are usually solitary but may be multiple. They appear in adulthood. The terms *eruptive infundibulomas* and *infundibulomatosis* have been used to describe cases with multiple lesions. In the rare generalized cases, there is a strong clinical resemblance to Darier disease, with accentuation on the neck, central chest, groin, and axillae. Histologically, the solitary and multiple cases are identical. There is a platelike proliferation of epidermal cells growing parallel to the epidermis and connecting to it at multiple sites. Clear, glycogenated cells similar to those of a trichilemmoma, sebaceous differentiation, cystic and ductal structures, and papillary mesenchymal bodies may be seen. Caution is required in interpreting biopsy specimens, as the edge of an infundibulocystic BCC can appear similar.

EPITHELIAL CYSTS AND SINUSES

Epidermal Cyst (Epidermal Inclusion Cyst, Infundibular Cyst)

Epidermal inclusion cyst is one of the most common benign skin tumors. It presents as a compressible, but not fluctuant, cystic mass from 0.5 cm to several centimeters in diameter (Fig. 29.51). The surface of the overlying skin is usually smooth and shiny from the upward pressure. These nodules are freely movable over underlying tissue and are attached to the normal skin above them by a comedo-like central infundibular structure or punctum. The pasty contents of the cysts are formed mostly of macerated keratin, which has a cheesy consistency and pungent odor. Epidermal inclusion cysts occur most often on the face, neck, and trunk but may be found in almost any location. They frequently result from plugging of the follicular orifice, often in association with acne vulgaris. They may also occur by epidermal implantation. Deep penetrating injuries, such as with a sewing machine needle or stapler, or even with nail biting, may result in epidermoid cysts growing within bone. In persons with dark pigment, the lining of the epidermoid cyst and its contents may be pigmented. Epidermoid cysts rarely appear

Fig. 29.51 Epidermal inclusion cyst.

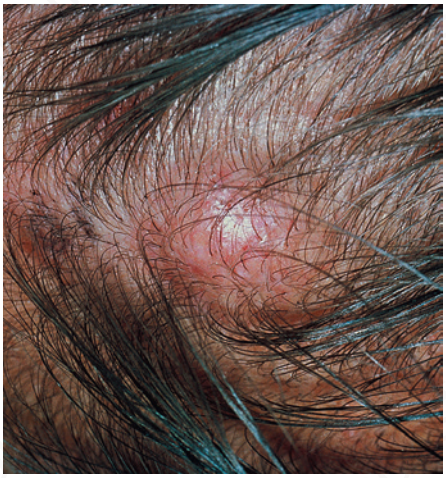

Fig. 29.52 Pilar cyst.

before puberty, and earlier onset should suggest an alternative diagnosis (e.g., pilomatricoma, dermoid cyst, Gardner syndrome). Lesions of the scalp are usually trichilemmal cysts. Rare cysts of the soles are caused by infection by HPV-60.

Epidermoid cysts may rupture and induce a vigorous foreign body inflammatory response, after which they are firmly adherent to surrounding structures and are more difficult to remove. Rupture is associated with the sudden onset of redness, pain, swelling, and local heat, simulating an abscess. Incision and drainage will confirm the diagnosis of inflamed cyst, when the smelly, cheesy material is evacuated. This will also lead to rapid resolution of symptoms. These episodes are often misdiagnosed as "infection" of the cyst, but cultures are usually negative, and antibiotic treatment is not required. Intralesional triamcinolone may hasten resolution of the symptoms. Rarely, malignancies such as SCC, BCC, and melanoma have arisen within epidermoid cysts. Rapidly enlarging cysts should be considered for excision, and histology should be reviewed carefully.

The epidermoid cyst is a keratinizing cyst, the wall of which is stratified squamous epithelium containing keratohyalin granules. It is differentiated from the pilar cyst by the different pattern of keratinization, although hybrid cysts with infundibular, trichilemmal, and even pilomatrical differentiation can be seen. Idiopathic scrotal calcinosis is the end stage of calcification of epidermoid cysts of the scrotum. Pilomatrical differentiation within an epidermoid cyst should suggest Gardner syndrome.

Surgical excision is curative, but the complete cyst and any associated "daughter" cysts must be removed. Enucleation of the cyst through a small incision or a hole made with a 4-mm biopsy punch or a laser may be attempted. A suture looped several times through the cyst and overlying skin can be used to exert traction on the cyst facilitating removal. A curette may be used to scrape out and snag all the fragments of the cyst wall. Alternatively, the lining of the cyst can be eradicated by cauterizing it with 20% trichloroacetic acid. Inflamed cysts may also be treated in this way, but the inflammation makes complete removal of the cyst more difficult. If any fragment of the cyst wall is left behind, the cyst may recur.

Proliferating Epidermoid Cyst

These tumors, derived from epidermoid cysts, occur more often in men (64%), and the most frequent sites are the pelvic/anogenital areas (36%), scalp (21%), upper extremities (18%), and trunk (15%). In rare cases, carcinomatous changes can be seen on histology, with anaplasia, high mitotic rate, and deep invasion. Proliferating epidermoid cysts are locally aggressive, but distant metastasis is rare. Malignant onycholemmal cyst may describe a rare slow-growing tumor arising from a subungual keratinous cyst.

Pilar Cyst (Trichilemmal Cyst, Isthmus-Catagen Cyst)

The trichilemmal cyst, also known as a wen, is similar clinically to the epidermoid cyst, except that about 90% of pilar cysts occur on the scalp (Fig. 29.52). Women over age 60 are predominantly affected. The cyst may be found rarely on the face, trunk, and extremities. An overlying punctum is not present, and lesions tend to be more mobile and firmer than epidermoid cysts. Hereditary trichilemmal cysts (autosomal dominant) link to the short arm of chromosome 3 but not to β-catenin or MLH1.

The trichilemmal cyst is lined by stratified squamous epithelium, which is derived from the outer root sheath. The lining cells demonstrate trichilemmal keratinization, increasing in size as they approach the cyst cavity and abruptly keratinizing without forming a granular cell layer. The cyst contents are homogeneous; they usually calcify and rarely ossify. Hybrid cysts with features of both an epidermoid cyst and a pilar cyst can be seen.

Treatment is the same as for the epidermoid cyst. Pilar cysts are much more easily enucleated, so more limited incision is required to remove the lesion.

Proliferating Trichilemmal Cyst/Malignant Trichilemmal Cyst

A spectrum of lesions ranges from typical pilar cysts with focal areas of epithelial proliferation to solid proliferating growths with

Fig. 29.53 Pilar cyst, proliferating type.

atypia that are best considered SCCs. The typical proliferating pilar cyst or proliferating pilar tumor is a large (up to 25 cm) exophytic neoplasm confined almost exclusively to the scalp and back of the neck. These lesions are approximately five times more common in women, and the mean age of patients is 65 years. They gradually enlarge and may ulcerate (Fig. 29.53). The vast majority of lesions are cured by local excision. Some lesions may recur and, less often, they may be locally aggressive. Focal areas of atypia and mitoses may be seen in benign-behaving, proliferating pilar tumors. In uncommon cases, there are focal areas that show frank SCC. These lesions should be called "malignant proliferating pilar tumor." Areas of SCC are characterized by increased cellularity, atypia, frequent mitoses, and, most important, invasion of the surrounding stroma. These tumors may behave aggressively. The clinical features that should suggest potential aggressive behavior are nonscalp location, recent rapid growth, size greater than 5 cm, and an infiltrative growth pattern clinically and histologically. In KID (keratosis, ichthyosis, deafness) syndrome, the development of malignant proliferating pilar tumor may occur in young adulthood and may be fatal.

Proliferating trichilemmal cysts are composed of proliferations of squamous cells with trichilemmal differentiation, forming scroll-like structures or small cysts. Lesions are usually well circumscribed. Focal cellular atypia, mitoses, and necrosis may be present and do not necessarily predict aggressive behavior. Cases with aggressive growth and metastases usually have cytologic atypia, as well as an invasive growth pattern. The presence of a clearly benign component and a second anaplastic component growing outward suggests the development of a carcinoma. Proliferating pilar cysts and their malignant counterparts express hair cytokeratins (cytokeratin 7), and malignant trichilemmal tumors express CD34, suggesting fetal hair root phenotype and trichilemmal differentiation.

Dermoid Cyst

Cutaneous dermoid cysts, also called congenital inclusion dermoid cysts, result from local anomalies in embryonic development and occur along embryonic closure zones. On the face, they occur above the lateral end of the eyebrow (external angular dermoid) (Fig. 29.54), at the nasal root, along the midline of the forehead, over the mastoid process, on the floor of the mouth, and anywhere along the midline of the scalp from the frontal to the occipital region. Dermoid cysts may also be found on the chest, back, abdomen, and perianal area. Nasal and external angular dermoids may be seen in multiple members of a family, suggesting a genetic component. Lesions usually present within the first year of life, although only 70% of lesions have been identified by age 5 years. The typical lesion is a few millimeters to several centimeters in diameter and located in the subcutaneous fat. A tethering to the underlying tissues and an underlying bony defect may be noted. They are nonpulsatile, firm, and cystic, and they do not transilluminate. A punctum or opening to the skin surface may be present, but dermoid cysts are not usually attached to the overlying skin. A tuft of hair may project from a pit, signifying the presence of an underlying sinus or cyst. Inflammation of the cyst caused by rupture (with extrusion of hair and a foreign body reaction) or infection may first bring the patient to the physician. Because the dermoid may connect to underlying structures, including the pleura and CNS, infection may spread to the CNS or lungs, with potentially serious consequences. Patients with spina bifida frequently develop dermoid cysts of the repaired portion of their spinal column. Dermoids overlying the lower spine may be associated with tethered cord and late development of ambulatory difficulties. At times, dermoids may be on the lateral buttocks. Dermal sinuses/dermoids may be associated with other findings of occult spinal dysraphism, including hyperpigmented patches, "skin tags," hemangiomas, and hairy nevi.

Histologically, the cyst wall is lined with keratinizing stratified squamous epithelium containing skin appendages, including lanugo hair. Portions of the cyst lining may demonstrate a wavy eosinophilic (shark tooth) pattern resembling that of a steatocystoma.

In a child, attempts at surgical removal or biopsy of a cyst over cleavage planes (including along the midline of the back) should not be attempted without proper assessment to rule out an intraspinal or intracranial communication, but this may not be necessary before removal of lateral eyebrow dermoids. CT or MRI is required. Any underlying bony changes detected by CT scan should be followed up with an MRI scan; cranial penetration by the cyst at times may be difficult to identify by CT. If an intracranial connection is detected, the patient should be referred to a neurosurgeon.

Pilonidal Sinus

Pilonidal cyst or sinus occurs in the midline sacral region at the upper end of the cleft of the buttocks. A pit may be all that is visible before puberty. Pilonidal cysts/sinuses usually become symptomatic during adolescence. The lesion becomes inflamed from rupture or less frequently infection. Pilonidal sinus/cyst often occurs with nodulocystic acne, dissecting cellulitis, and hidradenitis suppurativa (the acne tetrad). Histologically, the cyst/sinus is lined by stratified squamous epithelium of the type seen in normal epidermis or follicular infundibulum. Some pilonidal cysts/sinuses are composed of epithelium, which keratinizes without formation of a granular cell layer, analogous to the outer root sheath. Referral to a general surgeon is recommended, because recurrences may follow simple cystectomy and marsupialization. SCCs have been reported to arise from chronic inflammatory pilonidal disease.

Muzi MG, et al: Long-term results of pilonidal sinus disease with modified primary closure. Am Surg 2014; 80: 484.

Steatocystoma Simplex

Solitary steatocystoma (simple sebaceous duct cyst, steatocystoma simplex) occurs with equal frequency in adult women and men and occurs on the face, trunk, or extremities. The oral mucosa may also be involved. It is not familial, and solitary lesions are much less common than multiple ones. The cysts are usually 0.5–1.5 cm in size, although rarely, solitary steatocystomas more than 8 cm have been reported. The cyst contains an oily, yellow fluid and may contain vellus hairs. Histologically, the cyst is lined by stratified squamous epithelium. Small, mature, sebaceous lobules are present along the cyst wall and empty into the cyst. The luminal surface of the cyst is eosinophilic, wavy (shark tooth pattern), and ribbon-like, analogous to the sebaceous duct. "Hybrid" cysts may have portions of their lining of the steatocystoma type, with the other portions resembling pilar cyst, epidermoid cyst, or even pilomatricoma. Simple excision is curative.

Sunohara M, et al: Two cases of steatocystoma simplex in infants. Dermatol Online J 2012; 18: 2.

Fig. 29.55 Steatocystoma multiplex. (Courtesy Steven Binnick, MD.)

Steatocystoma Multiplex

Steatocystoma multiplex (SM) consists of multiple, uniform, yellowish, cystic papules usually 2–6 mm in diameter (Fig. 29.55), located principally on the upper anterior portion of the trunk, upper arms, axillae, and thighs. The lesions lack a punctum. The majority of patients present with dermal lesions, but multiple subcutaneous masses resembling multiple lipomas can occur. Lesions usually appear in adolescence or early adulthood, when sebaceous activity is at its peak. Development of SM can first occur in late adulthood. In severe cases, the lesions may be generalized, with sparing only of the palms and soles. At times the lesions may be limited to the face or scalp, a distinct form termed the *facial papular variant*. Lesions limited to the genital area have also been reported. Congenital and adolescent-onset linear lesions are rare. Steatocystoma may be larger (up to 2 cm) and prone to rupture and suppuration (steatocystoma multiplex suppurativum). If these lesions are widespread, the condition can be very disfiguring. Steatocystomas contain a syrup-like, yellowish, odorless, oily material. In the suppurative type, colonization with bacteria can occur, leading to foul odor and social isolation.

Histologically, the lining of the cyst is stratified squamous epithelium, with the cyst lining containing mature sebaceous glands. The epithelial lining is identical to the sebaceous duct. The luminal surface is wavy and eosinophilic and may stain with calretinin (perhaps only in the late-onset facial type). The granular layer is absent, but large basophilic granules may be seen focally in the epithelial cells in the upper layers of the cyst lining. In some cases, hair follicles occur in the cyst wall, and vellus hairs may be present in the cavity. A relationship with eruptive vellus hair cysts (EVHCs) has been suggested because of a similar clinical appearance, time of onset, and overlapping histologic features. It has been proposed that these clinical entities are a spectrum of the same disease process and should be classified as "multiple pilosebaceous cysts."

Often familial, SM demonstrates an autosomal dominant mode of inheritance. Sporadic cases, however, can occur. Keratin 17 missense mutations occur in familial (but not sporadic) SM, usually in a hypermutable site of exon 1 of the gene (the helix initiation motif). K17 is expressed in the nail bed, hair follicles, and sebaceous glands. This same genetic mutation also causes pachyonychia congenita type 2 (PC-2). Patients with PC-2 have milder keratoderma, but also natal teeth, pili torti, angular cheilosis, and hoarseness. These patients have multiple cysts, some of which are steatocystomas and some EVHCs. Milia, flexural abscesses identical to hidradenitis, and scrotal and vulvar cysts can also be seen in these kindreds. Hybrid cysts may occur. It is unclear why patients

with hereditary SM and K17 mutations identical to those seen in PC-2 have no other stigmata of PC-2. Oligodontia and partial persistent primary dentition can be seen in some kindreds with SM and K17 mutations.

The definitive treatment of individual lesions is removal. This may be accomplished with small incisions and gentle extraction. However, the sheer number of the cysts usually precludes this type of treatment, and the location on the chest makes healing with cosmetically acceptable scars an issue. Laser incision of the cysts may also be effective. They may remain clinically improved for many months; however, eventual recurrence is the rule. Oral isotretinoin, 0.75–1 mg/kg/day, has been reported to benefit the suppurative variant of steatocystoma. Long-term follow-up has not been reported.

Eruptive Vellus Hair Cysts

Eruptive vellus hair cysts (EVHCs) appear as multiple (up to hundreds), 1–4 mm, skin-colored or hyperpigmented, dome-shaped papules of the midchest and proximal upper extremities. They may be congenital but usually have their onset between ages 4 and 18 (in the first and second decades). Disseminated lesions have been reported. A unilateral distribution can occur. Facial lesions can be distinctly hyperpigmented and simulate a primary melanocytic disorder, such as nevus of Ota. The pinna of the ear may rarely be affected. Hidrotic and anhidrotic ectodermal dysplasia and Lowe syndrome have been associated with EVHC and familial cysts have been described with associated preauricular pits, lipomas, joint hypermobility, and cardiac defects. Onset in later adulthood with chronic renal failure has been reported in multiple cases. Clinically, EVHCs tend to be smaller than steatocystomas and may have an area of central hyperkeratosis or umbilication, a feature lacking in steatocystoma. Acne is distinguished by the lack of inflammatory lesions.

Histologically, the cystic epithelium is of the stratified squamous type; the cyst contents are composed of laminated keratin and multiple vellus hairs, and follicle-like invaginations may be present in the cyst wall. Steatocystoma may at times have vellus hairs, and EVHCs may have sebaceous glands in their lining. About 25% of EVHC lesions spontaneously resolve by transepidermal elimination. Topical tazarotene has been effective, but with no long-term follow-up. Similarly, lactic acid 12% and topical tretinoin can lead to improvement. Most treatments are surgical, including extraction, and CO_2 laser. Er:YAG laser is inferior to tazarotene and is associated with recurrence.

Milia

Milia are keratinous cysts 1–4 mm in diameter (Fig. 29.56). They are white and easily seen as cystic through the overlying attenuated skin. Milia are common, and multiple clinical patterns of milia have been described. Milia can be considered primary, appearing spontaneously, or secondary, caused by trauma, skin disease, or medication.

Primary milia occur congenitally (or shortly after birth in preterm neonates) in up to 50% of newborns. They favor the face, especially the nose, scalp, upper trunk, and proximal extremities of all races and both genders. They resolve over weeks. Rare kindreds with an autosomal dominant inheritance have profuse, essentially confluent, congenital milia on the face. These also spontaneously resolve. Adults and children frequently develop milia, especially on the cheeks, eyelids, forehead, and genitalia. In infants, milia localized to the areola may be seen. These milia tend to persist. *Multiple eruptive milia* is a term applied to lesions that occur spontaneously in too large a number to be considered benign primary milia of children and adults. Cases favor the head and erupt over weeks to months. This can be idiopathic or familial. Nasal crease milia appear in a horizontal row in the nasal crease in nonatopic persons. Some cases are congenital. Pseudoacne of the nasal crease may be related. Milia en plaque describes a rare disorder characterized by an erythematous plaque containing numerous milia. These lesions are usually on the head and neck, especially the periauricular or periorbital regions. They are most

Fig. 29.56 Milia. (Courtesy Steven Binnick, MD.)

common in middle-aged women. One 3-year-old child had widespread depigmented macules and patches with numerous milia in the depigmented areas, termed *generalized milia with nevus depigmentosus*.

Secondary milia can develop as a result of blistering skin diseases, such as epidermolysis bullosa, pemphigus, bullous pemphigoid, porphyria cutanea tarda, herpes zoster, polymorphous light eruption, lupus erythematosus, Stevens-Johnson syndrome, contact dermatitis, and many other conditions. They also tend to occur after trauma, such as dermabrasion, chemical peel, ablative laser therapy, skin grafts, and radiotherapy. Long-term topical corticosteroid therapy and use of occlusive moisturizers may result in the appearance of milia. Cyclosporine and 5-FU have been associated with the development of milia.

Multiple milia have been reported in a number of genodermatoses, such as congenital ectodermal defect; reticular pigmented genodermatosis with milia (Naegeli-Franceschetti-Jadassohn syndrome); congenital absence of dermal ridges, syndactyly, and facial milia; generalized BFH syndrome; basal cell nevus syndrome; atrichia with papular lesions; pachyonychia congenita type 2; Rombo syndrome; Brooke-Spiegler syndrome; Loey-Pictz syndrome; and Bazex syndrome.

Primary milia are small epidermoid cysts, derived from the infundibulum of the vellus hair. As with epidermoid cysts, primary milia are fixed and persistent. Secondary milia may be derived from eccrine ducts or hair follicles as they attempt to reepithelialize eroded epidermis. They are often transient and spontaneously disappear. Milia must be distinguished from milia-like idiopathic calcinosis cutis, miliary osteomas, syringomas with milia-like structures, trichoepitheliomas, comedonal acne, flat warts, and xanthelasma. Lesions of cutaneous T-cell lymphoma with prominent follicular mucinosis may have many milia. Treatment is incision and expression of the contents with a beveled cutting tipped hypodermic needle, 11 blade, or comedo extractor. No anesthesia is needed for most patients. Topical tretinoin (Retin-A) has been reported effective in treating milia en plaque and more generalized forms of milia involving the face. Minocycline has also been used to treat milia en plaque.

Verrucous Cysts (Cystic Papillomas)

Verrucous cysts resemble epidermoid cysts, except that the lining demonstrates papillomatosis and coarse hypergranulosis. Koilocytes may be present. On the sole, red granules resembling those in myrmecia are often seen. They have been shown to contain HPV and probably form as a result of HPV infection of a follicular unit or sweat duct (see Chapter 19).

Pseudocyst of the Auricle (Auricular Endochondral Pseudocyst)

Pseudocyst of the auricle presents as a fluctuant, tense, noninflammatory swelling on the upper half of the ear (Fig. 29.57). Most affected persons are between ages 20 and 45, and up to 90% are male. Pruritic disorders such as atopic dermatitis and systemic lymphoma, hard pillows in China, carrying heavy objects on the shoulder, helmet and earphone wearing, and a slap to the side of the head have all been associated with auricular pseudocysts. This strongly suggests that trauma plays a role, although patients will frequently deny trauma. The fluid collection is between the two layers of the bilaminate cartilage of the pinna. There is no cyst lining, with the affected cartilage showing focal degeneration and granulation tissue. Needle aspiration yields serous or bloody fluid. Simple aspiration is ineffective. Aspiration or drainage, followed by the application of a bolster or pressure dressing for several weeks, is usually effective. Because application of pressure for several weeks is required, a sutured-on bolster with buttons or gauze is easier for the patient than an externally applied dressing. Intracystic injections of corticosteroids, fibrin glue, or minocycline have been used in recurrent cases. Surgical intervention involves removal of the inner anterior portion of the cyst.

Cutaneous Columnar Cysts

Five types of cyst that occur in the skin are lined by columnar epithelium, as described next.

Bronchogenic Cysts

These small, solitary cysts or sinuses are most often located in the region of the suprasternal notch or over the manubrium sterni. Bronchogenic cysts can also occur on the chin, neck, and abdominal wall. A scapular location is rarely described. Boys are affected four

times more often than girls. Lesions are typically subcutaneous and rarely connect to deeper structures. Histologically, the cyst is composed of a wall lined by respiratory epithelium and may contain seromucinous glands and underlying fibromuscular connective tissue or cartilage. Gastric mucosa may also be seen.

Branchial Cleft Cysts

These present as cysts, sinuses, or skin tags along the anterior border of the sternocleidomastoid muscle or near the angle of the mandible. Branchial cysts are lined primarily with stratified squamous epithelium. Lymphoid follicles are often present, and smooth muscle is absent, distinguishing brachial cleft from bronchogenic cysts, although some evidence suggests that these cysts are related.

Thyroglossal Duct Cysts

Thyroglossal duct cysts virtually always occur on the anterior portion of the neck, near the hyoid bone. They present as a sinus, cyst, or recurrent abscess of the neck. Thyroglossal duct cysts are the most common cause of congenital neck anomalies in childhood. Presentation in adult life can occur. Malignancies (papillary adenocarcinoma, follicular adenocarcinoma, mixed papillary/follicular adenocarcinoma, adenocarcinoma, SCCs) arising from cysts have been reported in 1% of cases. Clinically, thyroglossal duct cysts are deep to subcutaneous tissue and usually are not managed by dermatologists.

Cutaneous Ciliated Cysts

Cutaneous ciliated cysts are usually solitary and located on the legs of females. Men account for only 10% of cases. These cysts have also been described in the perineum and vulva (vulvar ciliated cysts). The epithelium lining the cysts is cuboidal to columnar, with pseudostratified areas. Cilia are seen, and the lining cells stain strongly for dynein. This histology is similar to the normal fallopian tube, suggesting that the cysts are of müllerian origin. Ciliated metaplasia of the eccrine duct has been proposed for lesions occurring on the upper half of the body and in men. As with the median raphe cyst, the cavity is often filled with debris.

Median Raphe Cysts

Median raphe cysts of the penis are developmental defects lying in the ventral midline of the perineum from the anus to the urethra, most often on the distal shaft near the glans. They most frequently present as dermal lesions of less than 1 cm in young men and may appear suddenly after sexual intercourse–associated trauma. These cysts may appear as a cord or a series of beads (termed *canal-like*) (Fig. 29.58). They are lined by pseudostratified columnar epithelium with focal areas of mucin-secreting epithelium present. Ciliated cells may be present and, as with ciliated cysts in females, the cavity is typically filled with debris. Melanocytes may occasionally be present in the cyst wall, giving the cysts a pigmented appearance. Median raphe cysts do not stain with human milk fat globulin 1, distinguishing them from apocrine cystadenomas. Median raphe cysts do not connect with the urethra and can be treated with surgical excision.

CONGENITAL PREAURICULAR FISTULA

This anomaly occurs as a pit in the preauricular region, often in several members and generations of a family. On each side, just anterior to the external ear, there is a small dimple, pore, or fistulous opening that may extend as far as the middle ear. Most congenital preauricular fistulas are benign and do not require surgery. Complications of surgery are common, and complete excision of both the pit and the sinus tract should be the goal if surgery is attempted.

30 Melanocytic Nevi and Neoplasms

Bonus images for this chapter can be found online at expertconsult.inkling.com

Melanocytes originate in the embryonal neural crest and migrate to the epidermis, dermis, leptomeninges, retina, mucous membrane epithelium, inner ear, cochlea, and vestibular system. Nevus cells are a form of melanocyte with a tendency to aggregate into clusters of cells. Nevus cells lack dendritic processes but are otherwise similar to other melanocytes.

EPIDERMAL MELANOCYTIC LESIONS

The melanocytes occurring at the dermoepidermal junction (DEJ) are dendritic cells that supply melanin to the skin. These cells contain pigment granules (melanosomes). Melanocytes stain with the dopa reaction and silver stains because they contain melanin. Immunohistochemical stains, such as S-100, HMB-45, MelanA/Mart-1, MITF, and SOX-10, do not depend on the presence of melanin. These stains have largely replaced silver stains for the identification of melanocytes in biopsy specimens. Melanocytes of the epidermis transfer melanosomes through their thin, dendritic processes, where they are actively taken up by keratinocytes. Melanocyte numbers vary by anatomic site and are increased in sun-damaged skin, but they vary little among racial groups. The type, number, size, dispersion, and degree of melanization of the melanosomes determine the pigmentation of the skin and hair.

Treatment of epidermal pigmented lesions can be directed at pigmented keratinocytes, melanocytes, or melanosomes. Q-switched (QS) lasers target the melanosome. Lasers with a longer pulse duration lasting milliseconds (ms) result in melanocyte destruction. Laser treatment produces consistent lightening of ephelides, but the response is variable for café au lait macules, Becker nevus, and nevus spilus.

Ephelis

The common freckle occurs in light-skinned individuals in response to sun exposure. Histologically, freckles demonstrate pigmented basilar keratinocytes, and a mild increase in the number of melanocytes.

Nevus Spilus

Nevus spilus (speckled lentiginous nevus) presents as a light-brown or tan macule, speckled with smaller, darker macules or papules (Fig. 30.1). It frequently occurs on the trunk and lower extremities, tends to follow Blaschko lines, and is noted in approximately 2% of the population. The nevus spilus may be small, measuring less than 1 cm in diameter, or may be quite large and follow a segmental distribution, referred to as a "zosteriform" lentigo. Multiple sites may be involved in the same individual and may be widely separated by normal skin. Happle has suggested dividing the entity into two forms, a macular type and a papular type. The dark speckles in the macular type are more evenly distributed and represent junctional lentiginous nevi; malignant melanoma has been reported more frequently in this type. Nevus spilus maculosus is consistently found in phakomatosis spilorosea, whereas nevus spilus papulosus demonstrates compound or intradermal nevi and is seen in phakomatosis pigmentokeratotica.

Nevus spilus in combination with a nevus flammeus is called phakomatosis pigmentovascularis (see Chapter 28). Phakomatosis pigmentokeratotica includes a speckled lentiginous nevus, organoid nevus, hemiatrophy, and neurologic findings such as muscular weakness. Generalized nevus spilus has been associated with nevus anemicus and primary lymphedema. Nevus spilus has also been reported in association with nevus depigmentosus and with bilateral nevus of Ito.

Histologically, the flat, tan background may show only basilar hyperpigmentation, such as is present in a café au lait spot, or lentiginous proliferation of the epidermis with bulbous rete ridges. The darker speckles usually contain nevus cells and may occasionally demonstrate blue nevi or Spitz nevi.

Melanoma may rarely occur in nevus spilus and some have given rise to multiple melanomas, suggesting a first-hit postzygotic mutation predisposing to melanoma in some cases. A changing lesion should be biopsied. Removal by QS ruby laser or QS alexandrite laser has been reported as effective but may require many sessions for acceptable results.

Lentigo

Lentigo Simplex

These lesions occur as sharply defined, round to oval, brown or black macules. Lentigines usually arise in childhood but may appear at any age. There is no predilection for areas of sun exposure. Multiple lentigines may appear after clearing of plaques of psoriasis, including during biologic therapy. Histologically, lentigo simplex shows hyperpigmentation of basilar keratinocytes and an increase in the number of melanocytes in the basal layer. Melanophages are usually present in the upper dermis.

Solar Lentigo (Lentigo Senilis)

Solar lentigines are commonly known as "liver spots." They are persistent, benign, discrete, hyperpigmented, round to oval macules occurring on sun-damaged skin. The backs of the hands, cheeks, and forehead are favorite sites in the typical older patient. Red-haired, light-skinned individuals, especially those with high solar exposure, may develop many of these on the shoulders and central upper chest, even at an early age. Solar lentigines may be accompanied by depigmented macules, actinic purpura, and other chronic actinic degenerative changes in the skin. They may evolve into benign lichenoid keratoses and reticulated seborrheic keratoses.

Histologically, the rete ridges appear club shaped or show narrow, budlike extensions. There is a marked increase in pigmentation in the basal cell layer, especially at the tips of the bulbous rete. The number of melanocytes is slightly increased, and the upper dermis often contains melanophages.

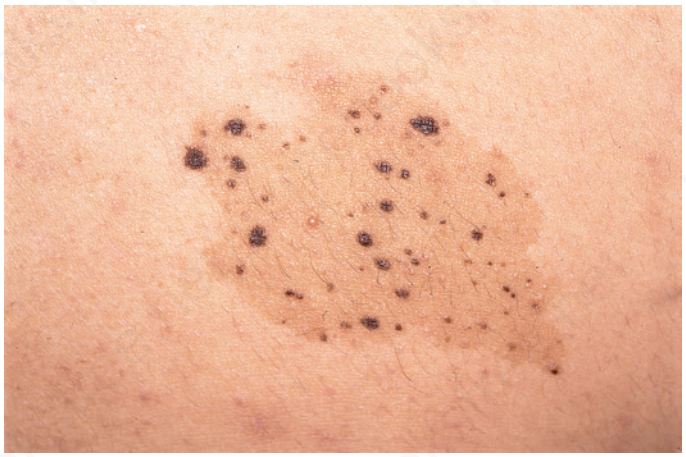

Fig. 30.1 Nevus spilus. (Courtesy Dr. Rui Tavares-Bello.)

Application of liquid nitrogen with a cotton-tipped applicator or cryospray unit is often an effective destructive modality. Argon, QS neodymium-yttrium-aluminum-garnet (Nd:YAG), frequency-doubled Nd:YAG, QS and long-pulse alexandrite, QS ruby, and Er:YAG lasers have been reported as effective. Intense pulsed light has also been used. Postinflammatory pigment alteration is the major complication seen with destructive modalities. Sun protection will reduce the number of new lesions. Bleaching creams containing 4% or 5% hydroquinone, used over several months, will induce temporary lightening. Hydroquinone-cyclodextrin (2%), 4-hydroxyanisole (4-HA), chemical peels, local dermabrasion, topical tretinoin, and adapalene are other treatment options. The combination of 2% 4-HA and 0.01% tretinoin is superior to either active component alone, and a commercial preparation containing these two ingredients plus 2% mequinol has been shown to lighten lesions.

Early lesions of lentigo maligna (melanoma in situ) may be light to medium brown and may mimic solar lentigines. Dermoscopy and confocal microscopy can improve diagnostic accuracy, but when in doubt, a biopsy is appropriate. Lentigo maligna, benign solar lentigo, and pigmented actinic keratosis all occur on sun-damaged skin, and collision lesions are common. If a lesion is not homogeneous clinically, representative biopsies should be taken from each color or shade of brown within the lesion.

PUVA Lentigines

Individuals receiving oral methoxsalen photochemotherapy (psoralen plus ultraviolet A, PUVA), may develop persistent pigmented macules with possible melanocytic atypia. These lesions may occur on sites that are normally protected from sunlight. High-dose single exposures to radiation may result in similar radiation lentigines in exposed skin.

Ink Spot Lentigo (Sunburn Lentigo)

Sunburn lentigines typically occur on the shoulders as small, extremely irregular, reticulated, dark-gray to black macules resembling spots of ink on the skin. Histologically, there is a mild increase in the number of melanocytes and increased melanin in both the basilar keratinocytes and the stratum corneum.

Labial, Penile, and Vulvar Melanosis (Melanotic Macules, Mucosal Lentigines)

Melanotic macules are usually light brown on the oral labial mucosa but may be strikingly irregular and darkly pigmented in the genitalia (Fig. 30.2). In females, the labia minora are most often affected, and in males, the glans and prepuce. Histologically, these lesions demonstrate broad, "boxcar" rete ridges with prominent basilar hyperpigmentation and a normal to slightly increased number of melanocytes. The melanocytes are usually morphologically normal.

Fig. 30.2 Vulvar melanosis.

Multiple Lentigines Syndrome

The lesions appear shortly after birth and develop a distinctive speckled appearance that has given rise to the designation LEOPARD syndrome. LEOPARD is Gorlin's mnemonic acronym for lentigines, electrocardiographic abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, and deafness. Inheritance is autosomal dominant. Multiple lentigines occur mainly on the trunk, but other areas may also be involved, such as the palms and soles, buccal mucosa, genitalia, and scalp. *PTPN11* gene mutations are seen in both LEOPARD syndrome and Noonan syndrome. Café noir spots noted in these patients are larger and darker than café au lait spots. Histologically, some are melanocytic nevi, whereas others demonstrate histologic features of lentigo simplex.

Moynahan Syndrome

Moynahan syndrome consists of multiple lentigines, congenital mitral stenosis, dwarfism, genital hypoplasia, and mental deficiency.

Generalized Lentiginosis

An occasional patient will have generalized lentiginosis without associated abnormalities.

Centrofacial Lentiginosis

Centrofacial lentiginosis is characterized by lentigines on the nose and adjacent cheeks, variously associated with status dysraphicus, multiple skeletal anomalies, and central nervous system (CNS) disorders. Mucous membranes are spared. Onset is in the first years of life. Lentigines of the central face are also typical of Carney complex.

Fig. 30.3 Inherited patterned lentiginosis.

Fig. 30.4 Becker nevus.

Carney Complex

Carney complex is also known as NAME syndrome and LAMB syndrome. This designation comprises cardiocutaneous myxomas, lentigines, blue nevi, and endocrine abnormalities. It is discussed in more detail with myxomas in Chapter 28.

Inherited Patterned Lentiginosis

O'Neill and James reported 10 light-complexioned black patients with autosomal dominant lentigines beginning in infancy or early childhood, but no internal abnormalities (Fig. 30.3). The lentigines are distributed over the central face and lips, with variable involvement of the dorsal hands and feet, elbows, and buttocks. The mucous membranes are spared.

Partial Unilateral Lentiginosis

Partial unilateral lentiginosis is a rare disorder of cutaneous pigmentation characterized by the presence of multiple simple lentigines, wholly or partially involving half the body. Conjunctival involvement has been reported. Agminated lentiginosis appears to be a similar if not identical entity.

Peutz-Jeghers Syndrome

Peutz-Jeghers syndrome is an autosomal dominant syndrome consisting of pigmented macules on the lips, oral mucosa, and perioral and acral areas. Gastrointestinal polyps, especially prominent in the jejunum, are frequently associated. It is discussed further in Chapter 36.

Becker Nevus

Becker nevus presents as a hyperpigmented, hypertrichotic patch on the upper trunk (Fig. 30.4) or proximal upper extremity. The lesion usually begins before puberty, and almost all patients are males. The lesion is typically associated with a smooth muscle hamartoma histologically. Usually, the lesion is asymptomatic and of little consequence, but some lesions have also been associated with connective tissue nevus, inflammatory linear verrucous epidermal nevus, basal cell carcinoma (BCC), phakomatosis pigmentovascularis, ipsilateral breast hypoplasia or abnormalities of underlying bone or of vascular, neural, or other soft tissue structures (Becker nevus syndrome). The pathogenesis may be related to postzygotic mutations in beta-actin and increased expression of androgen receptors within lesional skin. Treatment may not be necessary, but some patients desire removal of pigment or terminal hair associated with the lesion. Ablative 10,600-nm fractional laser and hair removal laser therapy have been used with partial success. Topical flutamide has also been used.

MELANOACANTHOMA

Cutaneous melanoacanthoma is an uncommon lesion first described by Bloch. Clinically, it resembles a pigmented seborrheic keratosis or pigmented BCC and tends to occur in older white men. Histologically, it is a benign epidermal neoplasm composed of keratinocytes and dendritic melanocytes. It is best considered a form of seborrheic keratosis. The starburst dermatoscopic appearance can be confused with that of Spitz nevus. Grouped and ulcerated lesions rarely occur.

Oral melanoacanthoma is also a proliferation of two cell types, melanocytes and epithelial cells, but appears to be a reactive lesion. It occurs as a macular or slightly raised pigmented area on the buccal mucosa, predominantly in young adult black women (Fig. 30.5). Rapid onset and spontaneous resolution are typical.

BENIGN MELANOCYTIC NEVI

Common moles, also known as nevocytic nevi or banal nevi, tend to increase in number during the first three decades of life. They are less common in doubly covered areas, such as the buttocks. They typically begin as sharply defined macular lesions, become papular, then gradually become soft and lose their pigment.

Sun exposure increases the number of moles in the exposed skin. Australians have more moles than Europeans. White persons have more than black persons, and individuals with a light complexion have more nevi than those with a dark complexion. Women have more total nevi and more nevi on the legs. Men have more on the trunk. Black persons have more nevi on the palms, soles, conjunctivae, and nail beds. A study of young British women showed an association of holidays overseas with an increased nevus count. The association was greatest in anatomic sites intermittently exposed to sunlight.

Eruptive nevi may occur in association with bullous diseases, severe sunburn, immunosuppression, or sulfur mustard gas exposure. The cheetah phenotype refers to patients with more than 100 uniform, dark-brown to black pigmented macules 4 mm or smaller. The evaluation of these patients can be challenging, because similar-appearing lesions range from junctional nevi to melanoma histologically.

Melanocytic lesions with a junctional component are more often removed during the summer months, whereas excision of intradermal nevi is relatively constant during the year. This suggests that some change in these lesions draws more attention during the summer months. Nevi may darken during pregnancy, but other changes should prompt consideration of a biopsy.

Clinical and Histologic Features

Features of benign nevi include a diameter of 6 mm or less, perfectly uniform pigmentation, flaccid epidermis, smooth, uniform border, and an unchanging size and color. Benign nevi tend to be round to oval and undergo a predictable course of maturation.

Junctional nevi are sharply circumscribed brown macules, varying in diameter from 1–6 mm. They usually appear between 3 and 18 years of age. During adolescence and adulthood, some become compound or intradermal. Small, well-nested junctional melanocytic proliferations are almost invariably benign. Benign junctional nevi associated with bulbous hyperplasia of the rete ridges are referred to as junctional lentiginous nevi. Lentigo maligna can appear well nested with an appearance similar to that of junctional lentiginous nevi. Any broad junctional melanocytic lesion on sun-damaged skin should be viewed with suspicion.

Compound nevi demonstrate both junctional and intradermal melanocytes. Benign compound nevi are well nested at the junction, with dispersion of individual melanocytes at the base of the lesion. They demonstrate bilateral symmetry but are not symmetric from top to bottom. Instead, with descent into the dermis, the melanocytes become smaller and spindled in appearance. Nests at the junction tend to be round to oval and are about equidistant from one another. Dermal nests are generally smaller than the junctional nests and become progressively smaller deeper in the dermis. Individual cells rather than nests are present at the base. Pigment is most prominent at the junction and becomes progressively less prominent deeper in the dermis. Intradermal nevi look similar to compound nevi, without the junctional nests.

In most benign nevi, there are no melanocytes above the DEJ. Individual melanocytes in a "buckshot" scatter throughout the epidermis are typical of superficial spreading melanoma. Sunburned benign nevi may also demonstrate buckshot intraepidermal scatter of melanocytes, and buckshot scatter may be seen in the central portion of acral nevi and Spitz nevi. Genital nevi often demonstrate large, poorly cohesive nests. They may also resemble dysplastic nevi histologically. A histologic resemblance to dysplastic nevi is also common in nevi from the scalp, ears, dorsal foot, and breast, even in patients with no other evidence of the dysplastic nevus syndrome.

On the palms and soles, the rete pattern follows the dermatoglyphs (Fig. 30.6). Nests in these locations tend to run along the rete ridges. If a benign palmar nevus is bisected across the dermatoglyphs, the nests will appear round to oval. If the same lesion is sectioned parallel to the dermatoglyphs, the nests will appear elongated and may mimic those of melanoma as an artifact of sectioning. Careful communication with the pathologist is essential when submitting an acral melanocytic lesion to the laboratory.

Malignant Degeneration

Almost half of melanomas occur in preexisting nevi, and an increased number of nevi represents a risk factor for melanoma. The signs of malignant transformation in pigmented nevi are

recent enlargement, an irregular or scalloped border, asymmetry, changes or variegation in color (especially red, white, or blue), surface changes (scaling, erosion, oozing, crusting, ulceration, or bleeding), development of a palpable thickening, signs of inflammation, or the appearance of satellite pigmentation. Symptoms may include development of pain, itch, or tenderness. The "ugly duckling" sign refers to nevi in an individual generally tending to share a similar appearance. Any mole that does not share the same characteristics should be considered for biopsy. Moles with dark areas that do not lie entirely within the lesion, but produce an extension beyond the border, may represent melanoma arising in association with a preexisting nevus. The clinician should alert the pathologist to the presence of these areas and the pathologist should section through the appropriate area. Perifollicular hypopigmentation is a common finding in benign nevi. When it occurs at the edge of the nevus, it may give the lesion a notched appearance. Dermatoscopic examination may be of value in this setting. Lesions with changing clinical or dermatoscopic features should be biopsied.

Nevi frequently darken with pregnancy or with oral contraceptive use. Nevi from normal persons have no estrogen or progesterone receptors, but there may be positive estrogen receptor binding in nevi from pregnant women, as is also found in malignant melanoma. The development of what appears to be a new pigmented nevus in a patient over age 35 should alert the physician to possible melanoma, because patients without the dysplastic nevus syndrome usually do not develop new nevi at this age.

Treatment

Acquired nevi should be removed if they show signs of malignant transformation. Nevi of the neckline, beltline, or other areas that are irritated may be removed to relieve the patient of the irritation. Nevi may also be removed if they are in a location where it is impractical to observe them. If a solitary, darkly pigmented lesion is present on the oral or genital mucous membrane, a biopsy should be performed, because nevi are uncommon in these locations. Nail matrix nevi and lentigines produce a pigmented nail band. The proximal matrix gives rise to the dorsal nail plate, and the distal matrix gives rise to the ventral nail plate. When the nail is observed end-on, the level of the pigment may be evident and indicates the location of the pigmented lesion in the matrix. A widening band indicates a matrix lesion increasing in diameter. Biopsy of a solitary, expanding, acquired longitudinal pigmented band in an adult is typically necessary to ascertain the cause. Hutchinson's sign (pigmentation of the nailfold) is an indicator of melanoma. Nail matrix melanoma in children is exceptional.

Conjunctival nevi occur, and most can be followed serially if the lesion has been present since childhood or has shown no evidence of growth. Changing pigmented lesions and those acquired after childhood are best evaluated in conjunction with an ophthalmologist. Most conjunctival nevi occur on the bulbar conjunctiva and often about the nasal or temporal corneoscleral limbus. Suspicion of melanoma should arise if a pigmented lesion occurs in the palpebral or forniceal conjunctiva, if lesions are not hinged at the limbus and are immovable, if they extend into the cornea, if there is canalicular obstruction that leads to tearing, or if adjacent dilated vessels are noted.

Combined melanocytic nevi are common. They consist of a banal nevus together with a blue nevus, Spitz nevus, or deep penetrating nevus. Two or more distinct populations of melanocytes are evident.

Melanocytic nevi may occur in lymph nodes and are present in about 10% of sentinel node biopsies. Nodal nevi typically occur in the capsule, in contrast to melanoma metastases, which are typically subcapsular. Nodal nevi are frequently associated with cutaneous nevi in the draining basin, especially nevi with congenital features.

Pseudomelanoma (Recurrent Nevus)

Melanotic lesions clinically resembling a superficial spreading melanoma may occur at the site of a recent shave removal of a melanocytic nevus. Melanocytic nevi occurring in areas of lichen sclerosus or bullous disease often have similar features. On dermatoscopic examination, a regular network and the presence of streaks suggest reactive pigmentation. Any truly suspicious lesion should be removed. Histologically, the junctional component often demonstrates a predominance of nonnested melanocytes, confluence of nests, and nests that vary in size and shape. The presence of a superficial dermal scar with remnants of the original nevus beneath this zone of fibrosis is an important clue to the correct diagnosis. Although atypical in appearance, the junctional proliferation remains entirely confined to the area overlying the scar.

Recurrent Spitz nevus is a particular problem because many of the histologic features of benign Spitz nevi overlap with those of melanoma. In benign recurrent Spitz nevi, the dermal component typically retains cytologic maturation, dispersion at the base of the lesion, and an immunostaining pattern typical for benign nevi. Recurrent blue nevi also present special difficulties. High cellularity, cellular pleomorphism, mitotic figures, and a lymphoid host response may be present. In the absence of marked cytologic atypia, frequent mitotic figures or necrosis en masse, the lesions are likely to be benign. Because of the special problems posed by recurrent Spitz and blue nevi, the initial biopsy of these lesions should be a complete excisional biopsy whenever possible. Congenital nevi have a higher rate of recurrence when surgery is done at a younger age.

Balloon Cell Nevus

Clinically, balloon cell nevi are indistinguishable from ordinary nevi. Histologically, they are composed of large, pale, polyhedral balloon cells. Generally, foci of ordinary nevus cells are also evident. Rarely, the lesions are composed entirely of balloon cells. Balloon cell change has been reported in cellular blue nevus as well. Balloon cell melanoma does exist, but the nuclei are large and pleomorphic, and the architecture of the lesion is that of melanoma. Balloon cell nodal nevi may be seen in sentinel node specimens.

Halo Nevus

Halo nevus is also known as Sutton nevus, perinevoid vitiligo, and leukoderma acquisitum centrifugum. The lesions are characterized by a pigmented nevus with a surrounding depigmented zone (Fig. 30.7). Halo nevi tend to be multiple and occur most frequently

Fig. 30.7 Halo nevi. (Courtesy Steven Binnick, MD.)

on the trunk, mostly in teenagers. The central nevus gradually loses its pigmentation, turns pink, and then disappears, leaving a round to oval area of depigmentation. Over time, the area repigments. Darkening of the central nevus rather than lightening has also been reported in association with the halo phenomenon. Halo nevi have been reported during infliximab therapy. Target-like pigmented nevi present with the appearance of an inverse halo nevus phenomenon.

The infiltrate contains many cytotoxic T cells and may represent immunologically induced rejection. The peripheral blood has been shown to contain activated adhesive lymphocytes that disappear when the lesion is excised. Patients also demonstrate antibodies to melanocytes and cell-mediated immunity to melanoma cells. There may be associated vitiligo.

Regressing melanoma may also have associated leukoderma, but the pattern is usually haphazard and confined to the pigmented lesion. Other lesions that may also have a surrounding zone of leukoderma include blue nevi and neurofibromas.

Histologically, halo nevi demonstrate a band of lymphocytes that extends throughout the lesion, intimately mingling with the melanocytes. In contrast, the lymphoid infiltrate associated with melanoma tends to aggregate at the periphery of the lesion. In early halo nevi, amelanotic melanocytes may be found in the leukodermic halo. Later, melanocytes are absent until repigmentation occurs. A granulomatous infiltrate may rarely be present. The term Myerson's nevus has been applied to eczematous change associated with a nevus. Hypopigmentation may be present.

A full mucocutaneous examination at diagnosis is indicated to exclude a concurrent melanoma, but this is rarely found. The decision to remove the nevus at the center of the halo is based on its morphologic features, as with any other nevus.

Congenital Melanocytic Nevus

Giant Pigmented Nevus (Giant Hairy Nevus, Bathing Trunk Nevus)

Giant pigmented nevi appear as large, darkly pigmented hairy patches in which smaller, darker patches may be interspersed or present as small satellite lesions. The skin may be thickened and verrucous. The trunk is a favored site, especially the upper or lower parts of the back (Fig. 30.8). Giant hairy nevi are present at birth and grow proportionally with the body. Widespread congenital dermal nevus with large nodules may affect the entire body, including the palms, soles, and oral mucous membrane. Some congenital melanocytic nevi have associated placental infiltration by benign melanocytes.

Fig. 30.8 Giant hairy nevus.

The incidence of melanomas developing in giant congenital pigmented nevi is between 2% and 15%. Approximately 60% of these melanomas appear within the first decade of life, and the majority arise in the dermis or subjacent tissue, rather than at the DEJ. About 40% of the malignant melanomas seen in children occur in large congenital nevi. The risk is greatest for axial lesions and those larger than 40 cm. In one study, 94% of large congenital nevi that gave rise to melanoma had satellite nevi.

Large axial lesions may be associated with neurocutaneous melanocytosis. The risk is greatest for large axial lesions with many satellite lesions, and almost half of patients with symptomatic neurocutaneous melanosis develop leptomeningeal melanoma. Neurocutaneous melanosis can be detected by magnetic resonance imaging (MRI).

Histologically, giant congenital nevi extend into the deep dermis and may involve the subcutis, fascia, muscle, and other underlying structures. Nevus cells are found in a patchy perivascular distribution and often extend in a patchy, single-file fashion between collagen bundles. Nests are often seen in association with adnexal structures or nerves. Extensive desmoplasia has been described. Estrogen and progesterone binding has been noted in congenital nevi. These receptors are generally absent from common acquired nevi.

Benign "proliferative" nodules within giant congenital nevi may be confused histologically with malignant change. Features useful in distinguishing the two include lack of high-grade atypia, lack of necrosis, rarity of mitoses, a lack of Ki-67 expression, evidence of transition between the cells of the nodule and those of the adjacent nevus, and lack of compressive expansile growth. Comparative genomic hybridization has demonstrated chromosomal aberrations in atypical nodular proliferations in congenital nevi, but many of these are numerical aberrations of whole chromosomes, suggesting a mitotic spindle defect. These differ from the chromosomal aberrations seen in melanoma.

Treatment decisions must be individualized. Half of all melanomas in giant congenital nevi occur in deep structures. Extensive surgery to remove the upper portions of the lesion reduces, but does not eliminate, the risk of melanoma. In patients with leptomeningeal melanosis, the risk of melanoma remains high. Satellite lesions and extremity lesions have a lower incidence of neoplastic conversion than large axial lesions, and the risk-benefit ratio of extensive surgery on these lesions differs accordingly. Some lesions are not amenable to excision because they involve functionally critical areas.

Serial staged excision is the method of choice whenever possible. Tissue expansion, cultured autologous cultured skin substitutes, and flap closure are especially useful in the head and neck region. Alternative approaches to treatment, such as dermabrasion, curettage, carbon dioxide (CO_2) laser ablation or treatment with QS Nd:YAG, ruby, and alexandrite lasers can lead to improvement in appearance. Therapy may also eliminate some nevus cells, with theoretic lowering of the melanoma risk. It is important to emphasize that most melanomas in giant congenital nevi occur in the dermal component rather than at the DEJ. Any treatment that alters the surface may alter detection of deep melanoma. Malignant transformation has been reported 20 years after dermabrasion. Regardless of the method of choice, lifelong periodic cutaneous examination and general medical evaluation are indicated.

Small and Medium-Sized Congenital Nevocytic Nevus

Small, congenital nevocytic nevi are generally defined as less than 2 cm in greatest diameter, and medium-sized lesions measure more than 2 cm but less than 20 cm. They are found in about 1% of newborns. About half eventually become hairy. Histologically, they share many features with giant congenital nevi but usually do not extend into the subcutaneous tissue. Many of the histologic features

associated with congenital nevi also occur in acquired nevi. The risk of melanoma in small to medium-sized congenital nevi is extremely low; it may be no greater or only slightly greater than the risk of melanoma arising in ordinary acquired nevi. One important difference is that malignant degeneration may occur in the deep dermal component of small congenital nevi, rather than at the DEJ. Most of the melanomas that do occur do so after puberty. Excision is recommended for changing lesions and may be considered for those of cosmetic concern and in areas difficult to observe.

Spindle and Epithelioid Cell Nevus (Spitz Nevus)

Spitz nevi typically appear as pink, smooth-surfaced, raised, round, firm papules (Fig. 30.9). Most frequently, Spitz nevi occur during the first two decades of life, although they occur in adulthood in about one third of cases. Infrequently, multiple lesions present as agminate (clustered) (Fig. 30.10) or disseminated lesions in children and adults. Although they usually contain no visible pigment, some lesions are pigmented. Occasionally, Spitz nevi can be blue-black in color. A starburst pattern is characteristic on dermatoscopic examination. Although dermoscopy and confocal microscopy are being used in this setting, both false-positive and false-negative studies occur, and histologic examination remains the "gold standard" for evaluation of suspicious lesions.

As with other nevi, Spitz nevi may be junctional, compound, or intradermal. Compound nevi are most common and are characterized by compact hyperkeratosis, hypergranulosis, and pseudoepitheliomatous hyperplasia. The cells are large, with round to spindled nuclei. Epithelioid cells have large vesicular nuclei with prominent nucleoli and ample pink cytoplasm. Adjacent to the nucleus, the cytoplasm typically has a more amphophilic hue, giving it a characteristic two-tone appearance, similar to the cytoplasm of the cells in reticulohistiocytic granuloma. The nests tend to be oval and oriented in a vertical direction, as are the nuclei within the nests, so that they appear to be "raining down" the adjacent rete ridges. Clefts are typically present adjacent to some of the nests, and superficial vascular ectasia is characteristic. Dull-pink globules (Kamino bodies) are seen within the epidermis. These represent trapped basement membrane zone material and stain similar to collagen with a trichrome stain as well as with immunostains for type IV collagen. Buckshot scatter of melanocytes may be noted within the epidermis overlying the center of the lesion, but the lesion is sharply circumscribed, and cells disperse as individual units between collagen bundles at the base of the lesion. Rosette-like structures may occur. In a review of 349 Spitz nevi, the presence of epithelioid and spindled cells was the only feature present in 100% of cases. Other findings, in descending order, included maturation (72%), inflammatory infiltrate (70%), epidermal hyperplasia (66%), melanin (50%), telangiectasias (40%), Kamino bodies (34%), desmoplastic stroma (26%), mitosis (23%), pagetoid extension (13%), and hyalinization of the stroma (8%).

Melanomas may have many of the previous features, but generally lack Kamino bodies, and often demonstrate broad lateral extension, deep mitoses, and large nests at the base of the lesion. Cytologic features that favor a diagnosis of melanoma over Spitz nevus include pleomorphism, mitotic figures, notching of the nuclear envelope, and a peppered moth chromatin pattern. In questionable cases, adjunctive studies may be of value. S-100A6 shows strong and diffuse expression in Spitz nevi. Other melanocytic nevi often express S-100A6 weakly or not at all. Melanomas may express S-100A6, but the expression tends to be weak and patchy in the dermal component and is often negative in the junctional component. HMB-45 typically stains Spitz nevi in a top-heavy fashion, whereas melanomas stain uniformly top to bottom. MIB-1 (Ki-67), a proliferation marker, may also be helpful as an adjunct to the histopathologic diagnosis of Spitz nevi. MIB-1–positive nuclei are rare in the deep portion of a Spitz nevus, whereas they are often numerous in melanoma. Comparative genomic

hybridization demonstrates chromosomal aberrations in the majority of melanomas, but most Spitz nevi show no aberrations. A minority of Spitz nevi show an isolated gain of chromosome 11p, the site of *HRAS*, but this aberration is not observed in melanoma. Specific gains or losses can be demonstrated with fluorescent in situ hybridization (FISH) probes. Studies of the mitogen-activated protein kinase (MAPK) pathway and genomic gains and losses may also prove helpful in this setting.

Junctional Spitz nevi usually show some degree of buckshot scatter of melanocytes and share many histologic features with melanoma. Lesions that lack sharp lateral circumscription are more likely to represent melanoma. Intradermal Spitz nevi lack overlying hyperkeratosis, hypergranulosis, or pseudoepitheliomatous hyperplasia, but the cells disperse as individual units at the deep margin. Dermal spitzoid lesions that remain nested at the deep margin are likely to represent melanoma. Desmoplastic Spitz nevi may be compound or intradermal, and are characterized by a dense, hypocellular collagenous stroma.
